C-terminus. Because of the hydrophobic nature of a protein that strongly interacts with fatty acids, the exact topology of the FATPs is difficult to predict. Studies with FATP1 revealed at least one α -helical transmembrane domain and several membrane-associated domains [3]. However, FATPs do not show any obvious similarities to other transporter families, e.g., the polytopic membrane transporters for hydrophilic substrates such as members of the GLUT family, or transporters of amphipatic and hydrophobic substrates, e.g., bile and cholesterol transporters. It has been demonstrated that FATP1 forms homodimers, and possibly higher-order complexes, most likely by interactions in the cytoplasmic loop. Coexpression experiments of nonfunctional FATP1 mutants with wild-type FATP1 revealed that oligomerization is required for their transport function. A 311-amino acid sequence motif is conserved in all mammalian FATP family members and is essential for the function of these proteins. An AMP-binding sequence (IYTSGETTGXPK), likely facing the cytosol, is found at the beginning of this sequence motif. This 11-amino acid motif is conserved in a number of proteins that either bind ATP or catalyze reactions that proceed through adenylated intermediates.

In vitro and ex vivo studies have shown that FATPs transport LCFAs and very long-chain fatty acids (VLCFAs) but no medium-chain fatty acids, fatty acid esters, or lipid-soluble vitamins [4]. LCFA transport is inhibited by prior protease treatment. Synthetic substrates for FATPs include ^{14}C -labeled fatty acids and the fluorescently labeled fatty acid analogue C1-BODIPY-C12. Using the latter substrate, differences in fatty acid uptake kinetics between FATP expressing 3T3 L1 adipocytes and 3T3 L1 fibroblasts, which are devoid of FATPs, can be readily appreciated (Fig. 2).

It has been shown that FATP1, -2, -3, -4, and -5 can also catalyze the formation of CoA thioesters of hydrophobic substrates such as VLCFAs and unconjugated bile acids. However, it is still an ongoing debate whether FATPs are (i) solely transmembrane transport proteins mediating LCFA uptake, possibly in close association with other proteins such as long-chain acyl-CoA synthetases (ACSLs), or (ii) are themselves membrane-bound long-chain and very long-chain ACSLs that trap LCFAs inside the cell following fatty acid diffusion across the plasma membrane, or (iii) combine the transport with acyl-CoA synthetase activity for optimal uptake, or (iv) are multifunctional proteins that mediate LCFA uptake independently of their esterification activities. Clearly, further investigations of the enzymatic and transport activities of FATPs are needed to resolve these important questions. Extrapolating from our current knowledge, it is likely that in vivo several fatty acid handling proteins such as fatty acid translocase (FAT/CD36), long-chain ACSLs, fatty acid binding proteins (FABPs), and acyl-CoA

binding proteins (ACBPs) interact with FATPs to facilitate efficient uptake of fatty acids (Fig. 1). In accordance with this hypothesis, FATP1 has been shown to associate with ACSL1 [5], suggesting that both proteins are essential for FFA uptake. As a model for LCFA uptake we have suggested the following mechanism [3]. In addition to a small, diffusional component, LCFAs are either directly transported by FATP complexes across the plasma membrane or, alternatively are first accumulated on the plasma membrane by binding to CD36, which subsequently hands on the fatty acids to FATPs. Within the cells, LCFAs are rapidly activated and metabolized by ACSLs or FATPs. Subsequent binding of fatty acids to intracellular LCFAs handling proteins facilitates the unloading of transporters and synthetases and acts as an intracellular fatty acid buffer.

FATP Null Mutants and FATP Polymorphisms

► **Knockout mice** have been reported for several FATPs [1]. As ► **insulin desensitization** has been closely linked to excessive fatty acid uptake and intracellular diacylglycerol and TG accumulation, these animal models were particularly evaluated in the context of protection from diet-induced type 2 diabetes (► **Type 2 Diabetes Mellitus (T2DM)**). In addition, studies on human subjects have also established genetic links between ► **polymorphisms** in FATP genes and metabolic alterations [1].

In hyperinsulinemic-hyperglycemic clamp studies, FATP1 KO mice were protected from the insulin-desensitizing effects of lipid injections. FATP1 KO mice were completely resistant to long-term diet-induced ► **obesity**, insulin-desensitization, and other parameters of the metabolic syndrome. Loss of FATP1 function reduced muscle TG content and prevented a lipid bolus induced reduction of IRS-1 tyrosine phosphorylation and PI-3 kinase association. FATP1 is also expressed on the plasma membrane of brown adipose tissue (BAT) and FATP1 KO mice showed reduced basal fatty acid uptake and displayed smaller lipid droplets in BAT. As a consequence FATP1 KO mice failed to upregulate fatty acid uptake and to defend their core body temperature following cold exposure suggesting that FATP1 is required for thermogenesis [6].

As yet, no human diseases have been identified as a result of FATP1 mutations. However, genetic polymorphisms in the human FATP1 gene have been linked to dyslipidemia. An A/G exchange at position +48 in intron 8 of the FATP1 gene has been shown to result in increased TG concentrations in female but not in male subjects. In a second study, the same polymorphism was linked to increased postprandial TG concentrations and smaller low density lipoprotein (LDL) particles. To date, it is still unknown if this polymorphism is associated with altered levels of FATP1 expression and/or function.

A FATP2 KO mouse has been generated and investigated in the context of the neurodegenerative endocrine disorder X-linked adrenoleukodystrophy. However, no association between FATP2 function and X-linked adrenoleukodystrophy was found. FATP2 KO mice exhibited a decreased peroxisomal very long-chain acyl-CoA synthetase activity and decreased peroxisomal VLCFA β -oxidation in liver and kidney. However, no VLCFA accumulation in either of these organs was observed. The consequences of FATP2 loss for hepatic and renal LCFA uptake are presently unknown.

To date, four studies on murine FATP4 deletions have been published. Both the introduction of a premature stop codon in exon 3 due to a spontaneous mutation as well as the deletion of exon 3 by gene manipulation resulted in an early neonatal lethality due to symptoms strikingly similar to restrictive dermopathy, a rare human genetic disorder. Neonate mice exhibited thickened, tight skin, and a disrupted epidermal barrier as well as facial deformations and breathing difficulties. Additional analyses of the genetically engineered mice demonstrated reduced esterification activities for C24:0, but not C16:0 or C18:1 (very) long-chain fatty acids in dermal and intestinal lysates from FATP4 null mice. No effects on LCFA uptake have been examined in these two studies. A third study described a deletion of exons 1 and 2 of the murine FATP4 gene resulting in embryonic lethality occurring before day 9.5 of gestation. This phenotype was ascribed to the absence of FATP4 in the yolk sac where it is normally expressed by the cells of the extra-embryonic endoderm, likely resulting in an impaired absorption of maternal lipids by the embryo during early embryogenesis. Isolated primary enterocytes from heterozygote mice had a 48% reduction in FATP4 expression and a 40% reduction in LCFA uptake. However, no malabsorption of lipids was detected *in vivo*. A fourth report describing an epidermal-specific conditional FATP4 KO mouse showed that these mice develop a hyperkeratosis with a disturbed epidermal barrier suggesting that epidermal FATP4 is essential for the maintenance of a normal skin structure and function. In humans, a polymorphism in exon 3 of the FATP4 gene leads to an amino acid exchange (G209S) that has been linked to decreased parameters for TG and insulin levels, body mass index (BMI), and systolic blood pressure.

FATP5 KO mice have been characterized in two studies focusing on the role of FATP5 in hepatic lipid and bile metabolism. LCFA uptake in primary hepatocytes isolated from FATP5 KO mice was reduced by 50% and hepatic lipid content in the KO mice was significantly reduced despite an increased fatty acid *de novo* biosynthesis. Detailed analysis of the hepatic lipidome of FATP5 KO mice revealed significant

quantitative and qualitative alterations among lipid classes. Similarly to FATP1 KO mice, homozygote deletion of FATP5 resulted in resistance to high-fat diet-induced weight gain and insulin-resistance. FATP5 KO mice displayed both decreased caloric intake and increased energy expenditure on this diet. How changes in hepatic lipid metabolism lead to altered feeding behavior is currently unknown. While the total bile pool in FATP5 KO mice was unchanged, a distinct shift from conjugated to unconjugated bile acids occurred as a result of FATP5 deletion. The remaining conjugated bile acids were exclusively derived from de novo synthesis, implying a role of FATP5 in the reconjugation of bile acids during enterohepatic recirculation.

Pharmacological Intervention

Insulin

Insulin stimulates FATP1-mediated fatty acid transport on the protein level but negatively regulates FATP1 mRNA transcription through a cis-acting insulin response promoter sequence, albeit no changes in FATP1 protein levels have been reported following insulin exposure. In basal adipose and muscle cells, most of the FATP1 protein is sequestered in an intracellular perinuclear compartment, where it colocalizes with the insulin-sensitive glucose transporter GLUT4. Insulin stimulation induces the translocation of FATP1-containing vesicles to the plasma membrane resulting in an increase in cellular LCFA uptake.

Phloretin

Phloretin inhibits FATP-mediated traversing of fatty acids across lipid bilayers. Phloretin is the aglycon of phlorizin and has been used to terminate the uptake of LCFAs and VLCFAs in timed in vitro uptake assays with cultured cells or in ex vivo uptake assays with isolated primary cells.

Thiazolidinediones

A peroxisome proliferator-activated receptor (PPAR) binding site was identified in the murine FATP1 promoter. Several reports have shown a positive regulation of mouse FATPs by ligands that activate PPAR- α , PPAR- γ , or PPAR- γ /RXR heterodimers.

TNF

Tumor necrosis factor alpha (TNF α) is a negative regulator of FATP expression and downregulates FATP mRNA and protein levels in several tissues.

Fever

CLARK M. BLATTEIS

University of Tennessee Health Science Center, College of Medicine, Memphis, TN, USA

Synonyms

Pyrexia; (Hyperpyrexia)

Definition

The term *fever* specifically defines the elevation of body core temperature (T_c) that characteristically occurs in most animals in response to the invasion of their body by infectious organisms such as bacteria, viruses, and fungi. It is also a frequent reaction to nonmicrobial illnesses (e.g., autoimmune and neoplastic diseases), some host-derived substances (e.g., antigen–antibody complexes), as well as to certain synthetic products (e.g., antitumor agents, immunoadjuvants). The English word *fever* stems from the Latin word *febris*; pyrexia is a synonym derived from the Greek word *pyretos*. In humans, T_c s above 38°C are generally considered clinical fevers. Hyperpyrexia is a medical emergency defined as a T_c over 41.1°C.

Our knowledge of the underlying mechanism of fever derives largely from the research using animals. Thus, generally in such studies, a fever-producing substance (▶**exogenous pyrogen**) is administered as a bolus to conscious rodents. In most cases, this material is an extract of the outer wall of gram-negative bacteria (*bacterial endotoxic lipopolysaccharide*, LPS); a multiphasic rise in T_c is consequently generated that, due to its causative agent, is prototypic ▶**endotoxic fever**. Importantly, however, this T_c rise is but one among an array of systemic, nonspecific, highly coordinated reactions typifying gram-negative bacteremia, all directed to combating the deleterious effects of the pathogenic compound. They are termed collectively the *acute-phase reaction* (APR), a pathognomonic collection of behavioral (Table 1) and physiological (Table 2) responses. Fever is the most manifest among these signs and, therefore, it is the hallmark of infection. Indeed, since the early 1900s, the measurement of body temperature has become a clinically routine practice in the detection of infectious disease.

Basic Mechanisms

The Febrile Course

T_c does not rise immediately following the entry into the body of an infectious pathogen. Rather, there is an

Fever. Table 1 “Sickness behaviors” typically elicited by infectious pathogens or their products

Withdrawal

interval, from minutes to days, during which the various host-generated reactions that eventuate in the development of fever (and the other components of the APR) take place. This period is called the *latent or prodromal* period. Its duration depends on the nature of the invading microorganisms and/or its products, its route of entry, its amount, the site of its localization, certain physiological variables of the afflicted host, and other factors. It is succeeded by the *phase of rising T_c or febrigenesis*. The height, duration, and other characteristics of the ensuing fever are also largely dependent on the amount and type of the pathogen. They can, however, be influenced by various endogenous (e.g., state of hydration) and exogenous (e.g., climatic) factors; to wit, dehydration and high ambient temperature (T_a) exacerbate fever. The upper limit of fever in humans is ~40.5°C. When T_c reaches its maximum, it remains there for a period of time, termed the *stable or plateau phase or fastigium*. Its magnitude and duration are also related to the dose (severity of the infection) and type of the pathogen, and can also be modified by extraneous factors. Finally, the fever breaks (*crisis*) and T_c begins to decrease toward its normal level. This phase is variously called *the phase of falling T_c , febrilysis, or defervescence*.

Functionally, the onset of fever is mediated by an increase in metabolic heat production (*thermogenesis*) and cutaneous vasoconstriction (to reduce heat loss from the skin), and by cessation of sweating, if present. The

increased heat production is achieved by the most visible sign of fever production, shivering (*chills*); in neonates and cold-acclimated rodents, in which shivering thermogenesis is normally replaced by brown adipose tissue (BAT) nonshivering thermogenesis, the latter substitutes for shivering in the production of fever. In a thermally neutral environment ($\sim 22\text{--}24^\circ\text{C}$ for humans), the contribution of increased thermogenesis to the T_c rise is usually relatively brief; a greater role is played by the reduction in blood flow to the skin effected by cutaneous vasoconstriction. This is manifested by a cold and pale skin, provoking subjective sensations of cold that prompt the afflicted subject to actively (i.e., behaviorally) seek warmer surroundings. The thermoeffector responses evoked are thus analogous to those caused by acute cold exposure; but, since they occur in a warmer environment, the consequently narrower gradient between skin (T_{sk}) and ambient (T_a) temperatures results in less heat flowing from the skin to the environment and more, therefore, being retained in the body; hence, T_c rises. Fever developing in the cold, however, requires more intense heat production, whereas a decrease in heat loss (i.e., more generalized cutaneous vasoconstriction) may be sufficient in the heat. During the plateau phase of fever, the cutaneous vasculature resumes its normal, relatively constricted state (inappropriate as compared to an expected dilated state at a T_c comparably elevated passively by heat exposure, but thereby helping to maintain T_c at its febrile level). Since the blood perfusing the skin is now warmer, T_{sk} rises and the skin condition changes to warm and pink; consequently, the earlier sensation of cold disappears. When the fever drive eventually abates, the effector mechanisms evoked resemble those of heat-exposed subjects, viz., T_c falls in conjunction with cutaneous vasodilation and drenching sweating, and the defervescing subject seeks a cooler environment.

It should be apparent from the preceding that the T_c rise of fever is not the unavoidable consequence of the *passive* gain of heat in excess of the capability of *active thermolytic* (heat-dissipating) *effectors* to disperse it; this characterizes **►hyperthermia**. Fever is, rather, the deliberate result of the *regulated* operation of *active thermogenic* (heat-producing) *effectors*; it thus develops as the result of an upward shift of the thermoregulatory **►set point**, that is, it represents the regulated adjustment of T_c to a higher than the basal level rather than an uncontrolled side effect of disease; fever is indeed characterized by the active defense of the new, higher T_c . Hyperthermia, thus, is dependent on the T_a , whereas fever can develop at any T_a . A characteristic thermoregulatory behavior that derives from this difference is that febrile subjects prefer warm thermal environments to facilitate heat storage, as already mentioned, whereas hyperthermic subjects choose cool ones to enhance heat loss. Fever is therefore clearly

distinct from hyperthermia, and the two terms should not be used interchangeably.

Various circulatory and respiratory adjustments that serve to support the increased metabolic demands of the heat-producing tissues accompany the febrile rise. These include increases in heart rate, increased blood flow to the thermogenic organs (viz., skeletal muscle, BAT), and associated adjustments and redistributions of the cardiac output. Hyperventilation also occurs transiently, resulting in a fall in $P_{a\text{CO}_2}$ and a rise in pH_a ; $P_{a\text{O}_2}$ is generally unaffected. Other changes involve endocrine, enzymatic, and cellular effectors involved in the provision and utilization of energy; these are analogous to those that sustain the increased heat production on cold exposure.

Pathogenesis of the Febrile Response

Fever arises as the result of a complex, phased sequence of interactions among soluble factors and cells that is initiated in the periphery by the presence of the pathogens or their products and is eventually transmitted to the brain, which modulates the febrile response [2]. The process is driven in the periphery and in the brain via mediators that provide proipyretic (e.g., **►pyrogenic cytokines**, prostaglandin (PG) E_2) and antipyretic (e.g., arginine vasopressin, nitric oxide) signals at different points along the fever pathway and whose sequence is time-dependent. **►Endogenous antipyresis** is an essential, autoregulatory feedback that serves to prevent an exaggerated fever from occurring during systemic infectious challenges [3]. However, the precise interplay of mediators, their sequence, and their site of action along the route to the brain and/or within it are still incompletely defined.

Many different substances are capable of causing fever; some common pyrogenic stimuli are listed in **Table 3**. These materials, however, are not the factors that directly induce fever and its nonthermal correlates. Rather, they induce in the host certain immunoregulatory mediators that entrain the APR. Thus, extraneous organisms or their products that have penetrated the body are immediately recognized through their unique molecular patterns (pathogen-associated molecular patterns, PAMPs) by specialized receptors on the host's immune cells. These receptors, called Toll-like receptors (TLRs), occur, predominantly, on mononuclear phagocytes (e.g., circulating and resident macrophages). Their activation transduces the pathogenic microbial signal into intracellular molecular processes that eventuate in the concatenated production of the factors that mediate the APR. LPS acts via the TLR4 receptor; other PAMPs activate other TLRs, but it would appear that the cascades of mediators thus produced are similar.

These proipyretic factors belong to the class of immunomodulatory polypeptides called **►cytokines**. Most prominent among these are interleukins (IL)-1 β

Fever. Table 3 Some common pathogenic stimuli that induce fever (“exogenous pyrogens”)

and -6, tumor necrosis factor (TNF)- α , and interferons (IFN)- α and - γ . Following the administration of LPS, TNF- α normally appears in the bloodstream first, followed by IL-1 β , and finally by IL-6; IFNs do not occur or occur very late – they are induced predominantly in response to viruses and their products. Their functional levels are modulated by the coincident release of their own antagonists, viz., specific target cell-surface antagonists (e.g., IL-1 receptor antagonist), soluble blood-borne receptors (e.g., soluble TNF receptor type II), and/or inhibitors of their synthesis (e.g., glucocorticoids) or their actions (e.g., arginine vasopressin in the POA).

How precisely circulating cytokines trigger the neural circuits that modulate the febrile response is still uncertain. Several possible mechanisms have been proposed: (i) active transport across the blood–brain barrier (BBB), which is otherwise impermeable to proteins; (ii) passage through “leaky portals” in the BBB, the so-called circumventricular organs, especially the *organum vasculosum laminae terminalis* (OVLT) which is located on the midline of the preoptic area (POA) of the anterior hypothalamus, the brain region controlling T_c ; (iii) interaction with endothelial cells in the blood–brain interface, causing the abluminal release of additional cytokines and/or of a further factor, PGE₂, which is considered to be the final, central fever mediator [5]; and (iv) activation of sensory nerves, particularly hepatic vagal and trigeminal afferents. However, because under certain experimental conditions, for example, the i.v. injection of LPS, fever develops before cytokines are detectable in the blood, it has been suggested that, alternatively, circulating LPS could directly trigger endothelial cells in the cerebral microvasculature or in the OVLT, that is, independently of circulating cytokines, via the circulating receptor for LPS, soluble CD14, which can act on these cells

(endothelial cells do not express the membrane-bound LPS receptor), engendering PGE₂. However, again, the synthesis of the enzyme that is thus specifically induced to catalyze the formation of PGE₂ from its substrate, arachidonic acid, cyclooxygenase (COX)-2, significantly lags the onset of fever. Indeed, experimental manipulations that inhibit either the actions of TNF- α or IL-1 β or the production of PGE₂ attenuate the late, but not the early, phases of the febrile response, indicating that cytokines and PGE₂ are more likely involved in the maintenance than in the initiation of fever [2]. Moreover, recent evidence has indicated that the LPS-stimulated secretion of cytokines and PGE₂ by cerebral endothelial cells is polarized luminally, that is, toward the blood, and that the thus activated cells are not localized to the POA region, but nonselectively across the brain. Hence, an alternative, rapid, signaling pathway to the POA must operate in this model. Very recently, evidence was adduced that the fever-triggering factor is PGE₂, very rapidly elaborated not in the POA, but by hepatic macrophages (Kupffer cells, Kc). Two disparate views have been advanced as to what obtains. One holds that the Kc are activated by LPS acting via the TLR4 system, inducing within 30 min COX-2-dependent PGE₂ (COX-2 is constitutively expressed in Kc) which is released into the circulation, coupled to a carrier, albumin, and transported to the brain into which it, as a lipophilic molecule, freely diffuses [5]. There is indeed good evidence that COX-2 is upregulated in the liver and that PGE₂ is detectable in the blood within 30–45 min post-LPS administration, but no compelling evidence exists that blood-borne PGE₂ passes into the POA. The other view argues that the Kc are activated by an immune mediator, complement component C5a, itself activated immediately on contact with LPS, causing the release (within 2 min) of PGE₂ into the liver interstitium; the released PGE₂ then activates

hepatic vagal afferents that project to the POA via noradrenergic connections in the medulla of the brain. Norepinephrine (NE) is consequently very quickly released in the POA, activating two of its receptors, α_1 and α_2 . Stimulation of the first inhibits warm-sensitive neurons in the POA, thereby reducing peripheral heat loss (by inducing cutaneous vasoconstriction) and, hence, causing the first febrile rise and stimulation of the second activates after a ca. 60–90 min delay POA COX-2, inducing the production of PGE₂ and the second phase of fever. Nitric oxide, also concomitantly liberated in the POA, counteracts the release of NE, thereby limiting fever height and duration. All the steps in this sequence have been confirmed by their blockade by cognate antagonists and by vagotomy [8].

Pharmacological Interventions

Fever has been recorded and associated with disease throughout history and, prior to the discovery of infectious pathogens, was taken as an illness in its own right. Now, however, although disagreeable and debilitating, fever is generally considered to be a healing response. Indeed, although no direct link between fever and host survival has definitively been demonstrated, there remains little doubt that it is a defensive response to the invasion of the body by infectious organisms and that its heat is beneficial as an adjuvant to the various immunological functions that are coactivated with it by creating the optimal thermal environment for their precisely timed and patterned expression, particularly during the early phases of the host's responses, that is, the APR [9].

Nevertheless, the use of antipyretics, viz., nonsteroidal anti-inflammatory drugs, such as aspirin, ibuprofen, naproxen, is very popular, particularly since the reduction in T_c is also associated with the relief of the untoward symptoms of sickness behavior, thus moderating the discomfort level and consequently alleviating the anxiety of both the afflicted patients and their caregivers. It is true, however, that the increased metabolic rate associated with fever production could represent a potential strain for those whose energy reserves may be limited, such as the malnourished, elderly, neonates, cancer patients, patients with metabolic diseases, and others. Similarly, the tachycardia and polypnea associated with sustaining the increase in metabolism may put at risk patients with a diminished capacity to increase cardiac work (e.g., congestive heart failure) or to hyperventilate (e.g., chronic obstructive pulmonary disease, asthma). Patients with dysfunctional kidneys may also be imperiled. There is, therefore, merit in attenuating fever in such patients. But, in general, it may be just as well not to treat the T_c rise per se in the absence of high-risk predisposing factors or when the fever is not unduly prolonged or rises to temperatures above 41°C.

Fibrates

Fibrates are fibric acid derivatives, including e.g. bezafibrate, gemfibrozil, fenofibrate or clofibrate. Fibrates cause a marked reduction in circulating very low density lipoproteins (VLDL) as well as a modest (10%) reduction in low density lipoproteins (LDL) and an approximately 10% increase in high density lipoproteins (HDL). Many of the effects of fibrates on blood lipids are mediated by their interaction with ►peroxisome proliferator activated receptor (PPAR), which regulates gene-transcription in a variety of organs. Fibrates bind to the α -isotype of PPAR (PPAR α), which is expressed primarily in the liver and brown adipose tissue and to a lesser extent in kidney, heart and skeletal muscle. Fibrates reduce triglycerides through PPAR α -mediated stimulation of fatty acid oxidation, increased lipoprotein lipase synthesis and reduced expression of apoC-III. A major side-effect of fibrates is myositis, which is rare but can be severe. Fibrates are clinically used to treat elevated levels of triglycerides.

- Peroxisome Proliferator-Activated Receptor (PPARs)
- HMG-CoA Reductase Inhibitors

A δ -fibres

A δ -fibres are small diameter myelinated afferent fibres. As part of the pain sensory system they are present in

nerves that innervate the skin and deep somatic and visceral structures.

► Nociception

Fibrin

Fibrin is an elastic filamentous protein elaborated from its precursor, fibrinogen, which is present in plasma at high concentration. Fibrin is formed in response to the actions of thrombin. Thrombin cleaves small peptides from the fibrinogen molecule, forming fibrin monomers that will begin to polymerize and become crosslinked.

- Fibrinolytics
- Coagulation/Thrombosis

Fibrinogen

Fibrinogen, a glycoprotein with an overall homodimeric structure (340 kDa), is synthesized by the liver and secreted into the blood, where its concentration is $\sim 10 \mu\text{M}$. If its N-terminal portion is removed by serine proteases (e.g., thrombin, snake venoms), the remaining part, the fibrin loses its solubility, and forms aggregate (the blood clot, the main structure of a thrombus). The homodimeric structure allows fibrinogen to cross-bridge activated integrin $\alpha\text{IIb}\beta 3$ molecules on adjacent platelets, the crucial step in platelet aggregation.

Synonyms

Fibrinolysis; Thrombolysis

Definition

Fibrinolytic enzymes (proteases) are used to dissolve thrombus, the insoluble aggregate of ►fibrin and platelet including several additional cellular and molecular components of the blood.

Mechanism of Action

The term fibrinolysis means the degradation of fibrin (present as an insoluble protein molecule in the blood, which is useful to prevent bleeding and is dangerous if it is formed inside the blood circulation). However, the system *in vivo* is more complicated because fibrin exists in a compartment with several cellular and molecular components, which modulate fibrinolytic processes. In addition, the fibrinolytic enzymes are synthesized in proenzyme (zymogen) form. Thus, their activation is a prerequisite for their function. Moreover, both the fibrin degradation and the zymogene activation are controlled at multiple levels. Although there are several proteases with the capacity to digest fibrin, such as trypsin, elastase, cathepsin G, extracellular matrix metalloproteinases, in medicine, ►plasmin is considered to be the main fibrinolytic enzyme [1]. A simplified model of the ►plasminogen–plasmin system is illustrated by Fig. 1.

Fibrin Degradation

Fibrin is formed from ►fibrinogen synthesized by the liver and secreted into the circulation. The conversion of fibrinogen to fibrin is initiated by a serine protease, thrombin. Thrombin, at the same time, can activate a transglutaminase enzyme, factor XIII present in

Fibrinolytics. Figure 1 The plasminogen–plasmin system. Plasminogen activators (PA) convert plasminogen (Pg) to plasmin (P), and the latter solubilizes fibrin (F) via digestion, resulting in fibrin degradation products (FDP). Both reactions, the plasmin activity and plasminogen activation, are controlled by inhibitors, such as α_2 -plasmin inhibitor (PI) and plasminogen activator inhibitor-1 (PAI-1), respectively.

the blood bound to fibrinogen. The activated factor XIII (F-XIIIa) thereafter forms crosslinks (isopeptid bonds) between fibrin molecules. In addition, F-XIIIa is able to crosslink α_2 -plasmin inhibitor (α_2 -PI, see later) to fibrin. Thus, at least three forms of fibrin substrate may exist for the fibrinolytic enzyme, plasmin. The rate of their digestion is different; fibrin degradation is more efficient than that of crosslinked fibrin, and the degradation of fibrin crosslinked with α_2 -PI is less efficient [2]. The reactions are illustrated in Fig. 2.

Plasminogen Activation

Plasminogen, a single-chain glycoprotein (92 kDa) is synthesized by hepatocytes and secreted into the blood circulation, where its concentration is fairly stable ($\approx 2 \mu\text{M}$). It is converted to plasmin by plasminogen activators; all plasminogen activators cleave the Arg₅₆₁-Val₅₆₂ peptide bond yielding plasmin (83 kDa), which consists of two chains held together by disulfide bridges. The conformation change in plasminogen during activation results in the appearance of active site (Ser, His, Asp) of the enzyme. Native plasminogen is not a susceptible substrate to activators, however, removal of its N-terminal portion either conformationally (e.g., binding to fibrin) or proteolytically (e.g., hydrolyzing peptide bond at Lys₇₆ by plasmin) makes peptide bond Arg₅₆₁-Val₅₆₂ sensitive to plasminogen activators. The latter reaction, the acceleration of plasminogen conversion to plasmin by plasmin indicates that plasminogen activation is under positive feedback control [2].

Regulation of Plasminogen Activation

There are endogenous and exogenous plasminogen activators. Endothelial cells (and tumor cells) synthesize

both urokinase-type (uPA) and tissue-type (tPA) plasminogen activators. uPA is produced in a zymogen form, and is converted to active enzyme by plasmin (and kallikrein), this reaction indicates a positive feedback control. tPA is secreted by an active enzyme conformation, which means that it is responsible, very probably, for the initiation of fibrinolysis. tPA is not an efficient enzyme (uPA is more active, approximately by an order of magnitude), however in the presence of cofactors it becomes as efficient as uPA (Fig. 3). Fibrin, the substrate of plasmin, at the same time, is a cofactor for tPA (uPA activity is not affected by fibrin). Besides fibrin, endothelial cell surface, myosin, actin, some extracellular matrix proteins, certain denatured proteins, and additional components may also serve as cofactor for tPA, but their exact *in vivo* role is not clear yet.

The fibrinolytic reactions are controlled by endogenous blood plasma inhibitors as well [3].

The α_2 -Plasmin Inhibitor

One of the most efficient plasmin inhibitor is α_2 -PI (70 kDa), which is synthesized by the liver, secreted into the blood circulation, where its concentration is $\sim 1 \mu\text{M}$. It rapidly forms equimolar complex with plasmin, and in this complex, the active site of the enzyme is irreversibly blocked. The complex, thereafter, is removed by the liver. It is remarkable that when plasmin is bound to its substrate (fibrin), it is protected against its primary inhibitor, α_2 -PI: the rate of inactivation decreases by ~ 400 -fold (Fig. 4) [3].

There are several additional plasmin inhibitors in the blood, e.g., α_2 -macroglobulin, α_1 -proteinase inhibitor, antithrombin, but their role in the control of fibrinolysis is questionable, because their action on plasmin is eliminated by fibrin.

Fibrinolytics. Figure 2 Various fibrin structures for plasmin. Fibrinogen (Fg) is converted to fibrin (F) by thrombin (T), and thrombin can also convert factor XIII (XIII) to activated factor XIII (XIIIa). The latter produces crosslinks between fibrins (FxxF) and also may crosslink fibrin with α_2 -plasmin inhibitor (FxxFxxPI). The efficiency of digestion of these plasmin substrates by plasmin, resulting in the soluble fibrin degradation products (FDP), is different. The amount of FDP formed in time is expressed in arbitrary units.

Fibrinolytics. Figure 3 Plasminogen activation (a): Kinetics of plasminogen activation by uPA (urokinase-type) and tPA (tissue-type) plasminogen activators. Effect of fibrin (b): Ternary complex formation between enzyme (tPA), substrate (Pg) and cofactor (F). Abbreviations: plasmin (P), fibrin (F), plasminogen (Pg). Plasmin, formed in time, is expressed in arbitrary units.

Fibrinolytics. Figure 4 Inactivation of plasmin by α_2 -plasmin inhibitor: Effect of fibrin. The inactivation rate of free plasmin is very rapid (the second order rate constant: $k'' \approx 430 \times 10^4 \text{M}^{-1} \text{s}^{-1}$), while of fibrin bound plasmin is slow (the second order rate constant: $k'' \approx 1 \times 10^4 \text{M}^{-1} \text{s}^{-1}$). Inactivation of plasmin in the figure is shown in arbitrary units. Abbreviations: plasmin (P), fibrin (F).

Termination of Plasminogen Activation

There are several blood plasma inhibitors for plasminogen activators as well. Among them, the most significant is the plasminogen activator inhibitor-1 (PAI-1). It is a glycoprotein (52 kDa), synthesized by endothelial cells and is present in the blood circulation (mainly in platelets) at varying concentration up to 2 nM. This inhibitor forms equimolar complexes with both tPA and uPA, where the enzymes lose their activity. The regulation of the amount of plasminogen activators and PAI-1 is not clearly known.

A Compartmental Approach to Fibrinolysis

Similarly to blood coagulation, reactions of fibrinolysis occur on the interface of fluid-and solid-phase structures, generally in transiently formed compartments.

Enzymology of proteases in a water-phase is well known, but its alteration in a compartment is poorly understood. There are dramatical changes in reaction rates, in enzyme contractions and in enzyme sensitivity to inhibitors, which are not exactly described. In addition, besides fibrin and platelets there are several cellular and molecular components present in a thrombus compartment, where their influence on the basic fibrinolytic reactions is not known. To study this aspect of fibrinolysis is a task of the near future [4].

Clinical Use

Since plasmin in free form (not bound to fibrin) is extremely and rapidly inactivated by the inhibitor system (Fig. 4), plasminogen activators are used for treatment of thrombosis. Under such a condition, if plasmin is formed by the activators (especially by tPA) at the site of fibrin, the bound form can degrade fibrin because it is “protected” against the inhibitor system. In the medical practice, mainly two endogenous plasminogen activators, tPA and uPA, and one exogenous, the ▶streptokinase (SK) are used [1,4].

Tissue-Type Plasminogen Activator

The ▶tissue-type plasminogen activator (tPA) is a single-chain glycoprotein (sctPA) with 68 kDa molecular mass, present in blood at ~ 60 pM concentration (20% in free form, 80% in a complex with PAI-1). The N-terminal portion of tPA consists of a finger, an epidermal growth factor (EGF) and two kringle domains. Its C-terminal part comprises the catalytic domain, which is homogenous to that of other trypsin-like serine proteases. The sctPA can be converted by plasmin to a two-chain form (tctPA), but the biological significance of this modification is not known. tPA levels in vivo are influenced by various factors, such as hormones, exercise etc., but the exact control of its synthesis and release is not well known. tPA is also produced by engineering technique and used as fibrinolytic drug. During applications, the PAI-1 level should be overtitrated by tPA, which is not a problem, because PAI-1 concentration is low.

Urokinase-Type Plasminogen Activator

The ▶urokinase-type plasminogen activator (UPA, urokinase) is a single-chain glycoprotein with 55 kDa molecular mass, produced by variety of cells, among them endothelial and tumor cells, and is present at ~ 70 pM in blood plasma. It consists of an EGF domain (responsible for binding to cell surface receptors), a kringle and a catalytic domain (the latter homologous to the trypsin-like proteases). Single-chain uPA (scuPA) has no catalytic activity, but following cleavage at the Lys₁₅₈-Ile₁₅₉ bond by plasmin (or kallikrein), the emerged two-chain form held together by S-S bridges (tcuPA) is a potent plasminogen activator. Thus, uPA

can contribute mainly to amplification of fibrinolysis. The main problem in the therapeutical application of uPA is that it activates plasminogen randomly (see (SK) as well).

Streptokinase

SK is a single-chain protein (47 kDa), produced by *Streptococcus hemolyticus*. SK is not an enzyme, but forms a complex with human plasminogen, and in the complex an active site of plasminogen develops, which acts as a plasminogen activator, converting a neighboring free plasminogen to plasmin. There are two problems with SK treatments. It activates plasminogen (like uPA) efficiently but randomly, thus fibrinolytic therapy is generally efficient only, when ► α_2 -plasmin inhibitor is consumed (blood concentration of plasminogen and its inhibitor is 2 μ M and 1 μ M, respectively), which on the other hand, may cause bleeding complication. In the future, perhaps a fibrin-dependent form of SK will be developed. If the N-terminal residues (59 amino acids) of SK are removed, the remaining portion becomes fibrin-dependent plasminogen activator in a complex with plasminogen. An additional problem with SK is that as a foreign protein it may provoke immunological complications, anaphylactic reactions, when it is used again.

There are several other sources and recombinant variations of plasminogen activators as well. To illustrate them, only a few examples are mentioned. Blood coagulation factor XIIIa can activate plasminogen, although not efficiently, but perhaps it may play a role in the initiation of fibrinolysis. It needs additional works. Staphylokinase (15 kDa), synthesized by *Staphylococcus aureus*, somehow is similar to SK, it also interacts with human plasminogen. Recombinant derivatives of tPA and uPA also exist. For example, reteplase, a tPA variant, consists of the kringle-2 and protease domains (lack of the finger and the kringle-1 domains) of the wild-type activator. Their mechanism of action and especially their possible clinical application are under investigation.

Summarizing the fibrinolytic therapy, it should be emphasized that efficient treatment needs urgent application of plasminogen activator (within a few hours) to prevent the formation of crosslinks in the fibrin structure (Fig. 2) and to find the localization of thrombus to emerge plasmin on the surface of fibrin to prevent rapid inactivation of the enzyme by the inhibitor system of fibrinolysis (Fig. 3).

Fibroblast Growth Factors

Fibroblast growth factors (FGFs) are a group of about 20 growth factors, which function through a group of receptor tyrosine kinases (FGF-R-1, -2, -3 and -4). They play multiple roles in the morphogenesis and growth of higher organisms.

- Growth Factors

Filamin

Also called filamin human actin-binding protein (ABP). A 280 kd dimeric actin-crosslinking protein that plays a key role in the anchoring of membrane proteins to the actin cytoskeleton and is responsible for the crosslinking of actin filaments into orthogonal networks in the cytoplasm. It is comprised of three functional domains: an N-terminal filamentous actin-binding domain, a C-terminal self-association domain, and a membrane glycoprotein-binding domain. As a protein involved in the remodeling of the cytoskeleton, Filamin A is central to the modulation of cell shape and migration.

- Cytoskeleton
- Transforming Growth Factor-Beta

First-order Kinetics

First order kinetics describes the most common time course of drug elimination. The amount eliminated within a time-interval is proportionate to the drug concentration in the blood.

- Pharmacokinetics

First-pass (Presystemic) Metabolism

First-pass metabolism is the elimination of an orally administered drug by the liver or sometimes the gut wall, before it reaches the systemic circulation. First-pass metabolism results in a decreased systemic bioavailability.

► Pharmacokinetics

FK506

Synonym

Tacrolimus

Definition

A secondary metabolite produced by *Streptomyces tsukubaensis*. This bacterium was initially isolated in a soil sample collected in Japan. FK506 is a macrocyclic lactone and shares structural similarity with rapamycin. Consistently, both rapamycin and FK506 bind the same immunophilin FKBP12 (FK506 binding protein of 12 kDa). However, unlike rapamycin-FKBP12 which binds and inhibits the TOR kinase, FK506-FKBP12 binds and inhibits the protein phosphatase calcineurin.

FK5096 is clinically used as immunosuppressant.

- TOR Signalling
- Immunosuppressive Agents
- Protein Phosphatases

FKBP12

Synonyms

12 kDa FK506-binding protein

Definition

FKBP12 is a member of immunophilin family that has prolyl isomerase activity and is related to the cyclophilins in function. FKBP12 binds immunosuppressant molecule FK506 (tacrolimus). The FBKP–FK506 complex inhibits calcineurin, a protein phosphatase, thus blocking signal transduction in the T-lymphocyte

transduction pathway. In addition, FKBP12 binds to ryanodine receptor/ Ca^{2+} -induced Ca^{2+} release channel to modulate its function.

Flare

The surrounding redness caused by the vasodilatation of local blood vessels in the skin (hyperaemia). Histamine released at the site of contact acts on sensory nerve endings in the skin. Impluses travel along the axon to other peripheral branches of the same neuron to cause release of vasodilatory peptide neurotransmitters from nerve endings serving a wider area of skin than the initial contact point. Impluses reaching the CNS are interpreted as itch and pain.

Flavin Mononucleotide (FMN)

Flavin Mononucleotide (FMN) ($\text{C}_{17} \text{H}_{21} \text{N}_4 \text{O}_9 \text{P}$) is a phosphoric ester of riboflavin that constitutes the cofactor of various flavoproteins.

► Vitamins B2

Flp/FRT

Flp/FRT is a system analogous to the cre/loxP system. Flp is a yeast enzyme that recognizes FRT sites. If two FRT sites have a parallel orientation, the DNA segment between these sites will be deleted by the action of the Flp recombinase.

► Transgenic Animal Models

Fluorescence in situ Hybridization (FISH)

A diagnostic method using fluorescence labeled DNA probes to detect and quantify the number complementary chromosomal sequences on a cellular resolution. A related technique that also allows assessment of gene amplifications, but without precise quantification of copy numbers is the chromogenic in situ hybridization (CISH). Here, instead of a fluorescent dye an enzyme that can generate a colored precipitate in the tissue samples is coupled to the DNA probe.

Fluoride

Fluoride forms a tetrahedral ion with aluminium, AlF_4^{B} , which forms a complex with the $\text{GDPX}\alpha\beta\gamma$ form of G-proteins. In the case of G_s , the complex $\text{AlF}_4^{\text{B}}\text{CGDP}$ behaves much as GTP or the more stable GTP derivatives, $\text{GTP}\gamma\text{s}$ or $\text{GPP}(\text{NH})\text{p}$, and causes activation of adenylyl cyclase through the complex $\text{AlF}_4^{\text{B}}\text{-XGDPX}\alpha_s\text{XC}$.

Fluoride stimulates bone formation by protein kinase activation mediated effects on osteoblasts. Fluorides have been used in the treatment of osteoporosis, but their anti-fracture effect is not undisputed.

Fluoroquinolones

A fluorine atom in position 6 of the basic structure of quinolones enhances the antimicrobial activity considerably. All widely used quinolones are fluorinated in position 6 and the term “fluoroquinolones” is often used to describe these drugs. However, some new quinolones with similar antimicrobial activity are not fluorinated in position 6 (e.g. garenoxacin, PGE9262932) and therefore the term “quinolones” is more appropriate to describe this group of antimicrobial agents.

Folate

- Folic Acid
- Dihydrofolate Reductase

Folic Acid

E. BACK¹, H. K. BIESALSKI²

¹Novartis Pharma GmbH, Nuremberg, Germany

²University of Hohenheim, Institute of Biological Chemistry and Nutrition, Stuttgart, Germany

Synonyms

Folate

Definition

Folic acid is sensitive to photodegradation as well as oxidative degradation and as an acid only slightly soluble in water, but in the salt form well soluble. 5,6,7,8-Tetrahydro-folic acid (H₄PteGlu) is derived from folic acid by two consecutive reductions using NADPH₂. H₄PteGlu and its derivatives are the biologically active vitamers. Reduced folates (H₂PteGlu or H₄PteGlu) are less stable than folic acid itself. Folate losses during food preparation are high, especially when foods are excessively heated or soaked in water. Bioavailability of natural folate from foods averages 50%, while folic acid from supplements or fortified foods is absorbed to more than 90%.

Spinach, salad, cereal germ, and bran as well as pulses are good sources of folic acid. Liver and yeast contain high amounts of this vitamin, too, but are not consumed frequently enough to be relevant for the coverage of daily requirements [1,2].

Folic acid or folate (Fig. 1) is the collective name for more than 100 derivatives of pteroyl-mono-L-glutamate. In plant and animal tissues, folic acid mostly occurs as pteroyl-oligo-L-glutamate (PteGlu_n), with up to eight glutamyl residues.

Mechanism of Action

Tetrahydrofolic acid (H₄PteGlu) accepts and transfers activated one-carbon units in the form of 5-methyl-

10-formyl-, 5-formyl-, 5,10-methenyl-, 5,10-methylene-, and 5-formiminotetrahydrofolate (Fig. 2). These activated metabolites are involved in the methylation of homocysteine to methionine, the conversion of glycine to serine, in histidine metabolism as well as in choline, purine, and pyrimidine biosynthesis.

5-Methyl-tetrahydro folic acid is furthermore, together with vitamin B12 and B6, required to regenerate homocysteine (see ► Vitamin B12, Fig. 1). Homocysteine results when methionine is used as a substrate for methyl group transfer. During the last few years, homocysteine has been acknowledged as an independent risk factor in ► atherosclerosis etiology. Folic acid supplementation can help reduce elevated homocysteine plasma levels and is therefore supposed to reduce the risk of atherosclerosis as well [2].

Clinical Use (Including Side Effects)

Folic acid deficiency is common even in industrial countries. High-risk groups to develop folic acid deficiency are pregnant and breastfeeding women, people who regularly take anticonvulsant drugs, oral ► contraceptives, or tuberculostatics, patients suffering from malabsorption, and chronic alcoholics. As folic acid is involved in cell proliferation, deficiency symptoms first become evident in tissues and cells with high proliferation rates, such as erythrocytes and epithelia.

It is recommended that women of childbearing age take 400 µg/d synthetic folic acid as a supplement in order to reduce the risk of neural tube defects of the embryo when they later become pregnant (periconceptional folic acid supplementation) [2]. When supplementing folic acid, it should be considered that this vitamin can mask the simultaneous presence of vitamin B12 deficiency. The typical symptom of vitamin B12 deficiency, megaloblastic (= macrocytic) anemia, will be reduced by high doses of folic acid, yet the nervous system will – in the long run – be irreversibly damaged (= ► funicular myelitis) when vitamin B12 is not provided as well.

Folic Acid. Figure 1 Structure of folic acid.

Coenzyme	R'	R''
Tetrahydro folic acid	-H	-H

Force Fields/Molecular Mechanics

Force field methods, also called molecular mechanics, are empirical approaches to calculate molecular geometries and energies. The general aim of a force field

calculation is to find that conformation of the 3D-dimensional structure of a molecule or complex with the minimal energy. The acting forces between the atoms are described by analytical functions with customisable parameters. Covalent as well as noncovalent forces are considered.

The basic idea of force fields is the assumption that bond length and bond angles adjusts whenever possible to standard values. Steric hindrance of nonbonded atoms can cause nonideal values of bond length and angle. The repulsive interaction is called van der Waals interaction. A force field equation to calculate the energy of the structure for a molecule contains at least the terms van der Waals interaction, bond length stretching, angle deformation and torsion angle deformations. Many force fields contain additional terms like electrostatic attraction and others. The derived force field for each term is achieved by calibration on experimental structural data, quantum-chemical calculation and, if included, charge-type calculations. There are a variety of different force fields calibrated for certain type of molecules and solutes. Among the force fields for proteins the AMBER force field is suitable for protein calculations in vacuum and water, the GRO-MACS force field is suitable for proteins in water and lipid environments.

Forskolin

Forskolin is a diterpene derivative from the plant *Coleus forskohlii*. It activates all mammalian isozymes of adenylyl cyclase except AC9 and AC10.

Active derivatives of forskolin include: 7-deacetyl-forskolin ($EC_{50} \sim 20\mu\text{M}$), 6-acetyl-7-deacetyl-forskolin ($EC_{50} \sim 40\mu\text{M}$), 7-deacetyl-7-O-hemisuccinyl-forskolin ($EC_{50} \sim 50\mu\text{M}$). The last of these has been used as an immobilized affinity chromatography ligand for the purification of adenylyl cyclases from tissues.

► Adenylyl Cyclases

FoxO1a

FoxO1a (previously known as “FKHR”, synonym “forkhead in rhabdomyosarcoma”, gene name: FOXO1a) is a transcription factor which is regulated by phosphorylation of three serine/threonine residues. Phosphorylation of these residues by the protein kinase Akt leads to inactivation and nuclear exclusion of FoxO1a. Insulin regulates FoxO1a-dependent transactivation of gene expression through activation of Akt. FoxO1a is thought to bind to a conserved consensus sequence (T(G/A)TTT) found in the promoter region of several insulin responsive genes. The promoter of the glucose-6-phosphatase contains three of these FoxO1a binding sites.

FYVE Domain

The FYVE domain is a phosphatidylinositol-3-phosphate-binding module of approximately 60 to 80 amino acids. It was named after the first four proteins, where this domain was described (Fab1p, YOTB, Vac1p and EEA1).

- ▶ Phospholipid Kinase

Fz Receptors

Frizzled (Fz) proteins comprise a family of seven-pass transmembrane receptors with a cysteine-rich extracellular domain. As a class, Fz proteins are structurally related to the superfamily of heterotrimeric **G-protein coupled receptors** (GPCRs). There are 4 *Fz* genes in *Drosophila* and 10 in humans, with close orthologs

in mice. Fz proteins participate in both Wnt/ β -catenin-dependent and Wnt/non- β -catenin signaling, but individual Fz receptors may differ in their basal (minus ligand) ability to activate signaling of each type, suggesting that structural differences among the Fz proteins contribute to functional specificity. There is contradictory evidence regarding the importance of the Fz extracellular domain for this specificity, but it is clear that the carboxyl-terminal tail and intracellular loops

contribute. There is evidence that other members of the seven-pass transmembrane receptor superfamily act as multimers on the cell surface. In the case of the Fz receptors there is no direct functional evidence for this, but crystallization studies have revealed a conserved dimerization interface in the extracellular cysteine-rich domain.

Definition

GABA (γ -aminobutyric acid) is an amino acid with mostly inhibitory functions in the mammalian central nervous system. Structures involved in releasing or binding GABA as a neurotransmitter constitute the GABAergic system. The GABAergic system is involved

in the regulation of vigilance, anxiety, muscle tension, epileptogenic activity and memory functions.

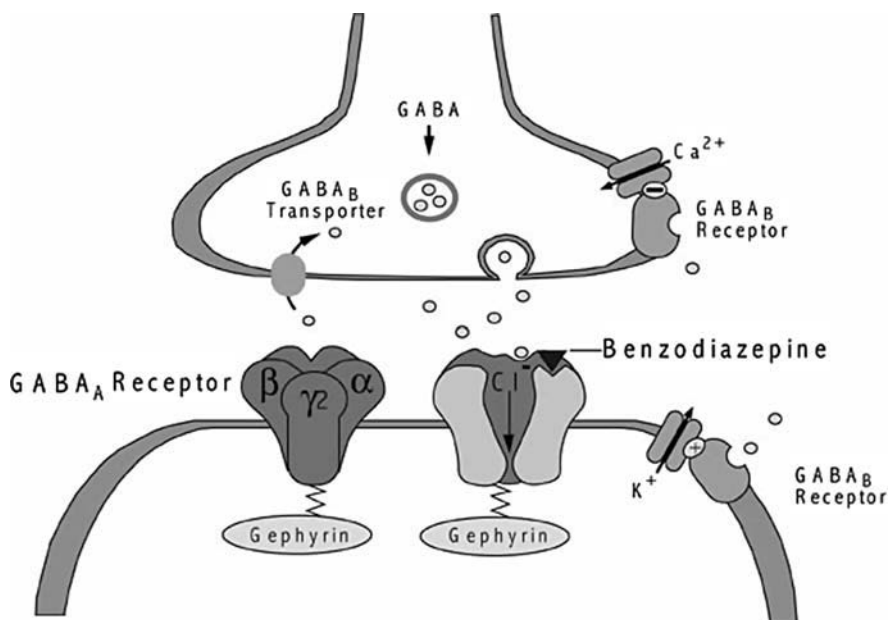

Basic Characteristics

GABA is the major inhibitory neurotransmitter in the mammalian central nervous system. It is synthesized in presynaptic terminals from glutamate by the action of the enzyme glutamic acid decarboxylase, stored in vesicles and released upon the arrival of an action potential. GABA binds to and mediates its effects via postsynaptic ionotropic GABA_A receptors and pre- and postsynaptic metabotropic GABA_B receptors (Fig. 1). Whereas the GABA_A receptors mediate fast responses, the GABA_B receptors mediate slow responses. GABA is removed from the synaptic cleft by GABA transporters and metabolized in a transamination reaction.

GABA_A Receptors

GABA_A receptors are pentameric membrane protein complexes that operate as GABA-gated chloride channels. They belong to the superfamily of ligand-gated ion channels. They have an extracellular N-terminal domain, four putative transmembrane domains and an extracellular C-terminal domain. The third intracellular loop contains consensus sequences for phosphorylation by protein kinases. The second transmembrane domain presumably lines the channel. On the cytoplasmic side, most GABA_A receptors are indirectly linked to the cytoskeletal protein gephyrin via the $\gamma 2$ subunit; these two components have been shown to play a role in

synaptic clustering of defined GABA_A receptors. The GABA_A receptor subunits are drawn from seven classes with mostly multiple variants ($\alpha 1$ – $\alpha 6$, $\gamma 1$ – $\gamma 3$, $\rho 1$ – $\rho 3$, δ , ϵ , θ). The α subunits share greater than 70% amino acid sequence identity, whereas from one subunit class to the other, e.g. α and γ , the amino acid sequence identity is in the range of ca. 30–40%. Most GABA_A receptors are composed of α , β and γ subunits with $\alpha 1\beta 2, 3\gamma 2$ being the most abundant receptor subtype. Some evidence suggests that the pentamers may contain two α subunits, two β subunits and one γ subunit. GABA_A receptors are responsible for the fast synaptic inhibition. Binding of GABA to the receptor is followed – in most cases – to hyperpolarization and thus functional inhibition of the postsynaptic neuron. GABA_A receptors are of physiological relevance because they play an essential role in the regulation of the excitability of the brain. They are, in addition, of pharmacological relevance since their activity is modulated by a variety of therapeutic agents. These include benzodiazepines, barbiturates, neurosteroids and general anaesthetics (Fig. 2). A subset of GABA_A receptors is frequently referred to as “GABA_C” receptor [2]. These receptors are composed of ρ subunits, which only assemble with each other and are found primarily in the retina. In contrast to the typical GABA_A receptors, these receptors are insensitive to the classical GABA_A receptor antagonist bicuculline. In the IUPHAR nomenclature [3] these receptors are classified as GABA_A receptors.

GABAergic System. Figure 1 GABAergic synapse. Schematic of a GABAergic synapse, depicting the major elements of signal transduction. Postsynaptic GABA_A receptors are pentameric ligand-gated ion channels assembled from various types of subunits. On the cytoplasmic site they are indirectly linked to gephyrin. GABA_B receptor occur pre- and postsynaptically and are coupled to calcium or potassium channels.

GABAergic System. Figure 2 Model of a GABA_A receptor and its binding sites. In addition to the binding site for the neurotransmitter GABA, GABA_A receptors have modulatory binding sites for a variety of ligands including benzodiazepines, barbiturates, neurosteroids, ethanol and general anaesthetics such as isoflurane, enflurane, etomidate and propofol. The positioning and size of the binding sites is arbitrary. One subunit has been removed to visualize the pore.

GABA_A receptors are widely expressed in the central nervous system [4], balancing the excitatory neurotransmission. The GABA_A receptor subtypes display a differential distribution. The $\alpha 1$ subunit, which is by far the most abundant α subunit, is expressed e.g. in cerebral cortex, hippocampus and thalamus, the $\alpha 2$ subunit e.g. in hippocampus, striatum and amygdala, the $\alpha 3$ subunit e.g. in monoaminergic and serotonergic neurons of the brain stem, in basal forebrain cholinergic neurons and in the reticular nucleus of the thalamus, the $\alpha 4$ subunit e.g. in the thalamus, the $\alpha 5$ subunit e.g. in the hippocampus, and the $\alpha 6$ subunit in cerebellar granule cells. Among the β subunits, the $\beta 2$ subunit is the most abundant, followed by the $\beta 3$ and $\beta 1$ subunits. The by far most abundant γ subunit is $\gamma 2$, whereas $\gamma 1$ and $\gamma 3$ are rare. In some instances, receptors contain a δ subunit presumably instead of a γ subunit. The GABA binding site is most likely located at the interface between α and β subunits. The binding site for modulatory benzodiazepines is, however, most likely located at the interface between α and β subunits. Recombinant receptors consisting of α and γ subunits are only activated by GABA, but not modulated by benzodiazepines. The GABA_A receptors containing the $\alpha 1$, $\alpha 2$, $\alpha 3$ and $\alpha 5$ subunits (in addition to β and γ subunits) are sensitive to modulation by classical benzodiazepines such as diazepam, whereas receptors containing the $\alpha 4$ and $\alpha 6$ subunits are not. The latter receptors are also referred to as “diazepam-insensitive” GABA_A receptors. Whereas the diazepam-sensitive α subunits $\alpha 1$, $\alpha 2$, $\alpha 3$ and $\alpha 5$ contain a histidine residue at a conserved position in the N-terminal extracellular region (positions $\alpha 1$ -H101, $\alpha 2$ -H101, $\alpha 3$ -H126 and $\alpha 5$ -H105), the diazepam-insensitive $\alpha 4$ and $\alpha 6$ subunits contain an arginine residue in the corresponding position ($\alpha 4$ -R99 and $\alpha 6$ -R100). Mutational analysis revealed that the

presence of a histidine residue or an arginine residue at this position in the α subunit determines whether the respective GABA receptor is diazepam-sensitive or diazepam-insensitive, respectively. Depending on their sensitivity to CL218872, GABA_A receptors can be further classified into those having a high affinity for CL218872 ($\alpha 1\beta \times \gamma 2$) and those having a low affinity for CL218872 ($\alpha 2\beta \times \gamma 2$, $\alpha 3\beta \times \gamma 2$ or $\alpha 5\beta \times \gamma 2$). A glycine in position 201 of the $\alpha 1$ subunit has been found to be necessary for high affinity binding of CL218872 to the respective receptor. The imidazopyridine zolpidem, which binds to the benzodiazepine site, has intermediate affinity for different GABA_A receptor subtypes: It has a high affinity for $\alpha 1\beta \times \gamma 2$, $\alpha 2\beta \times \gamma 2$ and $\alpha 3\beta \times \gamma 2$ receptors, but essentially no affinity for $\alpha 5\beta \times \gamma 2$ receptors. The rare $\gamma 3$ subunit may also confer zolpidem-insensitivity to GABA_A receptors.

Pharmacological Intervention

Several groups of CNS active drugs exert all or some of their clinical effects by their action on the GABAergic system.

Benzodiazepines

►Benzodiazepines act by shifting the GABA dose-response curve to the left and thus increase the affinity of the receptors for GABA. At a given concentration of GABA in a synapse, the chloride current will be increased. Benzodiazepines have no action in the absence of GABA (use-dependence) and cannot increase maximal physiological stimulation by a high concentration of GABA, i.e. their action is self-limiting, which most likely contributes to the safety of these drugs with respect to overdoses. They are used as anxiolytics, sedatives, hypnotics, anticonvulsants and central muscle relaxants. At the molecular level, benzodiazepines increase the opening frequency and thus the number of channels that are opened by a given concentration of GABA.

By introducing histidine to arginine point mutations in the $\alpha 1$, $\alpha 2$ and $\alpha 3$ subunits the respective GABA_A receptors are rendered diazepam-insensitive. Thus, it was found that the sedative, the anterograde amnesic and in part the anticonvulsant actions of diazepam are mediated by GABA_A receptors containing the $\alpha 1$ subunit, whereas its anxiolytic and muscle relaxant actions are mediated by GABA_A receptors containing the $\alpha 2$ subunit [5]. The anxiolytic action is observed at much lower concentrations than the muscle relaxant action.

Barbiturates

The binding site for ►barbiturates on the GABA_A receptor is less well defined. Barbiturates act by increasing the conductance level. In contrast to benzodiazepines, they also display direct agonistic action on GABA_A receptors. Also in contrast to

benzodiazepines, their action is not self-limiting, i.e. they can activate the GABA_A receptor to higher levels than high concentrations of GABA alone. These features may be responsible for the fact that overdoses of barbiturates are life-threatening.

General Anaesthetics

Both volatile and intravenous anaesthetics have been shown to modulate the activity of the GABA_A receptor, and the assumption is reasonable that these actions may contribute to at least some of the clinical effects of general anaesthetics. Though a binding site for general anaesthetics on the GABA_A receptor is still elusive, several mutations in the second and third transmembrane regions of α and β subunits have been identified that can abolish or inhibit the action of general anaesthetics. These include the volatile anaesthetics isoflurane and enflurane and the intravenous anaesthetics propofol, etomidate and also barbiturates. Interestingly, these mutations may affect the agonistic and the modulatory actions of general anaesthetics independently. Whereas mutations in both α and β subunits inhibit the actions of isoflurane and enflurane on the GABA_A receptor, only mutations in the β subunits inhibit the actions of propofol and etomidate. Since many general anaesthetics, in particular, the volatile anaesthetics also act on other excitatory and inhibitory neurotransmitters and also on two-pore domain potassium channels (background channels), the contribution of the GABA_A receptor system as a whole and specific GABA_A receptor subtypes in particular to certain anaesthetic endpoints is not known and may be different for each drug. In recombinant systems, the ϵ subunit, which is found in amygdala and thalamus and which is particularly abundant in the subthalamic nucleus, confers insensitivity of recombinant $\alpha\gamma\epsilon$ GABA_A receptors to general anaesthetics.

Neurosteroids

► **Neurosteroids** prolong the mean open time of recombinant GABA_A receptor channels. Whereas, at least in recombinant systems, the identity of the α and β subunits has little or no effect on neurosteroid action, substitution of the γ subunit by a δ subunit suppresses the GABA-modulatory activity of the neurosteroids.

GABA_A Receptor Mutants as Models for Disease

Several animal models based on the generation of targeted mutations (see also chapter “Transgenic Animal Models”) in GABA_A receptor subunits have been developed. Mice carrying point mutations in certain α subunits rendering the respective receptors GABA-sensitive but diazepam-insensitive have already been discussed in this chapter. They have provided information about pharmacological and at least indirectly also physiological roles of individual GABA_A receptor subtypes.

Mice lacking the $\gamma 2$ subunit die shortly after birth presumably due to a lack of receptor clustering. However, mice heterozygous for the $\gamma 2$ knockout allele display a limited reduction of GABA_A receptor function, visualized by decreased ligand binding and receptor clustering, notably in hippocampus and cortex. In addition, these mice display enhanced reactivity to naturally aversive stimuli such as novelty, exposed space and brightly illuminated areas, representing anxiety-related responses thought to include the activity of the septo-hippocampal system. Furthermore, the heterozygous mice display a heightened fear response in assessing the negative association of an ambiguous stimulus in cue discrimination learning; these mice perceived a partial stimulus as threatening as a fully conditioned stimulus [6]. They represent a genetic model of anxiety and represent a correlate of the GABA_A receptor deficit identified in patients with panic disorder.

Deletion of the gene encoding the $\beta 3$ subunit resulted in a loss of half of the GABA_A receptors at birth. Most homozygous knockout mice died in the perinatal period, perhaps in part due to a cleft palate, and the few survivors were interbred on a hybrid background and grew to normal body size. They displayed various neurological impairments including hyperresponsiveness to sensory stimuli, strong motor impairment and epileptic seizures, which might be due to the lack of GABA_A receptors containing the $\beta 3$ subunit that act as “desynchronizers” of neuronal activity. In these mice, the immobilizing actions of halothane and enflurane are also reduced.

Mice lacking the δ subunit, which is mainly expressed in cerebellum and thalamus, display an attenuation of ssatrighting reflex time following the administration of the neurosteroids, alfaxalone and pregnanolone, while the responses to propofol, etomidate, ketamine and the benzodiazepine midazolam were unaffected. This demonstrates the role of GABA_A receptors containing the δ subunit for neurosteroid action.

Mice lacking the $\alpha 6$ subunit display no change in the response to pentobarbital, general anaesthetics or ethanol, but are more sensitive to the motor-impairing action of diazepam in an accelerated rotarod test, though in a limited dose range only. These mice display significant compensatory changes in GABA_A receptor subunit composition and also GABA_A receptor expression levels in the forebrain. A selective posttranslational loss of the δ subunit revealed a close association of the $\alpha 6$ and δ subunits in vivo. In these mice, a compensatory upregulation of two-pore domain potassium channel, TASK-1, was found.

Mice lacking the $\alpha 1$ subunit have also been generated, as well as mice lacking the $\beta 2$ subunit. Given the fact that these are the most abundant α and β subunits respectively, it is surprising that these animals survive, presumably indicating the presence of compensatory mechanisms.

The GABA_B Receptor

The GABA_B receptor is a heterodimer of GABA_BR1 and GABA_BR2. GABA_BR1 exists in two isoforms that differ at the N-terminus, GABA_BR1a and GABA_BR1b. GABA_B receptors are coupled to second messenger systems via G proteins. Presynaptic GABA_B receptors influence neurotransmission by suppression of neurotransmitter release, presumably by inhibiting Ca²⁺ channels. Postsynaptic GABA_B receptors hyperpolarize neurons by activating an outward K⁺ current that underlies the late inhibitory postsynaptic potential (▶IPSP), presumably mediated by inwardly rectifying potassium channels of the Kir3 type.

Currently, baclofen is the only clinically used GABA_B receptor agonist. It is used as a muscle relaxant for treatment of spasticity in spinal injury and multiple sclerosis. The cloning of GABA_B receptors has renewed the interest in the search for more selective drugs and novel therapeutic indications.

Gaddum

The method of Gaddum compares equiactive concentrations of agonist in the absence and presence of a concentration of noncompetitive antagonist that depresses the maximal agonist response. These concentrations are compared in a double-reciprocal plot (or

variant thereof) to yield the equilibrium dissociation constant of the noncompetitive antagonist–receptor complex (chemical measure of the potency of the antagonist).

Definition

The ▶galanin receptors form a distinct subfamily of G protein-coupled receptors (GPCRs). Three ▶receptor subtypes have been cloned and characterized: GAL1, GAL2, GAL3. Structurally, each receptor is a typical ▶GPCR, i.e., a monomeric serpentine protein with seven helical transmembrane domains, an extracellularly directed N-terminus and an intracellularly directed C-terminus. Other GPCRs which are similar at the amino acid level (30–38%) include the somatostatin sst₄ and sst₅ receptor subtypes, the ORL1 (nociceptin) receptor and the GPR54 (KiSS-1) receptor. These galanin receptors are thought to mediate various effects of galanin and galanin-related peptide, such as those mood regulation, cognition, pain, growth, and energy balance [1, 2, 3].

Basic Characteristics

Galanin Overview

Galanin was first described in 1983 by Tatemoto et al. as a 29-residue C-terminally amidated peptide isolated from a porcine intestinal extract. The name “galanin” was assigned to reflect the presence of glycine and alanine in the N- and C-terminal positions, respectively. The N-terminal sequence galanin-1–14 is highly conserved across species, with 100% identity for example in porcine, human, rat, and mouse. Structure-activity analyses indicate the N-terminal region is the primary peptide pharmacophore involved in receptor recognition. The C-terminus is relatively less conserved across species; human galanin is particularly distinguished in this region for terminating at position 30 with an unamidated serine.

Galanin has a widespread distribution in regions such as brain, spinal cord, and gastrointestinal tract. Galanin is linked to physiological processes such as mood regulation, neuroendocrine release, alcohol abuse, cognition, seizure, nerve growth and regeneration, food consumption, cardiovascular and gastrointestinal function. Chronic ethanol consumption increases galanin mRNA in the hypothalamus, and high levels of stress increase galanin release in the central amygdala. Transgenic mice overexpressing galanin exhibit cognitive defects resembling those seen in ►Alzheimer’s disease; they also display an elevated threshold for thermal ►nociception, suppressed seizure in response to hippocampal kindling, and elevated release of central monoamines (such as norepinephrine and serotonin) after a forced swim stress. Transgenic mice with a loss-of-function mutation in the *galanin* gene exhibit defects in nociception, spinal reflex and, nerve regeneration in various models of pain and nerve injury; they also have fewer cholinergic neurons in the basal forebrain. Female *galanin* (–/–) mice show defects in prolactin secretion and lactotroph proliferation.

Galanin Analogs

The pharmacology of the galanin receptor system was first explored using galanin peptide analogs having agonist or antagonist activity: (i) galanin peptides containing modified and/or unnatural amino acids, such as D-Trp²-galanin-1-29, (ii) peptide fragments or extensions such as galanin-1-15 or galanin(-7-29), (iii) chimeric peptides in which the N-terminus of galanin (commonly galanin-1-13) is fused with a C-terminus comprised of a novel sequence as in the GALR2-selective agonist AR-M1896 (GAL(2-11)-Trp-Thr-Leu-Asn-Ser-Ala-Gly-Tyr-Leu-Leu-NH₂), or a fragment of a bioactive peptide such as NPY, bradykinin, substance P (well known examples are M15, M32, M35, C7, and M40). Galnon and galmic are two nonpeptide agonist structures which have also been shown to have pharmacological activity.

Galanin-like Peptide

In 1999, Ohtaki et al. reported the purification of a novel 60-residue peptide from a fraction of porcine hypothalamic extract, on the basis of functional activity in a GAL2 receptor assay. Residues 9–21 of the 60-residue peptide shared 100% sequence identity with galanin-1-13, thereby prompting the name “galanin-like peptide,” or GALP. ►GALP is more discretely localized than galanin; mRNA for GALP in rat and mouse brain is limited to hypothalamus (arcuate), median eminence and pituitary neural lobe, with additional expression observed in rat gut. GALP binds and activates GAL1, GAL2, and GAL3, with highest affinity for GAL3. The corresponding receptors are perhaps more accurately described as galanin/GALP receptors.

The GAL1 Receptor

The cloned human GAL1 receptor cDNA encodes a protein of 349 amino acids. Human GAL1 shares 42% amino acid identity with human GAL2 and 38% with human GAL3 (Table 1). GAL1 receptor homologs have also been cloned from rat and mouse, with amino acid identities of 92 and 93%, respectively, relative to human (Table 1). The human *GAL1* gene on chromosome 18q23 has an unusual intron/exon organization for a GPCR, with a coding region interrupted by two introns. The mouse *GAL1* gene has been mapped to chromosome 18E4, syntenic with the human *GAL1* gene, and has a similar intron/exon organization.

The cloned human GAL1 receptor binds porcine [¹²⁵I]-[Tyr²⁶]galanin and is functionally coupled to G_i/G_o-type G proteins or related pathways. Specific examples of ►second messenger effects measured in vitro include reduction of forskolin-stimulated cAMP accumulation and stimulation of MAP kinase activity. The cloned GAL1 receptor activates G protein-coupled inwardly rectifying K⁺ channels (►GIRKs) when transfected into *Xenopus* oocytes. Thus, native GAL1 receptors on mammalian neurons are likely to hyperpolarize and inhibit neurotransmitter release.

A pharmacological signature for GAL1 was based on rank order of binding affinity for galanin and derivatives: human galanin, rat galanin, porcine galanin > porcine galanin-1-16 > porcine galanin-2-29 > porcine D-Trp²-galanin > galanin-3-29. Among the chimeric galanin peptide constructs, the rank order of binding affinity is M32, M35, C7, M15 > M40. All peptides with measurable binding activity are agonists in vitro. The pharmacological profile is similar to that derived for the native GAL1 receptor in the Bowes melanoma cell line.

Human GAL1 receptor mRNA has been detected in multiple cell and tissue samples including Bowes melanoma cells, brain, gastrointestinal tract (from esophagus to rectum), heart, prostate, and testes. Rat GAL1 mRNA was detected in olfactory regions, many hypothalamic nuclei (including supraoptic nucleus),

Galanin Receptors. Table 1 Galanin receptor subtype relationships (% amino acid identity)

Receptor	Human GAL1	Human GAL2	Human GAL3	Rat GAL1	Rat GAL2	Rat GAL3
Human GAL1	100%					
Human GAL2	42%	100%				
Human GAL3	38%	58%	100%			
Rat GAL1	92%	41%	38%	100%		
Rat GAL2	40%	87%	58%	40%	100%	
Rat GAL3	37%	58%	92%	36%	55%	100%

Overall amino acid identity values were generated with the GAP program (GCG, Inc., Madison, USA).

amygdala, ventral hippocampal CA fields, dorsomedial thalamic areas, brainstem (medulla oblongata, locus coeruleus, and lateral parabrachial nucleus), spinal cord (dorsal horn), and pancreas-derived cells (RIN-14b). Rat GAL1 mRNA distribution and expression level were essentially constant when examined from embryonic day 20 to postnatal day 70, suggesting that GAL1 receptors in the CNS function broadly in normal synaptic transmission. Under certain circumstances, however, GAL1 mRNA is up- or downregulated, as in the following examples: (i) GAL1 mRNA was elevated in rat locus coeruleus after precipitated withdrawal from chronic morphine treatment. (ii) GAL1 mRNA was also elevated in rat hypothalamic nuclei after treatment with metabolic inhibitors (the glucose antimetabolite 2-deoxy-glucose or the fatty acid antimetabolite sodium mercaptoacetate, both of which stimulate feeding) or by salt loading. (iii) Hypothalamic GAL1 mRNA was decreased by hypophysectomy and also by lactation. (iv) Hypothalamic GAL1 mRNA was variable across the estrous cycle in female rats, and decreased in males by castration except when testosterone was administered. (v) GAL1 mRNA was decreased in the dorsal horn after inflammation or peripheral nerve injury.

The GAL1 receptor has been linked to multiple actions of galanin including feeding, nociception, neuroendocrine release, cognition, emotion, stress response, morphine withdrawal, metabolism, and gastrointestinal function. The following examples provide support: (i) In a study of rat feeding behavior, the galanin-induced feeding response was attributed either to GAL1 or a GAL1-like receptor, based on similarity between the *in vitro* pharmacological profile for GAL1 and the *in vivo* actions of various peptides when injected *i.c.v.* (Galanin produced a stronger feeding response than galanin-2-29, galanin-3-29 or galanin-1-16). (ii) In a study of the nociceptive reflex pathway in rat, intrathecal administration of a cell-penetrating peptide nucleic acid complementary to GAL1 attenuated the inhibitory effect of galanin on the flexor reflex, suggesting a role in pain processing. (iii) In an allodynic Bennett rat model, a GAL2-selective peptide AR-M1896 was inactive whereas a GAL1/GAL2-selective peptide AR-M961 increased the threshold for mechanical **▶ allodynia**. Based on these

data the GAL1 receptor was considered a potential target for the treatment of neuropathic pain. (iv) In human colonic cells, GAL1 mRNA was upregulated by the inflammatory nuclear transcription factor NF- κ B and also by pathogenic *E. coli*, resulting in an increase in Cl^- secretion; thus GAL1 may be partly responsible for excessive fluid secretion during infectious diarrhea. In a separate study of guinea pig ileum, GAL1 antagonists blocked galanin-induced inhibition of electrically induced contraction. (v) In a study of rat brain cortical slices, GAL1 antagonists blocked galanin-induced inhibition of acetylcholine release, consistent with a role in cognitive function. *GAL1* ($-/-$) mice also show deficits in trace-cued fear conditioning but not in other cognitive tests. (vi) *GAL1* ($-/-$) mice also showed increased anxiety-like behavior in the elevated plus maze although they were normal in other anxiety models.

Children with the 18q- syndrome exhibit a growth hormone insufficiency phenotype and display a common 2-megabase deletion in chromosome 18q resulting in loss of the *GAL1* gene; these data suggest a possible role for GAL1 in promoting growth and development. Interestingly, human subjects with aberrations in chromosome 18q mapping to the *GAL1* gene show tumor progression and decreased survival rate for head and neck cancers. It has since been reported that GAL1 mediates an antiproliferative in oral squamous cell cancers.

The GAL2 Receptor

The cloned human GAL2 receptor cDNA encodes a protein of 387 amino acids. Human GAL2 shares 42% amino acid identity with human GAL1 and 58% with human GAL3 (Table 1). The human *GAL2* gene, located on chromosome 17q25.3, has a single intron interrupting the coding region just after TM3. The cloned rat GAL2 receptor homolog has 15 fewer amino acids in the C-terminus and shares only 87% amino acid identity with human GAL2 (Table 1). The mouse GAL2 receptor has been cloned and mapped to chromosome 11.

The cloned human GAL2 receptor binds porcine [^{125}I]-[Tyr 26]galanin and couples readily to G_q/G_{11} -type G proteins or related pathways *in vitro*. Under certain conditions, GAL2 also appears to couple with G_i/G_o - and G_{12} -type proteins [1, 2]. Specific examples of

second messenger effects measured *in vitro* include inositol phosphate hydrolysis, intracellular calcium mobilization, stimulation of MAP kinase activity, reduction of forskolin-stimulated cAMP accumulation, and induction of stress fiber formation. The cloned GAL2 receptor activates Ca^{++} -dependent Cl^{-} channels when transfected into *Xenopus* oocytes. Native GAL2 receptors in H69 small lung cell carcinoma cells are proposed to activate the monomeric GTPase RhoA, which functions in cell migration.

A pharmacological signature for GAL2 was based on rank order of binding affinity for galanin and derivatives: human galanin, rat galanin, porcine galanin, porcine galanin-2-29, porcine galanin-1-16 > porcine D-Trp²-galanin > galanin-3-29. A distinguishing feature of GAL2 is its relatively high preference for porcine galanin-2-29. Among the chimeric galanin peptide constructs, the rank order of binding affinity is M32 > M35, C7, M15, M40. All peptides with measurable binding activity are agonists *in vitro*.

Human GAL2 receptor mRNA has a widespread distribution in several central and peripheral tissues including hippocampus, kidney, liver, small intestine, and retina; depending on the study GAL2 mRNA has also been found in hypothalamus and pituitary. In rat brain, GAL2 mRNA was found in anterior and posterior hypothalamus (including POMC neurons of the arcuate), dentate gyrus of the hippocampus, amygdala, pyriform cortex, dentate gyrus, raphe and spinal trigeminal nuclei, mammillary nuclei, cerebellar cortex (Purkinje cells) and discrete brainstem nuclei including dorsal motor nucleus of the vagus. Interestingly, GAL2 mRNA was relatively more widespread and abundant in neonatal rat brain studied on postnatal days 0–7 than in the adult, with highest levels in neonatal neocortex and thalamus. These data suggest that GAL2 may have distinct functions related to establishment of synaptic connections in the developing brain, with implications for neural damage and repair in the adult nervous system. In rat periphery, rat GAL2 mRNA was found in vas deferens, prostate, uterus, ovary, stomach, large intestine, dorsal root ganglia, and anterior plus intermediate lobes of the pituitary as well as pancreas-derived cells (RIN-m5f).

The GAL2 receptor has been linked to multiple actions of galanin including neurotransmitter and neuroendocrine release, growth, reproduction, seizure, cognition, emotion, nociception, nerve regeneration, peripheral metabolism, and gastrointestinal motility. Support is provided by the following examples: (i) In a study of rat jejunal contraction, the galanin-dependent contractions were attributed to GAL2 based on the abundance of GAL2 mRNA in the jejunum, and on the relative efficacy of galanin-2-29 and galanin-1-16 compared to galanin and galanin-3-29. (ii) GAL2 mRNA levels are modulated by nerve injury. Three days after peripheral tissue inflammation in the rat a

peak elevation of GAL2 mRNA was observed in dorsal root ganglia. Seven days after facial nerve crush in the rat a peak elevation in GAL2 and galanin mRNA was observed in motor neurons of the ipsilateral facial nucleus. Conversely, GAL2 mRNA in dorsal root ganglia was downregulated after axotomy. (iii) In a study of normal rats, intrathecal administration of the GAL2-selective peptide AR-M1896 produced mechanical and cold allodynia; thus GAL2 was proposed to mediate sensory processing in the spinal cord. (iv) In the Morris swim maze, rats injected with galanin in the dorsal and ventral dentate gyrus (an area of GAL2 mRNA expression) displayed a significant spatial learning deficit while maintaining normal swim speed and performance, consistent with a role for GAL2 in learning and acquisition. (v) *Galanin* ($-/-$) mice were found to have ~30% fewer cholinergic neurons in the basal forebrain than wild type counterparts, suggesting that galanin normally exerts a trophic effect in this region. In people with Alzheimer's disease, the dwindling population of cholinergic neurons in basal forebrain is hyperinnervated by neuronal fibers expressing galanin, prompting speculation that trophic effects mediated by a GAL2-like receptor might counteract the degenerative process. (vi) The *GAL2* gene is localized on chromosome 17q25 in a region associated with two diseases (hereditary neuralgic amyotrophy and Russel-Silver syndrome) that are characterized by short stature and low birth weight dwarfism, respectively, in addition to developmental defects. This relationship suggests a possible role for GAL2 in growth and development.

GAL2 ($-/-$) mice were originally reported to have normal function in a broad range of tests, suggesting either compensation during development or relatively subtle contributions from the GAL2 receptor subtype. Interestingly, they did show increased anxiety-like behavior in the elevated plus maze (like *GAL1* ($-/-$) mice while having normal responses in other anxiety models. Moreover, in a study of pain models and mechanisms, *GAL2* ($-/-$) mice showed decreased neurite outgrowth in adult sensory neurons, with significant deficits in models of neuropathic and inflammatory pain, consistent with previous proposals for a role of GAL2 in sensory processing.

The GAL3 Receptor

The cloned GAL3 receptor cDNA encodes a protein containing 368 amino acids. As shown in Table 1, the human GAL3 receptor is more closely related to the human GAL2 receptor (with 58% amino acid identity) than GAL1 (with 38% amino acid identity). The human *GAL3* gene is located on chromosome 22q12.2-13.1 and has the same intron/exon organization as *GAL2*, with a single intron interrupting the coding region just after TM3. The intron/exon pattern suggests a common evolutionary origin for GAL2 and GAL3, and a convergent evolutionary relationship to GAL1. The

intron in human *GAL3* contains a Pst 1 restriction site polymorphism of unknown significance. Rat *GAL3* shares 92% amino acid identity with the human homolog (Table 1). A mouse *GAL3* homolog has been cloned and mapped to chromosome 15.

The cloned human *GAL3* receptor binds porcine [¹²⁵I]-[Tyr²⁶]galanin and is functionally coupled to G_i/G_o-type G proteins. The cloned *GAL3* receptor inhibits forskolin-stimulated cAMP accumulation. The cloned *GAL3* receptor activates GIRKs when transfected into *Xenopus* oocytes. Thus native *GAL3* receptors on mammalian neurons are likely to inhibit neurotransmitter secretion, as proposed previously for native *GAL1*.

A pharmacological signature for *GAL3* was based on binding affinity for galanin and derivatives: porcine galanin, rat galanin > human galanin, porcine galanin 2-29 > porcine galanin-1-16 > porcine D-Trp²-galanin, galanin 3-29. A distinguishing feature of the *GAL3* receptor is that human galanin binds with slightly lower affinity than rat and porcine galanin. Among the chimeric peptides, the rank order of binding affinity is M32, M35, C7 > M15, M40. All peptides with measurable binding activity are agonists *in vitro*. The recent availability of nonpeptide *GAL3* antagonists SNAP 37889 and SNAP 398299 provide additional tools for documenting *GAL3* responses in native cells and tissues.

Human *GAL3* mRNA was detected centrally in regions such as cerebellum, amygdala, cerebral cortex, occipital lobe, frontal lobe, temporal lobe, putamen, caudate nucleus, and spinal cord. Human *GAL3* receptor mRNA was also detected in peripheral tissues such as thyroid, adrenal gland, skeletal muscle, pancreas, gastrointestinal tract, and testes. Rat *GAL3* mRNA was found in discrete regions of the CNS such as cerebellum, amygdala, hypothalamus (ventromedial, arcuate, paraventricular, and supraoptic nuclei), olfactory pathways, cerebral cortex, hippocampus, caudate putamen, central gray, medulla oblongata, and spinal cord. Rat *GAL3* transcripts were also detected in peripheral tissues such as pituitary (a particularly rich source), liver, kidney, stomach, testes, adrenal cortex, lung, adrenal medulla, spleen, and pancreas. In general, human and rat *GAL3* transcripts were widely distributed and more overlapping with *GAL2* than *GAL1*.

The *GAL3* receptor is linked to multiple effects of galanin including mood regulation, stress response, neuroendocrine release, alcohol abuse, cognition, ception, and energy balance. Small molecule antagonists such as SNAP 37889 and close analogs produce anxiolytic- and antidepressant-like effects after *in vivo* administration to rodents. The various models that support this link include rat forced swim, rat social interaction and guinea pig maternal separation, among others. Mechanistic studies indicate that *GAL3* antagonists may be working in part by modulating galanin-dependent serotonergic neurotransmission in the hippocampus and dorsal raphe nucleus.

Thus *GAL3* antagonists may represent an alternate class of therapeutic agents for the treatment of depression, anxiety, and stress-related disorders.

Additional support for a role of *GAL3* in psychiatric disorder has come from analysis of chromosome aberrations and polymorphisms. The chromosomal localization of the *GAL3* gene (22q12.2-13.1) places it in a possible susceptibility locus for ▶bipolar disorder (manic depressive illness). Interestingly, chromosome 22q is also a susceptibility locus for schizophrenia. Recently, a single nucleotide polymorphism in the *GAL3* gene was significantly associated with alcoholism.

Drugs

There are two descriptions of nonpeptidic ligands for galanin (*GAL1*) receptors: (i) A fungal metabolite Sch202596 (spirocoumaranone with a molecular mass of 353 D) was reported by Chu et al. in 1997 to bind the *GAL1* receptor in human Bowes melanoma cells with an IC₅₀ of 1.7 micromolar (Fig. 1). (ii) A series of 1,4-dithiin and dithiepine-1,1,4,4-tetroxides with molecular weights ~250–450 Da were reported by Scott et al. in 2000 to bind human *GAL1* in Bowes melanoma cells with affinities (IC₅₀ values) ranging from 0.19 to 2.7 micromolar (Fig. 1). Two of the dithiepinines were characterized as human *GAL1* antagonists, based on activity in a cAMP accumulation assay and also in a GTPγ³⁵S binding assay. The two dithiepinines of interest also blocked galanin-induced inhibition of acetylcholine release from rat cortical brain slices or synaptosomes, as well as galanin-induced inhibition of electrically induced contraction in the guinea pig ileum.

Significant progress has been made in the development of nonpeptidic ligands for the *GAL3* receptor (Fig. 1). 3-Arylimino-2-indolones including SNAP 37889 and SNAP 398299 were shown by Swanson

Galanin Receptors. Figure 1 Nonpeptide antagonists for *GAL1* (top) and *GAL3* (bottom).

et al. in 2006 to be potent GAL3 antagonists with binding affinity <20 nM and CNS penetrance after oral administration in preclinical models of anxiety and depression [4]. A close analog 3-(3,4-dichlorophenylimino)-1-(6-methoxy-pyridine-3-yl)indolin-2-one was demonstrated to have similar in vivo properties by Barr et al. in 2006 [5]. Availability of these structures may provide a way forward for elucidation of GAL3-mediated effects in humans.

Galanin-like Peptide (GALP)

GALP is a biologically active peptide comprised of 60 residues found in human, rat, mouse, and pig. Residues 9–21 of the 60-residue peptide share 100% sequence identity with galanin-1-13, thereby prompting the name “galanin-like peptide,” or GALP. GALP is known to bind and activate GAL1, GAL2, and GAL3 receptors.

Gasotransmitters

A family of endogenous molecules of gases or gaseous signaling molecules, including NO, CO, H₂S, and others. These particular gases share many common features in their production and function but carry on their tasks in unique ways, which differ from classical signaling molecules, in the human body. To be characterized as a gasotransmitters, all of the following criteria should be met: (i) It is a small molecule of gas, (ii) It is freely permeable to membranes. As such, its effects do not rely on the cognate membrane receptors, it can have endocrine, paracrine, and autocrine effects. In their endocrine mode of action, for example, gasotransmitters can enter the blood stream, be carried to remote targets by scavengers and released there, and modulate functions of remote target cells, (iii) It is endogenously and enzymatically generated and its production is regulated, (iv) It has well-defined and specific functions at physiologically relevant concentrations. Thus, manipulating the endogenous levels of this gas evokes specific physiological changes, (v) Functions of this endogenous gas can be mimicked by its exogenously applied counterpart, and (vi) Its cellular effects may or may not be mediated by second messengers, but should have specific cellular and molecular targets.

► Incretin Hormones

Gastrin

Gastrin is a peptide hormone, which is synthesized in cells of the mucosa of the gastric antrum and duodenum. It is secreted into the portal blood. The main effect of gastrin is the stimulation of secretion of acid by the parietal cells of the stomach. It also increases pepsinogen secretion and stimulates blood flow and gastric motility. The release of gastrin from G-cells in the gastric antrum is controlled by various mechanisms. Vagal stimulation to the antrum causes presynaptic release of acetylcholine, which causes the release of gastrin releasing peptide (GRP) from GRP-postsynaptic neurons, which directly stimulates the endocrine release of gastrin from G-cells. G-cells are also stimulated to release gastrin in response to protein digestion products on the luminal surface. These include amino acids and small peptides, which act directly on the gastrin-secreting cells. The release of somatostatin from D-cells, which are localized in the vicinity of G-cells has a negative influence on gastrin secretion. Release of somatostatin is enhanced by high luminal acidity, which provides a negative feedback for the endocrine pathway. Release of somatostatin is inhibited by vagal cholinergic neurons. Gastrin exerts its effects by binding to a ►G-protein coupled receptor (CCK₂) on ECL cells. ECL cells respond by a release of histamine, which by activation of ►G-Protein coupled receptors (histamine receptors) causes parietal cells to secrete H⁺ ions.

Gene chip technology; Transcriptome analysis

Definition

DNA ▶microarrays, or DNA chips consist of thousands of individual DNA sequences arrayed at a high density on a single matrix, usually glass slides or quartz wafers, but sometimes on nylon substrates. Probes with known identity are used to determine complementary binding, thus allowing the analysis of ▶gene expression, DNA sequence variation or protein levels in a highly parallel format.

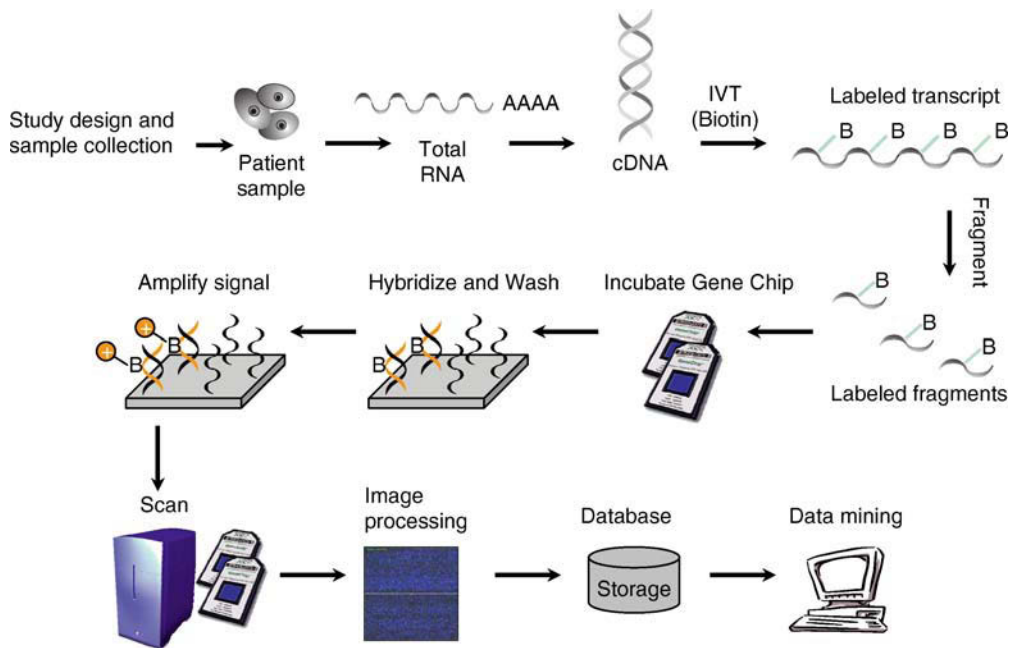

Description

High throughput technologies, like gene expression microarray are established to assess the activity status of genes in a highly parallel manner, i.e. synchronous analysis of the entire ▶‘transcriptome’ at the level of messenger RNA. DNA microarray technology is a multi-step process: (i) design and sample collection, (ii) preparation and labelling of RNA/cDNA,

(iii) hybridization to a selected microarray platform, (iv) scanning of microarrays, (v) statistical analysis, (vi) biological interpretation and validation of the results. Many factors influencing the microarray experiment and the variability at each step must be reduced to maximize the probability of uncovering biological knowledge. Careful experimental design of the microarray will ensure the maximal potential gain in efficiency and is particularly important if the resulting experiment is to be maximally informative, given the effort and the resources.

There are many protocols and different types of platforms available, e.g. GeneChips from Affymetrix, Illumina Bead Arrays, Arrays from Agilent, Applied Biosystems, GE Healthcare, customized spotted cDNA microarrays etc.; the basic procedure for a large-scale measurement of gene expression involves the preparation of total or mRNA from the biological sample(s) under investigation (e.g. ‘candidate’ tissue) and the hybridization of copied ‘labelled’ RNA or cDNA to the DNA elements on the array surface (Fig. 1).

To ensure a high reproducibility, fluctuations in sample preparation and hybridization need to be reduced to a minimum. Major sources of random fluctuations to be expected are in probe, target and array preparation, e.g. in mRNA preparation, ▶reverse transcription, labelling, target volume, hybridization parameters, overshadowing effects, non-specific background, variations in pin geometry during spotting of cDNA, slide inhomogeneities and image analysis. Replicates of each experiment should be used in order to reduce variability and to differentiate between experimental variation and real expression differences. Suitable internal controls ensure quality control measurements for samples and array. After the hybridization process, intensity values from the hybridized RNA samples are detected by phospho-imaging or fluorescence scanning and independent images are generated. Then background intensity is subtracted and signal intensities are usually normalized to compensate for experimental variability and to ‘balance’ the signals from the two samples being compared. All normalization techniques assume that all or a subset of spots (e.g. genes) on the array have an average expression ratio equal to one. The normalization factor is then used to adjust the data (signal intensities) from the two samples and to ensure that the total quantity of RNA hybridized to the array is the same. Mean spot or transcript intensities are calculated and ratios of intensities are used to account for relative expression differences. In a simple pairwise comparison of gene expression between two samples, the results can be shown in plots of the intensities or the log of the intensity ratios. Scatter plots are widely used to make the observed differential expression visible. For further details please see [1].

Gene Expression Analysis. Figure 1 Schematic representation of the experimental process of global gene expression analysis using Affymetrix GeneChip arrays.

Currently, there is a lack of widely accepted [QA/QC control metrics](#) for DNA microarray technologies, and there is currently no consensus on how to establish the reliability of the results obtained from a DNA microarray experiment (for more information please check MicroArray Quality Control (MAQC) project, [2]) QA/QC pass/fail filters to eliminate outlier arrays are used by some companies and organizations, and some array manufacturers recommend thresholds for certain platform-specific QC measurements. It might be useful to develop [spike-ins](#) and reference standards to evaluate the quality of a particular microarray experiment in the future. Another recent effort has produced a pair of reference RNAs for use with rat DNA microarrays that allows accuracy, reproducibility and dynamic range assessments [3]. Conceptually, this strategy could be used to produce reference materials for any organism, including human. Until such independent resources are widely available and consensus quality standards are developed and implemented by the microarray community, carefully adhering to the microarray manufacturer's recommended procedures offers the best current practice at this time. Because the microarray field is an evolving field, it is important to note that manufacturers occasionally change probe sequences and protocols, reflecting continuing improvements to this technology.

After the hybridization process, intensity signals from the hybridized RNA/cDNA samples are usually detected by phospho-imaging or fluorescence scanning and independent images are generated.

Microarray experiments generate large and complex data sets that constitute e.g. lists of spot intensities and intensity ratios. Basically, the data obtained from microarray experiments provide information on the relative expression of genes corresponding to the mRNA sample of interest. Computational and statistical tools are required to analyze the large amount of data to address biological questions. To this end, a variety of analytical platforms are available, either free on the Web or via purchase of a commercially available product.

Once the list of statistical significant de-regulated genes (De-regulated gene in the context of gene expression analysis usually means that the mRNA amount of a certain gene is different in the compared samples.) has been generated, the next step in the process is to interpret the biological meaning of gene expression changes and determine whether biological pathways may be of functional relevance to the mechanism of drug action, or maybe correlated to safety and/or efficacy.

A number of points should be addressed, e.g.:

- Are genes from a particular pathway or set of pathways significantly overrepresented in the list?
- How many pathways are affected?
- Can the mechanism of action be inferred from the functions of the pathways altered or from the pattern of expression across the genes within these pathways?
- What is the tissue specificity of the pathways and the gene function in relation to biological processes?

- What are the magnitude and/or pattern of the alteration in a particular pathway in relation to treatments with other compounds (related or unrelated) with known pharmacological or toxicological properties?

At present, no single tool can be used to find answers to all these questions, but a combination of tools can be used to address a particular question of interest as thoroughly as currently possible.

An overlap of the biological interpretations obtained with two or more different databases can facilitate a consensus on what the interpretation should be. However, this is not always the case. Consensus can be hindered by many factors including, but not limited to, absence of information on the compound of interest in the reference databases or a lack of annotation for particular pathways of interest. For example, subsets of genes may be placed in specific pathways in one system, but they may not be represented in the same pathways in another pathway analysis tool, or genes may not have been evaluated in a particular platform. In pathway analysis databases, the information may differ depending on which content is extracted from the literature and how that extraction is performed. A heavy reliance on the literature and on reference databases is recommended to extract functional information on specific gene lists and generate hypotheses on the biological significance of the relevant set of genes.

Pharmacological Relevance

Genomics, Proteomics and related disciplines that make use of systematic and highly parallel analyses of biological parameters serve support functions in several steps of the drug discovery process. Traditionally, the central focus in pharmaceutical research has been on target identification, since it had been expected that the discovery of novel genes involved in disease will help to discover new, effective and proprietary disease treatments. However, an abundance of potential target genes for many human diseases is publicly known as yet, putting the need to discover additional candidate genes into perspective.

Drugs currently on the market target a relatively small number of gene families, termed the ‘drugable genome’, dominated by the G protein-coupled receptor, kinase, protease, ion channel and nuclear hormone receptor gene families [4]. One strategy to identify novel drug targets is to mine the human genome for new members of the established families of drug targets. Such gene identification efforts based on homology searches can then be integrated with other approaches (e.g. microarray studies) to accumulate evidence that the presumed drug target is indeed a disease-modifying gene product. Alternatively, microarrays can be used ab initio to identify genes associated with pathology.

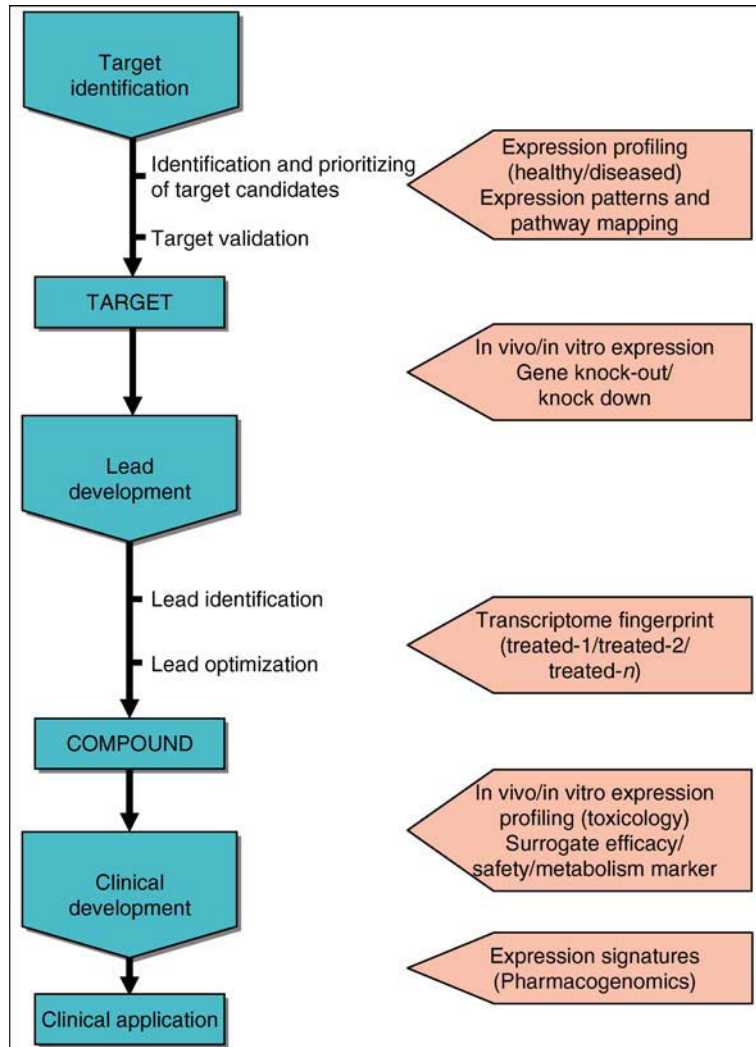

This strategy may also be used to implicate genes of unknown annotation or function in a disease process. Although microarrays are expected to have the potential to identify novel drug targets, the quality of the resulting candidate drug target is currently not easy to define. In addition, it should be looked at if the members of drugable gene families are properly represented in the ►transcriptome and/or if they are poorly expressed and below the detection limit of the current technology.

As a result of further technological improvements and decreasing costs, the use of microarrays will become an essential and potentially routine tool in understanding the mechanistic basis of action of many drugs.

The information about gene expression, global transcriptional changes induced by a particular drug and sequence variation might have an impact not only on therapeutic target identification, but also on many aspects of the drug discovery process and on drug efficacy. Microarrays are used at the following specified steps in the process of drug development:

- Target discovery, to identify genes or pathways with altered expression in diseased human tissues or in animal model of disease
- Target validation, to determine that a gene product is causative of disease symptoms or that activation of the target protein ameliorates disease symptoms. Agonist/activator or an inhibitor which may be therapeutic could be identified using microarrays
- ►Compound optimization, to screen a series of therapeutic drug candidates to find the compounds that are most specific for the target protein and those that cause unintended effects, i.e. improved understanding of the molecular mode of action including structure-activity relationships for on-target versus off-target effects
- Toxicology (►toxicogenomics), to identify potential human and environmental toxicants, and to find correlations between toxic responses to toxicants and changes in the genetic profiles of the objects exposed to such toxicants
- ►Drug metabolism, to predict whether a drug candidate will cause drug–drug interactions
- ►Drug efficacy, to identify the individual mode of action or adverse effects of a given drug, including identification of genes involved in conferring drug sensitivity and resistance
- Discovery of new diagnostic and prognostic indicators and ►biomarkers of therapeutic response, and prediction of patients most likely to benefit from the drug and use in general pharmacogenomic studies (Fig. 2)

At present, the use of microarrays in pharmacology is especially established in the field of oncology; by gene expression analysis with either tumour cell

Gene Expression Analysis. Figure 2 Contribution of gene expression profiling to the drug discovery process.

model systems or tumour tissue, mediators and mechanisms of drug response have been identified. One recent example is the use of in vitro drug sensitivity data coupled with Affymetrix microarray data to develop gene expression signatures that predict sensitivity to individual chemotherapeutic drugs, e.g. expression-based predictor of sensitivity to docetaxel [5]. Many of these signatures can accurately predict clinical response in individuals treated with these drugs. The integration of the chemotherapy response signatures with signatures of oncogenic pathway deregulation has led to the identification of new therapeutic strategies that make use of all available drugs. The development of gene expression profiles that can predict response to commonly used cytotoxic agents provides opportunities to better use these drugs, including using them in combination with existing targeted therapies.

Synonyms

Viral vectors; Gene transfer; Gene therapy

Definition

The basic principle of gene therapy is rather simple: therapeutic genes are transferred into the patient's cell and organs. The therapeutic effect is either achieved by correction of a genetic defect (e.g., single gene defects) or by expressing genes that positively affect disease course, patient status, and outcome. The vehicle used to transfer the therapeutic gene is still a major factor for the success or failure of gene-therapy trials.

Description

With the progress of the human genome project and functional genomics, the number of genes that could have a therapeutic impact is increasing at an astonishing pace. However, a major problem for successful gene therapy is the gene delivery vehicle.

Design of Viral Vectors

Viral vector design focuses mainly on the efficacy of gene delivery and on the biosafety of the engineered viruses. A prerequisite for the use of a virus as gene-therapy vehicle is to identify and eliminate pathological or toxic viral genes. Ideally, all viral genes are replaced by the gene of interest (also called transgene) (Fig. 1). The viral gene products required for the assembly of infectious particles and packaging of the vector into these particles are provided in *trans* by the so-called packaging cells, while necessary *cis*-acting factors like packaging signals are incorporated into the vector genome.

Regulation of Gene Expression

An important issue is the regulation of gene expression in the target cells and tissues. Although steady-state expression over prolonged time intervals is desired in many diseases, controlled expression of the foreign gene in a reversible manner will be highly desirable (e.g., gene therapy for insulin-dependent diabetes mellitus). To achieve more physiological expression profiles, novel regulatable systems that are controlled by endogenous (e.g., hormones) and/or exogenous (e.g., pharmacological agents) factors have to be developed. In addition, regulation of transgene expression by the gene product itself via negative or positive feedback mechanisms would be an additional desired feature.

Viral vectors are usually classified by the characteristics of the parental virus. Based on the viral genome, one can distinguish between DNA and RNA viruses (for details see [1, 2]).

DNA Virus Vectors

The most widely used DNA virus vectors are derived from adenovirus (Ad) and adeno-associated virus (AAV). Adenoviruses contain a 36-kb double-stranded DNA genome and can infect a broad spectrum of cells, including nondividing cells like hepatocytes and neuronal cells. Ad vectors can be produced at high

Gene-therapy Vectors. Figure 1 Design of gene-therapy vectors. (a) Schematic drawing of the genome of the parental virus. (b) The viral genes required for the production of infectious particles are provided in *trans* (right), the vector itself carries the gene of interest (transgene) under the control of a specific promoter.

titers ($\sim 10^{14}$ particle/ml) and can efficiently express transgenes in many different cells and tissues. However, transgene expression is only short-lived, because the Ad chromosome does not integrate into the host genome and is maintained as an episome. In addition, adenoviral infection causes a humoral and cellular immune response in immune-competent hosts. This immune response is directed not only against the viral particles but also against the infected cells. An unbalanced, massive immune response directed against Ad can be life-threatening to the patient especially if a high concentration of Ad vectors is administered [2]. Therefore, gutless Ad vectors that do not contain viral genes have been developed. Transgene expression from these gutless vectors has been reported to be more long-lasting and the host immune response less pronounced (see [1]). Replication-competent Ad vectors are especially promising for oncolytic therapy. To this end, Ad vectors, which preferentially replicate in tumor cells, have been designed.

AAVs are parvoviruses that are nonpathogenic to humans and carry a small genome of only 4.7 kb. Entry of AAV into the cell is mediated by binding to heparan sulfate proteoglycan. Integrin $\alpha v\beta 5$ and the fibroblast growth-factor receptor 1 act as coreceptors. In the absence of the so-called helper viruses (Ad and herpes viruses), AAV integrates into the host genome (human chromosome 19) and establishes latent infection. The integration of wild-type AAV is site-specific and requires the presence of the viral Rep protein, which is normally absent from AAV vectors. Therefore, recombinant AAV (rAAV) lacking the *rep* gene exhibits significantly lower integration frequencies and site-specific integration is lost. Nevertheless, long-term transgene expression can be achieved with rAAV, because extrachromosomal rAAV genomes can persist as episomes [1].

The development of AAV-based gene-therapy vectors is presently focused on the analysis of the properties of the different AAV serotypes, especially the host range of the virion shells of the different serotypes. By packaging

the AAV genome, e.g., from AAV-2 into the capsid of other AAV serotypes (crosspackaging), the tropism of AAV vectors can be changed. Crosspackaging can achieve efficient and specific transduction of target cells and tissues.

Another important issue is the size-limitation of AAV vectors: the maximum size of rAAV genomes is ~ 4.7 kb. To overcome this size constraint, dual vector systems with split-genomes have been developed [1]: dual vectors are based on episomal circular multimers formed by the AAV vector genomes. However, the efficacy of the dual vector system has been questioned.

Presently, 25% and 4% of all clinical gene-therapy trials use Ad and AAV vectors, respectively, as gene-delivery vehicle (Table 1). Although no pathology is known to be associated with AAV, the high frequency of antibodies against AAV (80% of the human population are seropositive for the most common AAV subtype) could be a major limitation for gene therapy using AAV-based vectors [3].

RNA Virus Vectors

The most commonly used RNA viruses are based on *Retroviridae*. Retroviruses are enveloped viruses that integrate into the host genome. All retroviruses contain a basic set of three genes: *gag* (the structural virion proteins), *pol* (essential viral enzymes), and *env* (the viral glycoproteins of the envelope). Prototypic retroviruses like murine leukemia virus (MLV) carry only this simple set of genes, while complex retroviruses like the lentiviruses carry additional regulatory genes. The first gene-therapy vectors were derived from prototypic retroviruses, and they were the first viral vectors to be used in clinical trials. Retroviral virions can accommodate ~ 7 kb of RNA and after reverse transcription in the target cells, the vector DNA is randomly integrated into the host chromosomes. Integration of the vector genome is of advantage if long-term (even life-long) vector expression is wanted. However, vector integration harbors the risk of insertional mutagenesis and

Gene-therapy Vectors. Table 1 Gene therapy – clinical trials

Vector	Number (of viral gene transfer protocols)
Adenovirus	25% (35%)
AAV	4% (5%)
Retrovirus	23% (32%)
Lentivirus	1% (1%)

Detailed information can be found at (► <http://www.wiley.co.uk/genetherapy/clinical/> and ► www4.od.nih.gov/oba/rdna.htm).

activation of proto-oncogenes. To cope with the latter problem, self-inactivating retroviral vectors have been developed which carry deletions of the essential viral promoter/enhancer sequences. However, incorporation of the so-called SIN (self-inactivating) mutations can result in a significant reduction of retroviral titers [1, 2].

A major drawback of vectors derived from prototypic retroviruses is that they can only transduce dividing cells. Therefore, these vectors cannot be used for gene transfer in many nondividing cells (e.g., muscle and brain cells).

To circumvent this problem, vectors that are based on lentiviruses have been developed. In contrast to prototypic retroviruses, lentiviruses do not require cell division for integration. Gene-therapy vectors have been developed from a broad spectrum of lentiviruses including human immunodeficiency virus (HIV), simian and feline immunodeficiency virus as well as visna/maedi virus. The most widely used lentiviral vector system is based on HIV-1. These vectors can efficiently transduce a broad spectrum of dividing and nondividing cells including neurons, hepatocytes, muscle cells, and hematopoietic stem cells [1, 2].

To address biosafety concerns, self-inactivating lentiviral vectors and stable packaging cell lines have been developed.

Apart from being a promising tool for gene therapy, lentiviral vectors are also important tools for molecular biology. These vectors efficiently transduce a variety of nondividing cells in vitro. Lentiviral vectors can be used to generate clinically relevant transgenic animal models (lentiviral transgenesis) (for a detailed review see [4]). Importantly, lentiviral transgenesis is not restricted to rodents (mouse and rat), but can also be used to generate transgenic animals in medically relevant livestock species (pig, cattle, chicken).

Finally, lentiviral vectors have been shown to transduce human embryonic stem cells. Therefore, this type of gene-therapy vector might also be used in stem cell-based therapies.

Retrovirus- and lentivirus-derived vectors are used in approximately one quarter of all gene-therapy trials (Table 1). The gene-therapy trial in patients suffering

from severe combined immunodeficiency-X1 (SCID-X1) led by Alain Fischer and colleagues initially reported the successful restoration of the immune systems of SCID patients [2]. In this trial, hematopoietic stem cells were transduced with vectors derived from simple retroviruses. Unfortunately, 3 years after the start of the trial, two of the patients developed leukemia. Detailed analysis of vector-integration sites revealed that the retroviral vector had integrated close to the protooncogene LMO2 [2]. These results clearly underline the risk of insertional mutagenesis inherent to gamma retroviruses (also known as oncoretroviruses, like MLV). Although lentivectors presently account for only less than 1% of the gene-therapy trials, the first publication of a clinical trial using a lentiviral vector in the *Proceedings of the National Academy of Sciences* [5] highlighted the potential of this vector system. This phase I trial evaluated the safety of a conditionally replicating HIV-derived vector expressing an antisense gene against the HIV envelope. Importantly, the study demonstrated not only safe and efficient gene delivery to the patients' T cells, but also no adverse clinical effects were detected during the follow-up for 2 years. Based on the encouraging results, a multicenter phase II trial was started (details can be found at ► <http://www.virxsys.com>).

Pharmacological Relevance

Although pharmacology still relies heavily on small chemical substances, biologicals like recombinant proteins, cell-based therapies, and gene-therapy approaches have great potential for the treatment of broad spectrum of diseases. Therefore, the focus of modern pharmacology should shift towards these innovative therapies.

Presently, 1,260 gene-therapy trials are underway worldwide (Tables 1 and 2). For details see ► <http://www.wiley.co.uk/genetherapy/clinical/>. Almost three fourths of all trials are based on viral vectors. The vast majority of nonviral gene-therapy trials use naked/plasmid DNA (18% of all gene-therapy trials).

At the present time, almost two thirds of all gene-therapy trials target immunological and oncological diseases (Table 2).

Potential Risks

An important safety issue of viral vectors is whether or not the recombinant viruses are able to replicate in the infected cells. Replication of viral vectors is unwanted in most gene-therapy approaches. Therefore, replication-defective vectors have been designed, which are able to perform only one initial infectious cycle within the target cell. In addition, replication-competent vectors have been designed, which are able to productively infect the target cell and to spread in the target tissue.

Immunological reactions of the host to either the delivery vehicle or its cargo are another concern. The host immune response might not only eliminate the vector

Gene-therapy Vectors. Table 2 List of most common therapeutic genes used in gene-therapy trials (viral and nonviral vectors)

Gene type	Number
Cytokine	27%
Antigen	16%
Tumor suppressor	11%
Suicide	8%

particles before they reach the target cells/tissues. In addition, it can also be directed against the product(s) of the genes delivered by the vector, especially if a null-mutation is replaced with a functional copy of the affected gene (in this case no immunological tolerance would exist for the product of the normal gene).

The development of leukemia in patients receiving retrovirally transduced cells, clearly underlines that insertional mutagenesis is a major concern for integrating vectors.

Gene Transfer

► Gene-therapy Vectors

Gene Transfer Mechanisms (Bacteria)

Genetic material can be transferred horizontally between bacterial cells either as free DNA by transformation or as plasmid DNA via conjugational

mating of bacterial cells or as fragments of chromosomal DNA with the help of bacteriophages. Some of these virus-like particles called transducing bacteriophages can incorporate fragments of chromosomal DNA of the bacterial cell into the bacteriophage. During the course of a second infection this foreign DNA instead of bacteriophage DNA is delivered to another cell and introduced into the respective locus within the chromosome by homologous recombination.

General Anaesthetics

KEITH WAFFORD

Merck, Sharp & Dohme Research Laboratories, Harlow, Essex, UK

Synonyms

Anaesthetic

Definition

General anaesthesia can encompass several different end points, the most critical of which can be defined as unconsciousness. A loss of sensation including that of any painful stimulus, and muscle relaxation are also desirable endpoints of general anaesthesia. Modern-day anaesthesia is accomplished using a balanced combination of different drugs to confer these different endpoints.

Mechanism of Action

General anaesthetics have been in use for the last 100 years, yet their mechanism of action are still not yet clearly defined. For many years it was thought that general anaesthetics exerted their effects by dissolving in cell membranes and perturbing the lipid environment in a non-specific manner. This theory derived from the observation that for a number of drugs which induced anaesthesia, their potency correlated with their oil–water partition coefficients. This Meyer–Overton correlation was accepted for a number of years, however in the last 15–20 years evidence has shown that a more likely theory is that of specific interactions of anaesthetics with proteins, particularly those within the CNS that mediate neurotransmission [1].

Two methods of anaesthesia are currently in use, the application of inhaled gaseous or volatile anaesthetics such as halothane, sevoflurane and isoflurane to maintain a level of anaesthesia. Older compounds in this category include nitrous oxide and chloroform.

The other method used is infusion of intravenous anaesthetics such as propofol, etomidate (for induction) and the barbiturates such as thiopental and pentobarbital. Investigations into the mechanism of anaesthesia have made use of all these compounds in order to identify a common mode of action linked to likely mechanisms within the CNS.

Research on anaesthetic mechanisms over the last 20 years has moved away from the lipid theory and focussed on specific protein interactions. The discovery that anaesthetics have major effects on receptors and channels within the nervous system have provided a clear and rational approach to understanding how anaesthesia is generated. Effects on ligand-gated ion channels currently offer the most likely mechanism of action, however some anaesthetics interact directly with voltage-gated channels [2]. In general, activity at voltage-gated ion channels are relatively weak and may not correlate with anaesthetic doses. Similarly, there have been some reports of interactions with G-protein coupled receptors but again at non-clinical concentrations.

Which of the ligand-gated receptors are affected by anaesthetics and are relevant in conferring unconsciousness and loss of sensation? Volatile anaesthetics and alcohols are quite promiscuous in their effects on ligand-gated channels, showing potentiation of inhibitory channels such as ►GABA_A and ►glycine receptors and inhibition of neuronal ►nicotinic, AMPA and ►NMDA receptors [3]. Where investigated these compounds also potentiate kainate and 5-HT₃ receptors (alcohols inhibit kainate). Intravenous agents are slightly more selective, potentiating GABA_A and inhibiting neuronal nicotinic receptors, however, effects on other ion channels are detectable at non-clinical concentrations. Ketamine is unique in having little effect on GABA receptors but strong inhibition of NMDA receptors. Recent studies using enantiomeric isomers of etomidate have suggested that the inhibition of nicotinic receptors is not what underlies the anaesthetic properties of this compound, but these effects are much more likely to be via potentiation of ►GABA_A receptors, a feature common to the majority of anaesthetic agents at clinically relevant concentrations. The potency of volatile anaesthetics is expressed as MAC (minimum alveolar concentration) and when expressed as aqueous concentration ranges from 0.2 to 30 mM in terms of plasma concentration. These values equate well with their potency at GABA_A receptors. Intravenous anaesthetic levels are estimated from measured drug concentrations in plasma during anaesthesia and range between 0.3 and 50 µM, however, this may underestimate the true receptor occupancy with the drug.

Many anaesthetics exist as enantiomeric pairs which when separated show selectivity in terms of anaesthetic potency. Studies on the action of anaesthetics at GABA_A receptors have mimicked this selectivity, again

providing evidence that anaesthetic effects are mediated via these receptors. The inhibitory component of all central nervous system transmission is primarily determined by GABA_A receptors, being present at most inhibitory synapses and on the majority of neuronal cell bodies. It is clear that as GABA is such a major inhibitory component, enhancement of GABAergic function will produce pronounced depression of neuronal activity, consistent with that observed during anaesthesia.

A considerable body of data now exists demonstrating that the majority of volatile and intravenous anaesthetics potentiate GABA_A receptor transmission both in vivo and in vitro. GABA_A receptors comprise of a number of subtypes dependent on the components of a pentameric arrangement of subunits, which combine to form an ion channel selectively permeable to chloride. These are made up of $\alpha, \gamma, \delta, \epsilon$ and θ , with the majority of receptors comprising of 2 α , 2 γ and a $\gamma 2$ subunit. While the subunits all have unique regional distribution the majority of these receptors show sensitivity to anaesthetic agents. One exception to this is etomidate which demonstrates receptor selectivity for those containing a $\gamma 2$ or $\gamma 3$ subunit with little effect at $\gamma 1$ containing receptors. Recent studies combining molecular biology and electrophysiology have addressed the question of the site of action of anaesthetics on the receptor and these have revealed that potentiation by volatile anaesthetics and alcohols are dramatically affected by specific mutations at a serine residue within the second ►transmembrane domain of the receptor [4]. A second residue, an asparagine in the third transmembrane domain, can also abolish effects of these agents when mutated. Further studies based on these residues have shown that the anaesthetic cut-off for receptor potentiation can be affected and that photoactivatable anaesthetics can covalently label these residues, suggesting that there may be a binding pocket for these agents within this region of the receptor. Interestingly, the majority of intravenous agents remain unaffected by these mutations indicating that a separate region is involved in the binding of non-volatile agents. The availability of GABA_A receptor subunit knockout mice, and the application of transgenic technology to generate mice containing receptor mutants such as those described above will considerably advance our understanding of anaesthetic mechanisms in the next few years.

Clinical Use (Including Side Effects)

General anaesthetics are administered for many surgical procedures where the patient is likely to undergo a severely painful procedure, and complete unconsciousness and immobility is required for the surgery to be performed. The most commonly used volatile anaesthetics are halothane, isoflurane and sevoflurane. Nitrous oxide is also commonly used, particularly during

childbirth. Side effects that may be encountered following administration of these agents are cardiovascular and respiratory depression, post operative nausea and vomiting, hepatotoxicity via metabolite induction of liver enzymes, and occasionally nephrotoxicity from breakdown products.

Intravenous general anaesthetics are becoming increasingly popular due to the ease of application and continuous monitoring. Their rapid recovery has resulted in an increased use of these drugs in ambulatory surgery. They currently represent at least 50% of the total anaesthetic market and are dominated by propofol, followed by thiopental, etomidate and ketamine. A growing method of applying these anaesthetics is by target controlled infusion. This apparatus pumps a continuous amount of drug into the blood, allowing the anaesthetist to set a desired plasma concentration, which the software inside the pump produces rapidly, but safely, by automatically controlling the infusion rate according to a continuous measure of either level of compound in the plasma or depth of anaesthesia, continuously monitored by EEG. This method known as TIVA (total intravenous anaesthesia) is becoming popular due to the ease of use and additional level of control it allows. Side effects associated with intravenous anaesthetics are less than the volatiles, particularly in regard to postoperative nausea and vomiting (especially propofol), however, cardiovascular and respiratory depression still cause problems with propofol and the barbiturates. Lack of cardiovascular side effects make etomidate particularly attractive for patients with a compromised heart condition, however, continuous infusion results in cortisol inhibition and adrenal failure, so etomidate can only be used for anaesthetic induction.

General Transcription Factors

General or basic transcription factors are required for every gene to allow the proper recruitment of RNA polymerases to ensure transcriptional activity. They bind to core promoters in the vicinity of transcriptional start sites in a sequential manner.

- ▶ Transcriptional Regulation

Genetic Polymorphism

A genetic polymorphism is a difference in DNA sequence that has a frequency of at least 1% in a population. Some DNA sequence differences change the expression or function of drug metabolizing enzymes or of drug transporters or of drug target proteins and can therefore affect the disposition and action of drugs and xenobiotics. These are called pharmacogenetic polymorphisms.

Genome-wide Association Study (GWA Study)

A study that investigates the statistical associations between a phenotype and a very large number of genetic markers supposed to inform on the global variability of the genome. Because GWA studies do not rely on a priori knowledge, they may lead to the discovery of new causes of disease.

- ▶ Pharmacogenomics

Genomics

The goal of genomics is to determine the complete DNA sequence for all the genetic material contained in an organism's complete genome.

Functional genomics (sometimes referred to as functional proteomics) aims at determining the function of the proteome (the protein complement encoded by an organism's entire genome). It expands the scope of biological investigation from studying single genes or proteins to studying all genes or proteins at once in a systematic fashion, using large-scale experimental methodologies combined with statistical analysis of the results.

Structural genomics is the systematic effort to gain a complete structural description of a defined set of molecules, ultimately for an organism's entire proteome. Structural genomics projects apply X-ray crystallography and NMR spectroscopy in a high-throughput manner.

Gephyrin

Gephyrin is an intracellular membrane trafficking protein implicated in plasma membrane targeting and clustering of inhibitory glycine and GABA_A receptors. The tubulin-binding protein forms oligomers, generating a submembraneous scaffold at the postsynaptic face of inhibitory synapses. This scaffold serves as an anchor to the inhibitory glycine receptor and subtypes of the ▶GABA_A receptor, preventing the receptor complexes from lateral diffusion. Additional components of the postsynaptic protein scaffold include the phosphatidylinositol 3,4,5-trisphosphate binding

proteins collybistin and profilin. Serving dual functions, gephyrin also contributes to the biosynthesis of the molybdenum cofactor, an essential coenzyme of dehydrogenases.

- ▶ Growth Hormone

Ghrelin

A 28 amino acid long peptide hormone, which stimulates appetite and secretion of growth hormone from the anterior pituitary, mainly produced in the stomach. The active form of ghrelin exists as an acylated peptide with O-n-octanoylation at serine 3 essential for its activity. Ghrelin has been identified as the endogenous ligand for the growth hormone secretagogue receptor (GHS-R) ▶G-protein-coupled receptor. The receptor is known to be activated by small synthetic molecules, called growth hormone secretagogues, which stimulate the release of growth hormone from the pituitary. GHS-R is mainly expressed in hypothalamic areas of the brain where ghrelin is thought to exert its orexigenic effects. The ghrelin system is presently the focus of an intense ongoing research effort to understand the regulation of body weight homeostasis and energy expenditure in order to find new avenues to treat obesity and related disorders.

Gitelman's Syndrome

A milder clinical course with symptoms usually not apparent before age 5–10, and hypocalciuria with hypomagnesemia has been the clinical distinction between Gitelman's syndrome and true ► [Barter's](#)

[syndrome](#). The identification of a linkage between NaCl cotransporter (NCC) mutations and the disease provides a justification for this classification, and an explanation for the distinctly different phenotypes.

► Diuretics

Glial Cells

Glial cells are cells within the central or peripheral nervous system which are not immediately involved in information processing. Glial cells play an important role in the metabolic homeostasis of brain tissue and in nervous system development.

Glibenclamide

Sulfonylurea derivative which lowers blood glucose by stimulation of insulin secretion. Enhances the effect of submaximal glucose concentrations on the ATP-dependent potassium channel in pancreatic β -cells. Its potency is 200-fold higher than that of earlier derivatives, and it was therefore designated 2nd generation sulfonylurea. Because of its high affinity to other proteins, glibenclamide (US name: glyburide) is retained in tissues and may cause protracted hypoglycemia in patients who eat irregularly. Extraprostatic, insulin-like effects of sulfonylurea derivatives have been described in vitro, but require concentrations that largely exceed the therapeutic levels.

► Diabetes Mellitus

Glomerular Filtration Rate

Glomerular filtration rate (GFR) is the volume of plasma-like fluid that is filtered per unit time across the glomerular capillary membranes to enter the tubular space. Filtrate formation is driven by the net filtration pressure that is equal to the capillary hydrostatic pressure diminished by the sum of capillary oncotic

pressure and tubular hydrostatic pressure. Although normally only 1% of the filtered NaCl and water is excreted as urine, reductions in GFR are often accompanied by parallel reductions in urine excretion.

GLP-1

- ▶ Glucagon-like Peptide-1
- ▶ Incretin Hormones

Glucagon

Glucagon is a single chain 21 amino acid polypeptide, which is synthesized mainly in the A-cells of the pancreatic islets as well as in the stomach. Glucagon secretion is stimulated by low, and inhibited by high, concentrations of glucose or fatty acids in the plasma. Sympathetic nerves and circulating adrenaline stimulate glucagon release via γ -adrenoceptors. Somatostatin, released from D-cells of the pancreas to the glucagon-secreting A-cells in the periphery of the islets, inhibits glucagon release. One of the main physiological stimuli for glucagon secretion is the concentration of amino acids, in particular arginine, in the plasma. Glucagon acts on the liver to stimulate glycogen breakdown and gluconeogenesis as well as to inhibit glycogen synthesis and glucose oxidation. The net effect is consequently an increase in blood glucose. In liver and fat cells, glucagon induces lipolysis, while in muscle it leads to catabolism of proteins. The actions of glucagon on its major target tissues are thus the opposite of those of insulin. Glucagon exerts its effects through specific receptors, which belong to the group of ▶**G-protein-coupled receptors**. The glucagon receptor is coupled to adenylyl cyclase via the G-protein G_s in a stimulatory fashion. Glucagon can be used clinically to treat hypoglycaemia in unconscious patients under emergency conditions.

- ▶ Gluconeogenesis
- ▶ Insulin Receptor

Glucagon-like Peptide-1 (GLP-1)

Glucagon, glucagon-like peptide-1 (GLP1), and GLP2 are three peptide hormones generated by cleavage of a common precursor polypeptide (preproglucagon). GLP1 stimulates insulin secretion from pancreatic B cells and inhibits feeding in fasted rats when injected into cerebral ventricles.

Synonyms

Corticosteroids; Glucocorticoid agonists; Steroids; Asthma controllers

Definition

Endogenous glucocorticoids (cortisol) are released from the zona fasciculata of the ►adrenal gland in response to stress. When in excess glucocorticoids can cause ►catabolism of muscle and release of amino acids; these are subsequently used to increase glucose synthesis by the liver (gluconeogenesis). The most important function of glucocorticoids in disease is to regulate the inflammatory response to exogenous stimuli. Exogenous glucocorticoids have been used clinically for over 50 years and have proved to be indispensable in the regulation of a variety of inflammatory and immune states.

Mechanism of Action

Inflammation is a central feature of many chronic diseases including ►bronchial asthma. The specific characteristics of the inflammatory response and the site of inflammation differ between diseases, but all involve the recruitment and activation of infiltrating inflammatory cells and, in asthma, activation of structural cells within the airway is also seen. These diseases are characterised by an increased expression of many mediators including cytokines, chemokines, growth factors, enzymes, receptors and adhesion molecules. Increased inflammatory gene transcription is regulated by pro-inflammatory transcription factors, such as nuclear factor- κ B (►NF- κ B). For example, NF- κ B is markedly activated in epithelial cells of asthmatic patients and this transcription factor regulates many of the inflammatory genes that are abnormally expressed in ►bronchial asthma.

NF- κ B is activated by all the stimuli thought to be important in the inflammatory response to allergen exposure seen in asthma and is the major target for glucocorticoids. NF- κ B is ubiquitously expressed within cells and is able to not only control the induction of inflammatory genes in its own right but can enhance the activity of other cell- and signal-specific transcription factors such as CAAT/enhancer binding protein (C/EBP) α and interferon response factor (IRF)-1. NF- κ B is activated by numerous extracellular stimuli including cytokines, such as tumour necrosis factor- α (TNF α) and interleukin (IL)-1 β , rhinovirus infection and allergen exposure. NF- κ B is held within the cytoplasm in an inactive state by an inhibitor protein I κ B α . Phosphorylation of I κ B α following cell stimulation leads to the dissociation of I κ B α from NF- κ B, enabling nuclear translocation and binding to specific DNA response elements within the *regulatory regions* of responsive genes.

Due to the large amount of DNA present within the nucleus it must be carefully packaged. In the resting cell DNA is tightly compacted around basic ►histone proteins, excluding the binding of the enzyme ►RNA polymerase II, which activates the formation of ►mRNA. This conformation of the chromatin structure

is described as “closed” and is associated with suppression of gene expression. Expression of genes is associated with enzymatic modification of core histones leading to alterations in chromatin structure. DNA-bound transcription factors recruit ►transcriptional coactivator complexes that contain intrinsic histone acetyltransferase (HAT) activity. This results in acetylation of specific lysine residues locally within the N-terminal histone tail. Acetylation of the σ -group on lysines provides a “mark” or “tag”, which is recognised by other coactivators and by chromatin remodelling engines leading to a relaxed DNA structure and allowing the recruitment of large protein complexes including RNA polymerase II. Not all NF- κ B sites are the same and the degree of NF- κ B activation induced by various stimuli and the activation of additional transcription factors or coactivators results in different patterns of inflammatory genes being up-regulated depending upon the precise cell and stimulus used.

Repression of genes is associated with reversal of this process under the control of histone deacetylases (HDACs). Deacetylation of histones increases the winding of DNA round histone residues, resulting in a dense chromatin structure and reduced access of transcription factors to their binding sites, thereby leading to repressed transcription of inflammatory genes.

Cytokines such as TNF α and IL-1 β , acting via NF- κ B, can induce histone acetylation in both a time- and concentration-dependent manner. Upon DNA binding, NF- κ B recruits transcriptional coactivators such as CREB binding protein (CBP) and p300/CBP-associated factor (PCAF).

Glucocorticoids exert their effects by binding to a cytoplasmic receptor (GR). GRs are expressed in almost all cell types. The inactive GR is bound to a protein complex that includes two subunits of the Heat Shock Protein (►HSP) 90, which thus act as cytoplasmic inhibitors preventing the nuclear localisation of unoccupied GR. Once the ligand binds to GR, HSP90 dissociates allowing the nuclear localisation of the activated GR-steroid complex and its binding as a homodimer to specific DNA sequences (GRES, GGTACAnnnTGTTCT) and interaction with ►coactivator complexes.

Glucocorticoids produce their effect on responsive cells by stimulating GR to directly or indirectly regulate the transcription of target genes. The number of genes per cell *directly* regulated by glucocorticoids is estimated to be between 10 and 100, but many genes are indirectly regulated through an interaction with other transcription factors and coactivator complexes. Glucocorticoids may suppress inflammation by increasing the synthesis of anti-inflammatory proteins, such as annexin-1, IL-10 and the inhibitor of NF- κ B, I κ B- α (Table 1). In addition, it is likely that glucocorticoid side effects, such as ►osteoporosis, cataracts, skin fragility

Glucocorticoids. Table 1 Glucocorticoid-sensitive genes

Increased transcription	Decreased transcription
Lipocortin-1/Annexin-1 (phospholipase A ₂ inhibitor)	Cytokines (IL-1, 2, 3, 4, 5, 6, 9, 11, 12, 13, 16, 17, 18, TNF α , GM-CSF, SCF)

and Hypothalamic-Preoptic-Adrenal axis suppression are due to gene activation.

GRs, as with NF- κ B and other transcription factors, increase gene transcription through an action on chromatin modifications and recruitment of RNA polymerase II to the site of local DNA unwinding. GR interacts with CBP and other coactivator proteins, including CBP, PCAF and steroid receptor coactivator-1 (SRC-1), which enhance local HAT activity. This raises the question “how can GR, or any other transcription factor, interact with its recognition site when DNA is compacted”? GR may bind to a GRE within the linker DNA between nucleosomes or alternatively GR may bind to a GRE when the residues which form the GRE are facing outwards from the compacted nucleosomal structure. Binding to the GRE may then modify the local chromatin structure further enabling GR access.

There is now clear evidence that GR does not stably associate with DNA but rather it has a “hit-and-run” mechanism of action. After activation GR tracks along DNA until it finds a GRE and resides on this site for less than 10s before being ejected and replaced by another GR. This ejection may allow binding of additional regulatory factors that enhance gene transcription such as HAT-containing complexes and may also play a role in feedback regulation and subsequent **►proteosomal degradation** of GR.

In spite of the ability of glucocorticoids to induce gene transcription, the major anti-inflammatory effects of glucocorticoids are through repression of inflammatory and immune genes. The inhibitory effect of glucocorticoids appears to be due largely to an interaction between activated GR and transcription factors, such as NF- κ B and activator protein-1 (AP-1, a heterodimer of Fos and Jun proteins), which mediate the expression of most inflammatory genes. The interplay between pro-inflammatory transcription factors and GR may reflect differing actions on specific NF- κ B/transcription factor/coactivator complexes activated by

differing stimuli resulting in local changes in histone modifications, recruitment of RNA polymerase II and changes in distinct profiles of inflammatory genes. Thus, glucocorticoids are able to attenuate the NF- κ B-mediated induction of histone acetylation by IL-1 β in lung epithelial cells and macrophages. This occurs by a combination of a direct inhibition of NF- κ B-associated HAT activity and by active recruitment of corepressor complexes containing HDAC proteins (Fig. 1). Overall, this results in the deacetylation of histones, increased tightening of DNA round histone residues, loss of RNA polymerase II and repression of inflammatory genes.

►Mitogen-activated protein kinases (MAPK) play an important role in inflammatory gene expression through the regulation of pro-inflammatory transcription factors and there is increasing evidence that glucocorticoids may exert an inhibitory effect on these pathways. Glucocorticoids reduce the stability of mRNA for inflammatory genes such as cyclooxygenase-2 (**►COX-2**) through an inhibitory effect on p38 MAPK kinase, through rapid induction of a specific p38 MAPK phosphatase (MKP-1) and subsequent dephosphorylation of phospho-p38 MAPK. GR has also been shown to prevent serine phosphorylation of c-Jun and, subsequently, AP-1 activation, by blocking the induction of the Jun N-terminal kinase (JNK) signalling cascade. Consistent with this, glucocorticoids also antagonise other JNK-activated transcription factors such as ETS-Like Kinase 1 (Elk-1) and Activating Transcription Factor 2 (ATF-2). Conversely, JNK can phosphorylate GR and thereby attenuate glucocorticoid responsiveness.

The importance of cross-talk in GR actions is indicated by the construction of a GR dimerisation-deficient mutant mouse in which GR is unable to dimerise and therefore bind to DNA, thus separating the DNA-binding (transactivation) and inflammatory gene repression (transrepression) activities of glucocorticoids. In these animals dexamethasone was able to inhibit AP-1- and NF- κ B-mediated gene transcription,

Glucocorticoids. Figure 1 How glucocorticoids switch off inflammatory genes. Inflammatory genes are activated by inflammatory stimuli, such as interleukin (IL)-1 β or tumor necrosis factor (TNF) α , resulting in activation of the transcription factor nuclear factor κ B (NF- κ B). NF- κ B translocates to the nucleus and binds to specific κ B recognition sites and also to *transcriptional coactivators*, such as CREB-binding protein (CBP) or p300/CBP-activating factor (PCAF), which have intrinsic *histone acetyltransferase* (HAT) activity. This results in acetylation of lysines in *histone* proteins, resulting in recruitment and phosphorylation of *RNA polymerase II* and subsequent increased expression of genes encoding inflammatory proteins. Glucocorticoid receptors (GR), after activation by glucocorticoids (GCs), translocate to the nucleus and, as a monomer, bind to *corepressor* proteins thereby inhibiting NF- κ B-associated HAT activity. In addition, GR is able to recruit corepressor proteins including *histone deacetylases* (HDAC) to the NF- κ B complex further enabling suppression of inflammatory genes. GR may also affect the phosphorylation of *RNA polymerase II* to block inflammatory gene expression.

but the ability to facilitate GRE-mediated effects such as cortisol suppression and T-cell apoptosis were markedly attenuated. This suggests that the development of glucocorticoids with a greater therapeutic window is possible.

Clinical Use (Including Side Effects)

Glucocorticoids are widely used to treat a variety of inflammatory and immune diseases. With the recognition that airway inflammation is present even in patients with mild asthma, treatment with glucocorticoids is now the mainstay of asthma therapy. Consequently, by far the most common use of glucocorticoids today is in the treatment of asthma and inhaled glucocorticoids have now become established as first-line treatment in adults and children with persistent asthma, the commonest chronic airway inflammatory disease.

Inhaled glucocorticoids reduce the number of infiltrating mast cells, macrophages, T-lymphocytes and eosinophils in the airway. Furthermore, glucocorticoids reverse the shedding of epithelial cells and the goblet-cell \blacktriangleright hyperplasia characteristically seen in asthmatic patients (Fig. 2). By reducing airway inflammation, inhaled glucocorticoids reduce \blacktriangleright airway hyperresponsiveness in adults and children with asthma. Current asthma guidelines suggest that the addition of a long-acting β_2 -agonist should be considered rather than

increase the glucocorticoid dose. The rationale for this is that long-acting β_2 -agonists can enhance glucocorticoid receptor activation and inflammatory gene suppression without affecting the side-effect profile.

Although glucocorticoids are highly effective in the control of asthma and other chronic inflammatory or immune diseases, a small proportion of patients with asthma fail to respond even to high doses of oral glucocorticoids. Resistance to the therapeutic effects of glucocorticoids is also recognised in other inflammatory and immune diseases, including rheumatoid arthritis and inflammatory bowel disease. Glucocorticoid-resistant patients, although uncommon, present considerable management problems. It is likely that there is a spectrum of glucocorticoid responsiveness, with the rare resistance at one end, but a relative resistance is seen in patients who require high doses of inhaled and oral glucocorticoids (glucocorticoid-dependent asthma). At present the limiting factor to treating these patients with ever increasing doses of glucocorticoids is the side-effect profile.

Generally, inhaled glucocorticoids have few side effects, the appearance of which depends on the dose, the frequency of administration, and the delivery system used. The most common side effect is dysphonia (hoarseness), which affects approximately one third of treated patients. Oropharyngeal candidiasis (thrush)

Glucocorticoids. Figure 2 Cellular effect of glucocorticoids. Glucocorticoids can affect the activation of most resident and infiltrating cells with the airway suppressing either cell number or mediator release or both. In addition, glucocorticoids are able to decrease vascular permeability (leak) within the airways that causes oedema and increase the expression of β_2 -receptors in smooth muscle cells.

may also be a problem for some patients, particularly the elderly, when the drug is given more than twice daily. There has been some concern that inhaled glucocorticoids may cause stunting of growth in children but recent evidence suggests that this is not a problem even in children treated with higher doses of inhaled glucocorticoids for a long period. Thinning of the skin, telangiectasia, and easy bruising are also classic side effects of both oral and topical glucocorticoids. The easy bruising linked to inhaled glucocorticoids is more frequently seen in elderly patients.

Oral glucocorticoids used to treat severe asthmatic subjects, however, give rise to more serious side effects. Glucocorticoids suppress the hypothalamic-pituitary-adrenal axis by reducing cortisol secretion by the adrenal glands. The degree of suppression depends upon the dose, duration, frequency, and timing of glucocorticoid administration. Oral glucocorticoid therapy also causes osteoporosis with an increased risk of vertebral and rib fractures, but there are no reports suggesting that long-term treatment with inhaled glucocorticoids is associated with an increased risk of fractures. In addition, long-term treatment with oral glucocorticoids increases the risk of posterior subcapsular cataracts; this may be a problem in a few patients taking inhaled glucocorticoids.

Due to the side-effect problems seen with high doses of inhaled glucocorticoids resulting from systemic absorption and the use of oral glucocorticoids in severely affected patients, there has been a search for safer glucocorticoids for inhalation and even for oral administration. As discussed above, a major mechanism

of the anti-inflammatory effect of glucocorticoids appears to be due to the inhibition of the effects of pro-inflammatory transcription factors (*transrepression*). By contrast, the endocrine and metabolic effects of glucocorticoids that are responsible for the systemic side effects of glucocorticoids are likely to be mediated predominantly via *transactivation*. This has led to a search for novel glucocorticoids that selectively *transrepress* without significant *transactivation*, thus reducing the potential risk of systemic side effects.

Several steroidal and non-steroidal glucocorticoid receptor selective dissociated agonists are in development by many pharmaceutical companies and some are now in clinical development. This suggests that the development of dissociated glucocorticoids with a greater margin of safety is possible and may even lead to the development of oral compounds that do not have significant adverse effects.

Now that the molecular mechanisms of glucocorticoids have been elucidated, this raises the possibility that novel non-steroidal anti-inflammatory treatments might be developed, which mimic the actions of glucocorticoids on inflammatory gene regulation. Inhibition of specific HATs activated by NF- κ B may prove useful targets, especially if they also repress the action of other pro-inflammatory transcription factors. Many of the anti-inflammatory effects of glucocorticoids appear to be mediated via inhibition of the transcriptional effects of NF- κ B and small molecule inhibitors of I κ B kinase-2 (IKK2), which activate NF- κ B, are now in development. However, glucocorticoids have additional effects so that it is not certain

whether IKK2 inhibitors will parallel the clinical effectiveness of glucocorticoids and they may have side effects, such as increased susceptibility to infections. Other treatments that have therapeutic potential as glucocorticoid-sparing agents include p38 MAP kinase inhibitors.

Glucocorticoids, Inhalable

Inhalable glucocorticoids are derivatives of the hormone cortisol, which are applied topically in the treatment of (allergic) ▶ **bronchial asthma**. In contrast to systemically applied glucocorticoids, these drugs are metabolized upon first liver passage into inactive forms, thus reducing the systemic side effects of unintentionally swallowed drug. Like all glucocorticoids they exert strong anti-inflammatory and anti-allergic effects.

Gluco-mineralocorticoid Receptors

HOLGER M. REICHARDT

Department of Cellular and Molecular Immunology,
University of Göttingen,
Göttingen, Germany

Synonyms

Glucocorticoid Receptor: GR; GCR; GRL; Nuclear Receptor Subfamily 3, Group C, Member 1 (NR 3C1); Glucocorticoid Receptor Type II

Mineralocorticoid Receptor: MR; MCR; MRL; Nuclear Receptor Subfamily 3, Group C, Member 2 (NR3C2); Glucocorticoid Receptor Type I; Aldosterone Receptor

Definition

Glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) are members of the ▶ **nuclear receptor superfamily** and they mediate the organism's response to cortisol and aldosterone, two steroid hormones synthesized in the adrenal gland [1]. GR is ubiquitously expressed and orchestrates a plethora of physiological processes including energy homeostasis, stress response, and inflammation. In contrast, expression of MR is largely restricted to epithelial cells in kidney and colon as well as the limbic system of the brain. Consequently, MR mainly controls water homeostasis and cognitive processes. Due to their central roles in many physiological processes, lack of either of the two receptors is incompatible with life.

Basic Characteristics

In the inactive state, both GR and MR reside in the cytoplasm bound to a complex of heat shock proteins (Hsps). The main ligands cortisol and aldosterone can freely cross the cell membrane owing to their lipophilic nature. Upon hormone-binding, the receptor is released and translocates into the nucleus (Fig. 1). Following homodimerization, GR and MR bind to specific response elements located in the promoter and enhancer region of responsive genes and thereby induce gene expression. Thus, both GR and MR act as transcription factors (TFs). In addition, evidence has accumulated that the two receptors may also heterodimerize, resulting in synergy or inhibition of transcription. Besides these DNA-binding-dependent mechanisms, GR only interacts with other transcription factors without direct DNA-contact itself [1]. This second mode of GR action, also known as ▶ **cross talk**, plays an important role in the regulation of the immune system. Furthermore, so-called nongenomic effects, occurring within seconds or minutes after hormone

Glucocorticoid Receptors. Figure 1 Molecular modes of glucocorticoid receptor action. Glucocorticoids (GCs) passively enter the cell and bind to GR, resulting in the release of associated heat shock proteins (Hsps). After translocation into the nucleus, GR modulates transcription either by binding of homodimers to glucocorticoid response elements (GREs) (1) or via protein–protein interaction with other transcription factors (TFs) (2). Alternatively, GRs interact with cytosolic signaling molecules such as PI3K (3). Finally, glucocorticoids presumably bind to yet uncharacterized membrane GRs (mGRs) and thereby elicit fast responses (4). His = histones, Pol = RNA Polymerase II.

exposure, have been described for both GR and MR. These fast responses may either be mediated by interaction with cytosolic signaling molecules such as PI3K or by binding of hormones to membrane-bound receptors. However, whether the latter ones are encoded by the classical GR and MR genes or rather represent unrelated proteins remains unknown.

Molecular Characterization of Glucocorticoid and Mineralocorticoid Receptor

The cDNA of GR was first cloned in 1985 [2]. GR is a 94 kDa protein and consists of 777 (alpha) amino acids in the human. The cDNA of MR was cloned 2 years later by homology screening and it represents a 107 kDa protein consisting of 984 amino acids in the human. GR and MR are formed of a modular structure consisting of three major domains, common to most members of the nuclear receptor superfamily. The central DNA-binding domain is the most conserved one and it consists of two Zinc-fingers. The first one is responsible for DNA-binding whereas the second one contributes to dimerization of the receptor. The C-terminal region is made of the ligand-binding domain, which is responsible for hormone binding and interpretation. Additionally, the hormone-dependent transactivation domain AF-2 and a nuclear-localization signal are located here. The

N-terminal domain is the least conserved region and contains the transactivation domain AF-1.

Human glucocorticoid receptor maps to the long arm of chromosome 5 (5q31–5q32) whereas human mineralocorticoid receptor maps to the long arm of chromosome 4 (4q31.1).

Between 5,000 and 100,000 GR molecules are found within almost every cell of the organism. The affinity constant for cortisol comes to around 30 nM, which is in the range of the concentration of free hormone in the plasma under normal conditions. Consequently, receptor occupancy can be expected to be 10–70%. This suggests that changes in cortisol secretion such as under stress conditions, directly translate into alterations in GR occupancy, leading to transcriptional responses.

Although MR also binds glucocorticoids, its main ligand in classical mineralocorticoid target tissues such as kidney and colon is aldosterone (K_d 1.3 nM). This can be granted to the ability of \blacktriangleright 11 β -hydroxysteroid dehydrogenase type II (11 β -HSD II) to convert active cortisol into its inactive metabolite cortisone in these tissues. Since aldosterone is no substrate for this enzyme it can readily bind to MR, leading to exclusive occupation of the receptor by aldosterone. In contrast, no such mechanism exists in brain and presumably

heart, resulting in predominant glucocorticoid-binding to MR. Since MR has an approximately tenfold higher affinity for cortisol than GR, it is almost completely occupied by hormone already under basal conditions.

Control of Glucocorticoid Secretion by the Hypothalamus–Pituitary–Adrenal Axis

Synthesis and secretion of glucocorticoids is controlled by a neuroendocrine cascade called the ►**hypothalamus pituitary adrenal (HPA) axis**. Stimuli such as stress or infection lead to the release of corticotropin-releasing hormone (CRH) in the hypothalamus. CRH is transported to the anterior pituitary, where it induces increased synthesis and secretion of adrenocorticotropic hormone (ACTH). Finally, ACTH stimulates release and production of glucocorticoids in the adrenal cortex. Protection from chronically elevated hormone levels is achieved by a negative feedback-loop where glucocorticoids inhibit their own production and secretion by binding to GR, mainly in the pituitary and in the hypothalamus. Further regulation comprises effects of GR and MR on glucocorticoid production exerted via higher brain centers such as the hippocampus. Superimposed to the regulation by the HPA axis, glucocorticoid serum levels show a circadian rhythm with high levels in the morning and low levels in the evening (in the human). Finally, a feedback loop connecting glucocorticoid production with the control of the immune system is operative. Cytokines released during inflammation stimulate glucocorticoid secretion, which in turn inhibits cytokine production. This shows that glucocorticoids acting via GR and MR are under complex regulation by the endocrine, immune, and central nervous system.

Physiological Functions of Glucocorticoid Receptor

Glucocorticoids derive their name from the finding that they play an important role in carbohydrate metabolism. They increase hepatic glycogen and gluconeogenesis, decrease glucose uptake and utilization in peripheral tissues and cause a tendency to hyperglycemia and reduced glucose tolerance. Furthermore, energy homeostasis is also influenced via effects on protein and lipid metabolism. An important function of glucocorticoids, which are widely employed in the treatment of autoimmune diseases, is their potent anti-inflammatory and immunosuppressive activity. Glucocorticoids inhibit the production and release of cytokines (IL-1 β , IL-6, TNF α), chemokines (IL-8), and various enzymes (COX-2, iNOS) and induce T cell apoptosis. Furthermore, they interfere with proliferation, leukocyte migration, and the generation of adaptive immune responses. In the central nervous system, glucocorticoids contribute to mood and memory formation. Further processes that are controlled by GR include erythropoiesis, bone formation, adrenalin

synthesis, and lung function. This shows that a plethora of physiological processes involves regulation by GR, also explaining the variety of symptoms observed in diseases related to GR dysfunction or after genetic manipulation in animals (see below).

Diseases Related to Glucocorticoid Dysregulation

The most common disease related to glucocorticoids is Cushing's syndrome. This disorder is characterized by hypercortisolism due to a pituitary or adrenal tumor. The elevated glucocorticoid levels lead to a large spectrum of symptoms, including obesity, hirsutism, hypertension, muscular weakness, depression, osteoporosis, short stature, facial plethora, fat redistribution, and atrophy of the skin. Treatment of Cushing's disease is either achieved by surgical removal of the tumor or by pharmacological interference with ACTH or cortisol hypersecretion. Addison's disease, in contrast, is caused by adrenocortical insufficiency mainly following autoimmune destruction or tuberculosis. Clinical features of hypocortisolism include fatigue, weight loss, anorexia, and hypotension. Treatment can only be achieved by life-long replacement therapy with both glucocorticoid and mineralocorticoid hormones. In contrast to the aforementioned syndromes, congenital adrenal hyperplasia (CAH) has a genetic cause. Mutations in genes encoding steroidogenic enzymes impair the production of both glucocorticoid and mineralocorticoid hormones. As a consequence of the disturbed negative feedback mechanism, ACTH levels are elevated resulting in enhanced androgen production by the adrenal gland. Finally, depression is also linked to GR and MR function in a yet not fully understood way. Elevated glucocorticoid levels and a blunted circadian rhythm usually accompany depressive illnesses, which both normalize after application of anti-depressants. However, whether glucocorticoids are cause or effect of depression remains to be elucidated.

Clinical Features and Genetic Basis of Glucocorticoid Resistance

Primary ►**glucocorticoid resistance** in humans is characterized by elevated plasma cortisol concentrations, a normal circadian pattern set at a higher level and resistance to adrenal suppression by dexamethasone in the absence of clinical signs of Cushing's syndrome. The absence of hypercortisolism is presumably due to the fact that glucocorticoid resistance is in balance with peripheral tissues, being as resistant to hormone as the central tissues of the HPA axis. In severe forms, primary glucocorticoid resistance is accompanied by an increase in mineralocorticoid secretion leading to hypertension and hypokalemic alkalosis. In women, overproduction of androgens causes signs of hirsutism. The causes of glucocorticoid insensitivity are diverse and not yet fully understood. For example, point mutations in

the GR gene leading to reduced hormone binding or transcriptional capacity, reduced number of receptor molecules due to heterozygosity, or splice-site mutations and changes in receptor associated proteins all have been accounted for the observed clinical symptoms. Additionally, resistance to glucocorticoids may also be acquired, following long-term glucocorticoid treatment of leukemia or asthma patients.

Animal Models for Glucocorticoid Receptor Function

Pepin et al. (1992) generated transgenic mice in which antisense RNA complementary to GR cDNA led to reduced expression mostly in neuronal tissues. Consequently, this was found to result in an impaired behavior, a defective response to stress as well as in obesity. King et al. (1995) generated transgenic mice where reduced GR expression was limited to the thymus. This leads to an altered thymocyte development, changes in the T-cell repertoire, and a reduced risk to develop autoimmune diseases.

Cole et al. (1995) reported on ►knock-out mice with a germ line deletion of GR. They demonstrated that lack of GR leads to perinatal death, atelectasis of the lung, and lack of adrenalin synthesis. To circumvent perinatal lethality, Tronche et al. (1999) and Brewer et al. (2003) generated tissue-specific somatic deletions of GR. This allowed to characterize GR function in the CNS, the immune system, and the liver in more detail. In particular, these approaches revealed novel aspects of organ-specific glucocorticoid physiology such as anxiety-like behavior, growth control, and polyclonal T cell activation.

Since GR can influence transcription through both the DNA-binding-dependent and-independent mechanisms, Reichardt et al. [3] attempted to separate these two modes of action by introducing a point mutation into GR. This mutation interferes with transactivation while transcriptional regulation via cross talk with other transcription factors such as AP-1 and NF- κ B remains intact (see above). In contrast to GR-deficient mice, these GR^{dim} mice are viable, revealing the importance of DNA-binding-independent transcriptional regulation by GR in vivo. Mutant mice lose the ability to transactivate gene transcription by cooperative DNA-binding, which results in impaired thymocyte apoptosis, erythropoiesis, gluconeogenesis, and memory formation. In contrast, most immunosuppressive and anti-inflammatory effects of glucocorticoids are functional in the absence of DNA-binding by GR.

To study the effect of an increased gene dosage of GR, Reichardt et al. (2000) and van den Brandt et al. (2007) generated rodent models of GR overexpression. These approaches confirmed that GR controls neuronal and immune functions in a dosage-dependent manner. These results highlight the importance of tight control of GR expression in target tissues and may explain

differences in the susceptibility of humans to inflammatory diseases and stress.

Physiological Functions of Mineralocorticoid Receptor

MR forms an essential component of the ►renin–angiotensin–aldosterone system (RAAS), which regulates salt and water homeostasis in the body. In particular, MR mediates the organism's response to aldosterone in tissues such as kidney, colon, and salivary gland. In the distal tubules of the kidney, it induces enhanced sodium and water retention in response to a reduction in extracellular fluid volume or a fall in blood pressure. Besides its role in salt and water homeostasis, MR appears to play a major role in the limbic system of the brain. Notably, high levels of MR are expressed in hippocampus and amygdala, where it modulates the transcriptional response to glucocorticoid hormones in concert with GR. Studies with specific MR ligands as well as analyses of genetically manipulated mice have indicated that MR in the brain is involved in the control of cognitive processes such as learning and memory and in the modulation of mood and anxiety.

Diseases Related to Mineralocorticoid Receptor

Several diseases involving dysregulation of MR function have been described although most of them are not causatively linked to the receptor itself. Pseudohypoaldosteronism for example is a syndrome of mineralocorticoid resistance characterized by urinary salt loss and dehydration. However, only very rarely mutations in the MR gene have been found in these patients so far. In most cases, this syndrome appears to be linked to defects in the subunits of the amiloride-sensitive sodium channel ENaC, a major target of mineralocorticoid action in the kidney.

Patients suffering from hyperaldosteronism usually present with severe hypertension and marked sodium retention, due to high levels of circulating aldosterone. Whereas primary forms of this disease are caused by certain tumors of the adrenal cortex, resulting in increased hormone production (Conn's disease), secondary forms can often be attributed to enhanced secretion of renin. In contrast, patients with apparent mineralocorticoid excess (AME) show unremarkable levels of aldosterone and cortisol. In fact, this syndrome can be explained by recessive mutations in the gene encoding 11 β -HSD II (see above). Diminished or absent activity of the enzyme leads to massive activation of MR in kidney by the comparably high concentrations of circulating cortisol and consequently to strong sodium and water retention.

Animal Models for Mineralocorticoid Receptor Function

Berger et al. (1998) generated MR knock-out mice by gene targeting. Until day 10 after birth, these mice develop normally. Later they show symptoms of pseudohypoaldosteronism, characterized by massive

loss of renal sodium and water, finally leading to death. The lack of MR causes a severe upregulation of the RAAS with a strong increase in most of its components. Using a salt replacement protocol, it was possible to rescue the mutant mice from postnatal death, thus facilitating the study of the physiological role of MR in the adult. Analyses of the brain revealed that loss of MR caused increased neurodegeneration in the hippocampus accompanied by reactive gliosis and decreased neurogenesis. Forebrain-specific MR knock-out mice reported by Berger et al. [4] confirmed that MR is involved in the control of learning and memory but not of anxiety-like behavior. This highlights distinct roles of GR and MR in the regulation of cognitive functions.

Drugs

GR Ligands

Glucocorticoid agonists mainly comprise cortisol, corticosterone, aldosterone, and synthetic steroids used in clinical therapy such as ►[dexamethasone](#), prednisolone, methylprednisolone, or triamcinolone. In addition, also some nonsteroidal compounds such as aziridines may bind to GR and regulate its activity. Agonists are defined as compounds, which bind to the receptor and elicit a transcriptional response. Cortisol and corticosterone have equal affinities for GR. However, due to the concentration of circulating hormone, cortisol is the principal glucocorticoid in humans and corticosterone in rodents. Aldosterone also displays high affinity for GR but since its concentration in plasma is about three magnitudes of order lower than that of cortisol, aldosterone does not play a physiological meaningful role for GR activity.

Glucocorticoid antagonists also bind specifically to GR. However, these steroids do not elicit a response but rather compete with agonists for binding and thereby prevent an agonist response. In addition, partial agonists are known, which elicit an intermediate response of GR. Well-known examples for glucocorticoid antagonists are ►[RU486 \(Mifepristone\)](#), which also binds to progesterone receptor, and the unrelated compound ZK98299, a presumably pure GR ligand. However, RU486 is not a full antagonist since this compound cannot inhibit some transcriptional activities of GR.

Synthetic glucocorticoids may be grouped in several classes. First, compounds that are more potent than naturally occurring glucocorticoids due to a higher binding affinity or decreased clearance rate. Due to both these effects, dexamethasone, for example, is over 10 times more potent than cortisol. Second, compounds which have less mineralocorticoid activity resulting in a reduced spectrum of MR-mediated side effects. Third, dissociating compounds that are unable to induce transcriptional responses which are mediated by DNA-binding of GR but which are still functional in

modulating transcription by interaction with other transcription factors (see above). This characteristic is expected to be useful in achieving potent anti-inflammatory and immunosuppressive effects (thought to be primarily mediated by interaction with other transcription factors) but lacking some of the adverse effects (presumably mediated by DNA-binding-dependent transcriptional regulation by GR). This principle has gained support from an animal model (GR^{dim}, described above), which mimics this dissociating principle in vivo.

MR Ligands

MR has a high affinity for mineralocorticoids such as aldosterone and DOC. In addition, MR also binds glucocorticoids although in mineralocorticoid target tissues this is prevented by the enzyme 11 β -HSD II (see above). Since mineralocorticoids are no substrate for 11 β -HSD II due to their cyclic 11,18-hemiacetyl-group, they are able to bind to MR despite the 1,000-fold lower concentration in plasma as compared with cortisol.

The main mineralocorticoid agonist in humans is aldosterone. Additionally, cortisol, corticosterone, and DOC have also mineralocorticoid agonistic activity. The synthetic steroid fludrocortisone (9 α -fluorocortisol) is extremely potent and usually chosen for replacement mineralocorticoid therapy. In contrast, aldosterone and DOC are not useful in oral therapy due to rapid degradation in liver after absorption.

Mineralocorticoid antagonists include RU26752, spironolactone, eplerone, and progesterone. Whereas endogenous progesterone may only play a role during the third trimester of pregnancy, ►[spironolactone](#), eplerone, and RU26752 are synthetic drugs, which have been developed for the treatment of pathological states of sodium-regulation and hypertension. These drugs bind to MR with equal affinity as aldosterone but are assumed to induce a transcriptionally silent state.

Definition

Glucose transporters are integral membrane proteins that catalyze the permeation of sugars into cells, along or against a concentration gradient.

Basic Characteristics

The Family of Glucose Transport Facilitators

Glucose transport facilitators (GLUT proteins) are uniporters which catalyze the diffusion of glucose into (or out of) cells along the concentration gradient [1, 2]. During this process, the proteins are believed to undergo specific conformational changes: Binding of glucose to the outward-facing binding site induces a conformational alteration that moves the substrate through the pore of the GLUT protein. Thereafter, glucose is released from the inward-facing binding site to the cytoplasm, and the transporter undergoes the reverse conformational change (Fig. 1a). Within most cells, glucose is rapidly phosphorylated and metabolized. Thus, under normal conditions the influx of glucose into cells does not alter its concentration gradient. In liver, kidney, and intestinal mucosa, GLUT proteins catalyze the efflux of glucose from cells, when the intracellular glucose concentration exceeds the serum glucose concentration.

The family of GLUT proteins comprises 14 structurally related members, GLUT1–12, HMIT, GLUT14 (29–65% identity). Among these, there are glucose (GLUT1–3, 4, 8, 14), fructose (GLUT5, 7, 11), polyol (GLUT12), and myo-inositol (HMIT) transporters [1, 2]. At present, the function of the other family members is incompletely characterized. The presumed secondary structure of all GLUT proteins is similar, with 12 membrane spanning helices, intracellular N- and C-termini and a large cytoplasmic loop. The three-dimensional structure of a structurally related transporter protein, the glycerol-3-phosphate transporter of *Escherichia coli*, confirmed the proposed model of GLUT proteins and of all other related transporters [2]. GLUT proteins carry charged residues at the intracellular surface of the proteins which are believed to provide the proper orientation and anchoring of the helices in the membrane, and to participate in the conformational changes during the transport process. Several sequence motifs, the sugar transporter signatures, are conserved in all family members, and are essential for the function of the proteins (Fig. 1b).

According to a comparison of the sequences, the GLUT family can be divided into three subclasses [1, 2]. Class I comprises the thoroughly characterized members GLUT1–4 and GLUT14 that are distinguished mainly by their tissue distribution (GLUT1, erythrocytes, brain microvessels; ► GLUT2, liver, pancreatic islet – several mutations within the GLUT2 encoding gene *SLC2A2* cause the ► **Fanconi-Bickel syndrome** – ; GLUT3, neuronal cells; ► GLUT4, muscle, adipose tissue; GLUT14, testis), their affinity to glucose, and their hormonal regulation. Class II comprises the fructose-specific transporter GLUT5 (testis, intestine, muscle) and three related proteins, GLUT7 (intestine, testis, and prostate), GLUT9

Glucose Transporters. Figure 1 (a) Proposed model of the mechanism of glucose entry into cells by facilitated diffusion. Glucose binds to an outward-facing site of the GLUT protein and induces a conformational change that moves the hexose through a pore in the protein. After glucose is released from its inward-facing binding site, the GLUT protein undergoes the reverse conformational change. Two inhibitory ligands (cytochalasin B and forskolin) bind to the cytoplasmic site of GLUT proteins. (b) Schematic model of the GLUT proteins with their predicted 12 membrane spanning helices. The figure highlights motifs that are considered specific for the GLUT family (sugar transporter signatures), and other residues that are highly conserved in all members of the family.

(pancreas, kidney, liver), and GLUT11 (heart, muscle, pancreas, placenta, kidney). For GLUT7 and GLUT11, fructose-inhibitable glucose transport activity has been demonstrated after expression of their mRNA in *Xenopus* oocytes. Class III comprises five isoforms: GLUT6 (brain, spleen, leukocytes), GLUT8 (testis, brain, adipocytes), GLUT10 (pancreas, liver), GLUT12 (heart, prostate), and HMIT, a myo-inositol transporter (brain). Glucose transport activity has been shown for GLUT6 and GLUT8.

Glucose transport activity is regulated through transcriptional and translational control of the GLUT proteins, through their activity, and through alterations of their intracellular distribution. Most importantly, the GLUT4 continuously cycles between an intracellular,

vesicular storage compartment and the plasma membrane of adipose and muscle cells [2, 3]. In basal cells, most transporters are sequestered in the intracellular compartment. In the presence of insulin, the translocation of GLUT4-containing vesicles to the plasma membrane is markedly accelerated, resulting in an increase in glucose transport uptake (see chapter Diabetes Mellitus). Proteins that presumably participate in this process are ▶VAMP2, ▶SNARE proteins, ▶syntaxin 4, ▶SNAP23, and Synip. In some cells, GLUT1 may also be sequestered through a discrete vesicular pathway, and translocated to the plasma membrane in response to energy depletion or lack of glucose.

For some of the GLUT isoforms, the phenotype of null mutants is known. Haploinsufficiency of the GLUT1 in

humans causes a syndrome of low glucose levels in the cerebrospinal fluid and drug-resistant seizures. Disruption of the *GLUT2* gene in mice leads to impaired insulin secretion and diabetes mellitus. In contrast, hepatic glucose output is normal in GLUT2-null mice, suggesting that an alternative pathway for glucose export from hepatocytes exists. Muscle-specific deletion of the GLUT4 results in a reduction of basal glucose transport and a near-absence of the effect of insulin, leading to hyperinsulinemia and impaired glucose tolerance. Furthermore, it is believed that impaired GLUT4 translocation in skeletal muscle is an important factor in the pathogenesis of insulin resistance in obesity and type 2 diabetes. In animal models of morbid obesity, transgenic overexpression of GLUT4 results in increased glucose uptake in muscle, and in improved whole body glucose disposal. Thus, strategies designed to enhance expression and/or translocation of GLUT4 might lead to an effective treatment of insulin resistance and type 2 diabetes [3]. Recently, it was demonstrated that deletion of GLUT3 causes early pregnancy loss during neurulation; the heterozygous mice showed fetal growth retardation but survived birth and developed normal body weight, body composition, glucose, and insulin tolerance. In contrast, GLUT8 was shown to be dispensable for embryonic development. GLUT8 null mutants had normal postnatal development, glucose homeostasis, and response to stress. They showed increased proliferation of hippocampal cells without defects in memory acquisition and retention [4].

The Family of Sodium-dependent Glucose Cotransporters

Sodium-dependent glucose cotransporters (SGLT) are located on small-intestine and kidney brush-border membranes. SGLT1, SGLT2, and SGLT3 are

structurally different sodium–glucose cotransporters with 59–75% identity, and no homology with the GLUT [5]. They catalyze glucose transport into the cell against a concentration gradient. This transport process is a cotransport of one glucose and of one (for SGLT2) or two (for SGLT1 and SGLT3) Na^+ ions in the same direction. The energetically favored movement of a Na^+ ion through the plasma membrane into the cell, driven both by its concentration gradient and by the membrane potential, is coupled to the movement of the glucose molecule. SGLT proteins exhibit binding sites for glucose and Na^+ on their exofacial surface. The simultaneous binding of Na^+ and glucose to these sites induces a conformational change, generating a transmembrane pore that allows both Na^+ and glucose to pass into the cytosol. After this passage, the proteins revert to their original conformation. In the steady state, Na^+ ions transported from the intestinal lumen into the cells are pumped by a Na^+/K^+ -ATPase across the basolateral membrane (Fig. 2). Glucose concentrated inside the cell by the symport moves outward through the basolateral membrane via GLUT.

The secondary structure of SGLT1 differs from that of other members of the family. As compared with SGLT2 and 3, SGLT1 contains a hydrophobic C-terminus which is assumed to form a 14th transmembrane. SGLT1 is a high-affinity transporter that mediates the sodium–glucose cotransport across the intestinal brush-border membrane. SGLT1 is also expressed in the proximal tubule S3 segments of the kidney. Mutations within the SGLT1 gene (*SLC5A1*; on chromosome 22q12.3) are described in patients suffering from ►glucose/galactose malabsorption.

SGLT2 is a low-affinity, high capacity sodium–glucose cotransporter located in the early proximal convoluted tubule S1 segment. SGLT2 comprises 13

Glucose Transporters. Figure 2 Transport of glucose in intestinal epithelium. Entry of glucose into the epithelial cells is catalyzed by a sodium-dependent cotransporter (SGLT) located in the apical membrane. The Na^+/K^+ ATPase in the basolateral membrane generates the Na^+ gradient that drives the sodium–glucose cotransport by SGLT against the concentration gradient of glucose. Glucose leaves the cell via a facilitated glucose transporter (GLUT) located in the basolateral membrane.

membrane spanning domains. In contrast to SGLT1, SGLT2 does not transport D-galactose. It has been suggested that a defect in the *SGLT2* gene (*SLG5A2* on chromosome 16p11.2) is responsible for ►renal glucosuria.

SGLT3 is also a low-affinity sodium–glucose cotransporter. SGLT3 mRNA was mainly detected in intestine, followed by spleen, liver, kidney, and muscle. SGLT3 comprises of 13 membrane spanning domains. SGLT3 has a lower affinity for Na⁺ than SGLT2 under identical sugar concentrations.

Over recent years, data collected from homology cloning and the Human Genome Project has indicated the presence of additional members of the SGLT-like transporters, which are still under investigation. Additional members (SGLT4–6) have been assigned but await complete functional and structural characterization. Amino acid comparisons of human SGLTs range between 57 and 71% sequence identity; they exhibit no homology with the facilitated glucose transporters [5].

Drugs

Insulin

At present, the only available drug that stimulates glucose transport is insulin. Insulin increases the abundance of the GLUT4 in plasma membranes of adipose and muscle cells by its recruitment from intracellular storage sites (for a detailed description of its mechanism, see Chapter Diabetes Mellitus).

Phlorizin

Phlorizin (phloretin-2'-β-glucoside) is a plant product from the bark of the apple tree which inhibits intestinal glucose absorption and renal reabsorption in proximal tubules by binding to SGLTs. This effect has been used to correct hyperglycemia in experimental, diabetic animals. SGLT2 has a higher affinity for the inhibitor than SGLT1.

Phloretin

Phloretin is the aglycon of phlorizin and inhibits the facilitated diffusion of glucose catalyzed by GLUT1 or GLUT4. It has been used to terminate the uptake of glucose in timed assays with isolated membranes or reconstituted transporters.

Cytochalasin B

Cytochalasin B is a fungal metabolite which binds to the internal site of helices 10 and 11 of the GLUT proteins, and potentially inhibits glucose transport in cells or isolated membrane vesicles ($K_D = 100$ nM). Because cytochalasin B binding can be inhibited by glucose in a competitive manner, it is believed that the ligand binds to the internal glucose binding site of the transporter.

Forskolin

The plant product forskolin (from *Coleus forskolii*) is a diterpene which directly stimulates adenylate cyclase. In addition, the agent potently inhibits glucose transport independent from changes in adenylate cyclase activity. Specific binding of forskolin to GLUT1 or GLUT4 is inhibited by glucose and cytochalasin B in a competitive manner, indicating that the ligand binds to a domain involved in glucose binding. Its binding site has been mapped to helix 8–10 of GLUT1/GLUT4 with the aid of the photoreactive 3-[¹²⁵I]odo-4-azido-phe-nethylamino-7-O-succinyldeacetyl-forskolin (IAPS-forskolin).

Glucose/Galactose Malabsorption (GGM)

Glucose/galactose malabsorption (GGM) is an intestinal monosaccharide (glucose and galactose) transport deficiency. The disorder manifests itself within the first weeks of life. The severe diarrhea and dehydration are usually fatal unless glucose and galactose are eliminated from the diet. Fructose and xylose are absorbed normally. Occurrence in both males and females, familial incidence, in particular in parental consanguinity, indicate autosomal recessive inheritance of

GGM. Several missense mutations in human sodium-dependent glucose transporters (SGLT1) have been described that cause GGM.

Glutamate

Glutamate is a small amino acid which constitutes the most important neurotransmitter at excitatory synapses in the mammalian brain. Glutamate can act on several different types of receptors including cation channels and ► G-protein-coupled receptors.

► Glutamate Receptors
► Ionotropic Glutamate Receptors
► Metabotropic Glutamate Receptors

Glutamate Receptors

Glutamate receptors are classified as AMPA, NMDA, and mGluR. All three subtypes are highly expressed at nociceptive synapses. AMPA and NMDA receptors are agonist-gated cation channels, which depolarize synaptic membranes upon activation. Ion channels associated with AMPA receptors demonstrate fast activation and inactivation kinetics and mediate rapid excitatory neurotransmission. Owing to their slow kinetic properties, their high Ca^{2+} permeability and their blockade by Mg^{2+} under physiological synaptic conditions, NMDA receptors potentiate synapses in several neural pathways, including those involved in chronic pain. mGluRs are ► G-protein-coupled receptors, which couple to G-proteins of the Gq family or the Gi/o family. Their activation at spinal synapses leads to the facilitation of postsynaptic responses and enhanced neurotransmitter release via calcium-mediated activation of intracellular signaling kinases.

Inhibitory glycine receptor; Strychnine-sensitive glycine receptor; Glycine-gated chloride channel; Glycine-gated anion channel

Definition

The amino acid glycine serves as an important mediator of synaptic inhibition, predominantly in brain stem, spinal cord and retina. Binding of the neurotransmitter to its postsynaptic receptors is antagonized by strychnine, a convulsant alkaloid from *nux vomica* [1]. The inhibitory action of glycine is distinct from its function as a coagonist to glutamate at a strychnine-resistant binding domain of the NMDA receptor. Inhibitory glycine receptors represent a family of ligand-gated chloride channels that exist as pentameric protein complexes which are assembled from ligand-binding α subunits and a structural γ polypeptide [2, 3]. At the postsynaptic membrane, glycine receptors are clustered by interaction with the tubulin-binding protein ► **gephyrin** [3]. ► **Hyperkplexia**, a human neurological disorder characterized by exaggerated startle responses and an increased muscle tone, is associated with mutant alleles of the glycine receptor $\alpha 1$ and γ subunit genes, *GLRA1* and *GLRB*. Likewise, homologous disease states exist in

mutant mouse lines carrying mutations of glycine receptor $\alpha 1$ and γ subunit genes [2].

Basic Characteristics

The Glycinergic Synapse and its Constituents

Glycinergic synapses show a widespread distribution throughout the CNS [1–3]. Glycine-mediated inhibition underlies the modulation of brain stem reflexes and the segmental regulation of spinal motoneurons by small interneurons including the Renshaw cells. The neurotransmitter pool of glycine is derived from both metabolic precursors and reuptake from the synaptic cleft. Synthesis of glycine from its precursor serine is catalyzed by the mitochondrial isozyme of ► **serine-hydroxymethyltransferase**, which is dependent on tetrahydrofolate and pyridoxal phosphate. Finally, glycine is degraded to CO₂ and ammonia by the glycine cleavage system, a mitochondrial enzyme complex. Mutations of its genes cause nonketotic hyperglycinemia, a devastating neonatal disease characterized by lethargy, seizures, and mental retardation in surviving patients. In the presynaptic terminal, the release fraction of glycine is stored in small synaptic vesicles. Vesicular loading of glycine is mediated by the vesicular inhibitory amino acid transporter (VIAAT or vesicular GABA transporter/VGAT), which is also involved in synaptic vesicular storage of GABA. Inhibitory miniature potentials recorded from rat motoneurons are consistent with the presynaptic vesicular release of the neurotransmitter into the synaptic cleft. The exocytotic release of glycine is a highly regulated process, where the vesicle protein synaptobrevin plays a pivotal role for vesicle fusion with the presynaptic membrane.

► **Tetanus**, a disease caused by the anaerobic, spore-forming rod *Clostridium tetani*, is associated with a presynaptic block of glycine release. The clostridial protein, tetanus toxin, possesses a protease activity which selectively degrades synaptobrevin. Consistent with a loss of glycinergic inhibition, the hypertonic motor symptoms of tetanus resemble strychnine intoxication. Once released into the synaptic cleft, glycine is rapidly taken up by sodium-dependent transporters characterized by distinct regional distributions. The transporters GLYT1a and GLYT1b represent splice variants of the same gene, differing in N-terminal structure. Both variants show a widespread distribution throughout the CNS, with GLYT1a predominating in the grey matter and GLYT1b in the white matter. In contrast, the transporter GLYT2 colocalizes with the strychnine-sensitive glycine receptor, suggesting a role in the termination of glycinergic inhibition.

Glycine Receptor Structure and Genetics

Receptor-binding of glycine induces the opening of an intrinsic anion channel highly selective for chloride and bicarbonate [2–4]. Depending on the low reversal

potential for chloride that prevails in many neurons of the mature CNS, this elicits inward chloride currents and a postsynaptic hyperpolarization. Glycine receptors are derived from a family of highly homologous subunit genes. This group of genes is part of the superfamily of ligand-gated ion channels which also includes the nicotinic acetylcholine, GABA_A, and 5-HT₃ receptors. Glycine receptor subunits assemble into pentameric channels thought to form a rosette-like arrangement surrounding a central ion pore. Glycine receptor isoforms are characterized by distinct developmental and regional expression patterns. The adult isoform, GlyR_A, is an oligomeric protein composed of ligand-binding α 1 and structural γ subunits. The neonatal isoform, GlyR_N, prevails in newborn rodents and is replaced by the adult type GlyR_A within two weeks postnatally. The GlyR_N protein appears to be a homooligomer composed of α 2 subunits. In addition to α 3 and α 4 subunits encoded by distinct genes, further complexity of α subunits results from alternative pre-mRNA splicing [3].

Glycine receptor α and γ subunit variants are characterized by transmembrane topologies common to the superfamily of ligand-gated ion channels [2, 3]. A large, N-terminal extracellular domain, which in the mature α 1 subunit comprises 220 amino acid residues, is followed by four transmembrane regions (TM1 to TM4) spanning the postsynaptic membrane. A fifth hydrophobic region preceding the mature protein represents the cleavable signal peptide. Displaying a rare ability among receptor channel polypeptides, glycine receptor α subunits are self-sufficient in creating homomeric receptor channels when subjected to recombinant expression. Recombinant glycine receptor variants faithfully reproduce pharmacological characteristics of their native counterparts from mammalian CNS. Attempts to elucidate structure–function relationships of glycine receptor subunits have led to the identification of structural motifs involved in distinct steps of ligand-gated ion conductance: (i) As deduced from radioligand-binding studies and whole-cell current recordings, glycine and strychnine bind to partially overlapping, but not identical, sites on the receptor. Determinants of ligand-binding and agonist-antagonist discrimination have been assigned to the N-terminal domain, where two stretches of amino acid residues preceding the TM1 domain were identified to contribute to the ligand-binding pocket. A recombinant switch in aromatic hydroxyl groups flanking position α 1(160) generated a γ -alanine receptor responsive to GABA. (ii) Domains involved in anion translocation include the TM2 region as well as the short loops flanking TM2 at the intracellular and extracellular faces of the plasma membrane. Receptor-gating, i.e., the open–close transition of the ion channel, has been interpreted as an intramolecular motion of TM2, where the flanking loops act as hinges

for the conformational transition. While two anion binding sites within the glycine receptor channel have been postulated from electrophysiological analysis, the pathway of chloride permeation across the membrane still awaits elucidation. ► **Desensitization** of glycine receptor ion channels is affected by intracellular determinants positioned within the short loop between TM1 and TM2, as well as within the large loop connecting TM3 and TM4. In particular, the splice variants α 3K and α 3L which differ in a motif located within the TM3–TM4 loop, also differ in desensitization behavior. (iii) Receptor assembly and heteropentameric subunit stoichiometry are governed by motifs, in particular an eight amino acid sequence, residing within the N-terminal extracellular regions of the receptor subunits.

Excitatory Action of Glycine Receptors in Developing CNS

In the embryonic CNS and in dorsal root ganglia, the neuronal reversal potential for chloride is above the membrane potential. Under these conditions, opening of glycine-associated chloride channels will result in depolarizing currents and subsequent excitation, once the neuronal threshold for formation of action potentials is exceeded. During a short postnatal period, glycine receptors are abundantly expressed in rat cerebral cortex which, by immunological criteria, correspond to the GlyR_N isoform. Activation of the cortical glycine receptors results in excitatory impulses and appears to be mediated by nonsynaptically released taurine [2]. The functional role of glycine receptor mediated excitation in the developing neocortex remains to be established.

Postsynaptic Clustering by Gephyrin

Glycine receptors associate with gephyrin, a tubulin-binding protein involved in the formation of postsynaptic receptor clusters [3]. Gephyrin is thought to form a submembraneous protein scaffold that dramatically reduces lateral diffusion of the receptor complexes. This interaction increases receptor life-time by stabilizing the protein remaining in its postsynaptic location in the plasma membrane. Receptor stabilization is activity-dependent, resulting in a loss of receptors under conditions of reduced glycinergic transmission, as induced by application of strychnine. Interaction of gephyrin and glycine receptor subunits occurs by means of an 18 amino acid residue motif located within the intracellular loop between TM3 and TM4. Gephyrin also interacts with GABA_A receptors, potentially via the GABA_A receptor associated protein (GABARAP). As additional components of the postsynaptic protein scaffold, phosphatidylinositol 3,4,5-trisphosphate-binding proteins have been identified, including collybistin and profilin. However, gephyrin also serves dual functions apparently beyond synaptic

organization, as it contributes to biosynthesis of the molybdenum cofactor, an essential coenzyme of a variety of dehydrogenases.

Disease Mechanisms

Based on its clinical resemblance to subconvulsive strychnine poisoning, glycine receptor dysfunction has long been considered a candidate mechanism of hypertonic motor disorders [1, 2]. As exemplified in the spontaneous mouse mutants spastic, spasmodic, and oscillator, glycine receptor defects result in hereditary neurological disorders. In the spastic mouse, the intronic insertion of a LINE-1 transposable element into the γ subunit gene *Glyrb* results in aberrant splicing and a consecutive loss of receptors. Consistent with a numerical receptor defect, the spastic phenotype is rescued by a transgene expressing γ subunit mRNA. The spasmodic mouse carries a missense mutation of the $\alpha 1$ subunit gene, *Glra1(A52S)* that diminishes agonist affinity. The spasmodic locus is linked by synteny homology to the human chromosomal region 5q31.3 carrying the human *GLRA1* gene. In the oscillator mutant, a microdeletion within the *Glra1* gene causes a complete loss of the glycine receptor isoform GlyR_A, resulting in lethality. During development, the postnatal appearance of all of these mutant phenotypes coincides with the switch from the unaffected neonatal (GlyR_N) to the diminished adult receptor isoform, GlyR_A.

Hyperekplexia (startle disease, stiff baby syndrome) is a congenital human motor disorder that follows autosomal-recessive as well as dominant modes of inheritance [2]. Affected patients exhibit an exaggerated startle response and increased muscle tone. Hyperekplexia is associated with a variety of *GLRA1* and *GLRB* mutant alleles that affect glycine receptor affinity and ion conductance. In the disease associated $\alpha 1$ subunit variants, the amino acid positions mutated cluster near segment TM2. In particular, the hyperekplexia allele $\alpha 1(P250T)$ predicts a substitution in the cytoplasmic loop TM1–TM2 (Fig. 1). Recombinant $\alpha 1(P250T)$ channels show reduced chloride conductance and enhanced desensitization, defining an intracellular determinant of channel-gating. In contrast, the mutation $\alpha 1(K276E)$ situated within the extracellular loop TM2–TM3, is without effect on channel conductance, but almost exclusively affects gating. Hyperekplexia mutations of *GLRA1* also give clues to glycine receptor regulation in the human: In several cases of recessive hyperekplexia, homozygosity for a null allele of *GLRA1* was found, consistent with a complete loss of gene function. Born to consanguineous parents, the affected children displayed relatively mild symptoms despite this “knockout” situation. In contrast to lethality of the null allele in homozygous oscillator mice, the complete loss of the $\alpha 1$ subunit is tolerated in

Glycine Receptors. Figure 1 Transmembrane topology of glycine receptor α subunits. Positions of amino acid exchanges $\alpha 1(P250T)$ and $\alpha 1(K276E)$ associated with the human neurological disorder hyperekplexia are as indicated by filled circles, amino acid residues involved in ligand binding and discrimination are indicated by open circles. The glycine receptor subunit variant $\alpha 3L$ carries a cytoplasmic insertion sequence (box) which is generated by alternative splicing. This insertion is missing from the splice variant $\alpha 3K$.

the human. This suggests that either the loss of glycine receptors is effectively compensated or that subunit regulation substantially differs among these species [5].

Drugs

The inhibitory glycine receptor still lacks a therapeutic pharmacology. The agonistic properties of glycine are imitated by a series of structurally related amino acids [1,2]. In spinal neurons, the relative potency of these agonists decreases in the order of: glycine > γ -alanine > taurine > α -alanine > serine. In contrast, the structurally related amino acid GABA is not an agonist at glycine receptors. Recombinant $\alpha 1$ subunit receptors respond to this group of glycinergic amino acid agonists, while recombinant $\alpha 2$ subunit receptors are preferentially activated by glycine and barely respond to γ -alanine and taurine. The convulsant alkaloid strychnine is a high affinity antagonist ($K_D \approx 10$ nM) of receptor binding by glycine ($K_D \approx 10$ μ M). Consistent with the physiology of glycinergic synapses, sublethal strychnine poisoning causes motor disturbances, e.g., increases in muscle tone and hyperreflexia. Further symptoms include alterations of sensory, visual, and acoustic perception. As a result of dysinhibition in auditory and motor centers, strychnine

generates excessive startle responses, while higher doses lead to convulsions and death. Glycine displaceable binding of [³H]strychnine is a highly specific probe of the glycine receptor. High affinity binding of [³H]strychnine has been demonstrated to spinal cord, sensory, and acoustic ganglia of the brain stem as well as to retina. Symptoms of strychnine intoxication correlate to the dysfunction of those CNS regions displaying high [³H]strychnine binding. In addition, numerous drugs and toxins including muscimol analogues, benzodiazepines, convulsant steroids, and picrotoxinin have been shown to exert strychnine-like effects, yet at significantly higher concentrations.

Glycine receptor function is modulated by alcohols and anesthetics [4]. Amino acid residue $\alpha 1$ (S267) is critical for alcohol potentiation, as mutation to small residues (Gly, Ala) enhance, and mutation to large residues (His, Cys, Tyr) diminish the ethanol effect. Glycine receptor modulation by Zn²⁺ involves structural determinants located within the large N-terminal domain. Additional glycinergic modulators include neuroactive steroids and the anthelmintic, ivermectin, which activates glycine receptors by a novel, strychnine-insensitive mechanism.

Glycogen Synthase Kinase 3

Synonym

GSK3

Definition

GSK3 phosphorylates glycogen synthase (GS), the key enzyme for glycogen synthesis which builds up the

glycogen by adding UDP-glucose. Phosphorylation of GS by GSK3 leads to inactivation of GS. GSK3 is a substrate of the protein kinase Akt. Stimulation of Akt by insulin leads to phosphorylation of GSK3, to inhibition of its kinase activity, and consequently to activation of GS and glycogen synthesis. Recently, a role of GSK3 in the regulation of insulin-dependent gene expression has also been described. GSK3 called zeste-white/shaggy in *Drosophila*, plays a key role in the degradation of β -catenin in the absence of Wnt signaling and is a promising target for pharmacological manipulation of Wnt signaling pathways in both cancer and other disease contexts. There are two isoforms (α and β), with GSK3 β being most important in Wnt signaling.

► Wnt Signaling

Glycopeptide Antibiotics

Glycopeptide antibiotics, a group which includes vancomycin and teicoplanin, are primarily active against gram-positive bacteria, including methicillin-resistant staphylococci. They have also been used against resistant enterococci. However, resistance against glycopeptide antibiotics is now emerging rapidly world-wide. Glycopeptide antibiotics inhibit the synthesis of the cell wall in sensitive bacteria by binding with high affinity to the D-alanyl-D-alanine terminus of cell wall precursor units. The drug is bactericidal for dividing microorganisms. Enterococcal resistance to vancomycin results from the alteration of the D-alanyl-D-alanine target to D-alanyl-D-lactate or D-alanyl-D-serine, which bind vancomycin poorly.

Golgi Apparatus

The Golgi apparatus is a stack of flattened vesicles that functions in posttranslational processing and sorting

of proteins. The Golgi apparatus receives proteins from the endoplasmic reticulum via the endoplasmic reticulum/Golgi intermediate compartment and directs them to endosomes, lysosomes or the plasma membrane. It is organized into a number of stacks of disc like compartments (cisternae).

- Intracellular Transport
- Protein Trafficking and Quality Control

Gonadorelin

- Gonadotropin-releasing Factor/Hormone (GnRH)

Gonadotropin-releasing Factor/ Hormone (GnRH)

GnRH is derived by proteolytic processing of a 92-amino acid precursor peptide to produce mature GnRH, a decapeptide. GnRH is released from neurons in the hypothalamus. GnRH release is intermittent and is governed by a neural pulse generator that is located in the mediobasal hypothalamus, that controls the frequency and amplitude of GnRH release. The GnRH pulse generator is active during fetal life and for about one year after birth, thereafter its activity decreases but increases again during puberty. The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins, which are also released in a pulsatile manner. The gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), are synthesized and secreted by gonadotrophs, which make up about 20% of the hormone-secreting cells in the anterior pituitary. GnRH is the main stimulus which induces secretion of LH and FSH. The continuous administration of GnRH, in contrast to the physiological intermittent action, leads to desensitization and down-regulation of GnRH receptors on pituitary gonadotrophs. This action forms the basis for the clinical use of long-acting GnRH analogs that suppress gonadotropin secretion. These compounds transiently increase LH and FSH secretion, but eventually desensitize gonadotrophs to GnRH, and thereby inhibit gonadotropin release. Synthetic GnRH is termed “gonadorelin”. GnRH and a variety of analogs with agonist activity like buserelin, leuporelin, goserelin or nafarelin can be given in a continuous fashion in order to achieve

gonadal suppression through the decreased production of FSH and LH. Gonadal suppression may be desirable to treat endometriosis, precocious puberty, sex hormone-dependent cancers (e.g. advanced prostatic cancer), or hirsutism due to the polycystic ovary syndrome.

- ▶ Contraceptives

Gonadotropins

The pituitary hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) together with the placental hormone chorionic gonadotropin are collectively called gonadotropins. They are large, glycosylated heterodimers composed of a common α -subunit and a hormone-specific γ -subunit. The main targets are the ovary and testes.

Gout

Gout is the consequence of hyperuricemia and is characterized by uric acid deposits in joints, bursae, tendons, kidney, and urinary tract. In the initial stage, gout is characterized by asymptomatic hyperuricemia. In the second stage, the disease manifests itself by acute gouty arthritis. The third (intercritical) stage is asymptomatic, and the fourth stage is characterized by progressive uric acid desposits in joints, bursae, tendons, kidney, and urinary tract.

G-protein-coupled Receptor Kinases (GRKs)

G-protein-coupled receptor kinases (GRKs) are a family of enzymes that catalyze the phosphorylation of threonine or serine residues on G-protein-coupled receptors. Characteristically, GRKs only phosphorylate the ligand-activated form of the receptors. Phosphorylation by GRKs usually leads to impaired receptor/G-protein coupling.

Definition

G-protein-coupled receptors (GPCRs) are a large family of plasma membrane receptors. Upon binding its agonist, a GPCR activates an intracellular heterotrimeric guanine nucleotide regulatory protein (G protein). The activated G protein modulates the activity of one or more enzymes or ion channels. G protein independent signaling pathways have also been identified for several receptors.

Basic Characteristics

Cells receive much of the information about their external environment by way of receptor proteins that span the plasma membrane. GPCRs are the largest family of plasma membrane receptors. They mediate response to the majority of hormones and neurotransmitters as well as the senses of sight, smell, and taste. These receptors have in common a seven transmembrane topology and functional interactions with heterotrimeric guanine nucleotide binding proteins (G proteins). GPCRs respond to a large variety of stimuli ranging from photons, ions, amino acids, and small organic molecules to peptide and protein hormones.

Analysis of the human genome reveals over 800 unique GPCRs [1]. The functional role for many of these GPCRs has not yet been determined and these have been designated as orphan GPCRs. GPCRs can be divided into five families based on sequence homology: the rhodopsin family, the secretin receptor family, the glutamate receptor family, the adhesion receptor family, and the frizzled/TAS2 receptor family. The rhodopsin family is by far the largest with over 700 members. Of these 460 belong to the subfamily of odorant receptors, and the rest are receptors for hormones and neurotransmitters.

GPCRs as a group constitute the largest family of targets for pharmacological intervention. They are critically involved in virtually every physiological system. A partial list of natural GPCR ligands includes protons, calcium, glutamate, GABA, acetylcholine, histamine, GTP/ATP, adenosine, cAMP, melatonin, epinephrine, serotonin, and dopamine. Peptide hormone GPCR activators include angiotensin, vasopressin, bradykinin, calcitonin, FSH, glucagon, somatostatin and a host of chemokines, opioids, and cannabinoids. Olfactory and gustatory sensory transduction involves GPCRs responsive to a large array of odorants and pheromones, and vision depends on the light-activated ligand retinal covalently bound to its own GPCR rhodopsin.

Receptor Structure

The structure of only one GPCR, bovine rhodopsin, has been solved at high resolution; however, it is thought that all GPCRs have the same core structure (Fig. 1) consisting of seven transmembrane (TM) spanning domains with an extracellular amino terminus and an intracellular carboxyl terminus [1]. The structures of GPCRs diverge most in the amino terminus, the carboxyl terminus, and the intracellular loop between TM5 and TM6. Amino termini are frequently glycosylated and range in size from 7 to 595 amino acids. The intracellular carboxyl terminus is typically tethered to the membrane by a lipid modification such as palmitoylation and ranges in size from 12 to 359 amino acids. The carboxyl terminus and the intracellular loop between TM5 and TM6 often contain sites for phosphorylation by one or more regulatory kinases such as protein kinase A, protein kinase C, or a member of the GPCR kinase (GRK) family. A disulfide bond between two highly conserved cysteines links the second and third extracellular loops of most GPCRs.

G-protein-coupled Receptors. Figure 1 Diagrams of the structural characteristics of G-protein-coupled receptors (GPCRs). (a) The secondary structure of a generic GPCR showing the seven membrane spanning domains and connecting loops. (b) A cartoon of the predicated three-dimensional structure of a generic GPCR based on the structure of rhodopsin. These diagrams were taken from [1].

Ligand Binding

The location of the agonist binding site is highly variable (Fig. 2). Monoamine hormones such as catecholamines, dopamine, serotonin, and acetylcholine bind within the TM core (Fig. 2a). Small peptide hormones bind to the amino terminus, the extracellular loops between TM domains and within the TM core (Fig. 2b). Large amino terminal domains form the binding site for glycoprotein hormones (such as follicle stimulating hormone) (Fig. 2c), as well as for ions (the Ca^{2+} -sensing receptor, Fig. 2d) and the neurotransmitters glutamate and GABA. Finally, in protease-activated receptors, the agonist is generated by proteolytic cleavage of the amino terminus of the receptor (Fig. 2e).

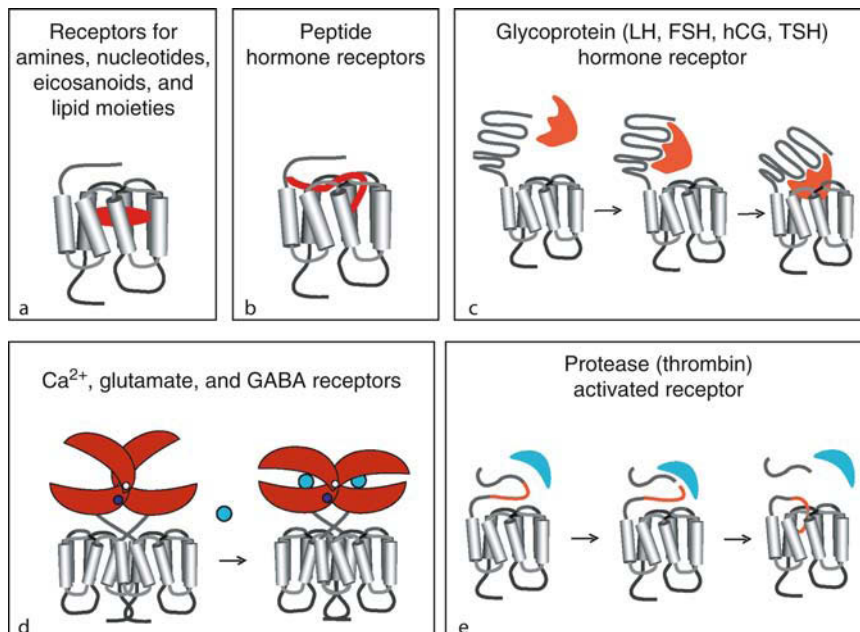

G-protein Coupling Domains

Mutagenesis studies have identified multiple sites of interaction between GPCRs and their cognate G proteins. These include the intracellular loop 2 between TM3 and TM4, the intracellular loop 3 between TM 5 and TM 6, and loop 4 formed between TM 7 and the lipid modification on the proximal carboxyl terminus (Fig. 1). Agonist binding (Fig. 3a) is thought to lead to subtle changes in the arrangement of the TM domains [2]. These conformational changes are transmitted to the associated G protein. In an interaction that has yet to be fully characterized, this movement triggers a G protein heterotrimer ($\text{G}\alpha\beta\gamma$) to dissociate into $\text{G}\alpha$ and $\text{G}\beta\gamma$ subunits, thereby unmasking interactive domains on both of the freed G protein subunits and on the receptor itself. Both dissociated $\text{G}\alpha$ and $\text{G}\beta\gamma$ subunits

are capable of modulating a variety of effector systems including adenylyl cyclase, phospholipase C and ion channels (Fig. 3b). Recent studies suggest that some GPCRs may also signal through G protein independent pathways [3].

Pharmacologic Modulation of Receptor Activity

Ligands that bind to GPCRs display a broad spectrum of activity ranging from full \blacktriangleright agonist, to partial agonists, to neutral \blacktriangleright antagonist, to \blacktriangleright inverse agonists. Some GPCRs are capable of activating G proteins even in the absence of a ligand. This ligand-independent activity is often referred to as basal or constitutive activity. Inverse agonists suppress this basal activity while neutral antagonists do not alter basal activity. Full and partial agonists increase G protein activation above that attributed to the basal, ligand-independent activity. Perhaps the most widely accepted model used to describe ligand modulation of GPCRs is the extended ternary complex model. In its simplest form, this model proposes that the receptor exists in two functionally distinct states in equilibrium: the inactive (R) and the active (R^*) state. In the absence of ligands, the level of basal receptor activity is determined by the equilibrium between R and R^* . The efficacy of ligands is thought to be a reflection of their ability to alter the equilibrium between these two states. Full agonists stabilize R^* while inverse agonists stabilize R . The majority of natural hormones and neurotransmitters act as agonists for their associated receptors. However, there is

G-protein-coupled Receptors. Figure 2 Diagram illustrating the binding sites for different families of hormones and neurotransmitters on their receptors.

G-protein-coupled Receptors. Figure 3 Signaling cycle for the β_2 adrenergic receptor (β_2 AR), a prototypical GPCR. (a) The agonist (adrenaline) binds to the β_2 AR, which leads to activation of the associated G protein (G_S). (b) $G_{S\alpha}$ dissociates and activates adenylyl cyclase (AC), which converts ATP to cyclic AMP (cAMP). cAMP activates protein kinase A (PKA) which phosphorylates and activates a channel. (c) Following G_S activation, a G-protein-coupled receptor kinase (GRK) associates with the agonist-occupied receptor and $G_{\beta\gamma}$. (d) GRK phosphorylates the receptor. (e) Arrestin binds to the phosphorylated receptor blocking further interactions with G_S . (f) Arrestin also promotes signaling through MAPK and other pathways independent of G protein activation. (g) Arrestin promotes internalization of the receptor into an endosomal compartment where the phosphate is removed. (h) The dephosphorylated receptor is recycled back to the plasma membrane.

substantial evidence that the agouti-related peptide behaves as an antagonist or possibly an inverse agonist for the melanocortin receptor.

While the simple two-state model is able to explain many aspects of GPCR function, there is a growing body of evidence that GPCRs are conformationally complex molecules having ligand-specific receptor states [2]. Thus, partial agonists induce an active conformation that is distinct from full agonists. Many GPCRs are known to activate more than one heterotrimeric G protein subtype. The efficacy profile for a panel of GPCR ligands may differ for different G protein subtypes. The term stimulus trafficking refers to the ability of specific ligands to preferentially direct GPCR signaling to one G protein subtype.

GPCR Dimers

There is abundant experimental evidence suggesting that many (if not most) GPCRs exist as homodimers and/or heterodimers [4]. The functional significance of dimers and their role in G protein activation remains to be determined for most GPCRs. Experimental evidence suggests that dimers may play roles in processing and maturation of newly synthesized receptor protein. Heterodimers may contribute to pharmacologic

diversity and heterologous regulation of one receptor subtype by another. Dimers are required for G protein activation by members of the Glutamate receptor family; however, rhodopsin and the β_2 adrenoceptor have been shown to efficiently activate G proteins as monomers. The requirement for GPCR dimers is most convincing for heterodimers such as the functional GABA $_B$ receptor formed by a GBR1/GBR2 heterodimer. The GBR2 behaves as a chaperone bringing the GBR1 to the cell surface. However, while GBR1 contains the main determinants for ligand binding, GBR2 is the major site of G protein coupling.

Regulation of GPCR Function

GPCR function has been shown to be regulated by several different mechanisms. The number of receptors on the plasma membrane may be regulated by transcription, mRNA stability, biosynthetic processing, and protein stability. In addition, the function of receptors in the plasma membrane can be influenced by regulatory phosphorylation and by association with other proteins that determine the subcellular location of receptors relative to other signaling molecules.

One of the most well characterized regulatory pathways for GPCRs is that mediated by the GRK

family [5]. After a signaling event, a multistage desensitization process begins with the agonist-dependent phosphorylation by a GRK of one or more serines or threonines located on intracellular domains of the receptor, particularly in the carboxyl terminus and the third intracellular loop (between TM5 and TM6) (Figs. 3c and d). This phosphorylation promotes the recruitment of an arrestin (Fig. 3e). Arrestins are a family of molecules that bind to agonist-occupied, phosphorylated GPCRs and interfere with G protein coupling. Arrestins may mediate receptor internalization (Fig. 3f) by way of clathrin coated pits or other mechanisms. Internalized receptors may be targeted for degradation (downregulation) or, after being dephosphorylated to restore functionality, they may be redeployed at the cell surface (Fig. 3g). In addition to GRKs, protein kinase A and protein kinase C have been shown to play roles in the desensitization of several GPCRs.

G-proteins and Wnt Signaling

Definition

The topological resemblance of the ▶Fz receptor to other seven-transmembrane receptors that couple to heterotrimeric G-proteins makes it logical to ask whether Fz receptors signal through ▶heterotrimeric G-proteins as well. Evidence in favor of this hypothesis includes that stimulation of mammalian tissue culture cells by expressing one of the Wnt/Fz combinations implicated in Wnt/β-catenin-dependent signaling can be blocked by ▶pertussis toxin and other G-protein inhibitors; in *Xenopus* embryos, ectopic expression of a ▶Regulator of G-protein Signaling (RGS) protein antagonizes Wnt/β-catenin-dependent signaling and causes defects resembling those caused by ectopic

expression of other Wnt pathway inhibitors; reduced $G_{\alpha o}$ in *Drosophila* impairs wnt signaling in the developing fly wing. Similarly, over-expression of Wnt5a in vertebrate cells activates a non-β-catenin signaling pathway that is selectively blocked by several G-protein inhibitors, including pertussis toxin. Work with chimeric Fz receptors containing the extracellular and transmembrane domains of the β₂-adrenergic receptor suggests that G-proteins may couple to the intracellular domain of Fz receptors. These experiments implicate $G_{\alpha o}$ and $G_{\alpha q}$ for Fz receptors activating Wnt/β-catenin-dependent signaling, and $G_{\alpha o}$ and $G_{\alpha t2}$ for Fz receptors activating Wnt/non-β-catenin signaling. Nonetheless, the role of heterotrimeric G-proteins in Wnt signal transduction remains a point of contention in this signaling field.

Definition

Growth factors are relatively small and stable, secreted or membrane-bound polypeptide ligands that mediate short-range cell-to-cell interactions. Growth factors and their cognate receptors function as a module that regulates various cellular processes, such as proliferation, differentiation, migration, or apoptosis. These modules are evolutionarily conserved, and their primary developmental function is determination of cell lineage through heterotypic cellular interactions. Many growth factors are versatile, promoting the appropriate biological outcome in several cell lineages, while others are more limited in scope. Growth factor expression is highly regulated, such that excessive growth factor activity is often associated with pathogenic hyperproliferation (e.g., cancer and psoriasis).

Classification

Growth factors are classified according to their structure and the family of receptors they activate. Whereas the definition of growth factors may broadly apply to lymphokines (e.g., interleukins; ILs) and cytokine-like members of the tumor necrosis factor (TNF) family, here we will consider only growth factors that bind to receptors of the receptor tyrosine kinase (RTK) superfamily. Growth factors bind such receptors with high affinity (in the low nanomolar range) and specificity, and they may be accordingly classified as ligands of a specific receptor subfamily [1] (see Table 1). For example, growth factors comprising an epidermal growth factor (EGF) motif bind to the ErbB subgroup of RTKs (also called type I RTKs). We will use this classification to elaborate on the shared mechanism of action of growth factors.

Mechanism of Action

Many growth factors are produced as prepropeptides, which are converted into biologically active forms, either soluble or membrane bound, by several steps of proteolytic cleavage and processing. These peptides, however, cannot penetrate the plasma membrane, and thus conveying the extracellular signal into the cell to promote the appropriate biological response entails the use of specialized receptors, traversing the plasma membrane [2]. The biochemical series of events that follows binding of a growth factor to the cell surface localized receptor, and culminating in cellular activation, is known as signal transduction (see Fig. 1).

The receptors have an extracellular ligand-binding domain, a hydrophobic segment traversing the plasma membrane, and an intracellular region which harbors a tyrosine kinase domain [2]. In most RTKs, the kinase is autoinhibited by the activation loop, which prevents the access of both ATP and substrate to the catalytic site. Ligand binding to the ectodomain induces large-scale conformational changes leading to receptor dimerization/

Growth Factors. Table 1 Summary of a number of growth factor families, the tyrosine kinase receptors they bind, and the major physiological consequences of their interactions

Growth factor family	Receptor tyrosine kinase	Major physiological functions
EGF family and neuregulins – EGF, TGF- α , Epiregulin, Amphiregulin, HB-EGF, Betacellulin, NRG1, NRG2, NRG3, NRG4, Epigen	ErbB family – ErbB1 (EGFR), ErbB2 (Neu, HER2), ErbB3, ErbB4	Morphogenesis, maintenance, and proliferation of epithelial, mesenchymal, and nerve tissues.
FGF (22 members): FGFs require heparan sulfate to activate their receptors	FGFR: Four members expressed as a number of splice variants	Proliferation of many cell types. Embryo patterning and organogenesis, bone development, angiogenesis
PDGF: Isoforms consist of homo- and heterodimers of A- and B-polypeptide chains and homodimers of C- and D-polypeptide chains	PDGFR: Consists of PDGFR α and β receptors	Embryonic development, particularly in the formation of the kidney, blood vessels, and various mesenchymal tissues. Proliferation of connective tissues, glial and smooth muscle cells
HGF: The ligands are heterodimers of A and B subunits linked by a disulfide bond	HGFR: Consists of three receptors: MET, SEA and RON	Motogenesis, morphogenesis, angiogenesis, and embryonic development
GDNF Family – GDNF, NRTN, ARTN, and PSPN	RET: Alternative splicing results in three isoforms	Required for enteric neuron development, kidney development, and spermatogenesis
VEGF family – VEGF-A, B, C, D, E and PLGF	VEGFR – VEGF receptor-1, 2, and 3	Formation and maintenance of vasculature
Angiopoietin family – Ang1, -2	TIE	Crucial for vessel stabilization
SCF: Due to splice variants there are soluble and membrane forms of SCF	KIT/SCFR	Hematopoiesis, gametogenesis, and melanogenesis
NGF family – NGF, BDNF, NT-3, and NT-4	TRK – TRK-A, B, C	Promotes neurite outgrowth and neural cell survival
Ephrins: Two classes, EphA and EphB, with a number of members within each class	EPHR: Two classes, EPHRA and EPHRB, with a number of members within each class	Patterning the developing hindbrain: Rhombomeres, axon pathfinding, and guiding neural crest cell migration

EGF, Epidermal growth factor; TGF- α , transforming growth factor- α ; AR, amphiregulin; HB-EGF, heparin binding EGF-like growth factor; NRG, neuregulin; FGF, fibroblast growth factor; PDGF, platelet-derived growth factor; HGF, hepatocyte growth factor; GDNF, glial-cell-line-derived neurotrophic factor; PLGF, placental growth factor; NRTN, neurturin; ARTN, artemin; PSPN, persephin; VEGF, vascular endothelial growth factor; SCF, stem cell factor; NGF, nerve growth factor; BDNF, brain-derived neurotrophic factor; NT-3,4, neurotrophin-3,-4; RET, rearranged during transfection; TIE, tyrosine kinase receptor in endothelial cells; Trk, tyrosine kinase receptor

oligomerization [3]. In cases where the receptors preexist as disulfide-linked dimeric receptors (e.g. receptors for insulin and insulin-like growth factors; IGFs), ligand binding causes a significant change in the juxtaposition of receptors. Conformational changes, however, are not confined to the ectodomain and transition to the ligand-bound active conformation is relayed across the plasma membrane and orients two kinase domains of two receptors to promote auto- and transphosphorylation of key tyrosines within the activation loop. This shifts the loop in a manner that releases its autoinhibitory effect (in contrast, phosphorylation of the loop is not a prerequisite for ErbB family kinase domain activation). Once activated, the kinase transfers phosphate groups to tyrosine residues of its own cytoplasmic tail and to nearby substrate proteins including dimer partners and other proteins participating in signal transduction.

Phosphorylated tyrosine residues of RTKs function as docking sites for a wide range of proteins containing **►Src homology**, **►2 (SH2) or**, **►phosphotyrosine-binding (PTB) domains**. Among these proteins are cytosolic kinases (e.g., PI3K), lipases (e.g., PLC- γ), phosphatases (e.g., Dep1), and ubiquitin ligases (e.g., Cbl), which are recruited to the receptor either directly or through **►adaptor proteins** (e.g., Shc and Grb-2) with multiple docking sites. Thus, a large multiprotein signaling complex is assembled at the membrane, with the receptor as the anchor. Recruited kinases phosphorylate additional proteins, further widening protein recruitment and branching of the signal, which is delivered to subcellular organelles, an example of which is the nucleus, where transcriptional regulators are activated and gene expression commences. ErbB-4, as well as some other RTKs, translocate a portion of the cytoplasmic domain into the nucleus, where the

Growth Factors. Figure 1 Growth factor-induced signal transduction pathways. Binding of growth factors (GFs) to their cognate receptors initiates the activation of intracellular signaling pathways, culminating in the nucleus, to propel and regulate key cellular processes. Demonstrated here are two of the best studied pathways: the pathway involving Ras and the MAPK cascade (*blue*), which activates multiple transcription factors (e.g., ETS, SAP-1, and CREB), which in turn regulate the expression of genes necessary for cell proliferation, differentiation, and migration; and the PI3K/Akt pathway (*green*), which modulates the activity of enzymes involved in the control of apoptosis (BAD) and metabolism (TOR, GSK). Both pathways are activated by binding of noncatalytic adaptor molecules (*brown*), which bind specific phosphorylated tyrosine residues of the receptor, thereby stimulating the first enzyme in a linear cascade of enzymatic reactions (see text for details).

catalytic fragment may participate in the regulation of gene expression.

Though the outcome of signaling events initiated by receptors within a family are distinct, some common themes have emerged. One of the signaling pathways common to many growth factor receptors is the route leading to stimulation of the mitogen-activated protein kinase, MAPK [4] (Fig. 1): ►Grb2, an ►SH2 and ►SH3 domain containing ►adaptor protein, is recruited to the phosphorylated receptor, either directly or through an ►adaptor protein called Shc. Upon receptor binding, Grb2 can interact through its ►SH3 domain with son of sevenless (SOS), a guanine nucleotide exchange factor. Translocation of SOS to a membrane proximal region facilitates its interaction with Ras, a membrane-anchored guanine-binding protein which SOS activates by exchanging GDP for GTP. Once Ras is in the GTP-bound form, it can recruit Raf, a cytosolic serine/threonine kinase, which in turn activates MEK, a dual

specificity protein kinase. MEK phosphorylates extracellular-regulated kinase (ERK) (also called MAPK) on both a threonine and a tyrosine residue within ERK's regulating domain, thereby activating it. Phosphorylated ERK translocates to the nucleus and activates multiple transcription factors, including ETS-1, ELK-1, and SAP-1. These transcription factors induce the expression of genes important for cell cycle progression and proliferation. In a similar manner, the GTP-bound form of Ras can also activate phosphoinositide 3'-kinase (PI3K), which generates specific inositol lipids. PI3K can be recruited directly by phosphorylated RTKs such as ErbB-3 (Fig. 1). A major target of PI3K lipid products is the protein kinase Akt (or protein kinase B; PKB). In quiescent cells, Akt resides in the cytosol in a low-activity conformation. Upon cellular stimulation, Akt is activated through recruitment to cellular membranes by PI3K lipid products and phosphorylation by 3'-phosphoinositide-dependent kinase-1 (PDK1). Akt is a serine/threonine

kinase that phosphorylates and inactivates proapoptotic proteins like BAD, procaspase 9, and FKHR-1, thereby promoting cell survival. Akt also induces proliferation by antagonizing the action of cell cycle inhibitors p21^{WAF1} and p27^{Kip1}, while at the same time increasing the activity of cell cycle promoters like cyclins D1 and D3. Furthermore, Akt stimulates cell metabolism and growth through activation of enzymes involved in glycolysis, glyconeogenesis, glycogen synthesis, and protein synthesis. Phospholipase C- γ , another **▶SH2 domain** – containing protein, hydrolyzes phosphatidyl 4', 5' bisphosphate (PIP₂) to diacylglycerol (DAG) and inositol-triphosphate (IP₃), once recruited to the plasma membrane following receptor activation. IP₃, a second messenger, binds to receptors on the membrane of the endoplasmic reticulum, resulting in the release of calcium, which in turn activates Ca²⁺ dependent protein kinases (e.g., the tyrosine kinase Pyk-2) and phosphatases (e.g., calcineurin). On the other hand, DAG binds to PKC, a serine/threonine kinase, thereby mediating its translocation to the membrane and its activation. Concomitant with the activation of signaling pathways, multiple mechanisms are set in motion to regulate and eventually attenuate signaling by activated growth factor receptors [5]. As in the case of EGFR and other RTKs, receptor internalization coupled to degradation is considered the most immediate and effective process that attenuates signaling by removing receptors from cell surface and targeting them for degradation in lysosomes. Phosphorylated receptors are tagged by conjugation of a 76 amino acid long molecule called ubiquitin; tagging is performed by a three-step enzymatic pathway culminating in a ubiquitin ligase called Cbl, which recognizes both the substrate receptor and the ubiquitin donor, an E2 ubiquitin-conjugating enzyme. A series of ubiquitin-binding endocytic adaptors subsequently recognize the ubiquitylated receptor and target it to regions of the plasma membrane called **▶clathrin-coated pits**. The latter invaginate to form a clathrin-coated neck that progressively moves inward, eventually generating a coated vesicle. This tiny vesicle shuttles to a vesicular compartment called the early endosome. Through acidification of the endosome's lumen, some ligand-receptor complexes are dissociated, leading to recycling to the plasma membrane, while other complexes remain intact. The latter are handed to the subsequent sorting compartment, the multivesicular body, where hydrolases are accumulated. It is in this compartment and the subsequent one, the lysosome, where degradation of the receptor is completed. Receptor activation also causes the recruitment of a number of other attenuators, such as **▶tyrosine phosphatases**, like the density-enhanced phosphatase-1 (DEP1), which dephosphorylates ErbB-1 as well as other RTKs, GTPase activating enzymes (e.g., GAP, which activates Ras GTPase activity) and other negative regulators. These proteins inhibit the signaling

cascade at multiple levels, thus realizing negative feedback loops, which help tuning and regulating the effect of growth factors.

Examples of Growth-Factor Families

EGF-Like Factors and Neuregulins

The EGF family includes EGF, transforming growth factor α , amphiregulin, epiregulin, epigen, betacellulin, HB-EGF, and neuregulins 1–4. All factors share a motif of 45–60 amino acids, including six cysteines, and their receptors belong to the ErbB family. These factors play an essential role in the development of epithelial organs, the heart, and the nervous system, as well as in tissue regeneration after injury and in wound healing. EGF-like growth factors are also involved in many kinds of cell-to-cell interactions in the adult body. For example, Neuregulin-1 is a key point in a complex signaling between neurons and glial cells, which stimulates and controls myelination. Neuregulin-1 also modulates expression and function of several neurotransmitter receptors, and altered neuregulin signaling is thought to have a role in many neurologic pathologies, like schizophrenia, multiple sclerosis, and peripheral neuropathies. Aberrantly expressed forms of ErbB proteins and their ligands are found in numerous tumors of epithelial and neuronal origins, and their presence often correlates with high tumor aggressiveness and reduced patient survival.

Fibroblast Growth Factors

Four receptors with a variety of **▶splice variants** bind more than 20 types of fibroblast growth factors (FGFs). Many FGFs require glycosaminoglycan heparin sulfate for receptor binding. FGFs play a critical role in the patterning of the embryo and in organogenesis, especially in bone development. Many genetic disorders like Chondroplasia, Apert syndrome, Pfeiffer syndrome, and Jackson–Weiss syndrome are associated with non-lethal mutations in one of the FGF receptors. FGF receptor activation has been shown to promote migration, proliferation, and differentiation of endothelial and other cells and has been implicated in angiogenesis.

Platelet-Derived Growth Factors

Disulfide-linked homologous subunits designated A, B, C, and D constitute platelet-derived growth factors (PDGFs), dimeric ligands that bind and activate two receptors, PDGFR- α and PDGFR- β . PDGF-A and PDGFR- α are expressed early while PDGF-B and PDGFR- β are expressed late during embryogenesis. Ablation of either the receptors or the ligands in mice results in embryonic or perinatal lethality with defects in alveologenesis, formation of the glomeruli in the kidney, cardiovascular disorders, and hematological abnormalities. PDGFs are potent mitogens for connective tissues and effective chemotactic factors for

inflammatory cells responsible for tissue repair and wound healing. Autocrine loops involving PDGFs have been implicated in sarcomas and gliomas, and they function in atherosclerosis, cardiac hypertrophy leading to heart failure, fibrosis of visceral organs, rheumatoid arthritis, glomerulonephritis, and proliferative vitreoretinopathy. In contrast, reduced PDGF signaling may contribute to the inability to heal chronic wounds such as diabetic ulcers.

Hepatocyte Growth Factors

The scatter factor (Hepatocyte Growth Factor; HGF) binds to Met, a single transmembrane protein with an extracellular α subunit and a membrane-spanning β subunit, whereas the macrophage-stimulating protein (MSP) binds to a related receptor called Ron. The ligands are heterodimers of A and B subunits linked by a disulfide bond. The A subunit contains one hairpin loop homologous to the plasminogen activation peptide, four **▶kringle domains** and a triple loop cysteine-rich motif. The B subunit is homologous to a serine protease, but it has no enzymatic activity. HGF has been implicated in liver development, conversion of mesenchyme to epithelium in organogenesis of the kidney, ovary and testes, myoblast migration, axon sprouting, and bone development. HGF expression is upregulated in response to injury in liver and kidney, where it helps regulating the process of wound healing and avoiding excessive fibrosis. Germ line and somatic mutations in Met were observed in patients with papillary renal carcinomas. Overexpression of Met has been implicated in myeloid malignancies and in carcinomas of the breast and bladder.

Vascular Endothelial Growth Factors

Three tyrosine kinase receptors called VEGFR-1 (Flt-1), VEGFR-2 (KDR/Flk-1), and VEGFR-3 (Flt-4), as well as Neuropilins (NRP) 1 and 2, are the players at the receptor level. Vascular endothelial growth factor (VEGF; also called vascular permeability factor, VPF) and its **▶splice variants**, as well as placental growth factor and its isoforms, serve as ligands. Activation by VEGF and semaphorin ligands results in the heterodimerization of VEGFR-2 with neuropilins. Heparin has been shown to play an important role in the signaling by this family. VEGF is predominantly an endothelial cell growth factor and is a prominent factor in the genesis and maintenance of the vasculature. VEGF and other factors are critical for physiological processes requiring angiogenesis, such as ovulation and menstruation. VEGF is induced by hypoxia and is expressed in tumors where the core is hypoxic. Secreted VEGF stimulates endothelial cells in the vicinity of solid tumors, and promotes the vascularization of the tumor and consequent tumor growth. VEGFs may also

play a role in chronic inflammatory diseases and in diabetic retinopathy, conditions characterized by excessive angiogenesis.

Clinical Applications

Several of the most formidable human diseases are characterized by aberrant signaling of growth factors and their cognate receptors, and thus these are constantly being pursued as targets for pharmacological intervention (Fig. 2). The ability of growth factors to stimulate cell proliferation and survival, for example, may help enhancing tissue healing and reduce organ damage in diseases of different origins. Recombinant forms of growth factors are currently being tested for potential usefulness in a variety of clinical settings, such as hepatitis, cirrhosis, renal fibrosis, multiple sclerosis, amyotrophic lateral sclerosis, and myocardial ischemia. Recombinant PDGF, for example, is currently employed as a drug (becaplermin) to facilitate the healing of diabetic ulcers. Growth factors may also be used for the production of artificial tissues, for example, for skin replacements and bone and connective tissue reconstruction. In contrast, blocking the actions of specific growth factors can help reduce uncontrolled cell proliferation, a characteristic of cancer (and also of diabetic retinopathy and vascular stenosis). Drugs in clinical use include small molecule **▶tyrosine kinase inhibitors** (TKIs) and antireceptor or antiligand monoclonal antibodies (mAbs). TKIs penetrate the plasma membrane and interact with the ATP-binding site of the receptor, thus preventing kinase activation. The ErbB-1 kinase inhibitors gefitinib and erlotinib, for instance, are both approved for a subset of Non-Small Cell Lung Cancer (NSCLC) patients. Another example is the broad-spectrum inhibitor, sorafenib, targeting both VEGFR and PDGFR, as well as the Raf kinase, which was approved for the treatment of renal cancer.

In contrast to TKIs, antireceptor mAbs bind to the extracellular domain of the receptor and exert inhibition of cell proliferation by several mechanisms. Trastuzumab, which targets ErbB-2 and is approved for the treatment of metastasizing breast cancer, is thought to stimulate an immune response against the tumor and to induce receptor internalization. Examples of other mAbs are cetuximab (approved for colorectal and head and neck cancers) and panitumumab (approved for colorectal cancer), which are directed against ErbB-1 and may act also by inhibiting ligand binding. Pertuzumab, currently in clinical trials, is an antibody which targets ErbB-2 and inhibits receptor dimerization. Some of the mAbs are directed against the ligands, rather than the receptors, an example of which is bevacizumab that targets VEGF and inhibits angiogenesis. This mAb was approved for the treatment of NSCLC and colorectal cancer; it is also being tested for many ocular

Growth Factors. Figure 2 Drugs blocking growth factor induced pathways of signal transduction. The signaling cascades set in motion by growth factors can be blocked by pharmacological interventions at different levels. Monoclonal antibodies can specifically bind to growth factors (e.g., bevacizumab) or to the extracellular domain of their cognate receptors (e.g., cetuximab). Tyrosine kinase inhibitors, on the other hand, are small molecules that traverse the plasma membrane and block kinase-domain activation. Some of them are specific to certain RTKs, like gefitinib and erlotinib (which are ErbB-1 blockers) and others inhibit the activity of multiple kinases (e.g., lapatinib or sorafenib). Several drugs block enzymes downstream of the receptors, such as drugs targeting individual effectors of the MAPK pathway or the PI3K/Akt pathway. An additional site for pharmacological intervention is the chaperone protein Hsp90, which is essential for the stability of many components of various signaling cascades, for example, ErbB-2, Raf, Pdk-1, and Akt. Inhibition of Hsp90 enhances degradation of its client proteins, leading to down regulation of the respective signals. Note that along with PDGF-receptor, imatinib inhibits also Bcr-Abl and c-Kit, the receptor for Stem Cell Factor. Red boxes indicate drugs that have already been approved for clinical use.

pathologies characterized by excessive angiogenesis, like diabetic retinopathy or macular degeneration.

Drugs that inhibit the signaling cascade downstream of the receptor at different levels (e.g., inhibitors of the MAPK or the PI3K/Akt pathways) have also been developed and are in various phases of clinical trials. ► **Chaperone** proteins like Hsp90, which are essential for the stability and function of many receptors, effectors, and transcription factors, can also be targeted by specific inhibitors (e.g., 17-AAG, 17-DMGA), thus enhancing degradation of the client proteins.

The successful clinical application of RTK-based therapeutics in the last 8 years instigates further research to generate the next generation drugs. Thus, antisense RNAs or dominant-negative receptor mutants are being tested for their ability to reduce receptor expression.

Intracellular single-chain mAbs are supposed to prevent membrane localization of the receptors. Antireceptor mAbs conjugated to radionuclides, or to prodrugs, are tested as well, and DNA vaccines may induce an active immune response against RTK overexpressing tumors.

Growth Hormone

Growth hormone (GH) is synthesized in the anterior pituitary. It belongs to the rather heterogeneous family of ► **cytokines**. Secreted GH is a mixture of polypeptides, the main polypeptide consisting of 191 amino acids. The receptor for GH is widely distributed. Like other members of the cytokine receptor family, it possesses one transmembrane domain. A single GH molecule binds to two receptor molecules and causes their dimerization. The newly formed dimer provides a binding site for a member of the Janus kinase (JAK) family (► **JAK-STAT pathway**). Clinically, recombinant human GH is used for the treatment of GH deficiency. GH deficiency in children leads to short stature. GH deficiency in adults has been associated with changes in fat distribution, increases in circulating lipids, decreased muscle mass and increased mortality from cardiovascular causes.

Growth Hormone Release-inhibiting Factor

Synonyms

Somatostatin

- Somatostatin

GSK3

Glycogen Synthase Kinase 3.

- Insulin Receptor

GTPase Activating Proteins (GAPs)

GTPase activating proteins (GAPs) stimulate the intrinsic GTP hydrolysis of GTPases.

- Small GTPases

GTPases

- Small GTPases
- Heterotrimeric G-Proteins

Guanine Nucleotide Dissociation Inhibitors (GDIs)

Guanine nucleotide dissociation inhibitors (GDIs) bind to small GTPases and inhibit the dissociation and thus the exchange of the bound nucleotide.

Guanylyl Cyclase

DORIS KOESLING

Pharmakologie und Toxikologie, Ruhr-Universität Bochum, Bochum, Germany

Synonyms

Guanylate cyclase; Guanyl cyclase

Definition

Guanylyl cyclases (GC) are a family of enzymes (EC 4.6.1.2) that catalyse the formation of the second messenger cyclic GMP (cGMP) from guanosine triphosphate (GTP). GCs are subdivided in soluble GCs and GCs that are membrane-bound and linked to a receptor. Activation occurs by nitric oxide (NO) and peptide hormones, respectively [1, 2].

Basic Characteristics

Activation of GCs leads to an increase of the intracellular messenger molecule cGMP. cGMP-signalling is mediated by three different groups of cGMP effector molecules: cGMP-activated protein kinases, cGMP-regulated \blacktriangleright phosphodiesterases and cGMP-gated ion channels, see Fig. 1. The cGMP increases are terminated by cGMP-degrading phosphodiesterases that reduce cGMP levels. cGMP plays a role in relaxation of smooth muscle, inhibition of platelet aggregation and in retinal phototransduction. It also participates in signal transduction within the nervous system. Moreover,

cGMP is involved in regulation of the water and electrolyte household as well as in bone metabolism. According to their structural features and their regulation, GCs can be divided into NO-stimulated and receptor-linked enzymes.

NO-Stimulated GC

NO-sensitive GC represents the most important effector enzyme for the signalling molecule NO, which is synthesised by \blacktriangleright NO synthases in a Ca^{2+} -dependent manner. NO-sensitive GC contains a prosthetic \blacktriangleright heme group, acting as the acceptor site for NO. Formation of the NO-heme complex leads to a conformational change, resulting in an increase of up to 200-fold in catalytic activity of the enzyme [1]. The organic nitrates (see below) commonly used in the therapy of coronary heart disease exert their effects via the stimulation of this enzyme.

NO-sensitive GC consists of two subunits, α and β . So far two isoforms of the enzyme have been identified; the ubiquitous $\alpha_1\beta_1$ isoform (α_1 -GC) and the

Guanylyl Cyclase. Figure 1 cGMP-signalling. Shown are the two groups of cGMP-forming guanylyl cyclases (receptor-linked membrane-bound GCs and NO-sensitive GCs) and the three effector proteins, which mediate the cGMP effects (see text for further explanation). ANP, A-type natriuretic peptide; BNP, B-type natriuretic peptide; CNP, C-type natriuretic peptide; Sta, heat-stable enterotoxin of *Escherichia coli*; PSD-95, post synaptic density protein 95.

less broadly distributed $\alpha_2\beta_1$ isoform (α_2 -GC). The N-terminal regions of the subunits are responsible for heme binding and heme coordination, whereas the cyclase catalytic domains are located in the C-terminal regions. The cyclase catalytic domain is conserved in the membrane-bound guanylyl cyclases as well as in the adenylyl cyclases (see below). Both isoforms show indistinguishable regulatory properties but may differ in subcellular distribution as the α_2 -GC isoform is able to interact with [▶PDZ domains](#) and has been shown to be associated with the postsynaptic adapter protein PDS95.

NO-sensitive GCs occur in relatively high concentration in vascular smooth muscle cells and platelets as well as in lung, kidney and brain. The NO-induced increase in cGMP causes smooth muscle relaxation and inhibition of platelet aggregation. Aside from the cardiovascular system, the NO/cGMP cascade has an important function in the nervous system, where it is thought to participate in synaptic plasticity, i.e. the use-dependent change efficiency of synaptic transmission. Knockout mice deficient in the β_1 or either one of the α subunits of NO-sensitive GC have been generated, and their phenotypes support and expand our current understanding of NO/cGMP signalling. The β_1 -deficient mice which are completely devoid of NO-sensitive GC, show a greatly reduced life expectancy and die of fatal gastrointestinal symptoms. In these mice, NO-induced relaxation is totally abolished as is NO-induced inhibition of platelet aggregation. The mice show a pronounced increase in blood pressure underlining the important role of NO in blood pressure regulation. The α_1 - or α_2 -subunit-deficient mice lack the respective isoform and therefore allow to study the role of the GC isoforms [3]. In concerns of tissues distribution, the isoforms occur in brain in similar amounts; in all other tissues tested, α_1 -GC represents the major isoform. In aortic smooth muscle cells, α_2 -GC, representing only 6% of the total GC content in WT, is sufficient to induce complete relaxation. The results show that in smooth muscle cells, α_2 -GC can functionally substitute for α_1 -GC and that a minor cGMP increase induces relaxation. Studies on synaptic plasticity in the visual cortex revealed an involvement of both GC isoforms in long-term potentiation (LTP) suggesting the occurrence of two NO/cGMP-mediated signals that have to work in concert for the expression of LTP.

Besides NO, other sGC-activating substances have been reported: Carbon monoxide (CO) is known to bind to heme groups with high affinity but has been shown to activate the enzyme only marginally (three- to fivefold). The compound YC-1 ([3-(5'-hydroxymethyl-2'-furyl)-1-benzyl indazole]) is a prototype of a new class of so-called NO-sensitisers. YC-1 causes a tenfold activation of NO-sensitive GC. Pharmacologically more interesting, YC-1 increases GC's sensitivity towards NO and CO suggesting potential beneficial effects of

YC-1 by increasing the responsiveness of NO-sensitive GC towards physiologically occurring NO. Besides increasing cGMP by GC stimulation, YC-1 was shown to inhibit phosphodiesterases thereby preventing cGMP degradation and further enhancing cGMP levels in intact cells. Thus, YC-1 may represent a new class of drugs that are of potential use in the treatment of cardiovascular diseases. YC-1-related compounds with a higher affinity for NO-sensitive GC have been developed and their therapeutic benefits are currently under investigation. In addition to the NO-sensitisers, NO-independent GC activators (BAY 58-2667, HMR1766) have been identified. The observation that higher effects were observed under heme removing conditions or with the heme free enzyme led to the assumption that these activators stimulate GC by replacing and mimicking the activated NO-heme conformation. The high potency of these NO- and heme-independent activators in vivo led to the postulate of a highly responsive oxidised state of NO-sensitive GC occurring under pathophysiological situations such as oxidative stress. The assumed redox-regulation of NO-sensitive GC awaits further experimental conformation.

Receptor-linked GC

Membrane-bound GCs belong to the group of receptor-linked enzymes with one membrane-spanning region [2]. Although all of these GCs share a conserved intracellular catalytic domain, they differ in their extracellular ligand-binding domains and are activated by different peptide hormones. The guanylyl cyclase A (GC-A) isoform acts as the receptor for the [▶natriuretic peptides](#) ANP and BNP, two primarily cardiac hormones that are involved in the regulation of blood pressure as well as in water and electrolyte household. ANP- and BNP-induced increases in cGMP levels mediate physiological effects such as smooth muscle relaxation, modulation of endothelial permeability, inhibition of aldosterone secretion in the adrenal cortex and salt and water excretion in the kidney. During chronic pressure or volume overload, the increased ANP and BNP levels exert local antiproliferative (ANP) and antifibrotic (BNP) effects in cardiac cells. A second ANP receptor, containing only a very short intracellular C-terminal region and without any GC activity, has also been identified. As intracellular signalling of this ANP receptor has not been detected, this protein was suggested to function as a "clearance receptor", removing excess ANP from the circulating blood. Another GC isoform, GC-B, displays the highest affinity for the C-type natriuretic peptide (CNP). CNP is mainly produced by vascular endothelial cells and exhibits local and autocrine/paracrine functions. Yet, occurrence of the GC-A and -B isoforms and the natriuretic peptides is not limited to the cardiovascular system; they may also play a role in the central nervous and other systems.

Further GC isoforms are GC-C, GC-D, GC-E and GC-F. Of these GC isoforms, GC-C is stimulated by the peptide hormone guanylin that occurs mainly in the intestine. GC-C is also activated by the heat stable enterotoxin of *Escherichia coli*, which pathophysiologically, can cause severe diarrhoea. Thus, GC-C and its ligand are probably involved in regulating the salt and water balance in the intestine. The other receptor-linked GC isoforms are restricted to sensory cells. GC-D is only expressed in olfactory neurons; GC-E and GC-F are exclusively found in the retina. Regulation of these GC isoforms by proteins that interact with the intracellular cGMP-forming domain has been demonstrated. Since no ligand to the N-terminal domain of such isoforms has been identified to date, it is not clear whether cGMP-forming activity is controlled by the receptor domain at all.

Drugs

Drugs Acting on Soluble GC

Clinically, the ►organic nitrates glyceryl trinitrate, isosorbide dinitrate and isosorbide mononitrate are mainly used in the treatment of coronary heart disease. They exert their main therapeutic effect by activating sGC via NO [4]. None of the nitrates release NO spontaneously, instead they undergo a complex enzymatic bioactivation that either yields NO or bioactive S-nitrosothiols. Enzyme(s) and cofactors required for this biotransformation have not been clearly identified, yet it appears that the activity of certain enzyme(s) and cofactors can vary within different regions of the vascular system which may cause, or may contribute, to the observed differences in NO sensitivity: Since nitrate-induced vasodilation is more pronounced in veins than in arteries, the organic nitrates cause marked venorelaxation and reduce central venous pressure. In turn, the preload and the cardiac work decrease, resulting in a relief of angina pectoris symptoms. Treatments with organic nitrates that reduce cardiac preload are also used in patients with heart failure. However, direct coronary dilation or redistribution of the blood flow to ischemic regions of the myocardium remains controversial.

In general, nitrates are either used to treat or to prevent acute episodes of angina, or they are applied to provide long-term prophylaxis against episodes of angina in patients with frequent angina attacks. For the appropriate application of organic nitrates, pharmacokinetic and pharmaceutical aspects have to be taken into account. A hepatic high capacity organic nitrate reductase rapidly inactivates organic nitrates by effectively removing nitrate groups. The bioavailability of the traditional organic nitrate glyceryl trinitrate is therefore very low, and for the immediate treatment of angina, the sublingual application of glyceryl trinitrate is preferred. This way the first pass effect is circumvented and a therapeutic blood level of glyceryl

trinitrate is rapidly achieved. The nitrate can be efficiently absorbed and exert its antianginal effect within minutes. However, because the drug's duration of effect is very short (15–30 min), sublingually applied glyceryl trinitrate is not suitable for maintenance therapy. In such cases, the sublingual application of isosorbide dinitrate, which is similar to glyceryl trinitrate, is advised. In comparison, isosorbide dinitrate has a slightly delayed onset of activity but its duration of effect (2 h) is more sustained. For a drug effect that lasts even longer, nitrates such as sustained-release preparations of nitroglycerin, isosorbide dinitrate or isosorbide mononitrate are administered orally at sufficient dosage to provide effective plasma levels after first-pass-degradation. Other options to administer nitroglycerin include transdermal and buccal absorption from slow release preparations. As an active metabolite of isosorbide dinitrate, isosorbide mononitrate is available for clinical use and has a bioavailability of 100%.

The major problem of nitrate-based prophylaxis of angina is the loss of drug efficacy. The continuous application of nitrates for more than a few hours leads to the development of nitrate tolerance. Although the precise mechanisms of this tolerance phenomenon are unknown, it is conceivable that tolerance occurs at the level of the metabolising enzymes and/or the NO-sensitive GC. Moreover, an increase in the production of NO-scavenging superoxide ion and counter-regulatory mechanisms are likely to contribute to the development of tolerance. However, since the marked attenuation of the nitrate effect is rapidly reversible upon discontinuation of the drug, any tolerance development can be controlled and is achieved by allowing a “nitrate-free” period of about 8 h (usually at night) within 24 h.

An option for patients who develop nocturnal angina is molsidomine, another NO-releasing compound that is believed not to induce tolerance. Molsidomine features a similar pharmacological profile as the organic nitrates. As a pro-drug, it is bioactivated in the liver and yields SIN-1 that decomposes, enzyme-independently, in a two-step reaction. In the first step, SIN-1 undergoes a base-catalysed ring opening to form SIN-1A. This in turn yields NO and the stable metabolite SIN-1C. As the onset of action of molsidomine is comparatively slow, it is not used to treat acute cases of angina. Furthermore, due to its putative carcinogenic effect, molsidomine should only be considered when treatment with organic nitrates is not sufficient, for example in the “nitrate-free” interval.

The acute adverse effects of the organic nitrates as well as molsidomine are directly related to their therapeutic vasodilation as they can cause orthostatic hypotension, tachycardia and throbbing headache.

Apart from the substances mentioned above, there is one other NO-containing compound, sodium nitroprusside (SNP), which effectively reduces ventricular

preload and afterload. This powerful vasodilator has to be administered parenterally and is used in intensive care units to deal with hypertensive emergencies that do not respond to other blood pressure lowering agents. In the presence of reducing agents such as glutathione, SNP spontaneously releases NO concomitantly with cyanide. Its most serious adverse effects are therefore related to the accumulation of cyanide.

In low doses, inhaled NO may have a beneficial therapeutic effect, since NO in the inspired air leads to pulmonary vasodilation. In persistent pulmonary hypertension of the newborn, NO inhalation has already been used with some success. NO inhalation as the treatment for acute respiratory distress syndrome, however, has been disappointing. Only transient improvements of oxygenation were detected and the outcome of placebo-controlled trials did not show any improvement

Drugs Acting on Receptor-linked GC

In theory, one could utilise GC-A ligands to lower blood pressure and to reduce blood volume as they increase the excretion of water and salt. Nesiritide, human recombinant BNP, is the first member of this new class of drugs approved for the initial intravenous treatment of acutely decompensated congestive heart failure. Whether nesiritide can be a valuable addition to the standard therapy of decompensated heart failure remains to be demonstrated.

Besides attempts to substitute natriuretic hormones with the recombinant form of BNP, there is a pharmacological approach to elevate the concentration of natriuretic peptides by inhibiting their degradation by the neutral endopeptidase. Of special interest are dual-function inhibitors that do not only block the neutral natriuretic peptide-degrading endopeptidase but also the angiotensin-converting enzyme, thereby decreasing the level of angiotensin II. The best characterised one

of these also called “vasopeptidase inhibitors”, omapatrilat, was shown to lower blood pressure in clinical trials, however, because of the occurrence of angioedema omapatrilat has not been approved yet.

Gyrase

Gyrase is another term for bacterial topoisomerase II. The enzyme consists of two A and two B subunits and is responsible for the negative supercoiling of the bacterial DNA. Negative supercoiling makes the bacterial DNA more compact and also more readily accessible to enzymes that cause duplication and transcription of the DNA to RNA.

- ▶ Quinolones

Haemostasis

Haemostasis is the mechanism activated after damage to the blood vessel wall that ensures that blood loss is restricted. Blood platelets are activated and adhere to elements on the damaged luminal surface of the vessel, eventually forming a platelet plug that stops the leakage of blood. Fibrinolytic mechanisms later produce lysis of the platelet mass when repair of the vessel has occurred.

Heat Shock Protein (HSP)

Synonyms

HSP

Definition

Eukaryotes respond to heat shock and other forms of environmental stress by inducing synthesis of heat-shock proteins (HSP). HSPs act, e.g., as chaperonins, a subclass of ▶chaperones with ATPase activity, maintaining the correct 3-D structure of large protein complexes. For example, the hsp90 proteins are a group of HSPs with an average molecular weight of 90 Kd. The precise function of hsp90 is unclear. The protein is associated with steroid hormone receptors, tyrosine kinases, eIF2alpha kinase, actin and tubulin.

Helicases

Group of evolutionary highly conserved enzymes involved in structural modulation of nucleic acids. Specific for either DNA or RNA they unwind double-stranded regions by dissociating paired purin-pyrimidin bases. A helicase domain is essential for enzymatic activity that is dependent on energy generated from nucleoside-triphosphate hydrolysis. RNA helicases are important during transcription, splicing, translation, and degradation of eukaryotic RNA.

Helicobacter Pylori

Helicobacter pylori is a spiral shaped bacterium that lives in the stomach and duodenum (the section of intestine just below the stomach). Most bacteria cannot live in the stomach since the environment is too acidic to survive. However, Helicobacter pylori has large amounts of urease, which converts urea to ammonia and carbon dioxide. Ammonia is used to maintain the periplasmic and cytoplasmic pH of the bacterium at neutrality, so this bacterium can survive. Helicobacter pylori causes peptic

ulcers, gastritis and cancer of the stomach. Peptic ulcers and gastritis are successfully treated with antibiotics effective against Helicobacter pylori.

- ▶ Proton Pump Inhibitors and Acid Pump Antagonists

Helix Bundle

A helix bundle is a protein composed of a series of rod-like helical domains linked by flexible segments and inserted into a membrane to form a cluster of helices roughly parallel to one another and perpendicular to the plane of the membrane.

Helix-loop-helix Motif

A helix-loop-helix motif is a DNA-binding motif, related to the leucine-zipper. A helix-loop-helix motif consists of a short α helix, connected by a loop to a second, longer α helix. The loop is flexible and allows one helix to fold back and pack against the other. The helix-loop-helix structure binds not only DNA but also the helix-loop-helix motif of a second helix-loop-helix protein forming either a homodimer or a heterodimer.

Synonyms

Colony-stimulating factors; Hematopoietic colony-stimulating factors

Definition

Hematopoietic (blood) cells transport oxygen and carbon dioxide, contribute to host immunity, and facilitate blood clotting [1]. A complex, interrelated, and multistep process, called ►hematopoiesis, controls the production as well as the development of specific marrow cells from immature precursor cells to functional mature blood cells. This well-regulated process also allows for replacement of cells lost through daily physiologic activities. The proliferation of precursor cells, the maturation of these into mature cells, and the survival of hematopoietic cells require the presence of specific growth factors.

All mature blood cells arise from primitive hematopoietic cells in the bone marrow, the pluripotent stem cells. Approximately 0.1% of the nucleated cells of the bone marrow are pluripotent stem cells and approximately 5% of these cells may be actively cycling at any one time. The stem cell pool maintains itself through a process of asymmetrical cell division: when a stem cell divides, one daughter cell remains a stem cell and the other becomes a committed colony-forming cell (CFC). The proliferation and differentiation of CFCs are controlled by hematopoietic growth factors. The hematopoietic growth factors stimulate cell division, differentiation and maturation, and convert the dividing cells into a population of terminally differentiated functional cells.

Ten types of mature blood cells have been identified; each one is derived from primitive hematopoietic stem cells in the bone marrow: erythrocytes (red blood cells);

platelets (thrombocytes); granulocytes (neutrophils, eosinophils, and basophils); monocytes and macrophages; tissue mast cells; B and T lymphocytes; and plasma cells (Fig. 1).

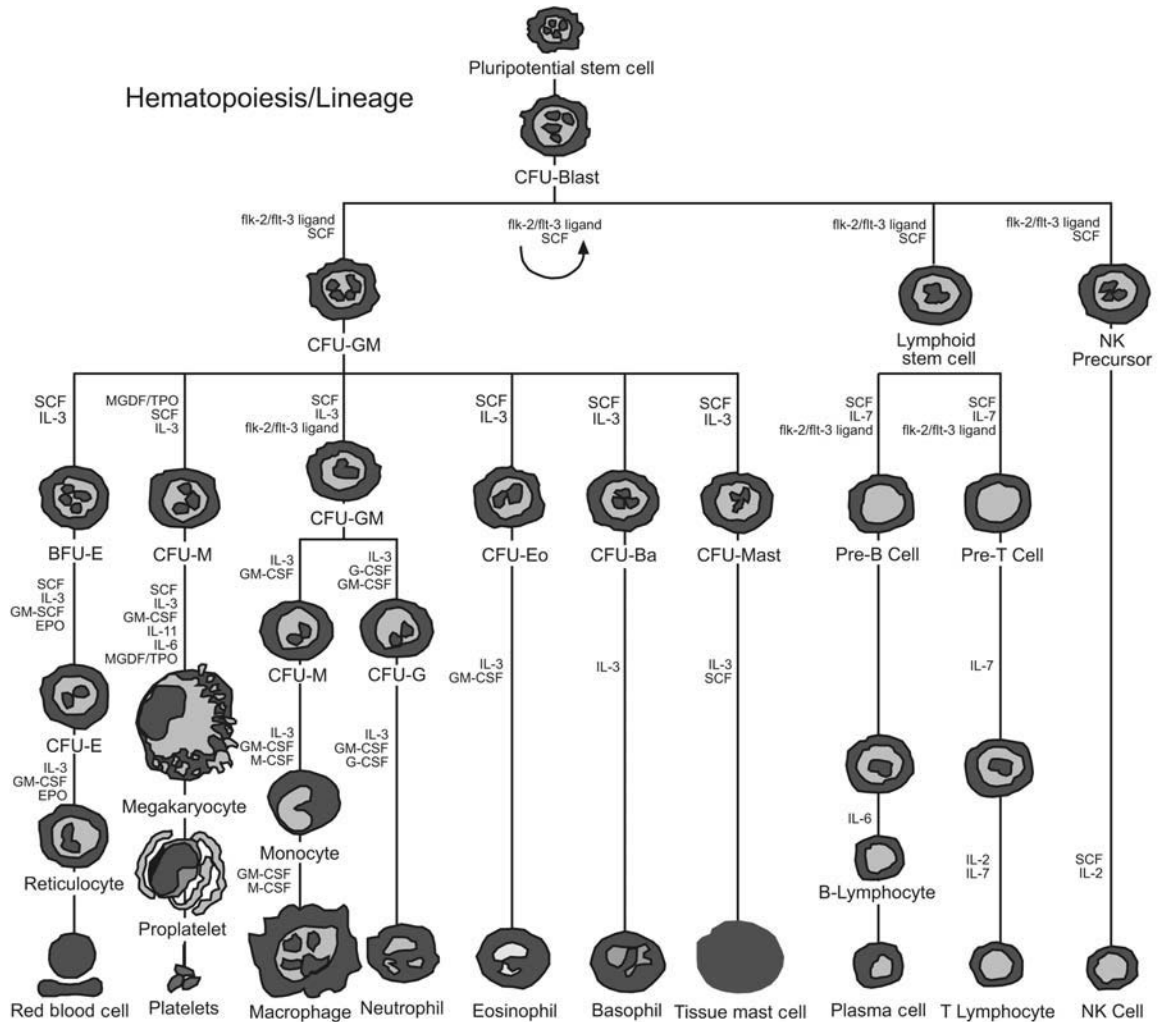

Mechanism of Action

Hematopoiesis is mediated by a series of growth factors that act individually and in various combinations involving complex feedback mechanisms to stimulate the proliferation, differentiation, and function of hematopoietic cells. The growth factors generally are glycoproteins that act through specific receptors found on the cell membrane surface of appropriate cells. The recombinant forms of hematopoietic growth factors are not always glycoproteins. The carbohydrate content varies for the growth factors and influences the mode of production for the recombinant forms and the molecular weight, but not necessarily the function of the growth factor.

More than 20 hematopoietic growth factors have been identified. The chemical properties of these growth factors have been characterized and the gene that encodes for the factor identified and cloned. Several hematopoietic growth factors are commercially available as recombinant human forms, and they have utility in clinical practice. These factors include; the recombinant forms of two myeloid hematopoietic growth factors, granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF); erythropoietin (EPO), the red cell factor; stem cell factor (SCF), an early-acting hematopoietic growth factor; and the platelet factors, thrombopoietin (TPO) and interleukin-11 (IL-11). T lymphocytes, monocytes/macrophages, fibroblasts, and endothelial cells are the important cellular sources of most hematopoietic growth factors, excluding EPO and TPO. EPO is produced primarily by the adult kidney and TPO is produced in the liver and kidney.

G-CSF (recombinant products: filgrastim, lenograstim, pegfilgrastim) maintains neutrophil production during steady-state conditions and increases production of neutrophils during acute situations such as infections [2]. Recombinant human G-CSF (rHuG-CSF) reduces neutrophil maturation time from 5 days to 1 day, leading to the rapid release of mature neutrophils from the bone marrow into the blood. The rHuG-CSF also increases the circulating half-life of neutrophils and enhances ►chemotaxis and ►superoxide production. Pegfilgrastim is a sustained-duration formulation of rHuG-CSF that has been developed by covalent attachment of a ►polyethylene glycol molecule to the filgrastim molecule [3].

G-CSF (recombinant products: molgramostim, sargramostim) is locally active and remains at the site of infection to localize and activate neutrophils [4]. Like G-CSF, GM-CSF stimulates the proliferation,

Hematopoietic Growth Factors. Figure 1 Schema of hematopoiesis, including some of the growth factors that influence the production of blood cells.

differentiation, and activation of mature neutrophils; and enhances superoxide production, ►phagocytosis, and intracellular killing. GM-CSF, unlike G-CSF, stimulates the proliferation, differentiation, and activation of mature monocytes/macrophages.

Erythropoietic factors (recombinant products: epoetin α , epoetin β , darbepoetin α) increase red blood cell numbers by causing committed erythroid progenitor cells to proliferate and differentiate into normoblasts, nucleated precursor cells in the erythropoietic lineage [5]. Tissue ►hypoxia resulting from anemia induces the kidney to increase its production of EPO by a magnitude of 10-fold or more. Patients with chronic renal failure are unable to produce adequate levels of endogenous EPO because of loss of renal function and must receive rHuEPO to maintain red blood cell counts. Darbepoetin α is another erythropoietic factor that has

an extended half-life due to its increased number of ►sialic acid-containing carbohydrate molecules. The newest erythropoietic factor is a third-generation molecule called CERA (continuous erythropoietin receptor activator) that incorporates a large polymer chain to produce a molecule with a half-life that is considerably longer than that of epoetin α or darbepoetin α [6].

SCF (recombinant product: ancestim) is an early-acting hematopoietic growth factor that stimulates the proliferation of primitive hematopoietic and nonhematopoietic cells [7]. In vitro, SCF has minimal effect on hematopoietic and nonhematopoietic progenitor cells, but it synergistically increases the activity of other hematopoietic growth factors, such as G-CSF, GM-CSF, and EPO. SCF stimulates the generation of ►dendritic cells in vitro and ►mast cells in vivo.

Thrombopoietic factors (no recombinant TPO product in clinical use at this time; IL-11 [recombinant product: oprelvekin] has marketing approval) stimulate the production of megakaryocyte precursors, megakaryocytes, and platelets [8]. Interleukin-11 has many effects on multiple tissues, and can interact with IL-3, TPO, and SCF. AMG 531, a recombinant peptibody in that binds to the thrombopoietin receptor Mpl and stimulates the production of platelets, is in phase 1 and 2 studies and has been shown to safely increase platelet counts in patients with immune thrombocytopenic purpura [9].

Clinical Use (Including Side Effects)

The use of recombinant hematopoietic growth factors (i.e., the commercially available forms of the native products) has been evaluated in many disorders affecting all types of blood cells. Recombinant human hematopoietic growth factors are identified as “rHu.” Not all uses discussed have received regulatory approval in all countries.

The myeloid growth factors rHuG-CSF and rHuGM-CSF have been tested and are used for the treatment of many neutrophil disorders, particularly neutropenia caused by ►myelosuppressive chemotherapy and other drugs, bone marrow transplantation, severe chronic neutropenia, leukemia, and AIDS. Neutropenia is a serious side effect of chemotherapy. Patients with neutropenia have a severely impaired ability to fight infections, and if not treated, neutropenia can be fatal. Peripheral blood progenitor cell transplantation is similar in principle to the more commonly recognized bone marrow transplantation, but collection of peripheral blood progenitor cells is less invasive than collection of bone marrow. rHuEPO is used to treat anemia, the condition of low number of red blood cells. Patients who are anemic often experience fatigue, headaches, shortness of breath, chest pain, and depression. Severe anemia can result in congestive heart failure. Anemia can be caused by myelosuppressive chemotherapy, kidney failure, and chronic diseases such as cancer. Another complication of chemotherapy is ►thrombocytopenia, an inadequate number of platelets, requiring transfusion. Thrombocytopenia can be caused by exposure to certain drugs and radiation, and can occur as the result of inherited diseases. Patients with thrombocytopenia bruise easily and may have serious internal bleeding that can cause death. rHuIL-11 acts on bone marrow to produce platelets.

When hematopoietic growth factors are used clinically, they can be associated with adverse effects. Very often patients who require hematopoietic growth factors are quite ill with their disease (i.e., cancer or kidney failure) or from their treatment (i.e., chemotherapy) and it is difficult to determine if a recombinant growth factor is responsible for a given side effect. Both rHuG-CSF and rHuGM-CSF are associated with mild-to-moderate

bone pain. It is possible that rHuGM-CSF can also be associated with fever and allergic-like reactions. In general, rHuEPO (as well as darbepoetin α) is well tolerated, but some patients experience flu-like symptoms, hypertension, or headaches. The most common event associated with rHuSCF is injection-site reactions (i.e., ►edema or ►urticaria). Administration of rHuIL-11 is associated with several toxicities, including fluid retention, anemia, and cardiac arrhythmias.

The recombinant hematopoietic growth factors have had a significant impact on the treatment of cancer, including prevention of serious infections and anemia.

Heme

Heme ($C_{34}H_{32}O_4N_4Fe$) represents an iron–porphyrin complex that has a protoporphyrin nucleus. Many important proteins contain heme as a prosthetic group. Hemoglobin is the quantitatively most important hemoprotein. Others are cytochromes (present in the mitochondria and the endoplasmic reticulum), catalase and peroxidase (that react with hydrogen peroxide), soluble guanylyl cyclase (that converts guanosine triphosphate, GTP, to the signaling molecule 3',5'-cyclic GMP) and NO synthases.

►Guanylyl Cyclase

Hemozoin

Hemozoin, also known as malaria pigment, is, in terms of its chemical composition, identical to β -hematin. Hemozoin is formed as a crystallization product of heme under the acidic conditions present in the food vacuole of malarial parasites. In the crystal, the heme molecules are linked into dimers through reciprocal iron-carboxylate bonds to one of the propionate side chains of each porphyrin. The dimers form chains linked by hydrogen bonds.

Hepatitis

Hepatitis is acute or chronic inflammation of the liver, which is frequently caused by infection with hepatotropic viruses. Several forms of viral hepatitis (A, B, C, D, E) are known, which result from infection with viruses belonging to separate virus families, differing in their genomic organization, replication strategies, morphology and modes of transmission.

► Viral Proteases

► Interferons

► Antiviral Drugs

Hepatitis C

Hepatitis C Virus (HCV) is the causative agent of hepatitis C, identified in 1989. HCV is a positive-strand RNA virus of the Flaviviridae family, known to infect human liver. Infection may be symptomless but may cause severe liver damage after several years. It is estimated that 1–3% of the world population are infected with HCV. The main route of transmission is parenteral with high incidence among intravenous drug users. Other risk factors are tattooing and needle stick injuries, whereas sexual transmission appears to be infrequent. About 20% of HCV cases cannot be associated with risk factors (sporadic infections) but correlate with low socio-economic background and enhanced contact with risk groups. Prior to the identification of the virus, blood transfusions, blood products or renal dialysis could lead to infection, due to unchecked contamination with HCV. Nowadays, reliable diagnostic assays are used to monitor the presence

of HCV in blood or blood products and have diminished the chance of infection to less than 1 in a million transfused units.

Heptahelical Domain

Heptahelical domains are protein modules found in all known G-protein coupled receptors, made up of seven transmembrane helices interconnected by three extra and three intracellular loops. For most G-protein coupled receptors activated by small ligands, the binding site is located in a cavity formed by transmembrane domains 3, 5, 6 and 7.

HERG-channels

HERG-channels are voltage-gated K^+ channels which belong to the ether-à-go-go (eag) family of K_v -channels. HERG stands for human eag related gene. Mutations in the human gene are associated with the long QT-syndrome LQT2. Together with MiRP1 (MinK-related peptide 1), HERG constitutes the cardiac rapid delayed rectifier K^+ channel (IK_R) which is responsible for the repolarization of cardiac action potential and therefore governs the action potential duration. Many drugs ranging from erythromycin to sotalol may block HERG-channels. Certain mutations in HERG-channels are associated with drug-induced arrhythmia.

- ▶ K^+ Channels

Heterologous Desensitization

Heterologous desensitization is a form of desensitization which does not require agonist binding of the receptor. Second messenger dependent kinases such as protein kinase A (PKA) and protein kinase C (PKC) are involved in this form of receptor desensitization. Heterologous desensitization simply depends on the overall kinase activity which is regulated by many different stimuli.

- ▶ Tolerance and Desensitization

Heterologous Expression System

Heterologous expression systems comprise prokaryotic organisms (e.g., *E. coli*) and eukaryotic cells (e.g., yeast, HEK293, *Xenopus* oocytes), which are used to functionally express foreign genes or cDNAs.

Heterotrimeric G-Proteins

Synonyms

G-proteins; Heterotrimeric GTP-binding proteins

Definition

Heterotrimeric G-proteins are part of a widely used transmembrane signaling system consisting of G-protein coupled receptors or binding proteins, (GPCRs), heterotrimeric G-proteins and a variety of effectors (enzymes or ion channels). Activation of GPCRs by extracellular ligands leads, via the activation of G-proteins, to the regulation of effectors. Heterotrimeric G-proteins consist of α -, β -, and γ -subunits. In order to convey a signal from an activated receptor to an effector, the heterotrimeric G-protein undergoes an activation–inactivation-cycle, which allows it to function as a regulatory molecular switch. In the basal state, the β/γ -complex as well as the GTP-bound α -subunit are associated, and this complex is recognized by an appropriate activated receptor. Interaction with the receptor results in the dissociation of GDP from the α -subunit and its replacement by GTP. Binding of GTP induces a conformational change, which results in the

dissociation of the α -subunit and the β/γ -complex. Both, the α -subunit and the β/γ -complex, are now able to regulate effectors. The reassociation of heterotrimeric G-protein is induced by the hydrolysis of GTP to GDP. Two ▶bacterial toxins have been found to specifically interfere with the G-protein activation–inactivation cycle, ▶pertussis toxin blocks the interaction of the activated receptor with several members of the $G_{i/o}$ -family of G-proteins whereas cholera toxin leads to the constitutive activation of some G-proteins including G_s . The inactivation of G-proteins is enhanced by various effector molecules as well as by a group of proteins called ▶“regulators of G-protein signaling” (RGS-proteins), which act as GTPase activators. There are four main subfamilies of G-proteins which are classified according to the identity of their α -subunits. The G_s -family mediates the stimulatory regulation of ▶adenylyl cyclases, whereas the $G_{i/o}$ -family mediates the inhibitory regulation of adenylyl cyclases. $G_{i/o}$ -family members are also involved in the stimulatory regulation of K^+ -channels (▶GIRK) and the inhibitory regulation of some ▶voltage-dependent Ca^{2+} -channels. The $G_{q/11}$ is involved in the stimulatory regulation of β -isoforms of ▶phospholipase C. The $G_{12/13}$ -family couples receptors to the activation of the ▶small GTPase RhoA.

High-throughput Screening

PAUL A. NEGULESCU

Vertex Pharmaceuticals Incorporated, San Diego, CA, USA

Definition

High-throughput screening (HTS) is the term used to describe the portion of the ▶drug discovery process in which ▶compound libraries are tested for an effect in an ▶assay directed against a molecular ▶target or biological mechanism. Although there is no precise definition of high-throughput per se, any process capable of performing 10,000 or more tests per day is generally considered a high-throughput screen. Achieving this screening rate often involves the use of robotics and automation to perform some or all steps in the assay. Therefore, the fundamental components comprising HTS are an assay, a compound collection, and some automated methods for carrying out the screen. Compounds that are identified as active by HTS are called hits and may be the starting points for further chemical optimization. A target is a protein or protein assembly whose function is believed to be important for promoting health or treating disease. An assay is used to measure the effect of the test compound on the target. There are many different assay formats that are compatible with HTS. However, in order to be suitable for HTS, an assay should be sensitive, informative, reliable, and simple to implement (i.e., relatively few steps). Assay performance can be measured statistically using commonly accepted standards. HTS is an important component of modern drug discovery and an area of active research and development in the pharmaceutical and biotechnology industries.

Description

Types of Targets

Any protein whose function is believed to be clinically relevant and suitable for modulation by a drug can be considered a drug target. Targets may be grouped

according to their functional class. Historically, many mammalian targets have been cell surface molecules such as receptors, transporters, or ion channels. More recently, intracellular targets such as kinases and nuclear receptors have received increased attention [1]. The targets in many infectious diseases are the genes essential for microbial growth or viral replication. It is estimated that current drugs target between 300 and 350 different molecular targets [2]. Estimates regarding the number of novel, therapeutically relevant targets that remain to be discovered as potential drug targets vary widely.

Types of Assays

Broadly defined, assays fall into two major categories: biochemical and cell based. Biochemical assays are based on isolated protein preparations, while cell-based assays utilize intact cells. Usually, cell-based assays rely on recombinant mammalian cell lines in which the target of interest is heterologously expressed. There are many different types of target-based assays ranging in complexity and information content. Among the simplest assays are ligand-binding assays that measure displacement of a radiolabeled ligand from a purified protein preparation by a test compound. These assays are best applied when the target has a well-defined binding site. G-protein coupled receptors (GPCRs) represent such a target class. For membrane-bound targets such as GPCRs, these binding assays can be carried out in membrane preparations. Binding assays, while simple, do not provide information on whether a test compound affects the function of a target.

Functional assays provide information as to whether a test compound activates, inhibits, or otherwise modulates the target. Functional biochemical assays can be performed on purified proteins such as enzymes (e.g., kinase protease). These assays typically utilize substrates to indicate the turnover rate of the enzyme. The most complex assays are cell-based functional assays. These assays are favored when it is necessary to measure the effect of a compound on target function in a cellular environment. For example, many ion channels are not ligand regulated and/or require multi-subunit assemblies to function. Therefore, the most practical way to screen these targets is to measure their activity in an intact cell. Measurements of ion flux, ion concentration, or membrane potential are all viable methods to screening these targets. Cell-based functional assays can be developed for most targets and are particularly useful when one is screening for a particular type of modulator. For example, in addition to detecting target activation or inhibition, these assays can identify allosteric modulators of target activity.

Not all cell-based functional assays are directed against a specific molecular target. Indeed many drugs

have been identified based on an observed effect of a compound on a cellular phenotype, such as shape, viability, or growth. An example of this is cyclosporin, a natural product initially identified for its antimicrobial effects and later found to inhibit T-cell proliferation. Such assays can be considered “phenotypic” in the sense that one is assaying for a change in some measurable cell parameter. The advantage of these types of screens is that they do not introduce a target-centric bias to drug discovery. A challenge for these assays is the difficulty in identifying the molecular mechanism of compound action, and the consequence of developing drugs without full understanding their mode of action. An alternative use of phenotypic assays is to screen for novel targets [3].

Assay Formats

While it is beyond the scope of this article to describe all the assay formats used in HTS, a general description of the types of readouts is pertinent. In general, HTS assays are either endpoint or kinetic assays. Endpoint assays take only a single read from a well (possibly with a pre-read before compound or reagent addition) and allow more flexibility for automation while kinetic assays require more precise processes and timings associated with multiple reads from the same well. Compounds may be preincubated or added acutely to the assay. Because HTS is an automated process, assay formats with minimal steps are preferred. The most favored assays are so-called “homogeneous” assays that require only addition steps and lack exchange or separation steps. Most assays utilize either radioactive, absorbent (colored), fluorescent, or luminescent reagents to determine the activity of the test compound in the assay. Optical detection methods for both biochemical and cell-based assays have improved in quality, sophistication, and ease of use in recent years and have contributed greatly to advances in the field. Because of the importance of the assay in the screening process, competitive advantage may be afforded to those who are proficient in the design and implementation of screening assays. The reader is referred to reviews for more information [4, 5].

Screening Formats

HTS is usually carried out in multiwell plates and the industry has settled on certain standard formats. One key standard is that most screening assays are carried out in 96 (8 × 12) or 384 (16 × 24) well plates with a standard footprint. This standard is important because most automation is optimized for use with these plates and attendant assay volumes in the 100 μL range. Furthermore, source plates containing test compound are typically stored in a similar configuration, allowing for more efficient transfer of test compound from the source plate to the assay plate. Various types of plates are available to match different assay formats, including

opaque plates for scintillation counting and clear plates for absorbance or fluorescence assays. For cell-based assays, plates are available with special surface coatings or treatments to render them suitable for incubation of cells. The industry is experimenting with miniaturization beyond 384 (e.g., 864, 1536, and 3456 well plates and assay volumes in the 1–10 μL range). Although there are promising examples of success in this area, miniaturized formats are not in widespread use as of 2002. This is due in part to the fact that the higher density formats require novel instrumentation and automation processes and represent a high barrier to entry. The industry is also experimenting with fundamentally different approaches such as flow-based, format-free, or panning methods. These methods face similar or greater barriers to entry as high-density plates. As technologies improve and costs decrease one would expect to see increased use of both high-density plate formats and, perhaps, completely novel HTS formats.

Compound Libraries

The quantity and quality of compound libraries are key considerations and drivers for HTS. The compound libraries of large pharmaceutical and screening companies can exceed 1 million samples, creating the need for significant infrastructure and technologies to complement HTS activities. There has been significant retrospective analysis of biological and chemical descriptors associated with “drug likeness” [6, 7] and many companies are attempting to fill chemical “space” with smaller, more precisely focused compound collections. Thus, many companies are reassessing the need for ever-larger libraries, with a prevailing trend toward quality rather than quantity. Nevertheless, drug discovery is still an inexact science and screening libraries in most companies still contain at least 100,000 samples. Libraries are synthesized and stored as either individual samples or as combinations. Individual samples offer the advantage of generally being of higher purity and allow for more rapid follow up. However, they are costly to generate and this method is not amenable to rapid exploratory chemistry. In the past decade, parallel synthesis and other methods have led to the notion of “combinatorial” chemistry in which sets of compounds are generated simultaneously [8]. These reactions generate multiple variants on a chemical theme and these are often stored as mixtures to be tested. Because both methods offer some advantage, many screening libraries are composed of compounds generated by both methods. Historically, most compounds were synthesized in house, making each library unique. More recently chemistry companies have begun commercializing libraries, so the prospect exists that many companies are screening similar, if not identical compounds against identical targets.

Automation and the Screening Process

With an assay and screening library in hand, automation and instrumentation complete the HTS process. An HTS lab typically consists of at least one automated system capable of moving plates from one task station to another. This is often accomplished by means of a robotic arm with substations arranged in either a linear or a radial fashion. A minimum suite of stations consists of an automated pipettor to add assay reagents or compounds, incubators (or racks) to store assay and/or compound plates, and a plate reader to detect the assay results. Additional stations may remove plate lids, change the orientation of plates, or read barcodes to keep track of plates. The steps associated with different assays can vary significantly depending on whether compounds are preincubated and/or whether the readout is endpoint or kinetic. Because different assays require different processes and timings, the efficiency of the system is maximized by software.

Measuring HTS Output: Data Quality and Validated Hits

If an assay has been properly designed and executed against an appropriate target and compound collection, the result should be quality data that identifies chemical starting points for further chemical optimization and drug development. Data quality (i.e., assay and screen performance) can be measured by objective statistical criteria based on assay statistical separation of positive and negative controls [9], but the quality and value of hits is less quantitative. Hits are scored and prioritized by biological and chemical criteria. Biological criteria include potency and selectivity against the target while chemical criteria take into account novelty, chemical properties, synthetic tractability, and scientific intuition.

Conclusion

HTS is a relatively young field, with some of the earliest references dating to the early 1990s and its impact on the efficiency of the drug discovery is yet to be fully assessed [1]. Like most new fields, the value of HTS to drug discovery is the subject of debate. Only time and disclosure by pharmaceutical companies of internal historical data will provide the metrics for long-term assessment of the method of broad screening activities. Indeed, one successful outcome of HTS would be if the generation of data sets that create a more rational basis for predicting which compounds will be appropriate for a given biological target. Thus, one role of HTS is to eventually limit the need for random screening of compound libraries. In addition, HTS methods are seeing broader applications in profiling compounds for other information relevant to drug design, including selectivity, physical properties (e.g., solubility), and in vitro metabolism. In an even broader sense, HTS has

driven and will continue to influence thinking about the role of engineering and automation at the interface of chemistry and biology. One undisputed legacy of HTS will likely be an increase in the technological sophistication of discovery research.

High-voltage-activated Ca²⁺ Channels

► Voltage-dependent Ca²⁺ Channels

Hill Analysis

A method for analysing saturation or competition binding curves from radioligand binding assays to determine whether the interaction between the ligand and receptor is competitive. The slopes of the Hill plot or coefficient should equal one if the ligand binds competitively. Slopes significantly greater than one may indicate

positive cooperativity; slopes less than one may indicate heterogeneity in binding or negative cooperativity.

► Drug-receptor Interaction

Hippocampus

The hippocampus, which got its name from the Greek word for seahorse, due to its form, is a nucleus in the depth of the temporal lobe. The hippocampus is important for the integration of sensory information, for spatial orientation and for memory formation. The hippocampal formation contains the ‘CA’ (cornu ammonis) regions, the dentate gyrus and the subiculum.

Hirudin

Hirudin is a polypeptide derived from the saliva of the leech *Hirudo medicinalis* that binds to the blood serine proteinase, thrombins, and thus blocks clot formation.

► Anticoagulants

► Proteinase-activated Receptors

Histamine

Neurotransmitter and biogenic amine derived from the amino acid histidine synthesized in hypothalamic tuberomammillary neurons (TMN) to maintain wakefulness, feeding rhythms, energy balance, neuroendocrine autonomic control, and memory functions; prominent immunomodulator and proinflammatory signal released from mast cells in response to allergic reactions or tissue damage.

► Histaminergic System

► Inflammation

► Allergy

► Orexins

► Emesis

Histamine and Emesis

Histamine may act as a neurotransmitter in the brain although it acts as an autacoid in the periphery. Histamine H1 receptors are present in the vestibular nucleus along with a high density of muscarinic cholinergic receptors. High densities of histamine H1 receptors are also found in the nucleus tractus solitarius and in the dorsal motor nucleus of the vagus. Intermediate levels are found in the nucleus ambiguus but are not detected in the area postrema. Histamine may also play a functional role in the vestibular apparatus since it increases firing of afferent nerves in the ampulla, an effect inhibited by histamine H1 and H2 receptor antagonists. It should be noted that not all central histamine H1 receptor antagonists are useful antiemetics. Many of those that are effective, such as diphenhydramine and promethazine also possess some ability as muscarinic receptor antagonists and this may contribute to their effectiveness. However, cyclizine is an effective antiemetic without having any marked affinity for muscarinic receptors.

► Emesis

Histaminergic System

STEPHEN J. HILL, JILLIAN G. BAKER
University of Nottingham, UK

Definition

Histamine is a biogenic amine that is widely distributed in the body and functions as a major mediator of inflammation and allergic reactions, as a physiological regulator of gastric acid secretion in the stomach, as a neurotransmitter in the central nervous system (CNS) and may also have a role in tissue growth and repair.

Basic Characteristics

Histamine is stored within granules of mast cells in almost all tissues of the body and has a major role as a local hormone (► **autocoid**) in the generation of allergic and inflammatory reactions. It is found in particularly high concentrations in mast cells in the lungs, skin and gastrointestinal tract and is also present in circulating basophils. ► **Allergens** and antigens bind to IgE antibodies on the surface of mast cells causing the IgE

to crosslink. This conformational change stimulates the release of pre-stored histamine (degranulation) from mast cells. Direct interaction of components of the ► **complement system** (C3a and C5a) with specific cell surface receptors can also trigger mast cell degranulation. A number of clinically used drugs (e.g. morphine, tubocurarine) and neuropeptides (at high concentrations, e.g. substance P) can also stimulate histamine release from mast cells directly via non-receptor mechanisms. In the gastric mucosa, histamine from stomach mast cells has an important physiological role in the secretion of gastric acid. Parasympathetic nerve stimulation (acetylcholine via the vagus) and gastrin release from G cells both activate gastric mast cells, releasing histamine. All three stimuli are able to act synergistically to activate the neighbouring parietal cells to produce more gastric acid.

Although mast cells and basophils probably account for >90% of stored histamine in the body, histamine is also present in platelets, enterochromaffin-like cells, endothelial cells, and neurons. Histamine can act as a neurotransmitter in the brain. Histaminergic nerves have their cell bodies within a very small area of the brain (the magnocellular nuclei of the posterior hypothalamus) but have axons in most areas of the forebrain. There is also evidence for axons projecting into the spinal (Fig. 1) cord. Finally, there is evidence that histamine synthesis can be induced in tissues undergoing rapid tissue growth and repair. In certain neonatal tissues (e.g. liver), the rate of synthesis of this unstored diffusible histamine (termed nascent histamine) is profound and may point to a role for histamine in cell proliferation.

Histamine is synthesized from the amino acid histidine via the action of the specific enzyme histidine decarboxylase and can be metabolized by histamine-*N*-methyl transferase or diamine oxidase. Interesting, in its role as a neurotransmitter the actions of histamine are terminated by metabolism rather than re-uptake into the pre-synaptic nerve terminals.

Receptors for Histamine

Histamine binds to and activates cell surface receptors. Four such receptors for histamine have now been identified so far (H₁, H₂, H₃, H₄) and their structural sequences determined following molecular cloning. All four are members of the G-protein-coupled receptor family and mediate their functional responses by activating specific ► **heterotrimeric G-proteins**. H₁-receptors coupled to G_{q/11}-proteins and mediate responses primarily via the activation of phospholipase C, which hydrolyses membrane phospholipid phosphatidylinositol-4,5-bis phosphate into the intracellular second messengers inositol 1,4,5-tris phosphate (IP₃) and diacylglycerol. IP₃ is released into the cytosol and stimulates the release of Ca²⁺ ions from intracellular stores, while

Histaminergic System. Figure 1 The Histaminergic system.

diacylglycerol remains within the plasma membrane and mediates responses via the activation of protein kinase C. Histamine H₂-receptors couple to G_s-proteins and stimulate the enzyme adenylyl cyclase, which is responsible for the synthesis of the second messenger cyclic AMP. In contrast, both the H₃- and H₄-receptors couple to the G_{i/o}-family of G-proteins, which inhibit adenylyl cyclase activity, and, in the case of the H₃-receptor, also inhibit neurotransmitter release in the CNS.

H₁-Receptor

The human histamine H₁-receptor is a 487 amino acid protein that is widely distributed within the body. Histamine potently stimulates smooth muscle contraction via H₁-receptors in blood vessels, airways and in the gastrointestinal tract. In vascular endothelial cells, H₁-receptor activation increases vascular permeability and the synthesis and release of prostacyclin, platelet-activating factor, Von Willebrand factor and nitric oxide thus causing inflammation and the characteristic ‘▶wheal’ response observed in the skin. Circulating histamine in the bloodstream (from, e.g. exposure to antigens or allergens) can, via the H₁-receptor, release sufficient nitric oxide from endothelial cells to cause a profound vasodilatation and drop in blood pressure (septic and anaphylactic shock). Activation of

H₁-receptors in the adrenal medulla stimulates the release of the two catecholamines noradrenaline and adrenaline as well as enkephalins. In the heart, histamine produces negative inotropic effects via H₁-receptor stimulation, but these are normally masked by the positive effects of H₂-receptor stimulation on heart rate and force of contraction. Histamine H₁-receptors are widely distributed in human brain and highest densities are found in neocortex, hippocampus, nucleus accumbens, thalamus and posterior hypothalamus where they predominantly excite neuronal activity. Histamine H₁-receptor stimulation can also activate peripheral sensory nerve endings leading to itching and a surrounding vasodilatation (‘▶flare’) due to an axonal reflex and the consequent release of peptide neurotransmitters from collateral nerve endings.

H₂-Receptor

The histamine H₂-receptor (359 amino acids) is best known for its effect on gastric acid secretion. Histamine H₂-receptor activation, in conjunction with gastrin and acetylcholine from the vagus, potently stimulate acid secretion from parietal cells. High concentrations of histamine are also present in cardiac tissues and can stimulate positive chronotropic and inotropic effects via H₂-receptor stimulation and activation of adenylyl

cyclase. In smooth muscle, H₂-receptor stimulation leads to relaxation and this has been observed in airway, uterine and vascular smooth muscle. In the immune system, histamine H₂-receptors can inhibit a variety of functions. For example, H₂-receptors on lymphocytes can inhibit antibody synthesis, T-cell proliferation and cytokine production. In the CNS, H₂-receptor activation generally leads to inhibition of nerve cell activity; however, in hippocampal neurones they produce a block of the long-lasting after-hyperpolarization and accommodation of firing, leading to potentiation of excitatory stimuli.

H₃- and H₄-Receptors

The histamine H₃-receptor (445 amino acids) was first identified as an ►**autoreceptor**, negatively regulating the synthesis and release of histamine from histaminergic neurons in the CNS. However, H₃-receptors have been identified on the terminals of many neurons in both the CNS, where they can inhibit the release of acetylcholine, serotonin, dopamine and noradrenaline, and on peripheral neurons where they inhibit the release of sympathetic neurotransmitters in human saphenous vein, heart, bronchi and trachea. Unlike the genes for H₁- and H₂-receptors, the *H₃*-gene contains ►**introns** (three ►**introns** and four ►**exons**) thus, multiple H₃-receptor isoforms (►**splice variants**) can be produced from the single *H₃*-receptor gene. So far, several isoforms of the H₃-receptor have been detected in different species including six splice variants in the human CNS and in some of these cases, the subsequent signalling functions appear to be different. As several different H₃-splice variants exist with different signal transduction capabilities, this splicing mechanism offers a way for tightly regulating the biological actions of the H₃-receptor in different tissues. The H₃-receptor also appears to be expressed in a ►**constitutively active** (Receptors are thought to exist in at least two states; (1) an inactive state and (2) an active state where the receptor can bind to its G-protein and elicit a functional response. Under basal conditions, the equilibrium between the two states of the receptor is substantially in favour of the inactive state. Agonists normally bind with higher affinity to the active form of the receptor and alter the equilibrium in a manner to increase the proportion of receptors in the active state. Sometimes, however, there is sufficient active receptor present under basal conditions to produce a measurable response in the absence of agonist. In this situation the receptor is termed to have constitutive activity (inverse agonist).) form in the CNS providing a means for pharmacological interference by ►**inverse agonists** as well as agonists and ►**neutral antagonists**.

The H₄-receptor (390 amino acids) is the most recently identified and unlike the H₃-receptor appears to

be exclusively expressed in the periphery. The H₄-receptor shows highest levels in bone marrow and leukocytes (mainly neutrophils and eosinophils), moderate levels in spleen and small intestine and has been detected on mast cells. It has a genomic structure consisting of two introns and three exons suggesting that splice variants may also occur.

Drugs

H₁-Antagonists

A large number of drugs have been developed as histamine H₁-receptor antagonists. These include mepyramine, chlorpheniramine, promethazine, triprolidine, diphenhydramine, cyclizine and cyproheptadine (although many of these are actually ►**inverse agonists**) and have proved to be very effective in the treatment of systemic and topical allergic and inflammatory disorders (hay fever, allergic rhinitis, insect bites, anaphylaxis, etc.). At therapeutic doses, many of the traditional antihistamines give rise to sedative effects because of blockade of the H₁-receptors in the brain. More recently, a second generation of H₁-antihistamines has been synthesized, which has poor blood-brain barrier penetration and therefore cause less central sedative effects. These include temelastine, acrivastine, astemizole, cetirizine and loratidine. Both chlorpheniramine and cetirizine exist as stereoisomers with markedly different affinities for the human histamine H₁-receptor. In the case of cetirizine, the active levo-isomer is now available for clinical use. Many H₁-receptor antagonists also possess marked muscarinic receptor antagonist properties (e.g. promethazine, diphenhydramine, cyclizine) and this 'side-effect' is exploited for the treatment of nausea and motion sickness. Several other classes of drugs, namely the antidepressants doxepin, amitriptyline and mianserin and the antipsychotic drug chlorpromazine, are also potent H₁-antihistamines.

H₂-Antagonists

The first H₂-antagonist that had selectivity for H₂- over H₁-receptors was burimamide; however, this compound is now known to be a more potent H₃-receptor antagonist. Cimetidine was developed directly from burimamide and proved to be an effective agent in the treatment of gastric and duodenal ulceration because of its ability to inhibit basal and gastrin-stimulated gastric acid secretion. A wide range of highly selective H₂-receptor antagonists are now available and are in regular clinical use including ranitidine, titotidine, nizatidine, famotidine and mifentidine. Most H₂-receptor antagonists penetrate poorly into the CNS, but zolantidine is an example of a selective brain-penetrating H₂-receptor antagonist. Studies in transfected cells overexpressing the H₂-receptor and demonstrating constitutive receptor activity have shown that cimetidine and ranitidine are both ►**inverse**

agonists at the H₂-receptors, while burimamide behaves as a ►neutral antagonist.

H₁- and H₂-Receptor Agonists

Selective agonists, like selective antagonists, are useful for scientific characterization of receptors. Although not clinically used, a number of potent agonists are available, which are able to selectively stimulate the histamine H₂-receptor. These include impromidine, arpromidine, sopromidine, dimaprit and amthamine. In the case of impromidine and apromidine, the compounds are 10–100 times more potent than histamine itself. However, while acting as agonists at the H₂-receptor, some of these compounds act as antagonists at other histamine receptors, e.g. arpromidine is a potent H₁-receptor antagonist, and impromidine a potent H₃-receptor antagonist. Selective agonists for the H₁-receptor (histaprodifen, *N*-methylhistaprodifen) have only become available recently.

Ligands for the Characterization of Histamine H₃- and H₄-Receptors

Agonists with good selectivity for H₃-receptors (relative to H₁- and H₂-receptors) have been developed and these include R- α -methylhistamine, imetit and imnepip. H₃-receptor antagonists include thioperamide, clobenpropit, iodoproxyfan, ciproxifan and impentamine and these all have substantially lower affinity for H₁- and H₂-receptors. The histamine H₄-receptor was discovered and cloned in 2000 and it is clear that there is considerable overlap in the pharmacology of the H₃- and H₄-receptors. High affinity H₃-agonists, e.g. R- α -methylhistamine, imetit and imnepip also have H₄-agonist properties although, their ►relative potency with respect to histamine is generally lower. For example, R- α -methylhistamine is several hundred-fold less effective as an H₄-receptor agonist than as a H₃-receptor agonist. The H₃-receptor antagonist clobenpropit also binds with high affinity to the H₄-receptor, but also possesses weak H₄-agonist activity. Thioperamide is an antagonist at both the H₃- and H₄-receptors, but has 5- to 10-fold lower affinity for the H₄-receptor. Thioperamide also has inverse agonist activity at both receptors. UCL 2138 (H₃ antagonist) and JNJ 7777120 (H₄ antagonist) represent two antagonists that have good selectivity between H₃ and H₄ receptors. Perhaps the most striking aspect of the pharmacology of the new H₄-receptor, however, is the fact that the atypical antipsychotic drug clozapine has agonist activity at the H₄-receptor but no agonist or antagonist activity at the H₃-receptor.

Drugs, Which Inhibit Histamine Synthesis, Metabolism and Release

Histamine synthesis from l-histidine can be selectively inhibited by α -fluoromethylhistidine. Metabolism by

diamine oxidase is sensitive to aminoguanidine, while *N*-methylation of histamine by histamine methyltransferase can be inhibited by SKF 91488, tacrine and metoprine. Sodium cromoglicate and nedocromil are drugs that inhibit mediator release from mast cells (e.g. histamine) and are used in the prophylaxis of asthma (in children), allergic rhinitis and allergic conjunctivitis. Ketotifen is an H₁-receptor antagonist that has also been reported to inhibit mast cell degranulation.

Histone

Histones are small, basic proteins required to condense DNA into chromatin. They have been first described and named in 1884 by Albrecht Kossel. There are five main histones: H1, H2A, H2B, H3 and H4. An octamer of core histones H2A, H2B, H3 and H4 is located inside a nucleosome, the central building block of chromatin, with about 150 base pairs of DNA wrapped around. The basic nature of histones, mediated by the high content of lysine and arginine residues, allows a direct interaction with the acidic phosphate backbone of DNA. The fifth histone H1 is located outside at the junction between nucleosomes and is referred to as the linker histone. Besides the main histones, so-called histone variants are known, which replace core histones in certain locations like centromeres.

►Histone Acetylation

Histone Acetyl Transferases (HAT)

An enzyme activity ascribed to many coactivators, which transfers acetyl groups to lysine residues of histone tails of the nucleosomes and thereby facilitate their disruption and the opening of the chromatin.

Synonyms

Lysine acetylation of histones

Definition

▶ **Histone** acetylation is a reversible and covalent modification of histone proteins introduced at the ϵ -amino groups of lysine residues. Histones and DNA form a complex – ▶ **chromatin** – which condenses DNA and controls gene activity. Current models interpret histone acetylation as a means to regulate chromatin activity.

Basic Mechanisms

All organisms must deal with the problem of packing DNA molecules of enormous size into the limited space of their cellular nuclei. Eukaryotes solve this problem by organizing their DNA into chromatin, a complex of DNA and dedicated packing proteins, so-called histones. This strategy allows an enormous reduction of the DNA's spacial requirement, up to 10,000-fold. Chromatin consists of repetitive building blocks called ▶ **nucleosomes** comprising four pairs of histones (H2A, H2B, H3, and H4) with about 150 base pairs of DNA wrapped around. The nucleosome is only the first stage of packing DNA and further condensation into higher-order chromatin structures takes place in order to reach most efficient packaging. The structure of condensed higher-order chromatin is still unknown, but the nucleosomal building blocks with their histone cores are maintained as the basic structural unit [1].

Histone proteins share distinct features including a high content of basic amino acids, lysines and arginines,

which represent up to 25% of all residues. They consist of C-terminal globular domains located inside the nucleosome, which interact with the DNA and other histones. In addition, histones possess N-terminal ▶ **histone tails** which appear largely unstructured based on X-ray crystallographic data and reach outside the nucleosomes. Whereas the globular domains form the scaffold around which the DNA is wrapped, the function of the histone tails is less obvious. Histone tails are not necessary for nucleosomal assembly or stability; however, their amino acid sequence is highly conserved throughout all eukaryotic organisms indicating an important biological function of some sort. Another intriguing discovery was that histone tails are subjected to intensive posttranslational acetylation of lysine residues [1, 2]. Although some histone acetylations have been discovered on the globular domains as well, the histone tails are the primary acetylation sites with about 20 positions known to date. Several experiments have shown that histone acetylation has a strong impact on gene activity. Two theories, the “charge neutralization model” and the “histone code theory” offer explanations of how histone acetylation mediated gene regulation might work.

The Role of Histone Acetylation in Gene Regulation

The first model assigning a physiological function to histone acetylation is based on the chemical change inflicted onto the lysine residues upon acetylation. As illustrated in Fig. 1 histone acetylation is a chemical conversion of a lysine's amino group into an amide group. This conversion results in the loss of a positive charge, which naturally occurs under physiological conditions, due to protonation of the amino group (see Fig. 1). According to the “charge neutralization model” the charged histone's tails interact tightly with the negatively charged phosphate back-bone of the DNA (see Fig. 2a). As a result the affected DNA is inaccessible to regulatory proteins like transcription factors and the encoded genes cannot be transcribed. This inactivation is reversed by histone acetylation, which neutralizes the charge of the histone tails. The tails detach from the DNA and genes within the deacetylated chromatin regions can be transcribed (see Fig. 2a). The “charge neutralization model” is capable of explaining several aspects of chromatin activity. However, recent investigations have revealed further details which require extensions of the current model.

A model called “histone code theory” includes more aspects of chromatin regulation which have been identified. The “histone code theory” predicts that histone acetylation and other posttranslational histone modifications serve as binding sites for regulatory proteins which mediate processes like gene transcription upon recruitment (see Fig. 2b) [3]. In this context histone modifications can be understood as

Histone Acetylation. Figure 1 Histone acetylation is a posttranslational modification of lysine residues of histones. This modification is catalyzed by histone acetyl transferases (HATs), which transfer an acetyl group (yellow) from acetyl-Coenzyme A onto the ε-amino group of the lysine residue. Histone deacetylation is catalyzed by histone deacetylases (HDACs), which hydrolyze the lysine bound acetyl group. HDAC inhibitors like Trichostatin A (TSA) are known to inhibit the deacetylation reaction *in vivo* and *in vitro*.

Histone Acetylation. Figure 2 Current models describing how histone acetylation can regulate chromatin activity. The nucleosome consists of two pairs of histone proteins H2A, H2B, H3, and H4 with 147 base pairs of DNA wrapped around. The N-terminal tails of the histones reach outside the nucleosome and can be acetylated at certain lysine residues. (a) “Charge Neutralization model”: Due to their positive charge the histone tails interact tightly with the DNA and block access to the DNA. As a result the chromatin is inactive (red). Histone acetylation neutralizes the charge and opens up the chromatin structure to become active (green). (b) “Histone code theory”: Patterns of histone acetylations and other modifications serve as recruitment sites for regulators of chromatin activity (yellow), which are needed to activate chromatin.

an instrument to store instructions about how the adjacent DNA should be handled. This theory takes into account further posttranslational modifications including ► [histone phosphorylation](#) and ► [histone methylation](#) have been identified which do not necessarily change the charge of the histone tails like lysine methylation [1, 3].

In addition protein domains have been identified which bind to modified histone tails. The so-called bromodomains bind to acetylated histone tail, but have little or no affinity to unmodified tails. Further known binding domains include chromodomains and SANT domains which possess preferential binding to methylated and unmodified tails.

An important aspect of the “histone code theory” is that some modifications can be passed on during cell division. As a result histone modification patterns including histone acetylation serve as a means to store inheritable traits of an organism which are not DNA encoded. This kind of information is generally termed ► **epigenetic information**.

The exact role of individual histone acetylations will have to be determined in the context of other modifications and the number of lysine residues effected. However, the general importance of histone acetylation as a regulator for chromatin activity is undisputed. This leads to the intriguing possibility to develop drugs that target histone acetylation for therapeutic purposes. The primary targets for drug development are the histone acetyl transferases (HATs) and the histone deacetylases (HDACs) which introduce and remove histone acetylations [2, 3].

Histone Acetyl Transferases (HATs)

Acetylation of lysine residues is catalyzed by dedicated enzymes, the so-called histone acetyl transferases (HATs). These enzymes use the ubiquitous metabolite acetyl-Coenzyme A (Acetyl-CoA) as the acetate source (see Fig. 1). The reaction is performed in a nonrandom manner and different HATs possess preferential acetylation sites. The first HATs to be identified belong to the GCN5 family. The corresponding gene in yeast has long been known to encode a transcriptional regulator and subsequent biochemical studies have proven the HAT-activity. Further HATs have been found including CBP/p300, which is involved in cell cycle progression and cyclic-AMP dependent gene activation. CBP/p300 is known to be a transcriptional coactivator which means it does not have preferential chromatin binding sites but can be recruited to specific locations by sequence-specific DNA binding proteins like transcription factors. Upon recruitment CBP/p300 acetylates the tails of the adjacent nucleosomes and thereby opens the chromatin structure for further transcriptional initiation factors [1, 2].

HATs do not appear as sole catalytic entities and are always embedded in large multi-protein complexes, which can comprise up to 20 different proteins and are more than 2 MDa in size [1, 3].

Histone Deacetylases (HDACs)

Histone Deacetylases (HDACs) catalyze the removal of the acetyl groups from lysines (see Fig. 1). Together with the HATs they are responsible for maintaining the level of histone acetylation throughout the genome. The family of HDAC proteins has been divided into four classes based on phylogenetic analysis and sequence comparison. HDACs of the classes I and II share the same Zn^{2+} -based reaction and are evolutionary related. Class IV HDACs also possess a Zn^{2+} -based reaction

mechanism but seem to have no relation to class I and II HDACs. The final class of HDACs (class III), which are better known as Sir2 proteins or sirtuins, share neither evolutionary nor mechanistic relations with the other HDACs. They do not require Zn^{2+} for catalysis but strictly depend on the cofactor NAD^+ , which they use as the acceptor of the acetyl group. Eleven Zn^{2+} -dependent HDACs of the classes I, II, and IV named HDAC 1–11 are known in mammals. In case of the sirtuins seven homologs named SIRT 1–7 have been identified in humans [2].

Like HATs, most functional HDACs are embedded in large multifunctional protein complexes, which also contain other chromatin modifying enzymes and coregulator proteins [1].

Pharmacological Relevance

The precise balance of the acetylated and deacetylated state of histones is an important feature of gene regulation. Imbalances can be found in many human cancers and often result from alterations in HDAC and HAT activities. In this context overexpression or aberrant recruitment of HDACs by oncoproteins are common in human cancers, as well as mutations in HAT encoding genes. These findings have challenged scientists to discover and explore chemical compounds capable of modulating such aberrant HDAC/HAT activities for academic and medical purposes.

Development of HDAC inhibitors (HDACi's) have been most successful to date. The first known type of HDACi's were short-chain fatty acids like butyric acid that inhibits HDACs in the millimolar range in vivo and in vitro [2]. However, these compounds suffer from a short in vivo half-life resulting in low plasma levels. In order to overcome these shortcomings prodrugs have been developed like Pivanex, which shows promising effects in different cancer cell lines and possess better plasma stability. The best known HDACi is the natural product Trichostatin A (TSA), which inhibits HDACs in the low nanomolare range and cells treated with TSA show a significant increase in histone acetylation levels. TSA is a hydroxamic acid based HDACi which inhibits HDACs through tight coordination of the essential Zn^{2+} -ion. However, TSA is primary of academic interest due to poor pharmacokinetics [2]. The most advanced HDACi to date is Zolinza also known as SAHA or Vorinostat. This compound belongs to the class of hydroxamic acids as well and inhibits HDACs in the nanomolare range. Zolinza is the first HDACi to be approved by the US Food and Drug Administration for treatment of certain malignant diseases [2]. Besides the short-chain fatty acids and hydroxamic acids other classes of HDACi's including electrophilic ketons, amino-benzamides, and cyclic peptides are currently being developed [2].

The HDACi's mentioned above inhibit exclusively Zn²⁺-dependent HDACs and not the NAD-dependent Sirtuins. Researcher also focuses on development of sirtuin inhibitors and first successes like the compound "sirtinol" have been reported. Finally, the development of HAT inhibitors is also pursued and to date some compounds like the peptide-based inhibitor "H3-CoA-20" or the small molecule "MB-3" are among the first molecules to show HAT inhibition [3].

Histone Methylation

Histone methylation is a common posttranslational modification found in histones. Histone methylations have been identified on lysine and arginine residues. In case of lysines S-adenosyl-methionine (SAM) dependent methyl transferases catalyze the transfer of one, two or three methyl groups. Lysine methylation is reversible and lysine specific demethylases have been

identified recently. Histone methylation seems to mediate long-term repression of transcription by recruitment of potent transcriptional repressors, such as heterochromatin protein-1 (HP-1).

► [Transcriptional Regulation](#)

Histone Phosphorylation

Histone phosphorylation is a common posttranslational modification found in histones, primarily on the N-terminal tails. Phosphorylation sites include serine and threonine residues, tyrosine phosphorylation has not been observed so far. Some phosphorylation events occur locally whereas others occur globally throughout all chromosomes during specific events like mitosis. Histone phosphorylation is catalyzed by kinases. Removal of the phosphoryl groups is catalyzed by phosphatases.

► [Histone Acetylation](#)

Histone Tails

Histone tails are the N-terminal regions of histones which reach outside the nucleosomes. They are not essential for the formation of nucleosomes but are required for the formation of higher-order chromatin structures. The histone tails are also known to be heavily posttranslationally modified by acetylation, phosphorylation, methylation, etc. and are important for the regulation of gene activity.

Statins

Definition

A class of important pharmacological compounds that are the most effective drugs for lowering plasma levels of low-density-lipoprotein (LDL)-cholesterol.

Mechanism of Action

HMG-CoA-reductase inhibitors (statins) inhibit the enzyme HMG-CoA-reductase that catalyzes the conversion of acetyl coenzyme A to mevalonate, which through several further biochemical steps is metabolized to cholesterol (Fig. 1). HMG-CoA-reductase is the rate-limiting enzyme for the endogenous formation of cholesterol in the human body, which takes place primarily in the liver. The reduced production of cholesterol leads to an increased formation (upregulation) of so-called ▶LDL-receptors on the surface of hepatic cells that remove cholesterol from the circulating blood. By this, the body ensures that its demand for cholesterol (cholesterol is a constituent of cell membranes, bile acids, and various hormones) is met, and subsequently plasma cholesterol is lowered. A second, although probably less important mechanism, by which statins reduce plasma cholesterol is by a reduction in hepatic synthesis of ▶very-low-density-lipoprotein (VLDL) and LDL. Statins therefore markedly reduce plasma levels of ▶atherogenic LDL-cholesterol and slightly reduce plasma ▶triglycerides carried in VLDLs and in addition slightly increase plasma levels of antiatherogenic ▶high-density-lipoprotein-cholesterol.

Furthermore, there is some evidence for pleiotropic effects (e.g., effects on hemostasis, vascular function, anti-inflammatory effects, and stabilizing effects on ▶atherosclerotic plaques) of statins. The clinical relevance of this (and the potential difference between the various statins) is at present uncertain but subject to intense investigation.

Clinical Use

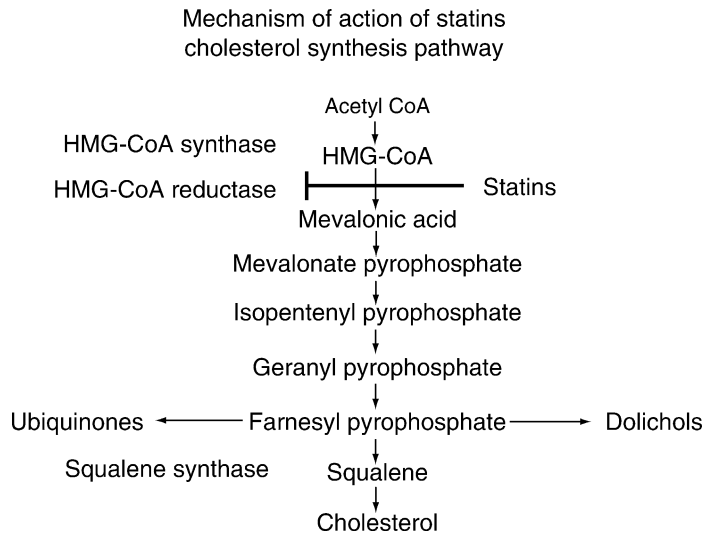

Statins are used to reduce LDL-cholesterol in subjects believed to have too high levels of cholesterol to reduce their risk of cardiovascular and in particular coronary heart disease. They are used both in patients with established vascular disease and subjects considered at high risk for cardiovascular disease, including subjects with genetic disorders of lipid and lipoprotein metabolism. Statins are by far the most commonly used and the most effective class of drugs for pharmacological lowering of plasma cholesterol. Statins were introduced as investigational drug compounds in the early 1980s and has been marketed since 1987.

Types of Statins

There are currently marketed four naturally derived statins (lovastatin, pravastatin, simvastatin, and rosuvastatin) and two synthetic statins (atorvastatin and fluvastatin). The structure of these statins is shown in Fig. 2.

Basic Pharmacology

The individual statins differ with respect to their pharmacological properties, but in general the clinical consequences of this are limited, but may occasionally

Two classes of statins

HMG-CoA-Reductase Inhibitors. Figure 2 The chemical structure of the fungal-derived and the synthetic HMG-CoA reductase inhibitors (statins).

be of importance with respect to side effects and interactions with other pharmaceutical drugs. Atorvastatin has the longest half-life and can be given at any time of the day, while other statins are best administered in the evening (lovastatin with the evening meal), perhaps due to the fact that hepatic cholesterol biosynthesis is greatest during the night time. Despite this, all of the statins can be given in one daily dose. The statins are mainly metabolized by the liver (approximately 90%) apart from pravastatin, where 60% of the drug is excreted by the kidneys. Therapeutically, much caution should be given if patients with liver or renal diseases are treated, and if statins are used in such

patients low doses should be administered under tight control.

Statins should not be used in pregnant women. If women with child-bearing potential are treated with statins efficient contraception should be secured. Statins should at present not be used in children unless they carry a very high risk of premature vascular disease and in this case only by very experienced lipid specialists.

Effect on Plasma Lipids and Lipoproteins

Statins may reduce total cholesterol and LDL-cholesterol levels in plasma by 50–60%, reduce plasma

triglycerides by up to 30% (best effect in individuals with high triglycerides) and increase HDL-cholesterol by 5–10%. It should, however, be mentioned that responsiveness to statins differ substantially between individuals. The major effect of statins is to reduce the atherogenic LDL-cholesterol fraction and this effect is dose dependent and typically increases by 6% for each doubling of the starting (lowest) approved dose of the drug. The effect on LDL-cholesterol varies between preparations in maximal approved doses from 30 to 60% in the following order of efficacy: fluvastatin < pravastatin < lovastatin < simvastatin < atorvastatin < rosuvastatin.

The effect of statins on plasma lipids and lipoproteins is rapidly seen and fully achieved after 4–6 weeks of treatment. The effect persists unchanged during continued use for several years, but after stopping the drug, LDL-cholesterol rapidly increases to pretreatment levels. Treatment with statins is therefore usually continued indefinitely and not as a short-term cure. Finally, it is generally advisable to use the statins that have documented their efficacy in clinical trials (evidence-based medicine).

Effect on Clinical Events

Several major well-conducted clinical trials have been published where subjects (4–10,000) have been treated with a statin or matching placebo for approximately 5 years. These studies have included patients with coronary heart disease as well as patients without preexisting heart disease. Moreover, more recent trials have included patient groups with diabetes, peripheral artery disease, and stroke. The results have been remarkably similar, with a reduction in deaths from vascular disease and heart attacks, and the number of revascularizations (bypass surgery or balloon angioplasty) of roughly 30% of the subjects given statin compared to those receiving the placebo. The reduction in mortality from coronary heart disease has been achieved without any indication of adverse trends in noncoronary mortality. Moreover, the benefit has been observed in various age groups including old people, in both genders and in groups of patients with elevated plasma cholesterol as well as in patients with cholesterol values considered normal. Recent trials have been focusing on more intensive lipid lowering by comparing high dose with low-dose statin therapy. The results clearly showed clinical benefit from aggressive lowering of LDL-cholesterol in patients with cardiovascular disease.

Side Effects

Abdominal symptoms including changes in bowel function, rash, and disturbances of sleep have been reported, but in general statins are remarkably free of side effects. Thus, in the large clinical trials comprising

several thousands of patients treated for approximately 5 years, side effects and the rate of discontinuation due to suspected side effects have been very similar in individuals receiving statins and placebo.

Two types of side effects, however, need to be considered. Approximately 1% of the subjects experience an increase in liver enzymes during statin treatment, and it is generally advised that a (repeatedly found) increase in liver enzymes to more than 2–3 times above normal levels should lead to discontinuation of the statin. This side effect is asymptomatic to the patient, reversible and generally occurs shortly after institution of treatment and with high doses of the statin. Myositis which, during continued treatment may progress to **rhabdomyolysis** and acute renal failure, is a serious but very rare complication seen in less than 0.2% of patients. The risk of myositis is greatest when a statin is given together with certain other drugs including (but not exclusively) erythromycin (antibiotic), nicotinic acid and fibrates (other lipid-lowering drugs), ciclosporin (used in transplanted patients), and some drugs used for systemic treatment of fungal infections. One statin, cerivastatin, was recently (year 2001) withdrawn from the market due to an unacceptably high incidence of rhabdomyolysis, in particular when used in combination with gemfibrozil.

If side effects occur on one statin, a change to another statin may be tried under supervision, but commonly the same side effect is encountered during treatment with the new statin. Statins (in particular simvastatin and lovastatin) that are metabolized via a hepatic enzyme system (C450) may interact with drugs metabolized by the same system (e.g., diltiazem and anticoagulant drugs) increasing plasma levels of the statin and/or the simultaneously used other drug. To date, however, few patient cases of clinically relevant drug interactions have been reported with the statins.

Treatment Control

The effect of a statin is usually determined by measuring fasting plasma lipids and lipoproteins after 4–6 weeks of treatment. Liver enzymes and eventually creatine kinase (in case of myositis liver enzymes are usually also elevated) are measured simultaneously to exclude side effects related to liver and muscles. After the treatment goal has been reached, blood sampling is usually performed 1–2 times a year.

Homologous Desensitization

Homologous desensitization is a form of desensitization which is mediated by agonist-induced activation of the same receptor. ►G-protein-coupled receptor kinases (GRKs) and arrestins are involved in this process, which leads to an uncoupling of the receptor from its G protein.

- Desensitization
- Heterologous Desensitization
- Tolerance and Desensitization

Homologous Proteins

Two proteins with related folds and related sequences are called homologous. Commonly, homologous proteins are further divided into orthologous and paralogous proteins. While orthologous proteins evolved from a common ancestral gene, paralogous proteins were created by gene duplication.

HSV

Synonyms

Herpes Simplex Virus

Definition

Acute infection with Herpes simplex viruses (HSV) results in painful rashes on skin and mucous membranes. HSV-1 mainly causes cold sores around the mouth (herpes labialis) or eyes (keratitis), whereas infection by HSV-2 mostly results in sores in the genital or anal area. Less frequently, HSV also causes severe infections in newborns or potentially fatal encephalitis. HSV remains latent and can be reactivated by stress, suppression of the immune system or other infections.

Humanized Monoclonal Antibodies

JULIA HEAD, TOM GELDART
Department of Medical Oncology, Southampton
General Hospital, Southampton, UK

Definition

Monoclonal antibodies (mAb) are molecules that recognize and bind a specific foreign substance called an **▶ antigen**. They are produced from a single clone of **▶ B lymphocytes**. Conventionally, mouse mAb have been generated for experimental and diagnostic use. Techniques have been developed to humanize mouse mAb to facilitate their therapeutic use in humans. It is also now possible to make mAb which are fully human.

Mechanism of Action

Antibodies perform a key role in the vertebrate immune system recognizing specific foreign antigens and directing a targeted, adaptive, immune response designed to protect the host from a wide variety of pathogens. Antibodies are also known as immunoglobulins. They are large, Y-shaped **▶ glycoproteins** produced by specialized white blood cells known as B lymphocytes. Each B lymphocyte expresses immunoglobulin mAb on its cell surface where it acts as a receptor for one specific antigen. Following antigen recognition through surface immunoglobulin, B lymphocytes may differentiate and multiply into clones of antibody forming cells known as plasma cells. Plasma cells produce and secrete large quantities of antibody in soluble form. The antigen specificity is identical to the membrane-bound surface immunoglobulin receptor. Within the immune system, billions of antibodies with differing antigen specificities are produced. Individual B lymphocytes, or a clone of B lymphocytes, however, produce antibody of a single specificity only. Antibodies produced from clones of an

individual B lymphocyte will have identical antigen specificity and are known as mAb.

All antibodies possess the same basic Y-shaped structure comprised of two identical heavy and two identical light polypeptide chains linked together by a series of non-covalent and covalent disulphide bonds. Both light and heavy chains are folded into discrete regions called domains. Light chains exist in two different forms called κ and λ . Five distinct classes of antibody IgA, IgD, IgE, IgG and IgM are recognized in most vertebrates with antibody class being determined by heavy chain type, (α , δ , ϵ , γ or μ , respectively). Antibodies are bifunctional molecules: The arms at the top of the Y structure are primarily concerned with antigen binding and are known as Fab fragments. The amino acid sequences that make up part of each Fab fragment are characterized by sequence variability and are therefore referred to as variable regions. Within each variable region, three short polypeptide sequences show immense variability. These hypervariable regions together create the specific antigen binding site and as such are referred to as complementarity determining regions (CDRs). The intervening peptide fragments between the CDRs within the variable region act as a scaffold for the CDRs and are known as framework regions. The two Fab fragments are joined at an area of structural flexibility known as the hinge region. The remainder of the antibody molecule (the stem of the Y) is known as the Fc fragment and has a relatively constant structure. The Fc fragment is responsible for mediating immune effector functions such as complement activation or [phagocyte](#) binding following antigen recognition.

Antibodies are highly specific, binding only to a restricted part of a given antigen known as an epitope. Given the billions of antibody specificities that may be produced by the immune system, an antibody that recognizes an epitope on virtually any molecule may be produced. It is this property that makes antibodies immensely powerful tools for experimental, diagnostic and therapeutic procedures.

In the laboratory, an antibody may be raised by injecting antigen into an animal and then collecting the resultant antibody rich serum. However, this antiserum will contain a variable heterogeneous polyclonal mixture of antibodies produced by any number of different B lymphocytes that recognize a variety of epitopes present on the given antigen. In contrast, antibodies produced from identical copies or clones of a single B lymphocyte will have identical antigen epitope specificity and are known as mAb. In 1975, Köhler and Milstein won the Nobel Prize for devising an experimental technique enabling stable and permanent production of mAb. Mice were injected with an antigen of interest thereby eliciting an antibody response. Antibody producing B lymphocytes (isolated

from these animal's spleens) were then fused with cells previously derived from an immortal B lymphocyte tumour (myeloma). Hybrid cells (hybridomas) with the ability to make the specific antibody of interest and multiply indefinitely were then selected out, propagated and cloned, thereby providing a permanent and pure source of mAb from a single progenitor cell. Because mouse B lymphocytes are used to derive these hybridomas, the mAb produced by this system is of mouse origin (murine). Although murine mAb have proven to be of immense importance in experimental and diagnostic techniques, their use in human therapy is problematic. Firstly, murine antibodies may be recognized by a patient's immune system as foreign, leading to the generation of a human anti-mouse antibody (HAMA) response. HAMA responses may adversely affect the clinical efficacy and half-life of the antibody but also cause the clinical symptoms of [serum sickness](#). Secondly, because the Fc fragment of the mAb is murine rather than human, it may fail to activate appropriate immune effector functions, and as such, prove ineffective ([Figure 1](#)).

It is clearly unacceptable to immunize humans to raise antibodies and technically it has proven difficult to produce fully human antibodies by cell fusion techniques. Therefore, in an attempt to overcome the HAMA response and improve the clinical efficacy of murine derived mAb for therapy in humans, genetic engineering techniques have been developed to "humanize" murine antibodies. Chimeric antibodies with mouse variable regions and human constant regions may now be produced. This technique involves cloning the genes that encode for mouse antibody variable regions (specific to an antigen of interest) and inserting them into a vector along with the appropriate genes encoding for human immunoglobulin constant domains. This vector is then transfected into an appropriate cell line such as Chinese hamster ovary cells. These cells are then screened and cloned like conventional hybridomas. Colonies that secrete the resultant chimeric antibody can then be propagated, thereby providing a stable source of chimeric mAb. This humanization concept can be taken a step further to produce "CDR grafted" mAb. This approach requires the synthesis of a totally novel variable region using gene sequence information for the three epitope specific CDRs of interest from the variable regions of a mouse mAb, with compatible sequences from human variable framework regions. These humanized variable regions can then be linked to human constant region genes that, when expressed in an appropriate cell line, may produce a humanized mAb. In practice, the grafting of murine CDRs alone may result in some loss of antigen binding affinity, and a number of framework region amino acid residues may also need to be reintroduced alongside the CDRs to maintain antigen affinity. The result of both

Humanized Monoclonal Antibodies. Figure 1 Schematic representation of mouse, human, chimeric and

these approaches is to produce a mAb for human therapy that is specific to the antigen of interest, is less immunogenic, has a longer biological half-life and is more efficient at recruiting human Fc dependent immune effector functions.

An alternative technique for producing fully human mAb is the use of phage display libraries. Gene segments encoding for human variable domains of antibodies may be fused to genes that encode for ▶bacteriophage coat proteins. Bacteria may then be infected with the bacteriophage and the resultant phage particles that are produced will have coats that express the appropriate variable domain proteins. In this manner, phage display libraries may be built up consisting of a large collection of phages ($>10^{10}$), each expressing a different variable domain specific for a different antigen. Phage display libraries may then be challenged with an antigen of interest and phages that express appropriate antigen binding domains isolated and cloned. The gene encoding the variable region of interest may then be recovered from the isolated phage,

joined to the remaining parts of a human immunoglobulin gene and transfected into an appropriate host cell capable of antibody secretion. The result is production of a fully monoclonal human antibody with appropriate antigen specificity. One final approach to produce fully human mAb is to utilize transgenic animals. This technology requires deletion of an animal's own immunoglobulin genes and the subsequent introduction of human immunoglobulin gene segments. Subsequent antigen immunization then results in the generation of a fully human immunoglobulin.

mAb are thought to exert their therapeutic effect through a variety of mechanisms: In the treatment of conditions such as cancer, mAb may selectively bind to antigen on cells of interest, thereby targeting them for destruction through recruitment of the host's own immune system. Secondly, mAb may act by blocking cellular communication, a mechanism thought to be important in the treatment of some autoimmune inflammatory conditions. At the molecular level, this effect might be achieved by binding and disabling

cell surface receptors, or by binding and inactivating the signalling molecules themselves. Finally, mAb may provide their own inhibitory or stimulatory signals on binding cell surface receptors, a mechanism also thought to be of importance in mAb cancer therapy.

Clinical Use (Including Side Effects)

A number of chimerized, humanized, and one human mAb have now been approved for therapeutic use in humans in the treatment of autoimmunity, malignancy, infection and cardiovascular disease (Table 1). Some of the currently licensed mAb will be discussed here. A much larger number of mAb are currently being evaluated in Phase I, II and III trials. In general, chimeric, humanized and human mAb are very well tolerated with few side effects. Chimeric or humanized mAb still have the potential to evoke host immune response to the variable domains or CDRs of the antibody; so-called HACA (human anti-chimeric antibody) or HAHA (human anti-human antibody) responses, although these responses are uncommon. Short-lived and occasionally severe infusion-related acute hypersensitivity reactions such as fever, skin itching, shivering, respiratory compromise and low blood pressure sometimes occur. Such effects may

be abrogated by slowing the infusion rate or by co-administration of antihistamines and steroids.

Infliximab, a chimeric mAb against tumour necrosis factor (TNF) α has proven beneficial in the treatment of inflammatory diseases such as Crohn's disease and rheumatoid arthritis. TNF is a ►cytokine with a broad spectrum of pro-inflammatory biological activities. Infliximab binds TNF thereby blocking its activity. Clinical trials have clearly demonstrated significant clinical efficacy compared to placebo or conventional therapy. TNF blockade by Infliximab has been associated with a number of specific side-effects, notably an increase in opportunistic infections and the development of other autoimmune syndromes. Delayed hypersensitivity manifested by joint and muscle aches, rash and facial swelling have been reported rarely in patients retreated with Infliximab after a considerable treatment-free interval. Adalimumab is a more recently developed fully human anti-TNF. As of July 2006, it had been approved for the treatment of rheumatoid arthritis, ankylosing spondylitis and psoriatic arthritis. Basiliximab, a chimeric mAb, and Daclizumab, a humanized IgG mAb, are two mAb that are thought to exert at least some of their clinical effects through cell signal blockade. They are both licensed for the

Humanized Monoclonal Antibodies. Table 1 Major monoclonal antibodies FDA approved for clinical use

Monoclonal antibody	Mechanism of Action	Disease
Rituximab	Anti-CD20	B-cell NHL
Tositumomab	Radiolabelled anti-CD20	Follicular NHL
Ibritumomab	Radiolabelled anti-CD20	B-cell NHL
Gemtuzumab	Anti-CD33	AML
Alemtuzumab	Anti-CD52	CLL and T-cell lymphoma
Trastuzumab	Anti-HER2	Breast cancer
Cetuximab	Anti-EGFR	Colorectal cancer, Head and Neck cancers
Bevacizumab	Anti-VEGF	Colorectal cancer
Abciximab	Glycoprotein IIb/IIIa antibody	Coronary angioplasty
Infliximab	Anti-TNF α	Inflammatory bowel disease, rheumatoid arthritis, ankylosing spondylitis
Adalimumab	Anti-TNF α	Rheumatoid arthritis, ankylosing spondylitis
Eculizumab	Anti-complement protein C5	Paroxysmal nocturnal haematuria
Omalizumab	Anti-IgE	Asthma
Efalizumab	Anti-CD11a	Psoriasis
Ranibizumab	Anti-FAB fragment of VEGF	Macular degeneration
Basiliximab	Anti-IL-2 CD25	Allogeneic organ transplantation
Daclizumab	Anti-IL-2 CD25	Allogeneic organ transplantation
Palivizumab	Anti-RSV glycoprotein	Viral infections

suppression of graft rejection following allogeneic organ transplantation. Both mAb are specific for the interleukin-2 (IL-2) receptor (CD25) expressed on activated T lymphocytes, blocking IL-2 receptor binding and its resultant T lymphocyte proliferative effect. Rituximab, another chimeric IgG mAb, binds to CD20, a transmembrane protein present on normal and malignant B lymphocytes. It has proven efficacy in non-Hodgkin's lymphoma and has been shown to be effective both as a single agent and in combination with standard chemotherapy. Early clinical trials are also beginning to show impressive therapeutic activity in some autoimmune conditions, such as rheumatoid arthritis. Rituximab probably works through a variety of mechanisms that include immune effector targeting and receptor signalling. Ibritumomab tiuxetan – the murine parent anti-CD20 antibody of rituximab – is a mAb in conjunction with a chelator (tiuxetan) to which radioactive isotope is added (either yttrium-90 or indium-111). Treatment of B-cell NHL with Ibritumomab showed higher response rates in clinical trials compared to treatment with rituximab alone and in addition, demonstrated efficacy in patients who were no longer responding to rituximab. Trastuzumab, a humanized IgG mAb directed against the extracellular domain of the HER2 (ErbB-2) epidermal growth factor, has proven efficacy in patients with breast cancer whose tumours overexpress the HER2 receptor. Its effect is likely to be mediated through a number of mechanisms that include signal blockade and immune effector recruitment. Again, the antibody is effective as a single agent and has been shown to provide significant additional benefit to cytotoxic chemotherapy. Of note, Trastuzumab, particularly in combination with certain chemotherapeutic agents, has been associated with longer term cardiac dysfunction. The basis for the observed cardiotoxicity is, as yet, not fully explained.

Cetuximab is a chimeric mAb that targets the epidermal growth factor receptor (EGFR) which may be overexpressed on the surface of cancer cells. It is licensed for the treatment of metastatic colorectal, and head and neck cancers. Common side effects include acne-like rash, dry skin, lethargy, fever, constipation and abdominal pain. A second drug licensed for use in metastatic colorectal cancer is Bevacizumab, a humanized mAb that targets vascular endothelial growth factor (VEGF). VEGF is a protein that stimulates new blood vessel formation and it has recently emerged as a key player in tumour angiogenesis. VEGF expression is induced by hypoxia and glucose deprivation and it is almost universally expressed in tumours. Phase III randomized trials have demonstrated that the addition of bevacizumab to standard chemotherapy can improve overall survival in colorectal and lung cancer patients and progression free survival in patients with breast

cancer. The most common side effect is hypertension, but more serious adverse effects include thromboembolic events and gastrointestinal perforation. A modified fragment of the bevacizumab antibody has been developed and recently approved for use in macular degeneration (ranibizumab). Reports from clinical trials have shown substantially better outcomes in patients with choroidal neovascularization than conventional treatments such as laser or photodynamic therapy. Abciximab is the Fab fragment of a chimeric mAb against the platelet glycoprotein IIb/IIIa receptor. This receptor is involved in the final common pathway of platelet aggregation and thrombus formation, and Abciximab can successfully inhibit receptor function. Abciximab also binds to the vitronectin receptor found on platelets and endothelial cells inhibiting its pro-coagulant function. As an adjunct to aspirin and heparin, it has proven beneficial in the treatment of high risk patients undergoing percutaneous transluminal revascularization procedures for coronary artery disease, reducing the need for subsequent revascularization and the risk of myocardial infarction and death. Bleeding and a low platelet count are recognized complications of therapy. Finally, mAb have been developed to treat infective diseases. One example, Palivizumab, is a humanized mAb directed against an epitope on the fusion glycoprotein of the respiratory syncytial virus (RSV). It has potent neutralizing and fusion inhibitory activity against RSV. It is licensed for the prophylactic treatment of infants at high risk of infection with this virus and randomized trials have proven clinical benefit compared to placebo.

mAb have revolutionized experimental and diagnostic laboratory techniques. The humanization of murine mAb and the ability to make fully human reagents has allowed the development of a wide variety of generally safe, clinically useful, therapies. It seems likely that the humanization approach may well be superseded by the production of fully human antibodies produced by phage display techniques or through the use of transgenic animals. Given the large number of mAb currently undergoing pre-clinical development and being evaluated in clinical trials, the indications for mAb therapy are set to increase dramatically.

11β-Hydroxysteroid Dehydrogenase Type II

11β-hydroxysteroid dehydrogenase type II (11β-HSD II) is a steroid metabolizing enzyme which is specifically expressed in epithelial tissues such as kidney or colon. 11β-HSD II is an NAD⁺-dependent enzyme which has a low K_m for physiological glucocorticoids. The reaction in the dehydrogenase direction is essentially irreversible. 11β-HSD II converts active glucocorticoids into their inactive ketoform, e.g. cortisol into cortisone. Since aldosterone possesses a cyclic 11,18-hemiacetyl-group, it is not a substrate for 11β-HSD II. Thus, this mechanism ensures protection of mineralocorticoid target tissues from transcriptional activation by glucocorticoids. Mutations in the 11β-HSD II gene are responsible for the syndrome of apparent mineralocorticoid excess.

Hyperactivity Disorder

- ▶ Psychostimulants

Hyperaldosteronism

Hyperaldosteronism is a syndrome caused by excessive secretion of aldosterone. It is characterized by renal loss of potassium. Sodium reabsorption in the kidney is increased and accompanied by an increase in extracellular fluid. Clinically, an increased blood pressure (hypertension) is observed. Primary hyperaldosteronism is caused by aldosterone-producing, benign adrenal tumors (Conn's syndrome). Secondary hyperaldosteronism is caused by activation of the renin-angiotensin-aldosterone system. Various drugs, in particular diuretics, cause or exaggerate secondary hyperaldosteronism.

- ▶ Aldosterone
- ▶ Diuretics

Hyperalgesia

Increased responsiveness to noxious stimuli is termed hyperalgesia. It occurs following injury or disease and encompasses enhanced responses as well as reduced thresholds to a given noxious stimulus. 'Primary' hyperalgesia occurs in the damaged area whereas 'secondary' hyperalgesia occurs in the area surrounding it.

- ▶ Pain and Nociception

Hypercholesterolemia

Elevated levels of cholesterol in the circulation.

- ▶ HMG-CoA-Reductase Inhibitors
- ▶ Low-Density Lipoprotein Receptor Gene Family

Hyperekplexia

Hyperekplexia (startle disease, stiff baby syndrome; OMIM databank: #138491) is a congenital human motor disorder that follows autosomal-recessive and dominant traits. Affected patients suffer from exaggerated startle responses to unexpected acoustic and tactile stimuli as well as episodic muscle stiffness. The startle response may trigger a sudden loss of postural control resulting in immediate and unprotected falling. In addition to profound startle responses, affected neonates exhibit a severe muscular hypertonia which may cause fatal apneic attacks. Muscle tone normalizes during infancy, while excessive startling persists throughout life. The clinical appearance varies considerably even within families with more than one afflicted member. A variety of mutant alleles of the glycine receptor subunit genes *GLRA1* and *GLRB* have been found to cause hyperekplexia. These mutations affect glycine receptor affinity and ion conductance, or represent null alleles.

- ▶ Glycine Receptors

Hyperglycaemia

Elevated level of glucose in the blood.

- ▶ Diabetes Mellitus

Hyperinsulinemic Hypoglycemia of Infancy (HI)

HI usually presents at birth or within the first year of life and is characterized by excessive insulin release independent from blood glucose. Most cases of HI are sporadic with an estimated incidence of 1 in 27,000 live births in Ireland and 1 in 50,000 in Finland. However, in some isolated communities the disease incidence is much higher, e.g. 1 in 3,200 in the central area of Finland and 1 in 2,500 in the Arabian peninsula. Mutations in 5 different genes account for HI: the K_{ATP} channel subunits *SUR1* (*ABCC8*) and *Kir6.2* (*KCNJ11*) and the metabolic enzymes glucokinase

(GCK), glutamate dehydrogenase (GLUD1), and short-chain 1-3-hydroxyacyl-CoA dehydrogenase (SCHAD). Mutations in SUR1 (ABCC8) are the most common cause of HI (for details see ▶ATP-dependent K^+ channel). Gain-of-function mutations in the genes for the glycolytic enzyme glucokinase (GCK) and the mitochondrial enzyme glutamate dehydrogenase (GLUD1) produce HI by increasing ATP synthesis. As a result, K_{ATP} channel activity decreases and insulin secretion is stimulated. Usually, mutations in GCK and GLUD1 produce a mild form of HI that does not require pancreatectomy.

▶ATP-dependent K^+ Channel

Hyperkalemia

Hyperkalemia is an excess of potassium in the blood. Clinical symptoms are muscle weakness and cardiac arrhythmias. It is caused by, e.g., hyperaldosteronism and angiotensin-converting enzyme (ACE) inhibitors.

Hyperplasia

Hyperplasia is the enlargement of an organ due to an increased number of cells.

▶Growth

Hyperpolarization-activated and Cyclic Nucleotide-gated Channels (HCN)

▶Cyclic Nucleotide-regulated Cation Channels

Hyperpyrexia

▶Fever

Hypersensitivity

Hypersensitivity (or allergy) describes an inappropriate immune response to foreign substances, allergens, giving rise to irritant or harmful reactions.

▶Allergy

Hypertension

Hypertension is a chronic elevation of blood pressure which is a major modifiable risk factor for cardiovascular and renal disease. There is no specific level of blood pressure where clinical complications start to occur; thus the definition of hypertension is arbitrary but needed in clinical practice for patient assessment and treatment. The diagnosis of hypertension in adults is made when the average of two or more diastolic blood pressure measurements on at least two separate visits is ≥ 90 mmHg or when the average of multiple systolic blood pressure readings on two or more separate visits is consistently ≥ 140 mmHg. Isolated systolic hypertension is defined as systolic blood pressure ≥ 140 mmHg and diastolic blood pressure < 90 mmHg. Essential, primary, or idiopathic hypertension is defined as high blood pressure in which causes of secondary hypertension or monogenic (mendelian) forms are not present. Essential hypertension accounts for 95% of all cases of hypertension. This condition is a

heterogeneous disorder, with different patients having different causal factors that lead to high blood pressure and usually requires pharmacological treatment.

- ▶ Blood Pressure Control
- ▶ Antihypertensive Drugs

Hyperthyroidism

Hyperthyroidism (thyrotoxicosis), defined as excessive thyroid activity, causes a state of thyroid hormone excess (thyrotoxicosis) characterized by an increased metabolic rate, increase in body temperature, sweating, tachycardia, tremor, nervousness, increased appetite and loss of weight. Common causes of hyperthyroidism are toxic multinodular goiter, toxic adenoma or diffuse toxic goitre (▶ Graves' disease). ▶ Antithyroid drugs (methimazol, carbimazole, propylthiouracil) block thyroid hormone production and are hence suitable for the treatment of hyperthyroidism.

- ▶ Antithyroid Drugs

Hyperuricemia

Hyperuricemia is defined as serum uric acid concentration $>416 \mu\text{mol/L}$ or 7.0mg/dL . With increasing serum uric acid concentration, the risk of acute gouty arthritis increases, but asymptomatic hyperuricemia does not have to be treated pharmacologically.

- ▶ Anti-gout Drugs

Hypnotic

A medication that causes induction of sleep. The majority of currently available hypnotics (for example benzodiazepine receptor agonists) act via potentiating the brain's inhibitory GABAergic systems, in turn reducing the activity of arousal (i.e. wake promoting) neurotransmitter systems.

- ▶ Sleep
- ▶ GABAergic System
- ▶ Benzodiazepines

Hypoaldosteronism

Hypoaldosteronism is defined as a deficiency of aldosterone. Renal secretion of potassium is decreased, causing hyperkalaemia. The treatment is replacement of a mineralocorticoid, e.g. fludrocortisone.

- ▶ Aldosterone
- ▶ Gluco-mineralocorticoid Receptors

Hypocretins

Synonyms

Orexins

- ▶ Orexins

Hypoglycaemia

Hypoglycaemia is a reduction of blood glucose concentration to below normoglycaemia (euglycaemia). Severe hypoglycaemia will deprive the brain of adequate glucose (neuroglycopenia), which causes impaired neural function and can result in coma and death. Sulphonylureas, prandial insulin releasers and insulin can cause hypoglycaemia if administered in excess or if taken without appropriate food consumption.

- ▶ Insulin Receptor
- ▶ ATP-dependent K^+ Channels

Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism is a genetically heterogeneous disorder characterized by infertility and

absent or incomplete pubertal maturation. If the gene for the ►GnRH receptor is affected by loss of function mutations, a complete GnRH-resistant form of the disease is observed.

- Protein Trafficking and Quality Control
- Gonadotropin-releasing Factor/Hormone (GnRH)

Hypokalemia

Hypokalemia is a reduction of plasma K^+ concentration below 3.5 mM. Hypokalemia can result from a reduction in dietary K^+ intake and from a shift of K^+ into the intracellular space. The most common of hypokalemia, however, is renal K^+ loss (i.e., caused by diuretics).

- Diuretics
- Hyperaldosteronism
- Epithelial Na^+ Channels

Hypomethylating Agents

DNA hypomethylating agents like decitabine stop the methylation of DNA by eliminating the enzyme DNA methyltransferase 1, which adds methyl groups to CpG sites of DNA. Increased methylation of CpG sites in the promotor area of a gene is related to the gene's gradual shut down. Decitabine and other hypomethylating agents work by removing the methyl groups, enabling the gene to become active again, which is vital in the case of tumor-suppressor genes, which normally protect cells from becoming cancerous.

- Antimetabolites
- Epigenetics
- DNA Methylation

Hyposensitization

Hyposensitization is an empirically founded immunotherapy which is characterized by repeated exposure to the responsible (clearly defined) allergen. It can lead to a diminished Type I (IgE-dependent) allergic reaction.

- Allergy

Hypotension

Hypotension is defined as abnormally low blood pressure. In most cases, hypotension is adequately treated with general measures (e.g. physical exercise), drug treatment is rarely required. Drugs used for the treatment of hypotension include α -adrenoceptor agonists and compounds which activate both α and β adrenoceptors.

- α -Adrenergic System
- β -Adrenergic System
- Kinins

Hypothalamus

Brain structure below the thalamus and main portion of the ventral region of the diencephalon, controlling homeostatic and nonhomeostatic basic body and brain functions, including circadian and feeding rhythms, energy metabolism, thermogenesis, sympathoadrenal, and neuroendocrine outflow (secretion of hormones by the pituitary gland), behavioral state and memory functions.

- Hypothalamus-pituitary-adrenal (HPA) Axis
- Circadian Rhythms
- Appetite Control
- Orexins
- Antiobesity Drugs

Hypothalamus–Pituitary–Adrenal (HPA) Axis

Regulatory circuit controlling glucocorticoid secretion and synthesis by the adrenal gland. In an endocrine cascade, corticotropin releasing hormone (CRH) in the hypothalamus stimulates adrenocorticotrope hormone (ACTH) in the anterior pituitary, which then acts on the adrenal gland in order to release glucocorticoids. In a negative feedback loop, the hormone inhibits the HPA axis via binding to glucocorticoid receptor and mineralocorticoid receptor, thus ensuring homeostasis of glucocorticoid serum levels.

- ▶ Gluco-mineralocorticoid Receptors

- ▶ Antidepressant Drugs

during development causes cretinism, characterized by retardation of growth and mental deficiency.

- ▶ Antithyroid Drugs

Hypothyroidism

Decreased activity of the thyroid gland results in hypothyroidism and, in severe cases, myxoedema. It is often of immunological origin and the manifestations are low metabolic rate, slow speech, lethargy, bradycardia, increased sensitivity to cold, and mental impairment. Myxoedema includes a characteristic thickening of the skin. Therapy of thyroid tumours is another cause of hypothyroidism. Thyroid deficiency

Hypoxia

Lack of oxygen in blood or tissues. Tissue hypoxia can be caused by injury, inflammation, or tumor growth, due to disruption of blood supply. Tissue hypoxia is normally associated with acidosis, as anaerobic metabolism leads to production of lactic acid.

- ▶ Proton-sensing GPCRs
- ▶ Hematopoietic Growth Factors

IC₅₀ Values

The IC₅₀ value is that concentration of a drug that reduces the activity (or binding) of another drug to an enzyme by 50%. Under certain conditions it can be used to express the affinity of the enzyme inhibitor.

- ▶ Drug Interactions
- ▶ Drug-receptor Interaction

Idiopathic Hypercalciuria

Hypercalciuria is clinically defined as a daily urinary calcium excretion greater than 100 μM/kg, and it is associated with nephrocalcinosis, urinary stone formation, proteinuria, and renal failure. The genetic background is probably heterogeneous. Two hypercalciuric syndromes, Dent's disease and X-linked recessive nephrolithiasis, have been linked to mutations in the gene encoding a voltage-gated chloride channel (ClC-5).

IKK Complex (IKK Family)

The IκB kinase (IKK) complex is a high molecular weight (600–900 Kd) multisubunit complex present in the cytosol of most cell types. It contains two highly homologous catalytic subunits, IKKα (or IKK1) and IKKβ (or IKK2) that are serine/threonine protein kinases. They are structurally related and contain an amino-terminal kinase domain, a central leucine zipper region required for their dimerization and a carboxyl-terminal helix–loop–helix domain, which mediates protein interaction. The catalytic subunits interact through their carboxyl-terminal end with the third subunit, IKKγ (or NEMO for NF-κB essential modulator). IKKγ is the regulatory subunit of the IKK complex. It is structurally composed of protein–protein interaction motifs including two coiled–coiled domains, a leucine-zipper domain and a zinc-finger domain. IKKγ is essential for the structural organization and stability of the complex. IKKγ also has a regulatory function as it connects the IKK complex to potential upstream activators. The IKK complex phosphorylates Iκβ-α, an inhibitor of NFκB, removing it from the NFκB dimer and allowing NFκB activation. The IKK complex is involved in Toll-like receptor signalling.

- ▶ Nuclear Factor Kappa B
- ▶ Toll-like Receptors

Ikr

Ikr is a rapidly activating component of the delayed rectifier potassium current. Ikr stands for potassium (K) rectifier (r) current (I). Ikr is characterized by delayed

activation and slow inactivation and contributes to repolarization phase of the action potential. Terikalant, originally thought as a highly specific blocker of I_{K1} channels, possesses even higher blocking affinity for I_{kr} than for I_{K1} .

- ▶ Inward Rectifier K^+ Channels
- ▶ K^+ Channels

Imidazoline Receptor

The imidazoline receptor is a hypothetical receptor for a subgroup of α_2 adrenergic agonists, which are characterized by their imidazoline structure (e.g. moxonidine). So far, there is no proof of the existence of imidazoline receptors.

- ▶ α -Adrenergic System

Immediate Early Genes

Immediate early genes, e.g., c-fos, c-jun, and c-myc, are the first genes whose expression is induced in cells after a growth stimulus. They encode transcription factors and induce the expression of other growth-related genes.

Immune Complexes

Immune complexes are aggregates of antibodies with their (foreign) antigens which physiologically initiate the clearance of the substance via ingestion and subsequent intracellular degradation by phagocytic leukocytes. In type III allergic reactions immune complexes cause disease.

Immunity

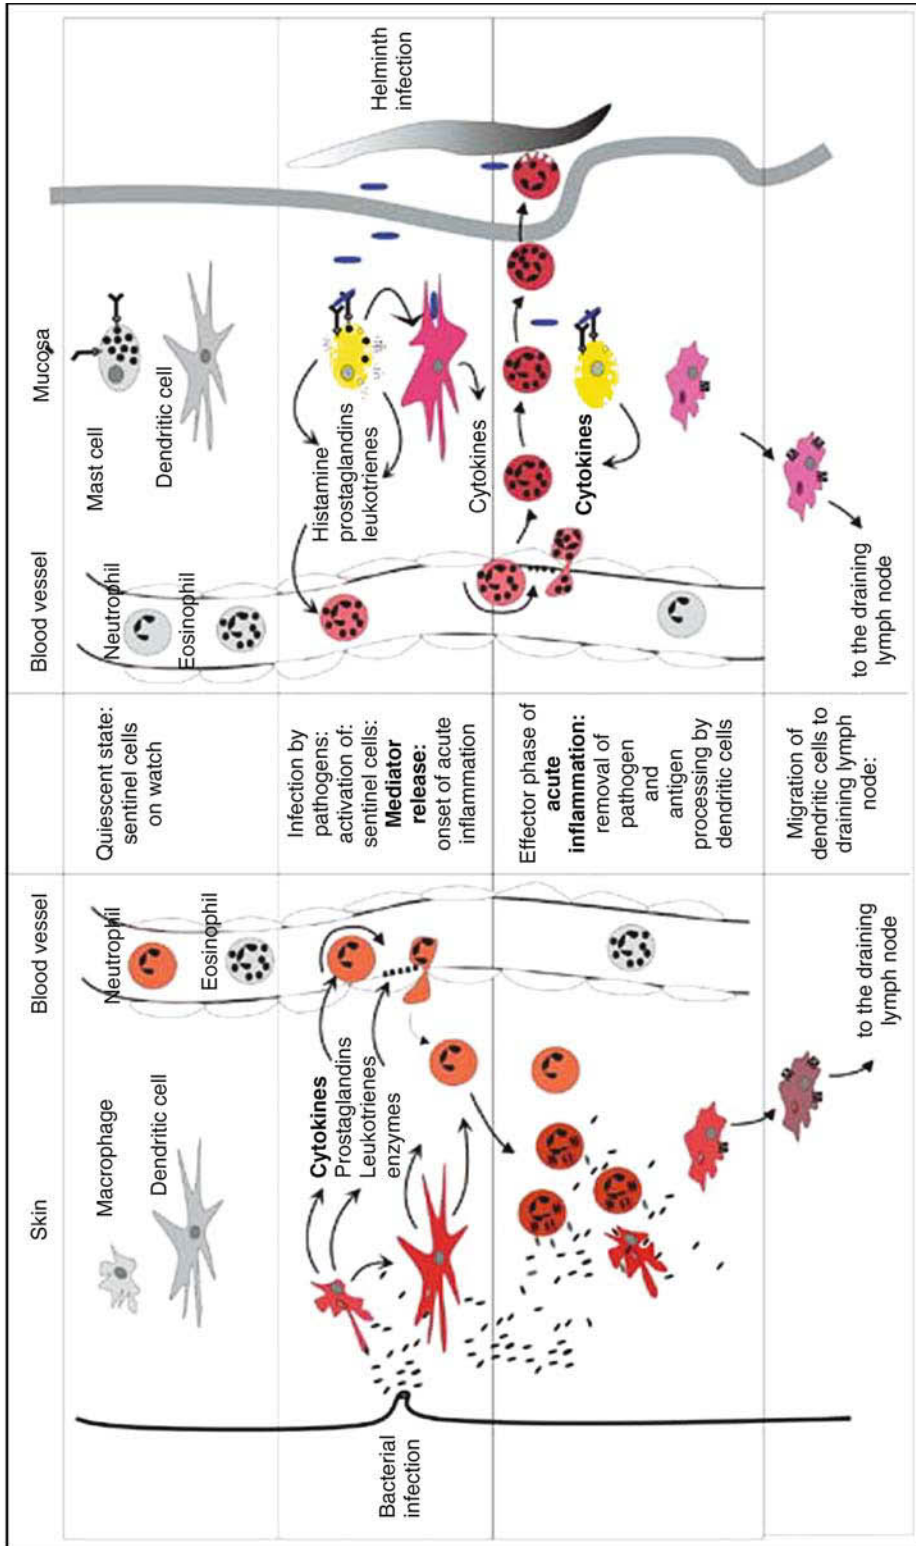

Definition

Immune defense is the ability of higher organisms to identify and combat potentially harmful microorganisms such as viruses, bacteria, fungi, protozoa, and helminths by highly sophisticated mechanisms involving soluble factors (▶ **Humoral Immunity**) and immune competent cells (▶ **Cellular Immunity**). In humans two arms of the ▶ **Immune System** exist that comprise the innate immune response and the adaptive immune response. The latter is characterized by a high specificity as an immunological memory-enabling adaptation to a given microbial environment. Mechanisms of immune defense are also utilized to identify and eliminate injured tissue or (neoplastic) tumor cells.

Basic Characteristics

Acute Inflammation is the Immediate Response of Innate Immunity to Pathogens.

The task of ▶ **innate immunity** is to respond rapidly to challenges by pathogens by mounting an acute inflammatory response (▶ **inflammation**) preferably at the site of infection in order to avoid a systemic spreading of pathogens (summarized in **Fig. 1**). Humoral components of innate immunity include the complement system, defensins, or antibacterial enzymes such as lysozyme. Cellular components of innate immunity comprise dendritic cells, monocytes/macrophages, mast cells, neutrophilic and eosinophilic granulocytes, basophils, and natural killer cells. Tissue macrophages, dendritic cells, and mast cells serve as sentinel cells at critical sites of pathogen entry such as skin and mucosa. They recognize structures from pathogens via pattern recognition receptors. Depending on the nature of the pathogen and its site of entry these sentinel cells release typical mediators including ▶ **cytokines**, ▶ **chemokines**, prostaglandins, leukotrienes, and in the case of mast cells, also histamine. Thus, dendritic cells and macrophages preferably recruit and activate neutrophilic granulocytes and mount an antibacterial response (left hand side of **Fig. 1**), Bacteria are ingested by phagocytosis and subsequently inactivated and degraded. Mast cells provide an environment enabling

Immune Defense. Figure 1 Innate immune responses after challenge of skin or mucosa: Acute inflammation and priming of adaptive immunity.

eosinophils to become activated to secrete effector molecules with the aim to combat pathogens too large to become phagocytosed such as helminths (right hand side of Fig. 1). The activated infiltrating leukocytes support the resident phagocytic cells by effectively removing and/or killing the pathogens (neutrophilic granulocytes and monocytes/macrophages) or by killing (virus-) infected host cells (NK cells).

While cells of the ►innate immune system can combat invading microbes autonomously, their effector mechanisms are also used and greatly enforced by the ►adaptive immune system. This includes enhanced complement activation and phagocytosis by antibodies as well as boosting the activation of phagocytic cells by cytokines such as interferon (IFN)- γ . On the other hand, innate immunity is indispensable for initiating an adaptive immune response.

The Dendritic Cell Is the Innate Link to Adaptive Immunity

Parallel to orchestrating acute inflammatory processes by providing an optimal milieu of cytokines, mediators, and adhesion molecules in order to recruit and activate effector cells to the site of infection, dendritic cells also serve as professional antigen-presenting cells for cells of the adaptive immune system (►antigen presentation; ►antigen receptors). After having ingested pathogens or pathogenic structures they move out of the (inflamed) tissue into the draining lymph node (bottom part of Fig. 1). During this migration they process antigens and present peptides from ingested particles, mostly from microbes on MHC class II molecules, which become upregulated.

Activation of the Adaptive Immune Response

In the specialized environment of secondary lymphoid tissues such as lymph nodes or spleen, dendritic cells provide the requirements for naive T-lymphocytes to become activated and to proliferate. The professional antigen-presenting cells present peptides in MHC II, express ►costimulatory molecules, and release cytokines into the immunological synapse, which is formed by the antigen-presenting cell and the naive T-lymphocyte. Thus, cells of innate immunity initiate and facilitate the activation of naive lymphocytes, and it is easily conceivable that their cytokines and adhesion molecules will instruct the naive T-lymphocyte during activation and differentiation to T-effector cells.

Cellular Components of Adaptive Immune Responses are T- and B-Lymphocytes whereas Humoral Components are Antibodies.

The hallmark of T- and B-lymphocytes is that each single lymphocyte expresses antigen receptors of a single specificity that was created randomly during the development of that individual lymphocyte. This is achieved mainly by sequential genetic rearrangement

of the gene segments coding for either the β - and α -chain of the T-cell antigen receptor or the heavy and light chain of the surface immunoglobulin, which serves as B-cell antigen receptor. In theory, this process is able to generate up to 10^{13} specificities, some of which can react with antigens of its own body. These self-reactive lymphocytes are eliminated by selection processes within the thymus (T-lymphocytes) or bone marrow (B-lymphocytes) establishing ►central tolerance. The remaining mature naive T- and B-lymphocytes, each carrying antigen receptors with single antigen specificity, create the immunological repertoire of about 10^8 antigen-specific lymphocytes in human beings. Upon encountering their specific antigen, lymphocytes proliferate – thereby expanding the antigen-specific cells (clone) – and become effector cells (►clonal selection). In strict contrast to T- and B-lymphocytes, cells of the innate immune system do not rearrange genes to create receptors recognizing pathogenic structures; innate immune receptors are always germline configured. In addition, cells of the innate immune system do not start to proliferate after activation.

T-Lymphocytes

This class of lymphocytes differentiates from immunologically incompetent hematopoietic stem cells of the bone marrow within the thymus – hence, the name thymus-dependent (T-) lymphocytes. Two major subclasses develop simultaneously, T-helper lymphocytes (Th) and cytotoxic effector lymphocytes (Tc). The cytotoxic T-lymphocytes (carrying on the surface the differentiation marker CD8) destroy cells, which carry their cognate antigen bound to MHC class I molecules on the surface by inducing apoptosis. From an evolutionary point of view Tc cells appear to have developed predominantly to cope with virus infections. As viruses can only replicate within cells, Tc eliminate them by destroying their producers.

For an effective defense, antigen-specific Tc has to proliferate, whereby up to a 10^7 -fold increase in numbers may occur. This process is regulated by T-helper lymphocytes, which recognize their specific antigen when it is presented on MHC-class II molecules with their T-cell antigen receptor and CD4. A subpopulation, Th-1 cells, provides the central growth factor, interleukin-2 (IL-2). These cells also secrete IFN- γ , which represents the strongest activator of macrophages and thus recruits the innate immune system for adaptive immune responses, especially for the removal of bacteria or fungi.

A second population of Th-cells, Th-2, regulates B-cell responses (see below) by secreting a different set of cytokines including IL-4, IL-5, IL-6, IL-10, or IL-13.

Th-1 and Th-2 cells develop during an immune response from a common ancestor, the Th-0 cells. Th-1 cells, once generated, promote their own differentiation

Immune Defense. Figure 2 Cytokines involved in the development of adaptive immune responses in secondary lymphoid tissues such as the lymph nodes or spleen. Abbreviations: B: B-lymphocyte, IFN: interferon, Ig: immunoglobulin, IL: interleukin, NK: natural killer cell, TE: T-effector (cytotoxic) lymphocyte, TH: T-helper lymphocyte

and simultaneously block the development of Th-2 cells. Vice versa also Th-2 cells promote their own differentiation and inhibit that of their counterpart. In addition, Th-1 development is initiated by secretion of IL-12 and IL-18 from cells of the monocytic lineage, often stimulated by, e.g., bacteria, and Th-2 by secretion of IL-4 from mast cells. Thus the balance between Th-1 and Th-2 cells is central for a physiological defense mechanism, which usually affects T- as well as B-cell responses (schematically depicted in Fig. 2). If it is skewed toward Th-1, chronic inflammatory situations may occur, if it is skewed toward Th-2, allergy can be the result.

The Th-1/Th-2 paradigm forms a core mechanism regulating the nature of an immune response. More recently, this concept was further developed by identifying Th-subsets with predominantly suppressing properties, T-regulatory cells (Treg). These cells also play a major role in keeping those cells at rest, which have escaped central tolerance (peripheral self tolerance).

B-Lymphocytes

Also derived from the hematopoietic stem cells, B-lymphocytes differentiate in the bone marrow. Upon binding of an antigen to its immunoglobulin receptor a B-cell starts to proliferate and differentiate into plasma cells synthesizing and secreting antigen-specific antibodies. Initially high molecular weight IgM is secreted, upon continued or repeated antigen-binding the B-lymphocyte switches to other immunoglobulin classes, IgG, IgA, or IgE, which preserve the original antigen

specificity. These antibody classes fulfill different functions. IgM is very effective in activating complement that can kill bacteria and thus constitute an early defense mechanism against invading infectives. Because of its size, however, it does not penetrate into tissues. IgG, which is the most abundant immunoglobulin, can reach sites outside the circulation, it is less effective in complement activation, but additionally induces phagocytosis by interacting with immunoglobulin Fc-receptors on phagocytic cells. IgA is secreted into gut, mucosal membranes of the respiratory tract or tear ducts and constitutes an early barrier for invading infectives literally outside of the body. IgE has an important function in fighting infections that are too large to be ingested by cells, such as parasites. In highly industrialized countries, IgE is predominantly associated with allergy.

Effective antibody synthesis and switching from IgM to the other Ig-classes requires help by Th-cells, predominantly but not exclusive by Th-2 cells. The master cytokine responsible for a switch to IgE and thus development of an allergy is IL-4.

Drugs

Reasons to Intervene in Immune Defense Mechanisms

Immune defense mechanisms can become deleterious for an individual when they are not controlled properly. Then they can cause disease. In such situations therapy is aimed to dampen immune reactions. Important examples are septic shock, allergy, ► **autoimmune diseases**, and chronic inflammatory diseases such as rheumatoid arthritis. Also, the success of organ transplantation

depends on the inhibition of the immune response against the foreign organ.

However, several situations can be anticipated in which support of the immune system is required. These include congenital defects in the immune repertoire, acquired immune deficiencies such as in HIV infection, but also situations in which the immune system is compromised after treatment of patients, e.g., after radiation or chemotherapy.

Support of Immune Mechanisms

Vaccination

Probably the oldest and most efficient method of supporting immune defense mechanisms is vaccination. The principle is to induce an immune reaction toward an attenuated, dead, or denatured pathogen or parts of it in order to raise a high titer, high-affinity specific antibody response or to generate memory T-effector cells. Upon reexposure this will allow rapid and efficient clearance of the pathogen before it can cause harm. If such protective antibodies are generated by vaccination of the individual, one calls this active immunization. If the antibodies are raised in other individuals or animals and injected into the recipient for immediate protection this is denominated passive immunization. Vaccination has proven to be an extremely powerful and successful tool to combat many viral infections, with increasing success also in bacterial infections.

Tumor Cell Vaccination

Tumor cells are recognized and killed by cytotoxic T-cells. Unfortunately, frequently the cytotoxic response mounted against the tumor cells is not sufficient in patients to eliminate the tumor. The number and activation status of tumor-specific T-cells can be increased by tumor-cell vaccination. This technique uses dendritic cells derived from the patient that are loaded with tumor antigens by different methods. This results in the presentation of peptides of the tumor cells on the dendritic cell. These modified antigen-presenting cells are reintroduced into the tumor patient where they are capable of either mounting a nonexistent antitumor response by T-cells or by enhancing an existing but inefficient T-cell response to the tumor. This novel strategy is presently in an experimental stage with encouraging clinical results.

Use of Antibodies

Human immunoglobulin preparations from pools of a great number of people (>1,000) with assumed antibodies against common viruses are used as a means of "passive immunization" in acute infections. More specific antibody preparations with high titers from patients who recovered recently from a viral disease or were immunized against toxins are also available in

some countries. With the advent of monoclonal antibody technology a series of murine antibodies were probed with respect to therapeutic intervention. To avoid rapid formation of human antimouse antibodies, often non-antigen binding parts of the antibody molecule are replaced by human homologues (humanized monoclonal antibodies). The use of therapeutic antibodies is rapidly increasing, including antitumor antibodies, antibodies that prevent blood clotting, or inhibit immune reactions (see below).

Application of Recombinant Cytokines

Several cytokines are in clinical use that support immune responses, such as IL-2, IFNs, or colony-stimulating factors. IL-2 supports the proliferation and effector function of T-lymphocytes in immune compromised patients such as after prolonged dialysis or HIV infection. IFNs support antiviral responses or antitumoral activities of phagocytes, NK cells, and cytotoxic T-lymphocytes. Colony-stimulatory factors enforce the formation of mature blood cells from progenitor cells, e.g., after chemo- or radiotherapy (G-CSF to generate neutrophils, TPO to generate platelets, EPO to generate erythrocytes).

Unspecific Stimulation of the Immune Response

Dead or live bacteria may be effective to stimulate inflammatory reactions of phagocytic cells against tumor cells. The best-characterized treatment is the use of *Bacillus Calmette Guerin* (BCG) in the case of bladder cancer where activation of the immune response is capable of controlling tumor growth.

Similar results may be obtained with muramyl dipetides and CpG oligonucleotides or $Al(OH)_3$, which is commonly used as adjuvants in the course of vaccination.

Inhibition of Immune Mechanisms

Two main strategies are presently used to suppress immune responses (summarized in Fig. 3). The first focuses on cytokines, the central mediators of the immune system. Efficient inhibition of cytokine production can be achieved by glucocorticoids. Specific anticytokine strategies include the use of monoclonal antibodies, soluble receptors, or receptor constructs.

The second target is the T-lymphocyte as the central regulatory cell of specific or adaptive immunity. Inhibition of T-cell activation can be achieved on different levels. Drugs like ciclosporin or tacrolimus (FK506) affect activation, whereas cytostatic drugs or sirolimus (rapamycin) inhibit proliferation. Specific elimination of T-cells can be achieved by anti-CD3 antibodies or anti-CD4 antibodies, unspecific cell killing of proliferating T-cells by cytotoxic drugs. The

Immune Defense. Figure 3 Drugs involved in suppressing innate and adaptive immune response. Abbreviations: mob: monoclonal antibody, TCR: T-cell antigen receptor, IL-2 interleukin-2, R: receptor, CD: cluster of differentiation.

aim is to impair immune reactions by removing the source of T-cell help (► [immunosuppression](#)).

Glucocorticoids

At pharmacological concentrations glucocorticoids are the most efficient inhibitors of the synthesis of several cytokines, including those produced by T-lymphocytes, like IL-2, IL-4, or IFN γ , or by inflammatory cells, e.g., IL-1, IL-6, IL-8, IL-12, IL-18, or TNF α (► [cytokines](#)). The molecular mechanisms of the inhibition of cytokine protein synthesis – in contrast to their physiological action, i.e., the induction of metabolic enzymes (► [glucocorticoids](#)) – is not completely understood. Contributing factors are the interaction of the cytosolic glucocorticoid receptors after they have bound glucocorticoids with transcription factors regulating cytokine synthesis, and thereby blocking their binding to DNA, as well as the induction of inhibitory proteins. Glucocorticoids are effective in severe forms of allergy, autoimmune diseases, and all forms of chronic inflammatory diseases.

Anticytokine Regimens (Treatments)

In addition to inhibiting cytokine synthesis by glucocorticoids, cytokine effects can be prevented by scavenging the cytokine either with neutralizing antibodies or soluble receptors or by blocking the respective cytokine plasma membrane receptors with blocking antibodies or receptor antagonists.

Examples are:

- Anticytokine antibodies Infiximab: Chimeric (mouse/human) monoclonal antibody against TNF α . Effective in the treatment of severe forms of rheumatoid arthritis where it can halt disease progression, or inflammatory bowel disease (IBD).

- Adalimumab: Complete human antibody against TNF- α with similar properties as infliximab.
- Soluble receptor constructs Etanercept: This genetically engineered drug consists of the extracellular part of the TNF-receptor type I and the Fc portion of human IgG. Its application in rheumatoid arthritis mirrors that of infliximab.
- Anticytokine receptor antibodies Basiliximab, Dacluzimab: Both are humanized monoclonal antibodies against the IL-2 receptor that block T-cell proliferation by inhibiting IL-2 and thus decrease the T-cell mediated frequency of rejection episodes in organ transplantation.
- IL-1 receptor antagonist Anakinra: A naturally occurring complete antagonist, effective in rheumatoid arthritis.

Immune System

The immune system is a distinct organ in vertebrates, specialized to defend against invading infections or poisons in order to preserve the integrity of the organism. For this task it is disseminated throughout the body in primary and secondary lymphoid organs and the circulating blood. It contains the cells responsible for innate and adaptive immunity and humoral factors.

- ▶ Immune Defense

Immunity

Immunity is the innate or acquired ability of a higher organism to successfully defend life against potentially harmful agents like infections or poisons.

- ▶ Immune Defense

Immunoglobulins (Immunoglobulin Superfamily)

- ▶ Antibodies
- ▶ Humanised Monoclonal Antibodies
- ▶ Allergy
- ▶ Table appendix: Adhesion Molecules

Immunomodulators

Immunomodulators are a group of mostly stimulatory effectors which act on cells of the immune system (e.g. cytokines, interferons).

- ▶ Cytokines
- ▶ Interferons

Immunophilins

Immunophilins are abundant proteins that catalyze the *cis-trans* isomerization of proline residues within proteins, generally to aid in protein folding. Immunophilins are not essential proteins, are the intracellular binding proteins of several immunosuppressive drugs. Cyclosporin A exerts its action after binding to cyclophilin. Tacrolimus and sirolimus predominantly bind to the protein ▶FKBP-12 (FK binding protein-12).

Hannover, Germany

Synonyms

Immunosuppressants

Definition

Immunosuppressive agents (immunosuppressants) are drugs that attenuate immune reactions. An application is indicated in case our immune system reacts inadequately leading to serious diseases or normal immune reactions are unwanted, e.g., following transplantations.

Mechanism of Action

Immunosuppressive drugs comprise a large spectrum of substances with different mechanisms of action where ▶T-lymphocytes represent a major target [1, 2]. In general, immunosuppressants can be divided into those that

- Inhibit T-lymphocyte proliferation in an unspecific manner
- Decrease the pool of circulating lymphocytes
- More specifically attenuate the activation of T-lymphocytes
- Inhibit the interaction between antigen or antigen-presenting cells (APCs) and T-lymphocytes

Antiproliferative Drugs Cyclophosphamide

This drug belongs to the group of alkylating antineoplastic drugs. Alkylation finally results in covalent crosslinkage of DNA strands that interrupts the

replication of all dividing cells including activated lymphocytes. Thus, both cellular and humoral immune reactions (antibody production) are inhibited.

Methotrexate Including its Polyglutamates

Methotrexate belongs to the class of antimetabolites. As a derivative of folic acid it inhibits the enzyme dihydrofolate reductase resulting in a decreased production of thymidine and purine bases essential for RNA and DNA synthesis. This interruption of the cellular metabolism and mitosis leads to cell death.

Inhibitors of De Novo Purine Biosynthesis

Inosine monophosphate dehydrogenase (IMPDH) is a key enzyme of purine nucleotide biosynthesis. Purine synthesis in lymphocytes exclusively depends on the de novo synthesis, whereas other cells can generate purines via the so-called “salvage pathway.” Therefore, IMPDH inhibitors preferentially suppress DNA synthesis in activated lymphocytes.

Azathioprine

In vivo azathioprine is rapidly converted into its active metabolite 6-mercaptopurine by the enzyme thiopurine methyltransferase (TPMT). The active agent inhibits IMPDH function. Furthermore, it also acts as antimetabolite of the RNA and DNA synthesis particularly in T-lymphocytes leading to cell death. Due to genetic polymorphism of TPMT, therapy may fail, thus it is currently discussed whether individual patients should be monitored before the use of azathioprine.

Mycophenolate Mofetil

The active metabolite of this drug is mycophenolic acid (MPA), which inhibits IMPDH, too. MPA is metabolized in vivo by glucuronidation. It has to be noted that its acyl glucuronide inhibits IMPDH with similar potency compared to the parent compound.

Mizoribine

This immunosuppressive drug, which is only marketed in Japan, is a nucleoside analog. Its phosphorylated form, mizoribine-5-phosphate, is a potent inhibitor of IMPDH activity.

Inhibitors of the De Novo Pyrimidine Biosynthesis

Leflunomide

The active metabolite of leflunomide, the ring-opened drug A771726, inhibits dihydroorotate dehydrogenase (DHOD) which is the key enzyme of the de novo pyrimidine synthesis. Inhibition of synthesis stops proliferation of activated lymphocytes. The leflunomide derivative FK778 which shows similar therapeutic efficacy but shorter half-life is investigated in clinical trials.

Brequinar

This drug also inhibits DHOD activity but has not been approved yet.

Immunosuppressive Drugs Acting by Lymphocyte Depletion

Antilymphocyte Globulin and Antithymocyte Globulin

Both globulins exert their effect by depletion of circulating lymphocytes either by complement-dependent lysis or by phagocytosis after opsonization. However, antilymphocyte globulin (ALG) and antithymocyte globulin (ATG) are nonhuman polyclonal antibodies. To prevent sensitization application is restricted to a time period of several days only.

Anti-CD3 (Muronomab-CD3)

Muronomab-CD3 is a murine monoclonal antibody directed against the CD3 complex of the T-lymphocyte antigen receptor. This drug selectively diminishes the T-lymphocyte pool resulting in a strong lymphopenia. Similar to other nonhuman antibodies the generation of human antimurine antibodies (HAMA) limits its long-term use.

Anti-CD4 (OKT-4a)

Murine monoclonal antibodies reacting with CD4, which is solely located on T-helper lymphocytes and monocytes/macrophages, may also be suited for immunosuppression.

Campath-1H (Alemtuzumab)

This is a humanized anti-CD52 ► [monoclonal antibody](#). At present it is in clinical use after bone marrow transplantation and for the treatment of refractory chronic lymphocytic leukemia.

Inhibitors of Interleukin-2-Induced T-Lymphocyte Proliferation

Anti-Interleukin-2 Receptor (CD25) Antibodies (Basiliximab/Dacluzimab/Inolimomab)

The chimeric human/murine (basiliximab and dacluzimab) or murine (inolimomab) monoclonal antibodies are specifically directed against a part (CD25) of the interleukin-2 (IL-2) receptor. Binding of one of these antibodies to CD25 thereby displaces physiological IL-2 and prevents proliferation of activated T-lymphocytes.

P70S6 Kinase Inhibitors (Sirolimus, Everolimus, Temsirolimus)

Sirolimus (SRL), also termed rapamycin is a macrolide lactone isolated from the ascomycete species *Streptomyces hygroscopicus*. After binding to its cytosolic receptor FKBP-12 the resulting complex inhibits the multifunctional serine–threonine kinase mTOR (mammalian target of rapamycin). Inhibition of mTOR prevents activation of the p70S6 kinase and successive

G₁ to S phase cell-cycle transition. Transition is required for the onset of IL-2 induced T-cell proliferation. Additionally, SRL also attenuates growth factor induced proliferation of several nonimmune cells and also inhibits metastatic tumor growth and angiogenesis.

Everolimus (RAD) is a synthetic derivative (40-O-(2-hydroxyethyl)rapamycin) of SRL with a shorter half-life. Its molecular mode of action resembles that of SRL.

Another SRL derivative, temsirolimus, is in clinical trials for the treatment of various leukemias.

Inhibitors of IL-2 Synthesis

► Glucocorticoids

After diffusion through the cell membrane, glucocorticoids bind to their specific receptor, which acts as hormone-dependent transcription factor. In the nucleus transcription of several genes is regulated after binding at specific glucocorticoid responsive elements of the DNA or by transactivation through interaction with other coactivators. In several cell types glucocorticoids induce transcription of the protein I κ B α , which binds to the transcription factor NF κ B thus preventing its activation and nuclear translocation. The important feature for the strong immunosuppressive action of glucocorticoids is inhibition of the synthesis of those cytokines that are involved in the activation of lymphocytes, i.e., interleukin-1 and -2. Therefore, especially cellular immune reactions are affected. In addition, a short-term reduction of circulating lymphocytes in the blood is observed after glucocorticoid treatment, due to a reversible sequestration in the bone marrow.

Calcineurin Phosphatase Inhibitors

Cyclosporine A

Cyclosporine A (CsA) is a water-insoluble cyclic peptide from a fungus composed of 11 amino acids. CsA binds to its cytosolic receptor cyclophilin. The CsA/cyclophilin complex reduces the activity of the protein phosphatase calcineurin. Inhibition of this enzyme activity interrupts antigen receptor-induced activation and translocation of the transcription factor ►NFAT to the nucleus which is essential for the induction of cytokine synthesis in T-lymphocytes.

Tacrolimus

Tacrolimus (TRL), in the past also named FK506, belongs to the group of macrolides and is produced by a special actinomycete species. TRL binds to its cytosolic receptor FKBP-12, however, it also blocks calcineurin activity and subsequently cytokine synthesis.

Pimecrolimus (ASM 981)

ASM 981 is an ascomycin derivative that has been approved for topic application only.

Inhibitors of Interaction between Antigen or Antigen-Presenting Cells and T-Lymphocytes

15-Deoxy-Sperguanilin (Gusperimus)

The exact molecular mode of action of this drug, which is so far only marketed in Japan, is not clear. Presumably, it interferes with antigen processing in APCs.

CTLA4-Ig Fusion Protein (Belatacept)

This is an immunoglobulin fusion protein with the cytotoxic lymphocyte antigen 4 (CTLA-4) receptor. By binding to CD80/86 on APCs it inhibits the CD28 costimulatory signal in lymphocytes. It is speculated that this can result in tolerance but up to now there is only experimental data [3, 4].

Anti-CD40 Specific Monoclonals

Such antibodies, which are still in an experimental status inhibit CD40–CD40L (=CD154) interaction.

Vitamin D3 Analogues

In addition to its classical role as regulator of calcium homeostasis, 1,25-dihydroxyvitamin D₃ (calcitriol) displays immunosuppressive properties. Inhibition of T-lymphocyte proliferation seems to be mediated via regulation of CD80/86 costimulatory molecule expression on APCs. For clinical use as immunosuppressant, however, analogues of vitamin D₃ that do not influence calcium metabolism are needed.

Inhibitors of Adhesion Molecules and Lymphocyte Homing

CD2 Antagonist (Alefacept)

Alefacept is a human recombinant integrin LFA3–IgG fusion protein that binds to the CD2 receptor thus blocking T-cell activation.

Anti-CD11a Antibodies (Antilfa, Efalizumab)

These are murine or humanized antileukocyte functional antigen (LFA)-1 α antibodies that block LFA-1 α (CD11a)–ICAM-1 (CD54) interaction.

Anti-ICAM-1 Antibody (Enlimomab)

This murine antibody also blocks LFA-1 α –ICAM-1 interaction.

FTY720 (Fingolimod)

This experimental drug is a derivative of myriocin. After phosphorylation FTY720 modulates chemotactic responses and lymphocyte trafficking, leading to reversible lymphocyte sequestration in secondary lymphoid tissues. It is in clinical trials for the treatment of multiple sclerosis.

Clinical Use (Including Side Effects)

Specific immunity is a highly sophisticated defense mechanism of higher organisms. A high level of

specificity is given by immune responses directed against antigen epitopes of pathogenic microorganisms, foreign (transplant) or transformed cells (tumor), or even autologous cells (autoimmunity). Thus treatment with immunosuppressive agents is indicated for transplantations, systemic autoimmune diseases, chronic inflammatory diseases, and certain types of allergic diseases.

In any case, immunosuppressive therapy has to be carefully balanced in order to achieve a sufficient reduction of the unwanted immune reactions and to avoid complete suppression of host defense that might result in bacterial, viral, fungal, and parasitary infections or increases in the incidence of various malignancies. Besides these unspecific adverse effects of all immunosuppressants drug-specific side effects, i.e., organ toxicity or metabolic alterations (hypertension, hyperglycemia, hyperlipidemia) are apparent [5, 6]. All antiproliferative immunosuppressive drugs can lead to hematologic disorders like leukopenia, thrombocytopenia, and anemia indicating a continuous control of hematopoiesis.

Indications for the clinical use of immunosuppressive drugs are: transplantation, autoimmune diseases, chronic inflammatory diseases, allergic reactions.

Transplantation

The allogenic transplantation of solid organs, i.e., kidney, heart, liver, lung, small intestine, and pancreas, constitutes an absolute indication for a lifelong treatment with immunosuppressive agents. The major goal of the therapy is to prevent acute or chronic rejection of the donor organ. Patients transplanted with allogenic bone marrow have to be saved from nondesired immune reactions caused by transferred mature lymphocytes (graft-versus-host reaction).

Immunosuppressive therapy in allogenic transplantation consists of an induction phase (first 4 weeks) followed by the maintenance phase (normally lifelong). Because of the higher risk of acute organ rejection especially in the induction phase a combination of several immunosuppressants including antibodies with high dosages and blood target concentrations are utilized.

Treatment with specific antibodies (ALG, ATG, anti-CD3, anti-CD25) is indicated during the induction phase after transplantation and in the case of acute rejection for short time periods. Therapy with nonhuman antibodies may cause sensitization. Muromonab-CD3 might initiate a cytokine release syndrome (fever, chills, headache).

During the maintenance phase dose reductions are aimed. However, in most cases a dual or triple combination therapy is still necessary. The use of drugs with different mechanisms of immunosuppressive action allows the application of lower doses additionally resulting in decreased toxicity.

Glucocorticoids belong to the oldest immunosuppressive agents given to transplant recipients and are

part of most treatment regimens. However, due to their numerous side effects (see: glucocorticoids) particularly at high and continuous dosage, they are withdrawn or doses are largely reduced within months.

Current immunosuppressive regimens depend on a combination of a T-lymphocyte specific calcineurin phosphatase inhibitor (CsA or TRL) and a newer antiproliferative drug (MPA, SRL, RAD). Although CsA and TRL display a similar mechanism of action some differences in their side effect profiles are obvious. The most common unwanted effects of CsA comprise of nephrotoxicity, hepatotoxicity, neurotoxicity, hypertension, hyperlipidemia, increased diabetogenic risk, hirsutism, and gingival hyperplasia. TRL appears equally nephrotoxic but hypertension and hyperlipidemia occurs less; hyperglycemia is more frequent than after CsA treatment. Gingival hyperplasia is lacking but TRL may result in alopecia. In contrast, MPA, SRL, and RAD are not nephrotoxic, however, myelosuppression is a common side effect of these drugs. The use of MPA is limited by dose-related gastrointestinal disorders. SRL, RAD, CsA, TRL, and glucocorticoids induce hyperlipidemic effects including increases in cholesterol as well as triglyceride serum levels that have to be treated with hydroxymethylglutaryl coenzyme A reductase inhibitors (▶HMG-CoA-reductase-inhibitors).

Most immunosuppressive drugs applied in the maintenance phase after transplantation are substrates of the efflux pump P-glycoprotein (MDR1) and the cytochrome P450 3A4/A5 (CYP3A4/A5) metabolizing enzyme system in the gastrointestinal tract and the liver. Both MDR1 and CYP 3A4/A5 are focal points of numerous pharmacokinetic interactions. Thus, coadministered drugs can either induce (e.g., rifampicin, St John's wort) or inhibit (e.g., erythromycin, diltiazem, fluconazol) MDR1 and CYP3A4/A5 expression or activity resulting in reduced or elevated blood concentrations of the immunosuppressants. For this reason it is also advised that the oral intake of CsA and SRL should be interrupted by a 4 h interval.

Therapeutic Drug Monitoring

Individualization of treatment by therapeutic drug monitoring (TDM) is indicated for most immunosuppressive agents exhibiting a narrow therapeutic index and broad interindividual pharmacokinetic variability. A careful monitoring of the respective target concentrations of MPA, CsA, TRL, SRL, and RAD can help to minimize their toxicity and to reduce the incidence of acute organ rejection. It is a matter of discussion whether trough or maximum blood levels should be determined in clinical practice [7, 8].

Autoimmune Diseases

Immunosuppressive agents are indicated for the therapy of systemic autoimmune diseases (e.g., systemic lupus

erythematodes, myasthenia gravis) exhibiting severe organ-specific disorders which cannot be treated by other drugs. In general, immunosuppressive treatment of autoimmune disease is less successful as compared to organ transplantation, because of intraindividual variabilities.

Chronic Inflammatory Diseases

In the pathogenesis of many chronic inflammatory diseases (e.g., ►rheumatoid arthritis, glomerulonephritis, colitis ulcerosa, Morbus Crohn, atopic dermatitis, psoriasis) autoimmune processes play an important role, too. Although first of all nonsteroidal antiinflammatory agents or glucocorticoids should be applied, immunosuppressive agents may also be indicated.

Low-dose methotrexate is used for treatment of rheumatoid arthritis despite side effects such as disorders of the gastrointestinal tract and the liver. Leflunomide is also approved for this indication, however, hepatotoxicity limits its use as first option.

For the topical treatment of some chronic inflammatory skin diseases (like atopic dermatitis) immunosuppressive macrolides (like TRL and pimecrolimus) that permeate the inflamed epidermis are of benefit for patients. Severe side effects comparable to those after systemic application of TRL in transplanted patients (see above) have not been observed so far. For the treatment of psoriasis vulgaris these drugs are less effective. The CD2 antagonist alefacept may be a suitable alternative to allergic reactions.

Allergic reactions (especially those of type IV) can lead to disorders which resemble autoimmune or chronic inflammatory diseases. If an immediate elimination of the antigen is not feasible, immunosuppressive drugs can represent a reasonable addendum.

Inclusion Cell Disease

Hereditary lysosomal storage disorder with an heterogeneous clinical presentation including mental retardation and skeletal changes. The disease is caused by

mutations in the gene encoding the (UDP)-*N*-acetylglucosamine:*N*-acetylglucosaminyl-1-phosphotransferase. This enzyme mediates normally the transfer of mannose-6-phosphate to precursor lysosomal enzymes. Due to the loss of enzyme function, lysosomal enzymes are secreted instead of being correctly targeted to the lysosomes. As a consequence, large amounts of acid mucopolysaccharides, sphingolipids, and/or glycolipids accumulate in the lysosomes.

Incretin Hormones

RÉMY BURCELIN, PATRICE D. CANI,
CLAUDE KNAUF
Institute of Molecular Medicine RANGUEIL,
INSERM, IFR 31, Université Paul Sabatier, Toulouse,
France

Synonyms

Incretins: gut hormones that increase glucose-stimulated insulin secretion; GLP-1: glucagon-like peptide-1; GIP: Gastric inhibitory peptide or glucose-dependent insulinotropic peptide

Definition

An oral glucose load increases insulin secretion more efficiently than when glucose is administered

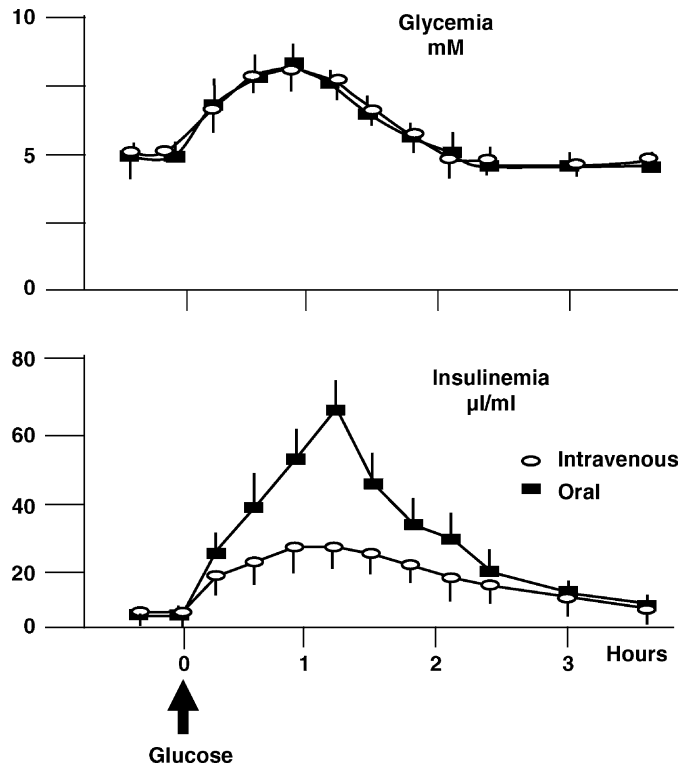

intravenously. This is due to the release by endocrine epithelial intestinal cells of hormone named incretins.

Basic Characteristics

Energy homeostasis is finely tuned by neural and endocrine factors that equilibrate energy intake and expenditure. An impairment of this balance would lead to metabolic diseases such as obesity, diabetes, ► **lipodystrophy**, or cachexia. To trigger metabolic programs suitable to maintain energy homeostasis, the body should first quantitatively and qualitatively detect nutrients; this is called metabolic reflex (Fig. 1). It is the role of specialized cells from the enteric area, known as the intestinal epithelium, where most of the nutrients are absorbed. These cells send a signal of endocrine or neural origin that triggers functions aiming to address energy to the proper tissues for storage or utilization. Among the signals involved in the metabolic reflex are incretins. The hormones released from the gut in response to nutrient ingestion potentiate glucose-stimulated insulin secretion. Indeed, the administration of an oral glucose load leads to a much greater stimulation of insulin release from the pancreatic β -cells of the Langerhans islet, compared with a similar glucose challenge given intravenously (Fig. 2). This entero-insular axis (Corresponds to the physical and biochemical connections between the gut and the pancreatic cells from the Langerhans islets. These connections are mostly ensured by the autonomic nervous system and hormones secreted by the gut, which directly targets the pancreas or needs the brain as a relay.) was responsible for ~50–70% of the postprandial insulin release [1]. From humoral extract of intestinal origin a first 42 amino acid long glucose-dependent ► **insulinotropic peptide**

Incretin Hormones. Figure 1 The metabolic reflex. Nutrients, essentially glucose, upon absorption will trigger the secretion of intestinal signals such as the incretins and be detected by specialized cells of neuronal origin and located in the hepatportal vein. The neural signal will be sent to the brain and together with the endocrine signal functions, it will be recruited.

Incretin Hormones. Figure 2 The incretin effect. Patients underwent an oral or equivalent intravenous glucose load so that the glycemic profiles became similar. In such conditions, the data show that the oral glucose load is more potent to stimulate insulin secretion than an equivalent intravenous glucose stimulus.

Incretin Hormones. Figure 3 Processing of the proglucagon. The proglucagon peptide is synthesized in pancreatic cells and cells from the gastrointestinal (GI) tract and the brain. Different proconvertases process the peptide so that in the pancreas the glucagon is produced whereas in the GI tract and the brain, the GLP-1 and GLP-2 peptides are mainly released.

(GIP) was isolated. It was characterized as being released by the duodenum following an oral glucose load and increasing glucose-stimulated insulin secretion. However, this peptide was not able to account fully for the

incretin effect. In 1983, Bell and coworkers cloned the proglucagon gene and identified two novel peptides, close to the pancreatic glucagon structure named glucagon-like peptide (GLP) one and two (Fig. 3). The first is a

37 amino acid long peptide but inactive on insulin secretion GLP-1. The second GLP-2, of similar length regulates epithelial intestinal growth. Later on, in 1986, the 7–37 amino acids fraction of the GLP-1 was discovered as the active form of the peptide on glucose-stimulated insulin secretion (GLP-1_{7–37} or 7–36amide). Then experiments of ►immunoneutralization, using mice deleted for the GIP and GLP-1 receptors, demonstrated that both peptides are dominantly involved in nutrient-stimulated insulin secretion and fully account for the incretin effect. GIP and GLP-1 are synthesized as propeptide. This is a common characteristic of peptide hormone that requires an intermediate form based on a longer peptide which will be processed during maturation and exocytosis by endo- and ►exopeptidases named proconvertases (PC_{1/3}-2, ►furin). The proglucagon gene is expressed in the α pancreatic, the intestinal epithelial, and some neuronal cells in the brain. Therefore, different sets of PC are involved in allowing glucagon to be secreted by the pancreas and GLP-1 by the intestine and brain cells.

Glucose-stimulated insulin secretion is the physiological action of incretins which has been the most described [2]. The receptors of both incretins are present at the surface of the insulin-secreting pancreatic B cells. Upon binding of the corresponding hormone, the cAMP concentration increases and it activates a protein kinase A and thereby, regulates numerous cellular functions involved in the closing of the ATP-sensitive K⁺ channel, calcium entry, and vesicular trafficking for the exocytosis of insulin-containing granules [3]. As insulin secretion depends on the energy status of the cell, i.e., the ATP/ADP ratio, the remarkable property of incretins is to increase insulin secretion in response to an earlier or a simultaneous priming of β -cell energy metabolism by hyperglycemia. Consequently, excessive amount of incretins cannot increase insulin secretion in euglycemic condition, such as while fasting, and therefore, cannot induce deleterious hypoglycemia. These hormones are totally dedicated to the absorptive phase and are hence, considered messengers of energy intake. Both hormones are equipotent in terms of insulin secretion. However, the GIP receptor is largely distributed at the surface of the β cells, the adipose tissue, the stomach, the bone, the endothelial cells, the lung, the liver, the brain, the heart, and the gut whereas the GLP-1 receptor is restricted to the brain, the β cells, and the heart.

Importantly, both incretins when secreted by the intestine are rapidly degraded by the ►dipeptidyl peptidase IV (DPPIV), which removed the two amino-terminus histidine-alanine residues, thereby, inactivating the incretins. This enzyme is present at the surface of the epithelial intestinal cells and capillaries in the vicinity of the K and L cells secreting GIP and GLP-1, respectively. It is also present in the

endothelium and degrades continuously the incretins. The DPPIV limits the half-life of the active forms of the peptides to less than a minute in the hepatoportal and systemic blood and hence, the accessibility of the β cell to the peptides. K cells are located in the duodenum, i.e., where most of the glucose ingested is absorbed and upon intestinal glucose absorption a large amount of GIP is secreted within minutes. Conversely, the L cells are distal to the glucose absorption location, in the proximal colon. The very short half-life and the distal location of the L cells suggest that GLP-1 secretion and action depend on an intermediary mechanism. This relay could be the enteric-hepato-portal glucose sensing system. This mechanism involves nutrients, upon intestinal absorption, accumulating into the hepatoportal vein and activating the corresponding glucose sensitive cells. The latter send a signal to the brain for the control of GLP-1 secretion and peripheral functions. This signal is of neural origin as vagotomy prevents glucose-stimulated GLP-1 secretion. Similarly, the control of insulin secretion does not wholly depend on the binding of GLP-1 on β cells. Numerous recent evidences show that a neural relay depending on GLP-1 is required to fully account for oral glucose-stimulated insulin secretion. The hepatoportal infusion of the GLP-1 receptor antagonist prevents oral glucose-induced insulin secretion and similar observations were made in mice detected for the GLP-1 receptor. In addition to the role of GLP-1 on the enteric-hepatoportal area for the control of insulin secretion, brain GLP-1 signaling is required for the control of the endocrine pancreatic function. Upon oral glucose absorption, in addition to the enteric secretion of GLP-1, arguments suggest that GLP-1 is also released by the brain. Areas of the brain stem are connected to the enteric areas with axons originating from the vagus nerve. The ascendant branch transmits the glucose signals and triggers cells in the brain stem. The proglucagon gene is expressed in cells from the area postrema and the nucleus from the solitary tract. Furthermore, neurons from both areas send projections to nuclei of the hypothalamus. As a matter of fact, cells in the hypothalamic areas express the GLP-1 receptor. Since the hypothalamus is now considered a major player responsible for the management of energy metabolism, brain GLP-1 signaling would represent an important contributor. The blockage of brain GLP-1 signaling by Exendin 9, an antagonist of the GLP-1 receptor, prevents oral glucose-stimulated insulin secretion showing hence, the major role of brain GLP-1 signaling. Interestingly, no role of GIP has been described on the enteric-hepato-portal glucose sensor (Corresponds to a structure present in the hepatoportal vein, which is located between the intestine and the liver and collects all mesenteric blood. Cells sensitive to glucose has been suggested to be located in the

hepatoportal vein.), suggesting that GIP is produced in larger amount (nM vs. pM, concentration in the blood of GIP and GLP-1, respectively) than GLP-1. GIP could directly reach the β cells and trigger insulin secretion whereas this seems unlikely for GLP-1 as the concentration is too low despite the very high affinity of the receptor.

The effect of incretins is not restricted to insulin secretion. GIP is also responsible, to some extent, to lipogenesis. GLP-1 has a positive isotropic effect on the heart rate, reducing gastric emptying, glucagon secretion, and food intake. Furthermore, GLP-1 also favors β -cell growth. All the latter effects are considered antidiabetic and antiobesity. Hence, numerous therapeutic strategies have been generated based on incretin secretion. However, the actors preferred strategies based on GLP-1 as the peptide conserves its effectiveness during diabetes, whereas, GIP does not seem to be potent anymore. Therefore, several strategies have been proposed based on GLP-1 physiology. The first one involves the GLP-1 analogue Exendin μ , discovered from the saliva of the Gila monster. This peptide presents a 60–70% homology to GLP-1, binds to the receptor with a high affinity, and is totally insensitive to DPP-IV. Furthermore, the renal clearance of Exendin μ is low, extending the half-life of the peptide to 12–18 h. The clinical trials showed an important reduction of the HbA1c, an index to the extent of diabetes. However, one to two subcutaneous injections per day are necessary for a full effectiveness of the therapy. Several strategies for further increasing its half life have been proposed based on microencapsulation of the peptide into slow-diffusing gels. Hence, a 1-week to a 1-month injection is proposed. Furthermore, there was also a significant reduction of the body weight which was probably due to the satiety effect related to the lowering of gastric emptying of the peptide. A second strategy involves the inhibition of DPP-IV activity. Although not specific to GLP-1, clinical trials showed an increased glucose-stimulated insulin secretion and a reduced HbA1c. This strategy has the physiological advantage to increase the secretion of GLP-1, i.e., at its enteric location, where important effects on insulin secretion have been showed. This strategy clearly represents a physiological approach, however, its lack of specificity could mask some secondary deleterious or unexpected side effects. The third strategy involves the physiological secretion of GLP-1 by means of dietary fibers. Recent evidence showed that the weight and blood-glucose concentration were reduced when patients or diabetic animals were eating dietary fibers such as oligofructose. The mechanisms involved the GLP-1 receptor as well as an increased expression of the proglucagon gene and concentration of the corresponding peptide in the intestine. Furthermore, the number of

L cells was augmented. This latter strategy is also promising as dietary fibers trigger a physiological secretion of the peptide in the vicinity of glucose sensitive cells, inducing the whole physiological cascade of action leading to the control of energy homeostasis.

In conclusion, the discovery of incretins has now come to an end in terms of therapeutic strategy of metabolic diseases since new medicines will be put on the market these coming years. However, a lot more needs to be done with regard to the physiological role of the hormones. Whereas the major field of investigation for GLP-1 now relates to the effect of the peptide on the central nervous system and on β -cell proliferation, for GIP it remains to understand its role in the numerous tissues where the corresponding receptor is expressed.

Drugs

The new drugs that are derived from incretin studies are currently getting authorization to be put on the market. The first one are GLP-1 like molecules. Exenatide (Amylin Corp.) is a peptide issued from the saliva of the Gila monster, a lizard producing large quantities of this peptide when eating its prey. This peptide binds the GLP-1 receptor with an affinity similar to GLP-1 but is not a substrate of DPP-IV and is hence, much stable. Exendin-derived peptides are currently being made and new formulation should ensure a 1 week-long stability allowing, for the diabetic patient, a once-a-week convenient injection. GLP-1 analogues are also being generated. These peptides have been so designed that the alanine in position 2 of the peptide has been removed to avoid the degradation of the molecule by the DPP-IV. Further modifications allow the analogue to bind to albumin and further increase its half life. Another set of strategies consists in inhibiting DPP-IV activity. The advantage of such strategy is that the compound can be administered orally whereas the peptides have to be injected subcutaneously. Both strategies should be complementary to improve the blood glucose profiles of the diabetic patients.

Inflammation

JOSEF PFEILSCHIFTER, ANDREA HUWILER
pharmazentrum frankfurt, Johann Wolfgang Goethe-
Universität Frankfurt am Main, Germany

Definition

Inflammation occurs when a living tissue is injured or infected by microorganisms. It is a beneficial, self-limited response that requires phagocytic cells and elements of circulating plasma to enter the affected area. In principle it may achieve resolution and repair as the ideal outcome of inflammation. The persistent accumulation and activation of leukocytes is a hallmark of chronic inflammation.

Basic Mechanisms

Introduction

The clinical characteristics of acute inflammation are familiar to anyone who has suffered from a burned or infected finger. The account comprises the cardinal symptoms of inflammation with heat, redness, and painful swelling that were reported by the Roman encyclopedist Celsus as calor, rubor, tumor, and dolor. Galen of Pergamon added a further sign of inflammation, the impaired function or *functio laesa*. Though unpleasant, these signs are indicators of useful processes going on with the aim for limiting tissue damage and infection and initiating repair. Inflammation starts after an initial injury by mechanical trauma, infections, UV-irradiation, burns, ischemia, and many others. It initially comprises the release of chemical mediators like histamine from a population of cells that are distributed throughout the connective tissue and are extremely sensitive to injury, the mast cells. The same is true for the blood basophil, which in many aspects resembles the mast cell. Histamine and secondary

mediators like eicosanoids and nitric oxide cause vasodilatation and increase the calibre of arterioles, capillaries, and venules, which results in increased blood flow to the injured area and consequently redness and heat. An increase in the vascular permeability causes the loss of solutes and proteins from the blood plasma, a process called exsudation, which leads to swelling and oedema formation (tumor). The local increase in tissue turgor and the activation of the kinin cascade with the generation of particularly bradykinin are major factors causing pain, the fourth cardinal symptom of inflammation. Besides these changes of the microcirculation the acute inflammatory response essentially requires the extravasation of leukocytes and phagocytosis of microorganism and cell or tissue debris.

Cells and Mediators of Acute Inflammation

The migration of phagocytic cells to the site of damage is one of the most fundamental components of the acute inflammatory response, and the key players in this process will be presented next.

The Endothelial Cell

The vascular endothelium plays an important role in regulation of vascular tone and permeability. Dilatation of arterioles to increase blood flow and constriction of endothelial cells of postcapillary venules causing exsudation of plasma constituents illustrates the complex nature of this cell type. Moreover, by expression of adhesion molecules and secretion of ►chemokines endothelial cells play an important role in the recruitment of leukocytes to the inflamed area. Endothelial cells express two basic types of adhesion molecules on their surface:

1. ►Selectins (E-Selectin, P-Selectin)
2. Members of the immunoglobulin gene superfamily (VCAM-1, ICAM-1, ICAM-2)

Selectins are a family of glycoproteins that allow the initial attachment and rolling of leukocytes on endothelial cells. Selectins are not expressed on the surface of resting endothelial cells but are exposed upon activation with a number of mediators like ►interleukin-1 (IL-1), tumor necrosis factor α (►TNF α), lipopolysaccharide or thrombin. Two endothelial selectins have been reported. E-selectin is synthesized *de novo* and expressed on endothelial cell surface following stimulation. The specific ligand for E-selectin is stored in Weibel–Palade bodies of endothelial cells and in α -granules of platelets and is translocated within minutes to the plasma membrane following exposure to inflammatory mediators. The ligand for P-selectin is the so-called P-selectin glycoprotein ligand-1 (PSGL-1), which has the sugar lacto-n-fucopentose III in its core domain and is present on hematopoietic cells.

The second class of adhesion molecules expressed on endothelial cells belong to the immunoglobulin gene superfamily. These transmembrane glycoproteins structurally resemble in certain parts the structure of immunoglobulins. Whereas intercellular cell adhesion molecule-1 (ICAM-1) and ICAM-2 are constitutively expressed on endothelial cells, the third member vascular cell adhesion molecule-1 (VCAM-1) is not present on resting endothelial cells but is upregulated together with ICAM-1 in the course of acute inflammation by cytokines like IL-1 or TNF α within a few hours. The counterreceptor on the cell membrane of leukocytes that binds to ICAMs and VCAM-1 belong to the ► **integrin** family of adhesion molecules.

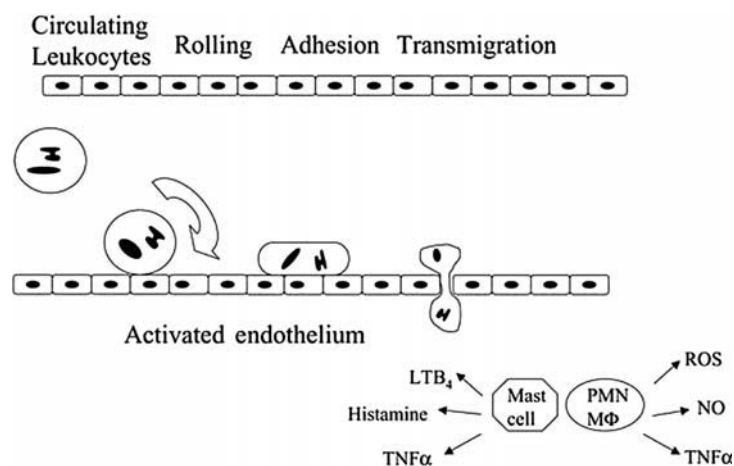

The Neutrophil

In the very early phases of the acute inflammatory response most of the cells invading the damaged area are polymorphonuclear neutrophils, also denoted as PMNs, which serve as initial line of defense and source of proinflammatory cytokines. These cells, which usually live for 4–5 days, circulate in the blood until they are attracted by ► **chemokines** into injured tissues. Whereas physical injury does not recruit many neutrophils, infections with bacteria or fungi elicit a striking neutrophil response. The characteristic pus of a bacterial abscess is composed mainly of ► **apoptotic** (*apoptosis*) and necrotic PMNs. Emigration of neutrophils from the blood starts with a process denoted as margination where neutrophils come to lie at the periphery of flowing blood cells and adhere to endothelial cells (Fig. 1). L-Selectin is expressed

constitutively on most leukocytes and interacts with ligands that are induced in endothelial cells exposed to inflammatory cytokines. The second class of surface molecules that mediate adhesion of neutrophils and monocytes to endothelial cells are the integrins. Leukocyte integrins are heterodimeric transmembrane proteins consisting of α and β chains with short cytoplasmic domains that are engaged in signal transduction. Many cells express integrins, and some of the known integrins are cell-type specific. Integrins mediate firm adhesion that follows the initial rolling of leukocytes along the endothelial cell lining. All the leukocyte integrins share a common small subunit, the β_2 subunit. There are at least four larger α subunits known that can associate with the β_2 subunit to form unique receptors. It is these β_2 -integrins that adhere to the endothelial ICAMs in the course of acute inflammation. Once the neutrophils have made firm contact to the endothelial cells they protrude pseudopodia and leave the blood vessel by squeezing through the gap between adjacent endothelial cells and subsequently pass the basement membrane (Fig. 1). The whole process takes a few minutes.

The Monocyte/Macrophage

The very early peak of neutrophil invasion into an inflamed area is followed several hours later by a wave of a second class of phagocytic cells, the macrophages. This biphasic pattern of inflammatory cell movement and accumulation is observed in most acute inflammatory responses. The mononuclear phagocyte in the blood is known as the monocyte and differentiates

Inflammation. Figure 1 Sequence of events in the recruitment of leukocytes in postcapillary venules adjacent to injured tissue. At the site of lesion, diverse reactive substances stimulate the endothelium to produce inflammatory cytokines, chemoattractants and other inflammatory mediators. The cytokine-activated endothelium expresses adhesion molecules that lead to the low affinity interactions between leukocytes and endothelium, which is mediated by selectins and described as rolling. Subsequently integrins mediate the firm adhesion of leukocytes, which allows emigration of the cells from venules into the interstitial compartment. Activated mast cells, PMNs and macrophages secrete cytokines (TNF α), lipid mediators (LTB₄) and other inflammatory players (histamine, NO).

into the macrophage upon entering into tissues. The differentiation process markedly increases the phagocytic and secretory capacities of the cell. Chemotactic factors that act on macrophages include complement cleavage products, membrane components of microorganisms and fibrin degradation products that also attract neutrophils. In addition, there are specific chemokines that act exclusively on macrophages. Macrophages in turn release large amounts of growth factors and cytokines.

Mediators of Inflammation

Many low weight compounds produced by microorganism-like formylated peptides as well as endogenous mediators are chemotactic for leukocytes and promote the inflammatory process. The main endogenous compounds are listed in Table 1 and are derived from activated plasma protein cascades that function as amplification mechanisms, are performed and released from activated cells or are de novo synthesized on demand by cells participating in or being affected by inflammatory events. The major modulators of leukocyte adhesion to endothelial cells are listed in Table 2.

Healing

The objectives of the inflammatory response can be viewed as a hierarchical ordered panel of events. The most successful consequence of an inflammatory response is the complete restoration of function and structure of the affected tissue, also denoted as resolution. If this is not possible, inflammation aims for healing by repair and replacement of lost tissue by scar tissue.

Central to resolution is the cessation of initiating stimuli, e.g. the killing of invading bacteria and

microorganisms, and the complete removal of inflammatory exudate. Whereas neutrophils carry out the killing of invading microorganisms that subsequently die by apoptosis, macrophages are mainly responsible for clearing dead neutrophils and fluid phase debris by phagocytosis and extremely active pinocytosis. It should be emphasized that the clearing of apoptotic cells by phagocytes is extremely fast and efficient, and dying cells release chemokines to speed up their removal by attracting macrophages. Moreover, cyto-

kines like interleukin-6 and antiinflammatory lipid mediators such as lipoxins or prostaglandins D₂ and E₂ play important roles in providing stop signals for acute inflammatory processes. Most macrophages emigrate from the inflamed site to reach draining lymph nodes. Subsequently tissue that has been lost must be replaced in an orderly fashion. The replacement of lost cells by compensatory proliferation and phenotypic change of surviving resident cells is part of the healing process. If the removal of inflammatory exudate fails, a process denoted as organization is triggered. The exudate is invaded by macrophages and fibroblasts and the formation of new blood vessels (angiogenesis) is initiated. This series of events finally results in the formation of tissue scar, which may be considered as an essential component of wound healing not only in skin.

Chronic Inflammation

If the endogenous control mechanisms of inflammation fail and resolution or healing by repair cannot be achieved, the inflammatory process may persist for weeks, months or even years and is termed chronic. The inflammatory macrophage is not only a ringmaster for safe resolution and repair of inflammation but also for chronicity of the disease. Some of the products secreted by macrophages are relevant to chronic inflammation such as IL-1, TNF α , IL-6 or IL-10, just to name a few. A further characteristic feature is the presence of activated B and T lymphocytes, which represent a local immune response to antigens presented to them by macrophages or dendritic cells. B cells differentiate upon activation to plasma cells that release immunoglobulins which in most cases is a good indicator of chronicity of inflammation. Further attempts to repair are clearly unsuccessful and tissue necrosis and inflammation continue as is the case in chronic ulcerative colitis or chronic pyelonephritis and other diseases. The mechanism by which the inflammatory response resolves is under intense investigations and may provide new targets in the treatment of chronic inflammation.

Inflammatory Caspases

Inflammatory caspases (caspase-1, -4, -5, -11 and -12) constitute a subgroup of the caspase family. Caspase-1 is the best characterized member and is responsible for the proteolytic maturation and release of the pro-inflammatory cytokines pro-interleukin (IL)-1 β and pro-IL-18. Caspase-1 gets activated in inflammasome complexes upon cellular stress, cellular damage and infection.

Influenza

Influenza is an acute viral disease caused by Influenza A (sporadic, epidemic, and pandemic) or B (sporadic outbreaks) virus. Symptoms typically occur suddenly and include high fever, chills, headache, muscle aches, sore throat, and malaise. Serious complications can be caused by bacterial superinfection of the respiratory tract.

Infrared Spectroscopy

Infrared spectroscopy is an analytical technique which differentiates molecules on the basis of their vibrational states.

Innate Immunity

Innate immunity describes inborn effector mechanisms defending the organism against harmful foreign substances by humoral (▶defensins, ▶complement) or cellular (phagocytic cells, natural killer cells) mechanisms. In innate immunity, recognition of foreign substances is always by receptors such as pattern recognition receptors, which are germ-line configured and not rearranged like the T- and B-cell antigen receptors. From a phylogenetical point of view, the innate defense system developed much earlier than the adaptive immune system of lymphocytes; the innate system is found in many invertebrates.

Inorganic Phosphate Transporters

Type 1 Na⁺-dependent inorganic phosphate transporters (NaP_i-1) are a family of proteins isolated in a screen for genes that increase Na⁺-dependent inorganic phosphate transport. Further characterization with heterologous expression of the rat kidney NaPi-1 isoform in particular, demonstrated that phosphate transport did not correlate with the level of messenger RNA (mRNA) expressed. However, expression did correlate with the saturable transport of inorganic anions such as penicillin and probenecid. It has also been shown that NaPi-1 mediates an anion conductance that can be blocked by transport substrates. The sialic acid transporter sialin, and the vesicular glutamate transporters VGLUT1 and VGLUT2 are closely related to the type I Na⁺-dependent inorganic phosphate transporters.

INSR (gene name)

Definition

The insulin receptor is a transmembrane ►receptor tyrosine kinase located in the plasma membrane of insulin-sensitive cells (e.g., adipocytes, myocytes, hepatocytes). It mediates the effect of insulin on specific cellular responses (e.g., glucose transport, glycogen synthesis, lipid synthesis, protein synthesis).

Basic Characteristics Structure and Function

The INSR is a heterotetrameric protein consisting of two extracellular α -subunits (molecular weight 135 kDa) and two membrane-spanning β -subunits (molecular weight 95 kDa). These subunits are covalently linked by disulfide bonds ($\alpha_2\beta_2$ -structure) (Fig. 1). The receptor is encoded by a single gene which is located on human chromosome 19 and consists of 22 exons (exon 1–11 = α -subunit, exon 12–22 = β -subunit). The single chain polypeptide precursor is posttranslationally cleaved in the endoplasmic reticulum into the α - and β -subunits which subsequently dimerize. Both subunits are glycosylated in the Golgi apparatus.

In addition to insulin, the INSR can also bind ►insulin-like growth factors (IGF1 and IGF2) albeit with considerably lower affinity (2 and 3 orders of magnitude, respectively).

The insulin-binding domain of the INSR is located within a cysteine-rich region of the α -subunits. Alternative splicing of exon 11 generates two isoforms of the α -subunit which differ in their C-terminus and in their tissue distribution (type A: leukocytes; type B: liver; type A and B: skeletal muscle and fat). The isoforms differ in their affinity to insulin (A > B), but their relevance for normal and impaired insulin action is not entirely clear [1, 2].

Activation of the tyrosine kinase activity of the INSR is essential for the receptor function. The tyrosine kinase domain of the INSR is localized in the

Insulin Receptor. Figure 1 Structure and function of the insulin receptor. Binding of insulin to the α -subunits (yellow) leads to activation of the intracellular tyrosine kinase (β -subunit) by autophosphorylation. The insulin receptor substrates (IRS) bind via a phosphotyrosine binding domain to phosphorylated tyrosine residues in the juxtamembrane domain of the β -subunit. The receptor tyrosine kinase then phosphorylates specific tyrosine motifs (YMXM) within the IRS. These tyrosine phosphorylated motifs serve as docking sites for some adaptor proteins with SRC homology 2 (SH2) domains like the regulatory subunit of PI 3-kinase.

cytoplasmic region of the β -subunit. In the absence of insulin, the α -subunits strongly repress the tyrosine kinase activity of the β -subunits. Binding of insulin releases this block through a conformational change, and induces dimerization and/or oligomerization of β -subunits which results in receptor transautophosphorylation. While several phosphorylated tyrosine residues in the catalytic domain (Y1158, Y1162, Y1163 of human INSR) are essential for the kinase activity of the receptor, phosphorylation of two tyrosine residues in the juxtamembrane domain (Y965 and Y975 of human INSR) is critical for the interaction of the receptor with other signaling components of the insulin receptor signaling cascade (Fig. 1) [1, 3].

Signaling through the INSR systems has evolved early and has been highly conserved during evolution. Proteins related to the human INSR gene product have been found in *Caenorhabditis elegans* (DAF-2) as well as in *Drosophila melanogaster* (DIR). Insulin-like signaling peptides (e.g., bombyxin) have been found in such distantly related organisms as the silkworm [1].

Structurally and functionally related receptors to the INSR in mammalian organisms are the insulin-like growth factor 1 receptor (IGF1R) and the insulin receptor-related receptor (INSRR). Although the function and signal transduction of the IGF1R and the INSRR resembles that of the INSR, major differences appear in the tissue distribution of the receptors. In contrast to the INSR, the IGF1R is expressed in adipocytes only at low levels and is almost absent in hepatocytes. The INSRR is an orphan receptor whose endogenous ligand is yet unknown. It has been found in few neuronal cell types (e.g., dorsal root ganglion and trigeminal neurons) and in the kidney.

Deletion of the INSR gene results in normal development but early postnatal lethality because of ketoacidosis. Organ specific INSR-knockout models (>95% reduction of the receptor protein content in the organ) exhibit less severe phenotypes. Mice with a liver-specific insulin receptor knockout (LIRKO) showed severe insulin resistance and hyperglycemia due to an increased hepatic **gluconeogenesis**, whereas the tissue-specific knockout of the insulin receptor in pancreatic β -cells (β -IRKO) results in an altered insulin secretion comparable to that seen in type-2-diabetes. Specific knockout of the IGF1R in β -cells results in a similar phenotype. In contrast, mice with a skeletal muscle-specific insulin receptor knockout (MIRKO) had normal blood glucose and normal glucose tolerance but elevated serum free fatty acids and triglycerides. Interestingly, mice selectively lacking the insulin receptor in adipose tissue (FIRKO) were protected against obesity and obesity-related glucose intolerance and showed an extended lifespan. Mice with a neuron-specific INSR knockout (NIRKO) developed an obese phenotype with mild insulin resistance and impaired

fertility. These central effects of insulin on the peripheral energy metabolism reflect an important role of insulin in the regulation of neuropeptide expression (e.g., NPY, POMC) in the brain. Combined deletion of the INSR, IGF1R, and the INSRR in male (XY) mice results in a female phenotype with ovaries, thereby providing evidence that the insulin receptor tyrosine kinase family is essential for male sex differentiation.

Taken together, these data emphasize the importance of insulin action in the liver for glucose homeostasis, in the regulation of insulin secretion from β -cells and indicate that the INSR plays an important role in the central regulation of body weight and reproduction [4, 5].

There are two clinical syndromes with an impaired function of the INSR: Leprechaunism is a rare genetic disease characterized by growth retardation, hyperinsulinemia, and insulin resistance due to mutations in the INSR gene. Acanthosis nigricans is a syndrome of hyperpigmentation and hyperandrogenism associated with hyperinsulinemia and **diabetes mellitus**. Insulin resistance in this syndrome is either due to mutations in the insulin receptor gene (type A), or to autoantibodies to the INSR (type B). Some patients with insulin resistance due to decreased expression, increased degradation or impaired insulin binding of the INSR have been described.

Signal Transduction and Insulin Action

Stimulation of the insulin receptor results in the activation of two major pathways [3]: (i) the **mitogen-activated protein (MAP) kinase cascade** (discussed in chapter **MAP kinase cascade**) and (ii) the **phosphatidylinositol 3-kinase (PI 3-kinase)** pathway which has been extensively studied in the context of the metabolic responses to insulin (summarized in Table 1 and Fig. 2).

The major intracellular target molecules of the tyrosine kinase activity of the INSR β -subunit are the **insulin receptor substrates (IRS)**. Interaction of phosphotyrosine-binding domains (PTB) within the N-terminal region of an IRS with the juxtamembrane phosphotyrosines of the INSR β -subunit results in tyrosine phosphorylation of consensus motifs (YMXM) in the C-terminus of IRS (Fig 1). Four different mammalian IRS isoforms have been identified (IRS1-4). IRS1 knockout mice develop a mild state of insulin resistance (impaired glucose intolerance) without diabetes, whereas knockout of the IRS2 gene causes a phenotype with severe insulin resistance (liver > muscle), diabetes, and impaired pancreatic β -cell function. Both IRS1 and IRS2 knockout mice exhibit growth retardation (IRS1 > IRS2). IRS3 knockout mice appear to be normal, whereas disruption of the IRS4 gene produces mild glucose intolerance and growth retardation in male animals. IRS1 and IRS2 are ubiquitously expressed. IRS3 is expressed only in

Insulin Receptor. Table 1 The effect of insulin on energy and glucose homeostasis

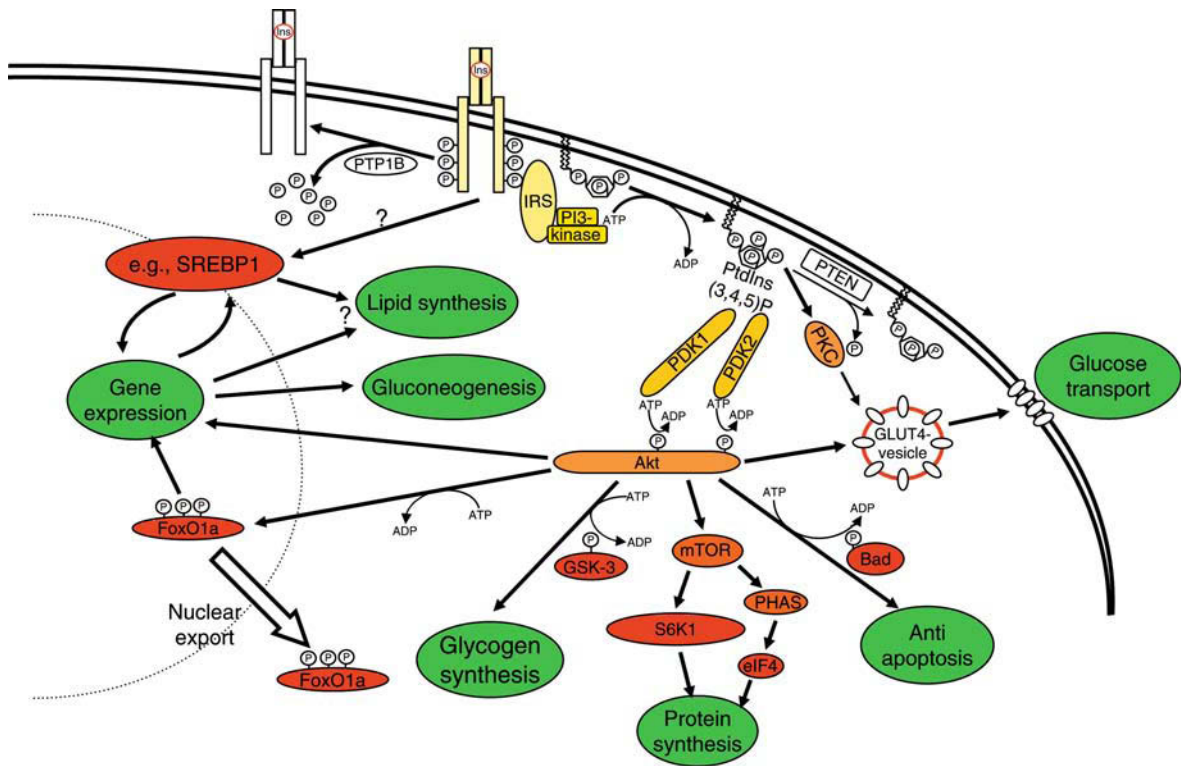

Organ	Effect	Mechanism	Comments
Liver	Activation of glycogen synthesis	Activation of glycogen synthase (GS)	Inactivation of glycogen synthase kinase 3 (GSK3) through phosphorylation by Akt
	Inhibition of gluconeogenesis/increased glycolysis	Inhibition of gluconeogenic gene expression/activation of some glycolytic enzymes	Akt-dependent inhibition of phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G6Pase) gene expression Decrease of cAMP, the second messenger of glucagon. Induction of pyruvate kinase and glyceraldehyde dehydrogenase
Fat	Increased glucose transport	GLUT4-translocation	PI 3-kinase/Akt mediated translocation of GLUT4 into the plasma membrane. Potential involvement of atypical forms of protein kinase C (PKC ζ and λ)
	Increased lipid synthesis/inhibition of lipolysis	Activation of lipoprotein lipase (LPL)/induction of fatty acid synthase (FAS)/inactivation of hormone sensitive lipase (HSL)	Facilitated uptake of fatty acids by LPL-dependent hydrolysis of triacylglycerol from circulating lipoproteins. Increased lipid synthesis through Akt-mediated FAS-expression. Inhibition of lipolysis by preventing cAMP-dependent activation of HSL (insulin-dependent activation of phosphodiesterases?)
Skeletal muscle	Increased glucose transport	GLUT4-translocation	see above (fat)
	Activation of glycogen synthesis	Activation of glycogen synthase	see above (liver)
	Increased protein synthesis	Increased amino acid uptake/increased translation of mRNA	Akt-mediated stimulation of system A amino acid transporter and stimulation of mRNA-translation through activation of p70S6kinase and elongation initiation factor 4 (eIF4). Possible involvement of atypical PKCs
Central nervous system	Reduction of body weight	Reduced appetite	changed expression of anorexigenic (e.g., POMC) and orexigenic (e.g., NPY) hypothalamic neuropeptides

Other, more general effects of insulin on cellular function include stimulation of cell growth (increase in DNA and protein synthesis), inhibition of apoptosis, and modulation of ion-channel activity.

adipocytes, β -cells, and hepatocytes; IRS4 mRNA is detected in thymus, brain, and kidney. Taken together, the data suggest that the major effects of insulin on metabolism are mediated via IRS1 and IRS2 [2, 3].

Tyrosine phosphorylated IRS interacts with and activates \blacktriangleright PI 3-kinase [3]. Binding takes place via the SRC homology 2 (SH2) domain of the PI 3-kinase regulatory subunit. The resulting complex consisting of INSR, IRS, and PI 3-kinase facilitates interaction of the activated PI 3-kinase catalytic subunit with the phospholipid substrates in the plasma membrane. Generation of PI 3-phosphates in the plasma membrane recruits phospholipid dependent kinases (PDK1 and PDK2) which subsequently phosphorylate and activate the serine/threonine kinase \blacktriangleright Akt (synonym: protein

kinase B, PKB). Three isoforms of Akt have been identified (Akt1, 2, 3). AKT1-knockout mice exhibit growth retardation and increased apoptosis, but no increased prevalence in diabetes. Disruption of the Akt2 gene produces diabetes due to insulin resistance of skeletal muscle and liver. Double knockout of AKT1 and 2 showed severe growth deficiency and died shortly after birth. There is solid evidence that activation of Akt is essential for the effect of insulin on glucose transport (\blacktriangleright GLUT4), glycogen synthesis, \blacktriangleright gluconeogenesis, protein synthesis, and gene expression [1, 3] (summarized in Table 1 and Fig. 2). Substrates of Akt are \blacktriangleright glycogen synthase kinase 3 (GSK3) and \blacktriangleright FoxO1a (previously known as FKHR), a transcription factor regulating the expression of gluconeogenic enzymes.

Insulin Receptor. Figure 2 Signal transduction of the insulin receptor. Activation of the insulin receptor leads to stimulation of the PI 3-kinase pathway. Generation of 3'-phosphorylated PI-phospholipids mediates the effect of insulin on glucose transport, cell survival, protein synthesis, glycogen- and lipid synthesis, gene expression, and gluconeogenesis. The protein kinase Akt plays a central role in the regulation of these PI 3-kinase dependent processes.

Also, phosphorylation of Akt results in activation of sterol regulatory-element binding protein 1 (SREBP1), a key transcription factor involved in regulation of lipogenic enzymes. In addition, some of the effects of insulin on cell proliferation and survival may be explained by an Akt-dependent inhibition of ▶apoptosis through phosphorylation and inactivation of proapoptotic proteins (e.g., BAD, Caspase 9).

INSR signaling is terminated by specific phosphotyrosine phosphatases (e.g., PTP1B) (▶tyrosine phosphatases), and mice lacking the PTP1B gene exhibit increased insulin sensitivity. Furthermore, it has been suggested that the lipid phosphatases PTEN and SHIP2, the ligand-induced endocytosis and degradation of the activated INSR, and the degradation of insulin by insulin-degrading enzyme (insulysin) are involved in the termination of insulin signaling.

Drugs

Agents Stimulating the Receptor or the Signaling Pathway

Insulin Analogs. At present, the only known ligands of the insulin receptors are insulin isotypes from different species and a number of synthetic analogs

with insulin-like activity. Five analogs generated by site-directed DNA mutagenesis are used in clinical practice because of their pharmacokinetic characteristics: Insulin lispro (swap of proline B28 and lysine B29), insulin aspart (generated by exchange of proline B28 for aspartate), insulin glulisin (generated by exchange of lysine B29 for glutamate) are rapid and short-acting insulins (▶diabetes mellitus). Insulin glargine and insulin detemir are long-acting analogs. Because of two additional arginines at B31 and B32, insulin glargine is soluble at low pH and precipitates after injection, forming a stable, long-acting depot. Insulin detemir is a truncated insulin derivative (threonine B30) that has been coupled to a long-chain fatty acid at lysine B29. This results in the formation of a slowly dissociating complex and an increased binding to albumin, which further delays its inactivation.

Thiazolidinediones (synonyms glitazones, insulin sensitizers; rosiglitazone, pioglitazone) are a novel class of oral antidiabetic drugs that activate the transcription factor ▶peroxisome proliferator-activated receptor (PPAR γ). Thiazolidinediones ameliorate insulin resistance in obese animal models and in individuals

with type-2 diabetes. They enhance the insulin dependent activation of the PI 3-kinase/Akt pathway, stimulate differentiation of preadipocytes, and redistribute intra-abdominal and hepatic triglycerides to subcutaneous adipose tissue stores. The marked reduction of hepatosteatosis is believed to be the primary reason for its antidiabetic effect. Furthermore, anti-inflammatory properties of thiazolidinediones have been suggested to contribute to their effect on insulin resistance in type-2 diabetes.

Concanavalin A is a plant lectin from the jack bean (*Canavalia ensiformis*) which binds with high affinity to mannose residues of glycoproteins. Concanavalin A is known to stimulate the tyrosine kinase activity of the INSR β -subunit with consecutive activation of kinases downstream the insulin receptor (IRS, PI 3-kinase). It is believed that Concanavalin A stimulates the activation and autophosphorylation of the INSR kinase through aggregation of the receptor, although the precise mechanism of action is unclear.

Vanadate (sodium orthovanadate or peroxovanadate) exhibits insulin-like effects in vitro (activation of insulin receptor tyrosine kinase, PI 3-kinase, Akt) and in vivo (diabetic rats, humans). These effects can be explained at least in part by the inhibition of phosphotyrosine phosphatases which deactivate the INSR tyrosine kinase.

Hydrogen peroxide (H_2O_2) exhibits insulin-like activity in isolated cells. Like that of vanadate, this effect is thought to be mediated by inhibition of protein-tyrosine phosphatases.

Agents Inhibiting Insulin Receptor Signaling

Insulin Analogs. Interestingly, several covalently dimerized insulin analogs are partial agonists of the insulin receptor. The intrinsic activity of the dimers decreases with the length of the spacer, with B29-B29²-suberoyl-insulin exhibiting the highest antagonist efficacy at the receptor [5].

Wortmannin is a fungus-derived inhibitor of PI 3-kinase. The agent binds and inhibits the enzyme covalently and irreversibly. It is very potent and considered to be highly specific (IC_{50} in most cells in the low nanomolar range).

LY294002 is a synthetic drug which reversibly inhibits PI 3-kinases. It is less toxic and also less potent than wortmannin. The IC_{50} in most cells is in the micromolar range.

Rapamycin is an immunosuppressive drug and an inhibitor of ▶S6K1 (also known as p70S6-kinase) which phosphorylates ribosomal S6 protein. S6K1 is activated in response to insulin via activation of Akt. Rapamycin binds to a specific target protein (mTOR, mammalian target of rapamycin) which is functionally located downstream of Akt, but upstream

of S6K1. The IC_{50} in most cells is in the high nanomolar range.

Insulin Resistance

Insulin resistance occurs when the normal response to a given amount of insulin is reduced. Resistance of liver to the effects of insulin results in inadequate suppression of hepatic glucose production; insulin resistance of skeletal muscle reduces the amount of glucose taken out of the circulation into skeletal muscle for storage; and insulin resistance of adipose tissue results in impaired suppression of lipolysis and increased levels of free fatty acids. Therefore, insulin resistance is associated with a cluster of metabolic abnormalities including: elevated blood glucose levels, abnormal blood lipid profile (dyslipidemia), hypertension, and increased expression of inflammatory markers (inflammation). Insulin resistance and this cluster of metabolic abnormalities is strongly associated with obesity, predominantly abdominal (visceral) obesity, and physical inactivity and increased risk for type 2 diabetes, cardiovascular and renal disease, as well as some forms of cancer. In addition to obesity, other situations in which insulin resistance occurs includes

pregnancy, infection or severe illness, stress, or during steroid use.

Insulin-like Growth Factor

Synonyms

IGF

Definition

IGF1 (also called somatomedin C) and IGF2 are ubiquitously expressed peptides with sequence homology to insulin. Both factors bind to specific receptors. The IGF1 receptor is a receptor tyrosine kinase with similar structure ($\alpha_2\beta_2$) and molecular function as the INSR. The receptor for IGF2 lacks a tyrosine kinase activity and is identical with the mannose-6-phosphate receptor. IGF1 also binds to the insulin receptor, although with much lower affinity; IGF2 binds to the IGF1 receptor with high affinity.

- ▶ Insulin Receptor

Integrase

Integrase is the enzyme of retroviruses that performs the incorporation of the viral DNA genome into the genome of the host cell. The enzyme is carried inside the viral particle and released into the host cell during infection. Upon back-transcription of the viral RNA genome into DNA by reverse transcriptase, integrase binds to the ends of this DNA product and removes two nucleotides. In a second step, integrase nicks the host cell genome and integrates the recessed viral nucleic acid into the cellular DNA.

- ▶ Viral Proteases

Integrin, α 4 β 1

The leukocyte integrin α 4 β 1 (also known as VLA-4 and CD49d/CD29) is a cell adhesion receptor, which is predominantly expressed on lymphocytes, monocytes and eosinophils. VLA-4 is generally selective for the CS1 domain within fibronectin, with an essential requirement for LDV sequence for binding. VLA-4 also binds to VCAM-1 as a counter receptor.

- ▶ Anti-integrins, Therapeutic and Diagnostic Implications

Integrin, α 4 β 7

The integrin α 4 β 7 is restricted to leukocytes and can bind not only to VCAM1 and fibronectin, but also to MAdCAM the mucosal addressin or homing receptor, which contains immunoglobulin-like domains related to VCAM-1.

- ▶ Anti-integrins, Therapeutic and Diagnostic Implications

Integrin, α IIb β 3

α IIb β 3 Integrin is a selective platelet integrin that generally binds to the RGD domain within fibrinogen and vWF. It mediates platelet-platelet aggregation that is essential for thrombosis and haemostasis.

- ▶ Anti-integrins, Therapeutic and Diagnostic Implications

Integrin, α v β 3

α v β 3 Integrin binds via RGD domain within various matrix proteins including vitronectin, osteopontin, and fibrinogen. It is widely distributed on various cells.

Integrin, α v β 5

α v β 5 Integrin generally binds to soluble and, with a higher affinity, to immobilized vitronectin via an RGD binding domain. α v β 5 integrin is expressed on endothelial, epithelial, and other cells.

► Anti-integrins, Therapeutic and Diagnostic Implications

Integrins

Integrins constitute a large family of α β heterodimeric cell surface, transmembrane proteins that interact with a large number of extracellular matrix components through a metal ion-dependent interaction. The term “integrin” reflects their function in integrating cell adhesion and migration with the cytoskeleton.

Integron

A DNA sequence with conserved flanking regions of typically 59 nucleotides and the structural gene encoding the integrase, an enzyme capable of cutting and religating specific DNA sequences to accumulate resistance genes inside the integron. This physical linkage of different antibiotic resistance genes assures the coselection and simultaneous spread of multiple resistance determinants even in the absence of selective pressure.

► Bacterial Resistance to Drugs

Interactions

► Drug Interaction

Interfacial Inhibitors

Drugs that bind at the interface of two (or more) macromolecules. Drug binding takes place within an intermediate configuration of the macromolecular complex. The drug-stabilized macromolecular complex alters the function of the macromolecular complex and is recognized by the cell as a damaging intermediate. The paradigms for interfacial inhibitors are camptothecins for the topoisomerase I–DNA complex, which is trapped by camptothecins as topoisomerase I cleaves the DNA. A number of natural products act as interfacial inhibitors for a wide range of macromolecular complexes. They include brefeldin A, rapamycin, paclitaxel, vincristine, tubulin, and aminoglycosides (Pommier and Cherfil, Interfacial inhibition: a Nature’s paradigm for drug discovery. Trends Pharmacol Sci 2005; 28: 136–145).

Interferon Stimulated Gene 15

Synonyms

ISG15

Definition

ISG15 is one the genes most strongly induced by type I interferons. Transcription is also up regulated upon viral infection, oxidative stress and treatment with lipopolysaccharide (LPS). Like ubiquitin, ISG15 can be conjugated to a wide range of target proteins. As mice lacking ISG15 are more sensitive upon herpes- and influenza-infections the ISG15 system apparently has a pivotal role in antiviral defense.

Definition

Interferons (IFNs) are a family of multifunctional secreted proteins in vertebrates. Their most prominent functions are their antiviral properties on homologous cells against a wide range of viruses. It is important to note that prior exposure to IFN is required to render cells resistant to viral infection and replication. In contrast to antibodies, IFNs have no direct neutralizing effect on viruses.

In mammals the type I IFN genes form a large multigene family comprising the species α , β , κ , ω , and τ . The best-studied species is the IFN- α group, which comprises at least 14 closely related genes in man, and the single IFN- β gene. These species are rapidly induced by viruses or ►double-stranded (ds) RNA molecules. IFN- β is produced in almost all cell types, whereas the most efficient IFN- α -producing cells are ►plasmacytoid dendritic cells (pDC). IFN- κ has been identified in ►keratinocytes where it is expressed constitutively without external stimuli. IFN- κ is also inducible by virus and by IFN- γ in monocytes and in ►dendritic cells (DC). IFN- ω constitutes a minor species of type I IFN co-induced by viruses with α - and β -IFN in leukocyte cultures. IFN- τ , formerly called trophoblastin or ovine trophoblast protein, was isolated from sheep and bovine embryonic tissues. This IFN species is not virus-inducible but is released constitutively by ►trophoblast cells during the period immediately prior to implantation and therefore seems to play a key role in the establishment of maternal recognition and of pregnancy in ruminants. All type I IFN species except IFN- κ are encoded by intronless genes on the short arm of human chromosome 9 or mouse chromosome 4 and bind to a common cell-surface receptor consisting of two distinct chains present on virtually all nucleated cells.

In contrast to the large group of type I IFN genes, type II IFN comprises only IFN- γ . The gene contains three ►introns, displays no homology to type I IFN and is expressed exclusively by T-lymphocytes and natural killer (NK) cells, following stimulation with certain interleukins (IL-2, IL-7, IL-12, and IL-18), ►mitogens or the specific antigen of sensitized T-lymphocytes. IFN- γ binds to its specific receptor as a homodimer. All natural type I and II IFNs are glycosylated, but non-glycosylated recombinant IFNs show the same spectrum of biological activities (►interferon measurement).

Type III IFNs, also named IFN- λ 1, - λ 2, and - λ 3 or IL-28A, B, and IL-29, respectively also display IFN-like activities and are induced by most viruses that also give rise to type I IFN production. The genes are located on human chromosome 1 and contain several introns. IFN- λ binds to two receptor chains distinct from type I and type II IFNs named IFNLR-1 and IL-10R2 the latter being a common chain for IL-10 and IL-22. Signaling

involves the Jak/“Signal-Transducer-and-Activator-of-Transcription” (STAT) pathway as all other IFNs and most interferon-stimulated genes (ISG) are also induced by IFN- λ species.

This essay will focus on IFN- α , - β , and - γ .

Mechanism of Action

Regulation of IFN Gene Expression

Type I IFN Induction

Type I IFNs are considered an integral part of the innate defense system (►innate immunity) against viral infection. Large amounts of IFN are produced in many cell types upon infection by various viruses, and production is tightly controlled at the transcriptional level. The predominant and best-studied species are IFN- α / β . Generally speaking, four major pathways can be considered as giving rise to activation of IFN- α and/or IFN- β and they are operating in a cell-type and virus-specific manner.

In the so-called “classical” pathway active in most cell-types, infection is detected as soon as viral replication is initiated and dsRNA intermediates are generated in the cytosol of the host cell. In addition to the dsRNA-dependent protein kinase (PKR), two RNA ►helicases, Retinoic-Acid-Inducible-Gene I (RIG-I) and Melanoma-Associated-Antigen 5 (MDA5), have been identified as the first cytoplasmic sensors of dsRNA. Structurally, RIG-I contains two and MDA-5 one ►caspase recruitment domains (CARD) enabling them to interact with the CARD of an adaptor molecule named Interferon-Promoter-Stimulator (IPS-1), MAVS, VISA, or Cardif anchored in the outer mitochondrial membrane [5]. This adaptor protein then recruits two different sets of kinases involved in downstream signaling: (i) the inhibitor of κ B (IKK)-related kinases TBK-1 and IKK ϵ which ultimately lead to phosphorylation of ►interferon-regulatory-factors (IRF) 3 and 7 and (ii) the I κ B-kinase complex consisting of IKK- α / β / γ subunits which phosphorylate the inhibitor I κ B, and mediate the release and activation of NF κ B (see also Fig. 1). Both sets of activated transcription factors translocate to the nucleus and bind to the IRF/PRDI and NF κ B/PRDII elements of the IFN- β promoter. These coordinated pathways then result in a moderate but rapid IFN- β response. The serine-threonine protein kinase PKR is also involved in virus-induced IFN synthesis since PKR-deficient cells show impaired IFN response to dsRNA and some RNA viruses. Pretreatment with IFN, however, completely relieves this defect, suggesting an involvement of the IFN-inducible helicase RIG-I in PKR-mediated IFN synthesis

An additional pathway leading to very efficient IFN- β responses involves one of the ►Toll-like-receptors (TLR), TLR3 which also senses dsRNA and is mainly expressed in ►dendritic cells (DC) and macrophages. Signal transduction then proceeds via the adaptor molecule TICAM/TRIF associated with the ►TIR-domain of

Virus infection results in a two-step induction of type I IFN

Interferons. Figure 1 The “Classical pathway”: virus infection results in two-step induction of type I IFN [4]. (A) *Green transparent*: (1) Following viral entry into the cell dsRNA intermediates formed during replication are recognized by RNA-helicases RIG-I or MDA-5. These helicases then interact with a signaling intermediate localized to the mitochondrial membrane called Interferon-Promoter-Stimulator-1 (IPS-1) via their common Caspase Activation and Recruitment Domains (CARD). This interaction initiates the formation of active kinase complexes containing IKK ϵ and TBK-1, which phosphorylate IRF-3 whereas those harboring IKK- α , - β , and - γ mediate activation of NF- κ B through phosphorylation and release of the bound inhibitor I κ B. NF- κ B and phosphorylated IRF-3 then translocate to the nucleus to stimulate the IFN- β promoter. This first step is a rapid process independent of protein synthesis due to the constitutive expression of IRF-3 with low to moderate yields of IFN- β . As can be seen from this simplified schematic view, IPS has a central role in initiating antiviral responses through both TLR3 and RIG-I-mediated pathways. (B) *Red transparent*: (2) In a positive feedback regulation the secreted “early” IFN- β then stimulates the type I IFN receptor and – via formation of interferon-stimulated-gene-factor 3 (ISGF3) – activates the IRF-7 gene through binding to its ISRE element (3). In concert with IRF-3 de novo produced IRF-7 (4) is also phosphorylated in the cytoplasm during ongoing viral infection (5), and following nuclear translocation as homo- or heterodimers both IRF-3 and IRF-7 activate IFN- α and IFN- β gene promoters. This second step is highly efficient resulting in an amplified “bulk” IFN response (6).

TLR3, which directly activates the TBK-1, not involving the CARD-containing adaptor IPS-1. Again the final step is activation of IRF-3.

The third pathway for IFN-induction involves detection of microbial nucleic acids by other types of

TLRs and is highly active in pDC which are robust producers of IFN- α and represent crucial effector cells of the innate defense system.

They express in endosomal compartments TLRs 7, 8, and 9 which specifically recognize ssRNA and

CpG-rich dsDNA, respectively. Following activation, these TLRs bind to a complex consisting of the specific adaptor molecule MyD88, TRAF6, and the kinases IRAK-1 and IRAK-4. IRF-7, which is also part of this complex is then phosphorylated by IRAK-1, forms dimers and shuttles to the nucleus to specifically activate the IFN- α promoter.

Efficient inducers of type I IFN also include bacteria or ▶lipopolysaccharide (LPS) derived from gram-negative bacteria. LPS is mainly recognized by ▶TLR4 on the cell membrane of monocytes and granulocytes. Signaling is then mediated via MyD88 for ▶TNF- α and ▶IL-6 or via TRIF/TICAM and IRF-3 for IFN- β responses. Interestingly, the gram-negative bacteria *Legionella pneumophila*, which are able to replicate in TLR4 negative human epithelial cells, induce IFN- β through activation of IPS-1 and IRF-3, a process that bypasses helicases RIG-I and MDA5.

Initiation of transcription requires activation of the IFN- α and - β ▶gene promoters located 110–40 base pairs upstream of the start codon. The events leading to activation of the IFN- β promoter have been studied in detail. This promoter is composed of an overlapping set of four regulatory elements, two of which are target sequences for members of the IRF family of ▶transcription factors. This family is comprised of nine members with remarkable homology in the DNA-binding domain, and IRF-3 and IRF-7 being crucial for inducing maximal type I IFN expression. The strong IFN- α/β response measured after viral infection is critical for host survival. As explained in Fig. 1, this response is due to a positive feedback regulation and is generated in a two-step process [4]. IRF-7 has been shown to represent the key element since the gene carries a sequence named “Interferon-Stimulated-Response-Element” (ISRE) – a conserved sequence in the regulatory region shared by most IFN-inducible genes – and also participates in the induction process through binding to the IFN- β promoter. Due to the pronounced effects IFNs have on the regulation of cell growth and immune functions, the duration of “bulk” synthesis is generally limited. Two mechanisms are known to mediate rapid post-induction turnoff of IFN- β gene expression: First, as a result of negative feedback mechanisms virus-inducible and even IFN-inducible competitive factors downregulate the IFN- β promoter activity as for instance, members of the SOCS-protein family and LGP2, another helicase protein lacking a CARD but able to interact with the IPS-1/RIG-1 complex to displace IKK ϵ and inhibit IRF-3 activation (see above); second, IFN- β mRNA has a rapid turnover due to an AUUUA motif in the 3'-non-coding region, conserved in many different cytokine mRNA. In addition, in non-induced cells repressor proteins prevent transcriptional activation of the IFN- β promoter.

Type II IFN Induction

In contrast to IFN- α/β , the expression of IFN- γ is strictly limited to T-cells and large granular lymphocytes, also often referred to as ▶natural killer (NK) cells. In naive T-lymphocytes, the capacity to express IFN- γ is gained during differentiation to the T_h1 lineage driven by specific antigen contact and requires the presence of unique transcription factors T-bet and Runx3 that bind to the *ifng* promoter. At the same time these factors repress the expression of IL-4 – a cytokine secreted by T_h2 lymphocytes and known to stimulate several immune cell functions antagonistic to IFN- γ – through binding to the *il4* silencer region. In addition, in cells that do not express IFN- γ a silencing effect by ▶DNA methylation has been postulated, since a CpG target region in the *IFN- γ* promoter near the ▶TATA box was found to be methylated (▶immune defense). Hypomethylation per se, however, does not result in IFN- γ expression. It is therefore assumed that in unstimulated cells nuclear factors keep the gene in the “off” position since continuous production of this highly active inflammatory cytokine would be harmful to the host by eliciting autoimmune responses (▶inflammation).

Signal Transduction and Biological Responses to IFNs

Any IFN-mediated activity requires binding to a specific receptor on the cell surface. The number of receptors varies from several hundreds to a few thousands per cell. All IFN- α species and IFN- β share the same type I IFN receptor to which they bind with similar affinity. IFN- γ binds to the distinct type II receptor. Both receptors are composed of one ligand-binding and one non-ligand-binding chain that associate, following contact with the specific IFN ligand. The signaling events following type I and type II IFN receptor stimulation are depicted on a simplified scheme in Fig. 2. Crucial components of this signaling pathway are the so-called ▶signal transducer and activator of transcription (STAT) proteins, which are activated by phosphorylation on tyrosine residues.

Although IFN- γ specifically activates genes carrying a γ -activated-sequence (GAS) element in their regulatory region, it can also indirectly activate genes harboring an ISRE via binding of the transcription factor IRF-1, since IRF-1 is inducible by both IFN- α/β and IFN- γ . In addition, efficient IFN- γ signaling is dependent on simultaneous or prior stimulation of the IFN- α/β receptor that results from a cross-talk between IFNAR1 and IFNGR1 receptor components. This is borne out by observations that on one hand a low constitutive IFN- β expression observed in some cell types, such as macrophages and embryonic fibroblasts, considerably enhances their sensitivity toward

Interferons. Figure 2 Receptor stimulation and signal transduction by type I and type II IFN. *Type I IFN*: The receptor is composed of two chains, IFNAR1 and IFNAR2c their cytoplasmic domains carrying the tyrosine kinases TYK2 and JAK1, respectively, which are essential for signaling. In addition, unphosphorylated STAT2 is found attached to JAK1/IFNAR2c and stabilizes association of this receptor chain with STAT1. Upon IFN- α/β binding, the receptor complex is formed (1), and bound IFN is internalized via receptor-mediated endocytosis. The receptor associated kinases JAK1 and TYK2 get into closer contact and are activated by transphosphorylation. Subsequently, TYK2 phosphorylates a tyrosine residue of the IFNAR1 subunit, which in turn recruits and phosphorylates STAT2. STAT1 molecules will then be recruited to the phosphorylated STAT2 to become phosphorylated as well. The phosphorylated STAT1/STAT2 heterodimer thus formed finally dissociates from the IFNAR1 chain and translocates to the nucleus where it associates with the DNA-binding protein p48/IRF-9 (2) to form the trimeric complex ISGF3. The ISGF3 complex binds to a conserved target sequence in the promoter of IFN-inducible genes. This ISRE is essential for activation by IFN- α/β . Interestingly, the ISRE shares significant homology with defined domains in the type I IFN promoter and can therefore also be stimulated by members of the IRF family. *Type II IFN*: The type II (IFN- γ) receptor is composed of two subunits, which are associated with the kinases JAK1 and JAK2. After binding of the dimeric IFN- γ the chains oligomerize (3). In contrast to type I IFN signaling pathway, the IFNGR-associated kinases only recruit STAT1 molecules to a C-terminal IFNGR1 sequence containing several tyrosine residues phosphorylated previously. The STAT1 molecules are also phosphorylated and dissociate from the receptor to form a homodimer (4) known as γ -activated-factor (GAF), which in the nucleus recruits additional transcription factors to form the STAT1 coactivator complex and interacts with defined elements of IFN- γ -inducible gene promoters named γ -activated-sequences (GAS) to stimulate gene expression. In cells constitutively secreting IFN- α/β – such as macrophages and embryonic fibroblasts – the IFNAR1 chain is constitutively phosphorylated. Through association with the nonligand-binding chain IFNGR2 (5) the phosphorylated IFNAR1 contributes to type II IFN signaling by providing phosphorylated STAT2 molecules that enable ISGF3 assembly (6) and activation of the ISRE in type I IFN-inducible gene promoters. IFN- γ is also able to activate genes independently of STAT1. This signaling pathway is dependent on JAK1 and JAK2 (7).

IFN- γ , whereas on the other hand the IFN- γ induced antiviral activity is strongly reduced in cells lacking the IFNAR1 chain.

STAT signaling occurs within minutes following activation but also underlies rapid deactivation by cytoplasmic phosphatases or antagonistic factors such as members of the SOCS-proteins themselves induced by activated STATs. Another group of proteins called PIAS (proteins that inhibit active STATs) inhibit binding of activated STATs to their target DNA sequences

whereas members of the family of ubiquitin ligases promote proteasomal degradation of STAT molecules.

Oligonucleotide arrays ([▶microarray technology](#)) using cRNA prepared from IFN- α/β and IFN- γ treated cells have identified >300 inducible genes, displaying cell-type specific variations. Not all of these genes are exclusively inducible by IFNs, some of them being also activated by virus infection, dsRNA, LPS, or other cytokines. A number of genes, in particular those involved in cell proliferation, are inhibited by type I IFN.

The antiviral properties of IFNs against many viruses with different infection and replication strategies often rely on the concerted action of many induced genes and their molecular mechanism still remains obscure. In some instances, however, the antiviral activity against particular viruses can be attributed to specific genes. Depending on the type of virus, there is evidence for IFN-mediated inhibition of virus uptake by the cell, inhibition of viral transcription, of viral protein synthesis, or of virus maturation, and release from the cell. More specifically, IFN-induced genes include the IRF family of transcription factors, a wide range of enzymes, e.g., the 2',5'-oligoadenylate-synthetase (2',5' OASE), RNaseL, and the protein kinase PKR (see below) as well as factors governing immune responses. Among these are the ►**proteasome** subunits LMP2 and LMP7 and ►**MHC** molecules that are essential for antigen processing and presentation, respectively. Type I IFNs also non-specifically induce the proliferation of CD8⁺ memory T-cells that interact with antigen-presenting cells to elicit immune responses. This effect is indirect, mediated through the secondary induction of IL-15. Interestingly, type I IFNs also exert growth arrest and thus prevent the induction of apoptosis in both CD4⁺ and CD8⁺ memory T-cells. This fine-tuned balance seems to depend on the amount of IFN secreted from fibroblasts, stromal cells, and monocytic cells and contributes to the long-lasting persistence of memory T-cells in the immune system. Dysregulation of its synthesis, however, may prevent elimination of autoreactive T- and B-cells and may be associated, for instance with T-cell-dependent chronic joint inflammation or the presence of autoreactive antibodies.

IFN-induced proteins involved in cell growth inhibition are considered ►**tumor-suppressor genes** [1] as for instance p53 and its downstream target gene, the cyclin-dependent kinase inhibitor p21/waf, the transcription factors IRF-1, IRF-8, and members of the p200 family. The latter inhibit several transcriptional activators including the ►**proto-oncogenes** c-myc, c-fos, and c-jun and bind to the retinoblastoma protein (Rb), which is a major player in cell-cycle regulation (►**Cell Cycle Control**). Among the IRF group of transcription factors, “Interferon-Consensus-Sequence-Binding-Protein” (ICSBP/IRF-8) is specifically induced by IFN- γ and its expression is limited to cells of monocytic and lymphoid origin. Cytogenetic analyses have provided evidence for tumor suppressor activities of both IRF-1 and ICSBP/IRF-8. Blood samples from patients with chronic myelogenous ►**leukemia** (CML) exhibited impaired ICSBP expression, whereas deletion of the *ICSBP* gene in mice led to a CML-like syndrome. Chromosomal deletions or point mutations within the IRF-1 locus are among the most frequent cytogenetic abnormalities in myeloid leukemia and myelodysplastic syndromes,

and experimental deletion of the IRF-1 gene facilitates oncogenic transformation in vitro. The tumor suppressor gene p53 is induced by IFN and once activated by multiple phosphorylation – an IFN-independent process, mainly mediated through exogenous cellular stress factors – acts as a transcriptional regulator [3]. A salient feature of activated p53 is enhanced ►**apoptosis** of transformed cells.

From a certain size, tumor growth is dependent on blood vessel supply, a process defined as ►**angiogenesis**. This process is dependent on growth factors such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) and involves dissociation of endothelial cells and basement membranes of pre-existing vessels by way of matrix ►**metalloproteinases** (MMPs). IFNs are known to mediate angiostatic effects by inhibition of bFGF and MMP expression in tumor cells and induction of the chemokine CXCL10 (IP-10) in macrophages and may thus contribute to inhibition of tumor spreading.

A complicated interplay exists between both types of IFN and ►**nitric oxide** (NO), the details of which are still not clear. NO generated by ►**inducible nitric oxide synthase (iNOS)** in macrophages in response to IFN- γ plays an important role in host defense against viruses, bacteria, and eukaryotic parasites but has also been implicated in the pathogenesis of chronic inflammatory syndromes. In contrast as revealed by in vitro studies, type I IFN displays regulatory functions on iNOS induction elicited by pathogens: enhanced expression in the presence of both pathogen and IFN but inhibition following pretreatment with type I IFN.

IFN-induced mediators of antiviral activity include a large number of proteins. The best studied are the Mx proteins, the kinase PKR, and guanylate-binding proteins (GBP) displaying GTPase activity. Additional IFN-induced genes with potent antiviral activity are ISG20, coding for a cytosolic RNase specific for several ssRNA viruses and ISG15, coding for a secreted ubiquitin-like protein.

The pathway leading to 2',5' OASE/RNaseL activation also contributes to the antiviral and antiproliferative effects of IFN- α/β . Both are induced by IFNs but require dsRNA or viral infection for activation. 2',5' OASE polymerizes ATP into 2',5'-linked oligoadenylates (2–5A) of different lengths. In turn, these molecules bind to and activate the latent RNaseL, which is also involved in IFN-mediated apoptosis. Much attention has also been attributed to the serine-threonine kinase PKR. In the presence of dsRNA, PKR undergoes autophosphorylation and phosphorylates selected cellular proteins such as the translation-initiation factor eIF2 α . Phosphorylation inactivates eIF2 α leading to an arrest of cellular protein synthesis. Most importantly, PKR displays the properties of a tumor suppressor since its inactivation in vitro causes malignant transformation

and prevents apoptosis of virus-infected cells. In addition to PKR and RNaseL, a variety of other proteins participate in the initiation of ►apoptosis; for instance p53, IRF-1, and TNF-Related-Apoptosis-Inducing-Ligand (TRAIL) induced by type I and type II IFN. The selective induction of TRAIL in T-cells and fibroblasts may also represent an important component of host defense against virus-infected or tumor cells. Due to its rather specific action on malignant cells and few adverse effects *in vivo*, TRAIL is a promising anti-tumor agent for clinical trials. Finally, in a tumor line a heterogenous group of IFN- γ induced Death-Associated-Proteins (DAP) has been identified and characterized. Each of these findings reveals that programmed cell death is part of the IFN-mediated cellular defense and reveals that elimination of infected cells is an efficient means for an organism to combat virus infection.

Type I and type II IFNs are also involved in bone homeostasis by regulating the differentiation of ►osteoclast progenitors. In these cells differentiation is mediated by the “receptor activator of NF κ B ligand” (RANKL), a cytokine belonging to the ►tumor necrosis factor (TNF) family. IFN- γ inhibits one of the downstream targets of RANKL, TRAF6 (TNF-receptor activated factor) thus preventing activation of NF κ B and c-jun kinase JNK. Most interestingly, another RANKL-signaling factor is the protooncogene c-fos which not only promotes osteoclastogenesis but also stimulates IFN- β expression via a novel mechanism probably involving the AP-1 transcription factor complex. In a negative feedback mechanism, IFN- β suppresses c-fos expression which ultimately maintains a fine-tuned balance of bone metabolism. Accordingly, *IFN- β* or *IFNARI*-deficient mice show disturbed trabecular bone architecture with reduced bone mass.

Clinical Use

IFNs were the first therapeutic products resulting from recombinant DNA technology. In view of their pronounced antiproliferative effects, crude preparations of natural leukocyte IFNs were already being used for the treatment of various tumors well before the availability of recombinant material. However, due to limited supply, the number of patients and duration of treatment did not allow for the evaluation of long-lasting beneficial effects. Today, numerous clinical trials have been conducted for a variety of different human diseases. Based on the results, approved indications have been formulated for the therapeutical application of IFNs (Table 1). Most of the responding tumors are of hematopoietic origin. IFN- α has therapeutic potentials for multiple myeloma, low-grade non-Hodgkin lymphoma, cutaneous T-cell lymphoma, and adult T-cell lymphoma. The overall response rates in hematological tumors were comparable to ►chemotherapy. Combination regimen mainly using recombinant IFN- α 2 and chemotherapeutic drugs yielded promising results with even higher rates of complete hematologic remissions and survival. For patients with hairy cell leukemia, a rare chronic lymphoproliferative disorder, IFN- α is the therapeutic agent of choice with overall response rates of 75%. Generally used treatment schedules consist of daily parenteral application for 6 months followed by maintenance treatment 3 times weekly for 1 year. Fortunately, in patients with hematologic relapses, readministration of IFN- α is successful in most cases. Good response rates have also been obtained for IFN- α treatment of CML. This hematopoietic stem cell malignancy is characterized by a reciprocal translocation of chromosomes 9 and 22, giving rise to the constitutive expression of the chimeric

Interferons. Table 1 Approved indications for interferon therapy either as adjuvant or for monotherapy

Malignancy class	IFN- α	IFN- β
Hematological malignancies	Hairy cell leukemia	
	Chronic myelogenous leukemia	
	Multiple myeloma	
	Low-grade non-Hodgkin-lymphoma	
	Adult T-cell lymphoma	
	Cutaneous T-cell lymphoma	
Other malignancies	Metastatic renal cell carcinoma	
	Metastatic melanoma	
	Kaposi sarcoma	
Virus-associated benign tumors		Anogenital warts
		Juvenile laryngeal papilloma
Viral diseases	Hepatitis B	
	Hepatitis C	
Diseases of unclear etiology		Multiple sclerosis

BCR-ABL tyrosine kinase that is essential for malignant transformation. Cytogenetic responses to IFN- α therapy were seen in 30–40% of the treated patients with complete responses in about 10%. Long term survival can therefore be expected in these patients. In 2000, the BCR-ABL tyrosine kinase inhibitor Imatinib has been introduced for CML therapy and meanwhile has proven more efficient than IFN- α therapy.

Metastatic renal cell carcinoma has a poor prognosis and resists conventional chemotherapy. Immunotherapy with IL-2 and/or IFN- α is currently regarded as the most effective therapy with, however, modest response rates of 15–20%. Similar results are also observed in patients with metastatic melanoma and the response to IFN- α and IL-2 correlates with the occurrence of tumor-infiltrating CD4⁺ T-lymphocytes identified in aspirates from melanoma metastases. Determination of these cells therefore seems to be a method to predict responders prior to the initiation of cytokine therapy.

Kaposi sarcoma (KS) – an angiogenic-inflammatory neoplasm – is the most prevalent cancer in ►HIV-infected patients and its appearance is preceded by infection with human Herpesvirus-8 (HHV-8). Although chemotherapy has become the treatment of choice approved by the FDA, there are also good response rates in patients treated with IFN- α . Fortunately, today highly active anti-retroviral therapy (HAART) has dramatically decreased the incidence of KS in AIDS patients.

Although there has been substantial success using IFN for the treatment of some cancers, until this point, the great majority of tumors are resistant or show an initial moderate response soon followed by disease progression under treatment. One likely reason for resistance is the progradient loss of susceptibility to IFN, which may be caused by downregulation of IFN receptors or perturbation of intracellular IFN-signaling pathways, a phenomenon also known from *in vitro* studies.

Since their discovery in 1957, type I IFNs have been noted to have protective effects against human viral infections. This is why, apart from malignancies, diseases of viral etiology have been successfully treated with IFNs. For anogenital warts, a commonly acquired sexually transmitted disease caused by Human Papilloma Viruses (HPV), the most effective response is obtained after intralesional administration of IFNs in contrast to systemic treatment that only prevents the development of new warts. Juvenile laryngeal papilloma is a rare but severe benign lesion also caused by HPV infection and mainly observed in childhood. Recurrence is a characteristic feature of this disease and calls for repeated surgical removal. Treatment with type I IFN has proven highly effective most importantly in preventing recurrence of lesions.

Successful treatment with IFN- α also includes patients with chronic ►hepatitis B virus (HBV) infections. Despite the availability of an efficient vaccine, chronic

HBV infection remains a major worldwide public health problem. The World Health Organization estimates that there are still 350 million chronic carriers of the virus, who are at risk of developing chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma. The success of IFN- α treatment – mainly performed as combined treatment with adenine-araboside – has been measured by the normalization of liver enzymes, loss of HBe antigen and of detectable viral DNA in the serum of patients. It has been estimated from several clinical trials that as many as 40% of treated HBV patients would respond to therapy with IFN- α or combined treatment with nucleoside analogues and IFN- α .

Similar to HBV, infections with ►hepatitis C virus (HCV) have a high rate of progression from an acute to a chronic state that frequently leads to cirrhosis or hepatocellular carcinoma [2]. Monotherapy for HCV infection with IFN- α or combined therapy with ribavirin and IFN- α is associated with initial rates of response as high as 40%. The rates of sustained responses are, however, lower and also depend on the viral genotype. In patients infected with HCV genotype 2 or 3, the response was maximal after 24 weeks of treatment, whereas patients infected with genotype 1 – the most frequent in the USA and Europe – required a minimum treatment course of 48 weeks for an optimal outcome.

Some improvement of clinical symptoms has been obtained with IFN- β monotherapy of multiple sclerosis (MS) although a definite cure has not been reported, even after treatment for years at highest tolerable doses 3 times weekly. The beneficial effects of IFN- β consist of significantly reduced clinical attack and relapse rates and delay of disability progression and are clearly dose-dependent with highest doses achieving maximal clinical responses. This chronic inflammatory disease of the central nervous system (CNS) is assumed to result from autoaggressive T-cell-mediated immune responses to self antigens such as myelin basic protein (MBP) but also to neurons. Stimulated by proinflammatory cytokines like IL-1, TNF- α , IFN- γ , and cellular adhesion molecules these T-cells and also macrophages cross the ►blood–brain barrier and gain access to the CNS. The trans-endothelial migration process involves the release of MMP, which cleave type IV collagen, a component of the blood–brain barrier. ►Astrocytes and microglia in the CNS are activated by the infiltrating immune cells, resulting in a chronic inflammatory process with irreversible axonal damage. The mechanism of the favorable response of MS to IFN- β treatment most likely resides within its immunoregulatory effects on the autoreactive T-cells. In this context, the therapeutic effects most likely are repression of IL-2 receptor expression and of IL-2 dependent release of MMP-2 and MMP-9 in a dose-dependent manner, resulting in inhibition of T-cell migration across the blood–brain barrier. In addition,

IFN- β reduces the induction by inflammatory cytokines of ►adhesion molecules and of ►MHC class I and II complex on endothelial cells, a process preceding attachment and transendothelial migration of T-cells. These anti-inflammatory effects of IFN- β exemplify antagonistic actions of type I and type II IFN. There is, indeed, much clinical evidence for the involvement of IFN- γ in inflammatory processes – through activation of iNOS and subsequent secretion of NO – leading to the establishment of ►autoimmune diseases as for instance in rheumatoid arthritis.

On the other hand, IFN- α may also be involved in the activation of autoreactive T-cells as has been proposed for type I diabetes. An IFN- α inducible ►superantigen, encoded by the truncated envelope gene of a human endogenous retrovirus and specifically activating V β 7 T-cells, has been detected in pancreatic lesions from type I diabetes patients, infiltrated by V β 7 T-cells. Since IFN- α expression could be detected in pancreatic β cells in concert with persistent viral infections, there is a clear link between viral infections and autoimmunity via IFN- α -stimulated ►superantigen expression.

Side Effects of IFN Therapy

During clinical trials aimed at defining the optimal IFN dose for therapy, various side effects became manifest with increasing doses. The most common side effects that develop independently of the IFN preparation used are transient nausea, skin reactions, chills, and fever, the latter two often being managed by prophylaxis with ibuprofen and paracetamol. In addition, however, therapeutic effectiveness is compromised by more severe secondary effects such as myelosuppression, cardiomyopathy, and impaired renal function requiring limitation of IFN therapy. Thyroid dysfunction resulting in ►hypothyroidism is also a known complication during IFN therapy in 10–20% of patients and may be caused by an autoimmune reaction. Fatigue is a common symptom of hypothyroidism and accounts for the most frequent side effect, reported in up to 50% of treated patients. IFN-mediated fatigue is recognized as a complex neurophysiologic phenomenon that is not transient but worsens with ongoing IFN therapy and may finally result in cognitive slowing, general lethargy, and depression. Finally, a substantial number of patients develop neutralizing antibodies during IFN treatment and their presence is associated with a poor therapeutic response. Most of these antibodies are specific for nonglycosylated, recombinant type I IFN.

In addition, clinical observations in IFN- α -treated hepatitis C or melanoma patients have suggested a promoting effect of type I IFN in autoreactive skin disorders such as *Lichen planus*. This inflammatory skin disease was, however, not restricted to IFN- α treated patients but was found to be associated with expression by so far unknown mechanisms of the IFN-induced MxA

protein and the appearance in skin biopsies of both ►chemokine receptor CXCR3⁺ lymphocytes and cells expressing the CXCR3 ligand CXCL10/IP10, which also represents an IFN-induced gene.

Second Generation IFNs

Improvements in therapy are expected through the development of “second generation” IFN. Reduced immunogenicity and enhanced stability have been reported for pegylated IFN- α , a conjugate of recombinant IFN- α and monomethyl-polyethylenglycol. Pharmacokinetic studies comparing pegylated and nonpegylated IFN- α preparations have revealed an increase of biological half life from 4 to 30 h and a sevenfold delay in the mean elimination time. Currently, pegylated IFN- α 2 in combination with ►ribavirin is considered the treatment of choice for chronic hepatitis C. For IFN- β , a complex with the soluble portion of the ligand-binding receptor chain IFNAR2 was tested in preclinical studies and showed a prolonged clearance and potentiated biological effects.

Interleukin-1 (IL-1)

The interleukin-1 (IL-1) family of proteins currently comprises IL-1 α , IL-1 β , and the IL-1 receptor antagonist (IL-1RA). The biological activities of IL-1 are shared by IL-1 α and IL-1 β , whereas IL-1RA is a true receptor antagonist. IL-1 is a key player in acute and chronic inflammatory diseases. Whether IL-1 has a role in normal physiology is still unresolved. IL-1 can

activate a wide range of cells important in both immunity and inflammation and is a promising novel target of anti-inflammatory therapy.

Intermediate Filaments

Intermediate filaments are present in most animal cells. They are composed of more than 50 proteins which are expressed in a cell-type specific manner. Their diameter is about 10 nm and thus between those of the larger microtubules and the smaller F-actin. They form scaffolds and networks in the cyto- and nucleoplasm.

- ▶ Cytoskeleton

Intermediate-density Lipoprotein (IDL)

Lipoprotein formed by hydrolysis of triglycerides in VLDL; elevated in type III hyperlipoproteinemia.

- ▶ Lipoprotein Metabolism

Intermittent Claudication

Cramping sensation in the leg or buttock precipitated reproducibly by walking or exercise that occurs as a result of decreased oxygen supply due to severe atherosclerotic disease of the peripheral vascular system. It typically subsides after a brief rest.

- ▶ Atherosclerosis

Internalization

Internalization is an agonist-induced endocytosis of membranous receptors which occurs in seconds to minutes. It involves the formation of receptor containing

vesicles (e.g., clathrin-coated pits) and is followed by an endosomal acidification permitting dephosphorylation of the receptor and dissociation of the agonist. Internalized receptors are recycled to the cell surface or degraded in lysosomes.

► Tolerance and Desensitization

International Normalized Ratio (INR)

The international normalized ratio (INR) is a method to standardize reporting of the ► **prothrombin time**, using the formula, $INR = (PT_{\text{patient}}/PT_{\text{control}})^{ISI}$, where PT indicates the prothrombin times (for the patient and the laboratory control), and ISI indicates the “international sensitivity index,” a value that varies, depending upon the thromboplastin reagent and laboratory instrument used to initiate and detect clot formation, respectively.

► Anticoagulants

Intima

The innermost layer of an artery, which consists of loose connective tissue covered by a monolayer of ► **endothelium** that resides on a basement membrane. In human arteries, the intima often contains resident smooth muscle cells even early in life. Atherosclerotic plaques form in the intima.

► Atherosclerosis

Intracellular Transport

Definition

The term intracellular transport comprises both the correct targeting and the mechanism of transport of

newly synthesized proteins and lipids to their destination and their retrieval from organelles and the plasma membrane to maintain the structural and functional organization of a eukaryotic cell.

Basic Mechanisms

At any given time, a typical eukaryotic cell carries out a multitude of different chemical reactions, many of them mutually incompatible. Therefore, cells have developed strategies for segregating and organizing their chemical reactions. Thus, e.g., multi-enzyme complexes have evolved. Of particular importance in this respect are the membrane-bounded compartments, such as the nucleus, endoplasmic reticulum (ER), Golgi apparatus, lysosomes, endosomes, peroxisomes and mitochondria. The specialized functions of each organelle require distinct protein and lipid compositions. Since, a cell cannot usually make these organelles from de novo, information is required in the organelle itself. Thus, most of the organelles are formed from pre-existing ones, which are divided during the cell-division cycle and distributed between the two daughter cells. Thereafter, organelle growth needs a supply of new lipids and proteins. Even in resting cells, lipids and proteins must be continuously delivered to organelles; some for eventual secretion from the cell, and some to replace molecules that have been degraded due to their physiological turnover. Therefore, the problem of how to make and maintain organelles is largely one of how to direct newly synthesized lipids and proteins to their correct destinations.

The synthesis of virtually all proteins in a cell begins on ribosomes in the cytosol (except a few mitochondrial, and in the case of plants, a few chloroplast proteins that are synthesized on ribosomes inside these organelles). The fate of a protein molecule depends on its amino acid sequence, which can contain sorting signals that direct it to its corresponding organelle. Whereas proteins of mitochondria, peroxisomes, chloroplasts and of the interior of the nucleus are delivered directly from the cytosol, all other organelles receive their set of proteins indirectly via the ER. These proteins enter the so-called ► **secretory pathway** (Fig. 1).

Stations of The Secretory Pathway

The journey along the secretory pathway begins with the targeting of the nascent polypeptide chain to the ER by a hydrophobic signal sequence. This signal sequence interacts with the signal recognition particle complex and the growing polypeptide chain is translocated across the ER membrane to the ER lumen or inserted into the ER membrane via a translocation pore. On the luminal side of the ER, various chaperones associate with the polypeptide chain in order to mediate translocation and to control and support correct folding. In addition, the newly synthesized protein undergoes co- and post-translational modifications, i.e. glycosylation, disulfide

Intracellular Transport. Figure 1 Model of intracellular transport within a mammalian cell. Export from the ER to the IC occurs in COPII vesicles. Anterograde transport from the *cis*- to the *trans*-side of the Golgi is mediated by COPI vesicles. COPI vesicles are also involved in retrograde traffic from the Golgi to the ER. Sorting and transport at the exit side of the Golgi to organelles of the endocytic pathway and to the plasma membrane is mediated by clathrin vesicles. Additionally, other types of vesicles may be involved in sorting at the Golgi-exit.

bond formation and oligomerization. Once the protein is properly matured, it passes the quality control of the ER and exits the compartment via transport vesicles. Protein transport from the ER to the Golgi complex involves the ER-Golgi intermediate compartment (IC), also termed 15°C compartment or vesicular tubular clusters. Although the nature as a stable compartment of the IC is discussed controversially, it is generally accepted that the IC plays a role as a sorting station of anterograde and retrograde membrane flow. Subsequently, en route through the secretory pathway, the secretory proteins next enter the Golgi apparatus at the *cis*-Golgi network (CGN). They continue their passage through the several sub-compartments of the Golgi (CGN, *cis*-, *medial*-, *trans*-Golgi and *trans*-Golgi network (TGN)), where proteins are subjected to various kinds of post-translational processing, e.g. remodeling

of *N*- and *O*-linked oligosaccharide side chains, sialylation and tyrosine sulfatation. Once a protein has reached the exit side of the Golgi, the *trans*-Golgi network, it has to be sorted to its final destination.

Transport Through The Secretory Pathway

The various transport steps between the stations of the secretory pathway are linked by a membrane flow, which is mediated by transport vesicles. In general, vesicles are formed from their donor membrane upon recruitment of coat proteins. Thereafter, the vesicles move to their target membranes where they dock. After uncoating they fuse with the target membranes. Export from the ER is the first step in the vectorial movement of cargo through the secretory pathway. The generation of vesicles from the ER is driven by the recruitment of a set of soluble proteins from the cytoplasm to the ER membrane that form a coat

structure, termed COPII. Components of the COPII coat have initially been identified as Sec (Sec for secretion) mutants of the yeast *S. cerevisiae* causing defects at distinct steps of intracellular transport. This led to the identification of three soluble protein components that make up the coat of ER derived transport vesicles: Sar1p, Sec23p complex and Sec13p complex. Sar1p is a small GTP-binding protein with a molecular mass of 21 kDa that shares primary structure identity with GTPases of the Ras family. The Sec23p complex is composed of two proteins: Sec23p, a 85 kDa protein and a tightly associated protein of 105 kDa called Sec24p. The Sec13p complex contains the 34-kDa subunit Sec13p and the 150-kDa protein Sec31p. The initial step of ►COPII vesicle formation is the recruitment of Sar1p-GTP to the ER membrane through a guanine nucleotide exchange reaction catalysed by the integral ER-membrane protein Sec12p. Next, the Sec23p complex is recruited, a prerequisite for binding of the Sec13p complex. As mentioned above, fusion of vesicles requires prior dissociation of the coat. Uncoating of COPII vesicles is achieved by hydrolysis of Sar1p-bound GTP, an action catalysed by Sec23p, part of the coat complex. GTP hydrolysis results in the dissociation of Sar1p from the vesicle membrane followed by the removal of the coat.

Anterograde transport of material from the *cis*- to the *trans*-side of the Golgi and also retrograde transport back from the Golgi to the ER is mediated via COPI coated vesicles. *In vitro* generation of ►COPI vesicles from isolated Golgi membranes has allowed their biochemical characterization. Components that make up the coat of COPI vesicles are the cytosolic proteins ADP-ribosylation factor 1 (ARF1) and ►coatamer, a stable heteroheptameric protein complex. ARF1, like Sar1p, belongs to the family of Ras GTP-binding proteins. The coatamer complex consists of seven different subunits termed [α , β -, β' -, γ -, δ -, ϵ - and ζ -COP (COP for coat protein)], present in a one by one stoichiometry in both the cytosolic and the membrane-associated form of the coatamer complex. Recently, an additional isoform of γ - and of ζ -COP was identified. The new isoforms are termed γ_2 - and ζ_2 -COP, and the original isoforms are referred to as γ_1 - and ζ_1 -COP. Each isoform is, like the other coatamer subunits, present in just one copy resulting in three different main heptameric protein complexes with only minor amounts of $\gamma_2\zeta_2$ -coatamer.

Similar to COPII, the formation of COPI-coated vesicles is initiated by recruitment from the cytoplasm to the membrane of the GTP-binding protein ARF1. Membrane binding and activation of ARF1 is triggered by the exchange of GDP for GTP, a reaction that requires catalysis by a nucleotide exchange factor. Several exchange factors for ARF1 have been characterized to date, all of them are soluble proteins found in the cytoplasm. An important difference between COPI

and COPII is the GTP hydrolysis reaction needed for uncoating. While for COPII disassembly Sar1p-mediated GTP hydrolysis is activated by the coat protein Sec23p, acceleration of GTP hydrolysis in ARF1 needs the activation by ARF-specific GAPs (GTPase activating proteins), which are recruited from the cytoplasm to the membranes.

Along their route through the Golgi, secretory and membrane proteins destined for the various post-Golgi pathways are intermixed. Thus, proteins of distinct routes, i.e. the endosomal and the secretory route, are sorted into individual types of transport vesicles at the TGN. Among the best characterized types of TGN-derived vesicles are ►clathrin-coated vesicles. In addition, several types of non-clathrin-coated vesicles have been identified but their specific functions remain to be characterized.

Biochemical characterization of clathrin-coated vesicles revealed that their major coat components are ►clathrin and various types of adaptor complexes. Clathrin assembles in triskelions that consist of three heavy chains of approximately 190 kDa and three light chains of 30–40 kDa. Four types of adaptor complexes have been identified to date, AP-1, AP-2, AP-3 and AP-4 (AP for adaptor protein). Whereas AP-1, AP-3 and AP-4 mediate sorting events at the TGN and/or endosomes, AP-2 is involved in endocytosis at the plasma membrane. Each adaptor complex is a heterotetrameric protein complex, and the term ‘adaplin’ was extended to all subunits of these complexes. One complex is composed of two large adaptins (one each of $\gamma/\alpha/\delta/\epsilon$ and β_1 –4, respectively, 90–130 kDa), one medium adaptin (μ 1–4, <50 kDa), and one small adaptin (σ 1–4, <20 kDa). In contrast to AP-1, AP-2 and AP-3, which interact directly with clathrin and are part of the clathrin-coated vesicles, AP-4 seems to be involved in budding of a certain type of non-clathrin-coated vesicles at the TGN.

A pre-requisite for clathrin-coat assembly is the recruitment to the membrane of an adaptor complex. Similar to what has been observed for the recruitment of coatamer to Golgi membranes, adaptor binding is dependent on the presence of ARF-GTP. However, in contrast to COPI vesicle formation, ARF-GTP is suggested to act in a process before budding and not as a stoichiometric coat component. Other differences between COP-coated and clathrin-coated vesicles concern their uncoating mechanism. Disassembly of clathrin-coated vesicles is believed to depend on the chaperone HSC 70 and on auxilin.

Membrane Proteins in Vesicle Formation and Cargo Selection

Formation of vesicles is likely to require interaction with the soluble coat components of cytoplasmic domains of certain integral membrane proteins that may serve as

coat receptors. Likewise, interaction of cytoplasmic domains of membrane cargo proteins with coat components may result in their selective packaging in a certain type of transport vesicle. Sorting of soluble cargo requires involvement of transmembrane receptors, which may couple sort in the lumen of an organelle to coat assembly at the cytoplasmic surface. The expected properties of a transmembrane cargo receptor include one or more transmembrane domains, a luminal domain able to interact with cargo species, and a cytoplasmic domain that interacts with coat subunits. Further, such proteins must cycle between the donor and the acceptor organelle. Coupling of coat assembly and cargo selection is best understood for clathrin-coated vesicles. The best known example for a cargo/coat-receptor is the ►mannose 6-phosphate receptor of TGN-derived clathrin-coated vesicles. On the luminal side, the receptor recognizes a mannose 6-phosphate signal of lysosomal hydrolases. On the cytoplasmic face, the receptor tail interacts with AP-1, thus initiating coat assembly. Sorting of membrane proteins into TGN-derived clathrin-coated vesicles has been shown to depend on a tyrosine-based motif (YXXF, where F can be replaced by a bulky hydrophobic amino acid) similar to the signal established for internalization via AP-2 at the plasma membrane. Sorting of membrane cargo into COPII pre-budding complexes was described for several proteins, and is believed to be mediated via an interaction with the Sec23p complex. For sorting of soluble cargo into retrograde COPI-coated vesicles, two types of membrane proteins are known to date that fulfill the criteria for cargo/coat receptors. One is the ►KDEL receptor, a multi-spanning membrane protein that mainly localizes to the Golgi and recognizes a carboxy-terminal tetrapeptide (KDEL) of soluble luminal proteins. The KDEL-sequence has been shown to serve as a retrieval signal of soluble proteins that have escaped from the ER. Another type of vesicular transmembrane proteins is referred to the p24 family, some members of which have been found in both COPII- and COPI-coated vesicles. These type I membrane proteins share a common structural organization: a large luminal domain, one-membrane spanning domain, and a short cytoplasmic domain with two conserved motifs: a di-phenylalanine motif and a di-basic motif at the extreme C-terminus. Two members of the p24 family, p23 and p24, were the first transmembrane proteins to be identified in COPI-coated vesicles. Both proteins are abundant in Golgi membranes and are concentrated into Golgi-derived COPI-coated vesicles where they are present in approximately stoichiometric amounts relative to ARF1 and coatomer. These proteins bind directly to coatomer and cycle within the early secretory pathway. It was also shown that both proteins interact with COPII *in vitro* and that they form hetero-oligomeric complexes with various members of the

►p24-family (p25, p26 and p27). Reconstitution of COPI-coated vesicles from chemically defined liposomes revealed that p23 is part of the minimal machinery for budding of COPI-coated vesicles. The data presently available make the p24 proteins strong candidates for coat receptors.

Mechanism In Vesicle Fusion

Once a coated vesicle is formed, delivery of its cargo to the correct destination depends on the accurate and specific recognition of the target membrane and subsequent fusion. A conceptual framework for explaining how transport vesicles dock to an acceptor membrane was formulated in the ►SNARE hypothesis. This hypothesis states that the specificity of vesicle targeting is generated by highly specific complexes that form between membrane proteins of the vesicle (v-SNAREs) and membrane proteins of the acceptor membrane (t-SNAREs). Structural and biophysical studies have shown that the cytoplasmic domains of v- and t-SNAREs form α -helical bundles with high thermal stability. During pairing of cognate v- and t-SNAREs the cytoplasmic core domains build a rod-shaped coiled-coil complex that is composed of four α -helices. Formation of this stable complex pulls the vesicle and the target membrane in close proximity, thus providing the driving force for fusion. Thus, the SNARE-complex represents the minimal machinery needed for the fusion process, as has been shown by reconstitution in liposomes with defined proteins. In addition, specificity of SNARE-pairing is controlled by so-called tethering proteins and another class of GTP-binding proteins, the Rabs.

Pharmacological Intervention

Progress during the last few years to understanding the mechanisms that underlie transport of proteins and lipids within the secretory pathway, as well as the sequencing of the human genome revealed that many human diseases are due to defects in intracellular trafficking, like, e.g. I-cell disease and familial hypercholesterolaemia. Obviously, a better understanding at the molecular level of intracellular transport within the secretory pathway, combined with increasing knowledge of the molecular basis of 'transport diseases' will open ways to therapeutic interventions.

Intrinsic Efficacy

Efficacy in drug receptor theory was originally defined by R.P. Stephenson (1956) as a dimensionless quantity of excitation given to a receptor to induce a response. Furchgott (1966) refined the definition to intrinsic efficacy as the quantal unit of stimulus given to a single receptor by an agonist. Subsequent research indicates that receptors mediate behaviors in addition to physiological response (some independent of ligands such as ▶ **constitutive receptor activity**). Hence a more encompassing definition of intrinsic efficacy is the property of a ligand that causes the receptor to change its behavior toward the host cell.

- ▶ Drug–receptor Interaction

Intron

Noncoding region only found in eukaryotic genes. During transcription in the nucleus, RNA is generated from both introns and ▶ **exons** – the coding regions – but the introns are excised by RNA splicing when mRNA is produced. During this process, the splicing machinery recognizes defined splice sites in the RNA sequence.

- ▶ Exon

Inverse Agonist

Receptor ligands that induce cellular reactions opposite to those caused by natural agonists, i.e., hormones or neurotransmitters, are called inverse agonists. These compounds show “negative intrinsic activity” on their receptor. Inverse agonists are assumed to stabilize the receptor in the inactive form. They can be used for silencing constitutively active receptors. A majority of antagonists not only preoccupy the agonist binding site on a receptor without affecting its equilibrium between the active and inactive states, but rather stabilize the inactive receptor conformation, thereby acting as inverse agonists.

Inwardly rectifying K⁺ channels; Anomalous rectifiers;
►Kir channels

Definitions

Inward Rectifier Potassium Channels or ►Kir Channels are a class of potassium channels generated by ►tetrameric arrangement of one-pore/two-transmembrane helix (1P/2TM) protein subunits, often associated with additional beta-subunits. ►Kir channels modulate cell ►excitability, being involved in ►repolarization of ►action potentials (see Fig. 1), setting the ►resting potential (see Fig. 1) of the cell, and contributing to ►potassium homeostasis.

Basic characteristics: Inward Rectifier Potassium Channels or ►Kir Channels are a class of potassium channels generated by ►Inward Rectification, which decreased conductance upon depolarization. In classical inward rectifiers, rectification is “strong” and currents rapidly decline at voltages positive to the reversal potential (see Fig. 2). In other ►Kir channels, rectification is “weak” and currents decline only gradually at voltages positive to the reversal potential (see Fig. 2).

Inward Rectifier K⁺ Channels. Figure 1 The role of inward rectifier (Kir) channels in cardiac action potentials. Depolarization is generated and maintained by Na and Ca currents (I_{Na} , I_{Ca}). Voltage-gated K currents (Kv) and Kir channels contribute to repolarization and maintenance of a negative resting potential.

Inward Rectifier K⁺ Channels. Figure 2 High [K⁺] inside cells relative to outside results in “normal” rectification, whereby outward (positive by convention) potassium currents (I) when cells are depolarized (V_m is positive relative to E_K), are bigger than inward (negative) currents at hyperpolarized (negative) voltages. Inward or anomalous rectifiers show “strong” or “weak” inward rectification whereby outward currents are smaller than inward currents.

Basic Characteristics

Seven subfamilies of eukaryotic ►Kir channels, each sharing ~60% amino acid identity between individual members within each subfamily and ~40% identity between subfamilies, are known [1]. In addition, multiple prokaryotic ►Kir channels (Kirbac1.1–9) are now being identified in bacterial genomes. We will focus on the eukaryotic channels.

Kir1 subfamily. Kir1.1 (ROMK1, gene *KCNJ1*) [1] encodes a “weak” (see below) inward rectifier and is expressed predominantly in the kidney. Alternate splicing at the 5' end also generates multiple Kir1.1 splice variants, Kir1.1a (ROMK2) through Kir1.1f (ROMK6), some of which are ubiquitously expressed in various tissues, including kidney, brain, heart, liver, pancreas, and skeletal muscle. In the kidney the renal Kir1.1 channels control salt reabsorption.

Kir2 subfamily. Four distinct Kir2 subfamily members (Kir2.1–Kir2.4; *KCNJ2*, *KCNJ12*, *KCNJ4*, *KCNJ14*) have been cloned to date [1], all encoding classical “strong” inward rectifiers that differ in single channel conductance and in sensitivity to phosphorylation and other second messengers. Members of Kir2 subfamily are highly expressed in the heart and skeletal muscle, but also found in a number of other tissues (e.g., nervous system). Kir2 subunits are the key players in cardiac inward rectifier current ► I_{K1} present in atrial and ventricular myocytes. Kir2.1 is a predominant isoform in all species while Kir2.2 and Kir2.3 may also

contribute. Kir2.4 is believed to be restricted to neuronal cells in cardiac tissue.

Kir3 subfamily. Four members of the Kir3 subfamily (Kir3.1–Kir3.4: *KCNJ3*, *KCNJ6*, *KCNJ9*, *KCNJ5*) express G-protein activated “strong” inward rectifier ▶K channels (▶GIRK channels) underlying G-protein-coupled receptor-activated currents in heart, brain, and endocrine tissues. Functional channels require coassembly of two different subunits (Kir3.1 and Kir3.4). Several studies have provided evidence for a promiscuous coupling between the various members of the Kir3 subfamily.

Kir4 and Kir5 subfamilies. These subfamilies of ▶Kir channels (Kir4.1 and Kir4.2, *KCNJ10*, *KCNJ15*, Kir5.1, *KCNJ16*) are abundantly expressed in brain and kidney. Kir4.1 forms “weak” inward rectifier ▶K channels when expressed alone while Kir5.1 does not form homomeric channels. Coexpression of Kir4.1 and Kir5.1 subunits results in formation of channels with properties significantly different from those of homomeric Kir4.1 channels. Little is known about the physiological role of channels derived from Kir4 and Kir5 subfamilies, although they are clearly involved in generating glial ▶Kir channels. The activity of Kir5.1/Kir4.1 heteromeric channels is very sensitive to intracellular pH and this property is conferred predominantly by the Kir5.1 subunits.

Kir6 subfamily. Two members (Kir6.1, Kir6.2, *KCNJ8*, *KCNJ11*) of this subfamily encode ATP-sensitive K⁺ channels (K_{ATP}) that are inhibited by intracellular ATP and activated by ADP, thereby coupling cell metabolism to ▶excitability [2]. K_{ATP} channels are found in many tissues including ventricular and atrial cells (Kir6.2 in the cell membrane, Kir6.1 presumably in mitochondrial membranes). Functional expression of active channels requires coexpression of Kir6.x subunits with a sulfonylurea receptor (SUR1 or SUR2). K_{ATP} channels display “weak” rectification, allowing substantial outward current to flow at positive potentials, and thus causing ▶action potential shortening, or loss of ▶excitability, when activated, for example, during metabolic inhibition [2].

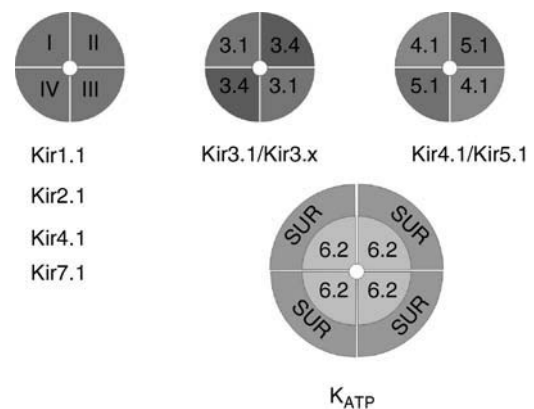

Kir7 subfamily. The only known member (Kir7.1, *KCNJ13*) is primarily expressed in brain, retinal pigment epithelium, but it is also found in a variety of other tissues, including kidney and intestine. This weakly rectifying channel has an apparently very low single channel conductance, very shallow dependence on external K⁺ and is virtually insensitive to intracellular Mg²⁺. The exact physiological role of this channel is obscure although suggestions are made that Kir7.1 may contribute to K⁺ recycling processes.

KirBac family. Multiple structurally related channel subunits are now being identified in bacteria, and by crystallization these provide templates for understanding Kir channel structure [3]. Functional roles in bacteria are unknown.

Molecular Structure of Kir Channels

All ▶Kir channels are ▶tetrameric proteins (see Fig. 3) of one-pore/two-transmembrane (1P/2TM) domain subunits which equally contribute to the formation of highly selective K⁺ channels. Most ▶Kir channels can be assembled in functional homotetramers while some require heteromeric assembly (see Fig. 3). For example, functional GIRK channels underlying IK_{ACh} (Acetylcholine-activated) current in atria are heteromultimers of two members of Kir3 subfamily: Kir3.1 and Kir3.4.

It should be noted that not all ▶Kir channels rectify strongly enough to fit the definition of classical rectification, such as observed in ▶cardiac I_{K1} channels. A feature of all K⁺ selective channels is the signature G-Y-G sequence within the pore loop (P-loop) (see Fig. 4) that acts as a filter, to confer high selectivity to K⁺ ions, and also contributes to single channel conductance and kinetics. Two transmembrane domains with N'- and C'-termini facing the cytoplasm flank the P-loop (see Fig. 4). The assembly of the Kir2.1 channel is supported by the presence of intrasubunit disulfide bonds between highly conserved cysteine residues (at positions 122 and 154) which are absolutely required for proper channel folding, although disruption of the bond with reducing agents does not disrupt channel activity once the channel is already assembled. Scanning cysteine mutagenesis studies of relatively large stretches of N- and C-termini of Kir2.1 reveal that nearly half of them are water accessible, and potentially facing the pore, in addition to residues in the second transmembrane region. There is accumulating evidence that the overall structure of the core region of all ▶Kir channels is very similar to that of the recently crystallized bacterial KirBac1.1 channel [3]. Crystal structures of the cytoplasmic domains of eukaryotic Kir2.1 and Kir3.1 channels have also been

Inward Rectifier K⁺ Channels. Figure 3

Kir channels may be homo- or hetero-tetrameric complexes, in some cases in tight association with beta-subunits (e.g., the K_{ATP} channel). SUR – sulfonylurea receptor.

Inward Rectifier K⁺ Channels. Figure 4 Kir channel subunits consist of two transmembrane domains (M1, M2), separated by a pore loop (P-loop) that contains the signature K⁺-selectivity sequence (-GYG-), as well as extended cytoplasmic N⁻ and C-termini. Several residues (indicated) have been implicated in causing rectification (see text).

resolved, again showing the presence of wide intracellular vestibule, large enough to accept multiple permeating and blocking ions. Recent results suggest that cytoplasmic domains of ►Kir channels may undergo structural changes to modulate gating and inward rectification.

The Mechanism of Strong Inward Rectification

Inward or “anomalous” rectification of potassium permeability refers to increases of potassium conductance under hyperpolarization and decreases under depolarization, the effect opposite to that of “normal” outward or delayed rectification that is seen in voltage-gated K⁺ channels (see Fig. 2). Classical ►inward rectification is so strong that only small currents can be measured in the outward direction at voltages positive to the K⁺ reversal potential (E_K) while large inward currents can be easily observed negative to it. This strongly voltage-dependent rectification also strongly depends on the concentration of external K⁺ ($[K_{OUT}]$), such that increasing K_{OUT} relieves the rectification, so that the mid-point voltage of rectification shifts nearly perfectly with corresponding change in E_K . It is now established that strong ►inward rectification results primarily from voltage-dependent block by intracellular organic cations called ►polyamines [1]. Of the ►polyamines, ►spermine (see Figs. 5 and 6) and ►spermidine are the most potent inducers of rectification although contributions of putrescine and of Mg²⁺ ions are also important. Both the steady-state and the kinetic properties of rectification result from the combined action of ►polyamines and Mg²⁺ ions. Micromolar concentrations of free ►spermine and ►spermidine are sufficient

Inward Rectifier K⁺ Channels. Figure 5 Proposed three-dimensional arrangement of the transmembrane region of Kir channels. Two of four subunits are indicated. The pore consists of a selectivity filter close to the outside part of the membrane, a central inner vestibule, and a cytoplasmic entrance. Spermine may block in the inner cavity or in the selectivity filter. Large intracellular vestibule where polyamines may also block the channel is not shown.

Inward Rectifier K⁺ Channels. Figure 6 Spermine (Amino-propyl-amino-butyl-amino-propyl amine) is a long linear naturally occurring polyamine containing four nearly equally spaced positively charged (at normal pH) amines. Although ~16 Å long, the molecule is only about 3 Å wide, similar to a dehydrated potassium ion.

to reproduce the degree of rectification seen in native cells [1]. Importantly, in cells the total ►polyamine levels are quite large (up to 10 mM), but most of polyamines are bound to various intracellular targets such as RNA, DNA, ATP and other primarily phosphate-containing molecules.

The degree of rectification varies greatly among members of the Kir superfamily and is fundamental to their respective functional roles. Kir2 and Kir3 encode classical “strong” inward rectifier channels, while other members encode channels with variably “milder” or

“weaker” rectification (see Fig. 2). For example, because of mild rectification of the K_{ATP} channel, its activation causes considerable shortening of the cardiac ▶action potential, thus reducing entry of Ca²⁺ through voltage-dependent Ca²⁺ channels and hence conserving ATP under conditions of metabolic stress. Conversely, the strong ▶inward rectification of Kir2.1 channels underlying I_{K1} current in the heart results in very small currents flowing through these channels during depolarization phase of ▶action potential while increased conductance around ▶resting potential leads to its stabilization [4].

Structural Elements of Inward Rectification

Each Kir subunit consists of two transmembrane helices (M1, M2), with a pore-forming selectivity filter linking them, and cytoplasmic N'- and C'-termini (see Fig. 4 and [3]). Based on the crystal structure of the related KirBac1.1 channel [3], the channel is proposed to be formed as a ▶tetrameric arrangement of these subunits, surrounding an external selectivity filter, an inner vestibule and a cytoplasmic entrance to the pore (see Fig. 3). Aspartate 172 located in the M2 region of Kir2.1 was the first residue implicated in the classical rectification of these channels and is sometimes referred to as the “▶rectification controller.” Later, a number of other residues in the C terminus of Kir2.1 were also shown to contribute to ▶polyamine-induced ▶rectification. Neutralization of some of these negatively charged amino acids may transform the strongly rectifying Kir2.1 channel into one that is nearly insensitive to blockage by ▶polyamines and Mg²⁺. Cytoplasmic residues located in the N terminus of Kir2.1, such as M84, may also be important for channel blockage by intracellular cations. At present the question about the exact location(s) of the binding sites for ▶polyamines remains controversial. Probably one ▶spermine molecule is required to completely block the channel, either within the inner vestibule, or perhaps within the selectivity filter itself. There have been reports that the Kir pore region may be “unprecedentedly wide” allowing simultaneous binding of three Mg²⁺ ions or three ▶polyamine molecules. Reconciliation of conflicting interpretations can probably be achieved by assuming that gating of ▶Kir channels may involve substantial conformational changes, including helix rotations and translational movements similar to those observed in the related bacterial *KcsA* channel [3]. The selectivity filter of Kir2.1 is probably the best candidate for the binding of *polyamines*. Despite the relatively large size of the ▶spermine molecule (~20 Å long) (see Fig. 3), its diameter is close to that of a dehydrated K⁺ ion, thus potentially allowing its head amine group to “squeeze” into the selectivity filter and block ion flow (see Fig. 6). ▶Polyamines may also permeate ▶Kir channels, and can clearly permeate, as well as block, other nonselective cationic channels, consistent with such an interpretation.

Known Diseases (Channelopathies) Resulting from ▶Kir Channel Mutations

Multiple ▶channelopathies resulting from mutations in ▶Kir channels are known.

Kir1.1. Bartter Syndrome. Several mutations in the core region as well as in the N' and C' terminus of Kir1.1 are found in patients with hyperprostaglandin E syndrome (HPS; renal disorder resulting from impairment of tubular reabsorption), an antenatal form of Bartter syndrome. Some of these mutations result in the loss of function of Kir1.1 channels causing impaired renal K⁺ secretion and NaCl reabsorption.

Kir2.1. Andersen's syndrome. Dominantly inherited Long QT syndrome (LQT), a disorder of cardiac ▶action potential repolarization is usually assigned to mutations in cardiac Na⁺ or voltage-gated K⁺ channels. Recently, it has been found that multiple mutations in *Kir2.1* cause Andersen's syndrome (LQT7), a rare disease characterized by periodic paralysis, cardiac arrhythmias, and dysmorphic features. Mutations in *Kir2.1* associated with Andersen's syndrome were found to cause dominant negative suppression of the wild type Kir2.1 channels when expressed in *Xenopus* oocytes or cultured cell lines thus mimicking the effects of the *Kir2.1* gene knock-out which is characterized by prolonged QT interval. Alternatively, mutation in the “▶rectification controller” of Kir2.1 channel (D172N mutation) was recently identified leading to a new form of Short QT syndrome (SQT3), which is characterized by a unique ECG phenotype. Another gain-of-function mutation in human *Kir2.1* gene (V93I) was also found to underlie a **familial atrial fibrillation**.

Kir3.2 Weaver mouse. A mutant mouse with cerebellar degeneration and motor dysfunction resulting from a serine for glycine substitution in the -GYG- sequence of the K selectivity filter of Kir3.2. G-protein activated K conductances are abolished in the cerebellar neurons, leading to Ca²⁺ overload and cell death.

Kir6.2/SUR Persistent Hyperinsulinemic Hypoglycemia of Infancy (PHHI) and Neonatal Diabetes. Lowered blood glucose normally causes decreased ATP/ADP ratios in the pancreatic islet β-cells, causing the opening of K_{ATP} channels, hyperpolarization, inhibition of Ca²⁺ entry and cessation of insulin secretion. In PHHI, K_{ATP} channel mutations lead to abolition of activity and hence maintained depolarization and maintained Ca²⁺ entry and insulin secretion. Many mutations in the SUR subunit abolish ADP activation of channels, but point mutations in Kir6.2 are implicated in abolition of channel activity in some cases. Conversely, K_{ATP} channel mutations that lead to increased activity and hence maintained hyperpolarization and failure of Ca²⁺ entry block insulin secretion and cause neonatal diabetes. Many mutations in the Kir6.2 and SUR subunits have now been identified, and

this has led to a change in therapy for the disease, from injected insulin to sulfonylurea pills [2].

Drugs

Voltage-dependent block by external Ba^{2+} and Cs^{+} ions, yet insensitivity to the Kv channel blocker tetraethyl ammonium (TEA) have been the classical tools to examine ►Kir channel activity. Recently, the honey-bee venom tertiapin has been found to be an effective blocker of certain (Kir1, Kir3) inward rectifier subfamily members. Tight association of Kir6 family members with SUR subunits endows K_{ATP} channels with a rich pharmacology: channel activity is very specifically inhibited by sulfonylurea drugs such as tolbutamide and glibenclamide, and is activated by a broad class of “potassium channel opening” (KCO) drugs such as pinacidil and diazoxide. A potent antiarrhythmic drug ►RP58866 and its active enantiomer RP62719 (known as ►Terikalant) has been shown to block IK_{ACh} (encoded by Kir3.x members) and ► I_{K1} (encoded by Kir2.x members) currents in the heart in the low micromolar range. Unfortunately, neither agent discriminates well between Kir and other ►K channels (e.g., underlying ►Ikr) and thus has not received much attention as a selective blocker for ►Kir channels.

Ion Channels

Ion channels are proteins which span the plasma membrane and can be opened by transmembrane voltage changes (voltage-dependent ion currents) or by binding of a neurotransmitter. Ion channels which are selective for Na^{+} or Ca^{2+} ions cause excitation, ion channels with selectivity for Cl^{-} or K^{+} usually cause inhibition of cells.

Ion channels are often multimeric and are regulated by a wide variety of mechanisms (e.g., ligand binding, voltage changes, phosphorylation).

HANNAH MONYER

Abteilung Klinische Neurobiologie, Interdisziplinäres Zentrum für Neurowissenschaften (IZN), Heidelberg, Germany

Definition

Most neurons in the central nervous system are stimulated by L-►glutamate, the major excitatory amino acid in the brain. The postsynaptic actions of

this neurotransmitter are mediated by two categories of glutamate receptors: the ionotropic glutamate receptors that directly gate channels and the metabotropic glutamate receptors that indirectly gate channels via second messengers. The ionotropic glutamate receptors can be further subdivided into N-methyl-D-aspartate (NMDA) receptors (▶NMDA receptor) and non-NMDA receptors, with AMPA (L- α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) and ▶kainate receptors constituting the latter group [1, 2]. These three major subtypes of ionotropic glutamate receptors are named according to their selective agonists NMDA, AMPA and kainate. These receptors mediate most of the fast excitatory neurotransmission in the brain.

NMDA- and AMPA receptors (▶AMPA receptor) are colocalized in the postsynaptic membrane of excitatory synapses. Glutamate released from presynaptic terminals binds to both types of receptors. Upon activation by glutamate, AMPA receptors generate the large early component of an excitatory postsynaptic current (EPSC) because of their rapid ▶gating kinetics. This synaptic current is mainly generated by Na^+ and K^+ , but not Ca^{2+} ions, since AMPA receptors in excitatory neurons are usually impermeable to Ca^{2+} . In contrast to this, NMDA receptors have relatively slow gating kinetics and contribute to the late component of the EPSC. The NMDA receptors are permeable for Na^+ and K^+ as well as Ca^{2+} ions and require extracellular glycine as a cofactor for activation. Most importantly, this activation is not only dependent on the presence of the agonist, but also depends on the membrane voltage. Therefore, the receptor is not involved in generation of the early component of the EPSC after the binding of glutamate. The channel gets activated only when the binding of glutamate plus the coagonist glycine and depolarization of the membrane occur at the same time. This voltage dependence is due to extracellular Mg^{2+} . At resting membrane potential extracellular Mg^{2+} binds tightly to a site in the pore and blocks the channel. Only at depolarized membrane potentials, which are generated by the AMPA receptors, Mg^{2+} is expelled from the pore by electrostatic repulsion, thereby lifting the Mg^{2+} block and Na^+ , K^+ and Ca^{2+} cations can cross the channel. Most neurons express both NMDA and AMPA receptors. However, the EPSC generated at resting membrane potential is mainly generated by activation of AMPA receptors. NMDA receptors do not contribute significantly to the EPSC since at membrane resting potential Mg^{2+} is blocking the channel. Only with increasing membrane depolarization NMDA receptors contribute to the EPSC, since Mg^{2+} is removed and ions flow through the channel.

Whereas the role of AMPA and NMDA receptors in fast synaptic transmission is well characterized, only few examples demonstrating synaptic responses due to kainate receptor activation are known so far.

Basic Characteristics

Sequence homologies and sometimes similarity in gene structure suggest a common evolutionary origin for all ionotropic glutamate receptors. The cloning of the ionotropic glutamate receptor genes revealed that NMDA, AMPA and kainate receptor subunits are encoded by at least six gene families (a single family for AMPA receptors, two for kainate, and two for NMDA receptors).

The primary structure of the cloned receptor subunit genes revealed prominent structural similarities between NMDA, AMPA and kainate receptors (Fig. 1). The transmembrane topology of these receptors is very different from that of other ionotropic channels. Members of other ionotropic receptor families, which are activated by acetylcholine, GABA (γ -aminobutyric acid) or glycine, contain four transmembrane segments. In contrast to these, the ionotropic glutamate receptor subunits contain three transmembrane domains (M1, M3 and M4) and a cytoplasm-facing membrane loop (M2), which connects the transmembrane domains M1 and M3 and forms the channel pore. Key amino acids in the M2 segment are responsible for the differences in ion selectivity displayed by the various receptor subunits. Two regions of the glutamate receptors are extracellularly located: the amino-terminus and the region between M3 and M4, which are involved in building the ligand-binding site. The carboxy-terminal part after M4 reaches into the cytoplasm of the cell and is important for intracellular modifications like phosphorylation or interaction with cytoplasmic proteins.

Both AMPA and NMDA receptors are multimeric, probably tetrameric, assemblies of various molecularly distinct subunits, giving rise to large receptor diversity. For AMPA receptors this is achieved by assembling the

Ionotropic Glutamate Receptors. Figure 1 Schematic structure of an ionotropic glutamate receptor subunit. The three transmembrane domains M1, M3 and M4 are shown as gray boxes, the membrane loop M2 forms the channel pore. The star indicates the position of key amino acids regulating the ion selectivity, e.g., the Q/R for AMPA, N for NMDA receptors. S1 and S2 designate the two ligand-binding domains. The alternatively spliced flip/flop exon occurs in AMPA receptors and is located extracellularly. Potential glycosylation sites are shown as trees in the N-terminal region.

receptor from four types of subunits, termed GluR (glutamate receptor)-A, -B, -C and -D (in an alternative nomenclature GluR1, GluR2, GluR3 and GluR4), with additional molecular diversity generated by ►RNA editing at the glutamine/arginine (Q/R) and arginine/glycine (R/G) site as well as alternative splicing of the flip-flop module. NMDA receptors are assembled from NR1 subunits and NR2A, B, C or D subunits. Several splice variants have been identified for the NR1 subunits, and the NR3 subunit, that has been identified recently, appears to be part of a glycine-gated channel. Kainate receptors are formed by subunits that can be divided into two subfamilies: the first subfamily contains the subunits GluR5, GluR6 and GluR7, whereas the second subfamily comprises KA1 and KA2. All subunits of the first group can form functional channels, whereas the subunits of the second group do not form homomeric channels. Several splice variants have been identified for the GluR5 and GluR7 subunits. This large number of combinatorial possibilities accounts for a considerable molecular diversity of glutamate receptor channels.

Recombinant expression of the AMPA receptor subunits has shown that homomeric AMPA receptors assembled from different subunits are different in a number of characteristics. These are mostly determined by the GluR-B subunit. Receptors formed from GluR-B subunits show low Ca^{2+} permeability whereas receptors assembled from GluR-A, -C and -D subunits are highly Ca^{2+} permeable. A single amino acid difference in the pore-forming segment M2 has been identified as the molecular determinant of the subunit-specific difference in Ca^{2+} permeability. Whereas the GluR-B subunit contains a positively charged arginine (R), the GluR-A, -C and -D subunits contain a neutral glutamine residue (Q) at this position. This amino acid exchange at the Q/R site is sufficient to abolish the permeability to Ca^{2+} , possibly through electrostatic repulsion, indicating that the Q/R site is the main determinant of the Ca^{2+} permeability in recombinant AMPA receptors. In native AMPA receptors, which are heteromeric assemblies, the Ca^{2+} permeability of recombinant receptors is determined by the GluR-B(R) subunits. Therefore strong differences in Ca^{2+} permeability can be observed between different cell types [1]. Excitatory neurons strongly express GluR-B(R), which leads to the formation of Ca^{2+} impermeable AMPA receptors. In contrast, inhibitory neurons express the GluR-B(R) subunit to a low extent and therefore contain AMPA receptors that are highly permeable to Ca^{2+} ions. The subunit composition and electrical properties of AMPA receptors can also vary in a synapse-specific manner within individual cells [6].

Interestingly, the genomic sequences of all AMPA receptor subunits contain a Q codon for this position and the R codon is selectively introduced into the GluR-B pre-mRNA by RNA editing [3]. Additionally, the Q/R site is a critical determinant of current

►rectification and single-channel conductance. In recombinant AMPA receptors, GluR-B(R)-containing channels show a linear current–voltage relation (I – V), whereas it is inwardly or doubly rectifying in AMPA receptors that only contain GluR-A, -C or -D subunits. It has been shown that this current rectification is due to a voltage-dependent block by intracellular ►polyamines, such as spermine or spermidine, which block GluR-B(R)-free but not GluR-B(R)-containing AMPA receptors. The physiological significance of this block is unknown, but it may act similar to the extracellular Mg^{2+} block of NMDA receptor channels. But whereas a single GluR-B(R) subunit per channel is possibly sufficient to abolish Ca^{2+} permeability, several GluR-B(R) subunits are necessary to suppress polyamine sensitivity. Another basic property of the AMPA receptor that is determined by the Q/R site is the single-channel conductance. If the receptor contains a GluR-B(R) subunit, it has a two- to three-fold lower single-channel conductance. Each AMPA receptor subunit exists as either a flip or a flop variant, which is determined by mutually exclusive splicing of an exon encoding a domain of 38 amino acids. Alternative splicing and editing of the GluR-B, -C and -D subunit at the R/G site influences receptor deactivation, desensitization and recovery from ►desensitization. The flip-flop module as well as the R/G site is probably located in the extracellular loop between M3 and M4, which is thought to be part of the agonist-binding site. This suggests relationships between agonist binding and gating properties of the receptor.

Functional NMDA receptors are heteromeric channels, which are composed of a principal NR1 subunit and modulatory NR2 subunits (NR2A, -B, -C and -D). They differ from AMPA receptors in several properties. Some of the most important properties are requirement for glycine for activation, the very high permeability for Ca^{2+} , the voltage-dependent block by extracellular Mg^{2+} and the slow gating kinetics. NMDA receptors require not only glutamate for activation, but also glycine as a coagonist. In the receptor the binding site for glutamate is generated by the NR2 subunit whereas the binding site for glycine is supplied by the NR1 subunit.

In contrast to AMPA receptors, NMDA receptor channels display a prominent Ca^{2+} permeability, which is largely independent of the subunit composition. It has been shown by mutational analysis that the Ca^{2+} permeability of recombinant NMDA receptors is dependent on a residue at a position equivalent to the Q/R site of AMPA subunits. Both NR1 and NR2 subunits contain an asparagine (N) residue at this position. Replacing this N with an R within the NR1 subunit led to the formation of NMDA receptors with a strongly reduced Ca^{2+} permeability, whereas exchanging N for Q in the NR2 subunit had only a small effect,

indicating that the N site of the NR1 subunit is the main determinant of the Ca^{2+} permeability of recombinant NMDA receptors. The situation is more complex for the other important property of the NMDA receptor, the extracellular Mg^{2+} block. Mutational analysis has revealed that the two residues downstream of the Q/R/N site are important for the control of the Mg^{2+} block. Furthermore, differences in Mg^{2+} sensitivity in the different NR1-NR2 combinations are generated at multiple locations throughout the subunit, including M1, the M1/M2 linker and the M4 segment.

Another characteristic distinguishing NMDA from AMPA receptors is the slow gating kinetics. Whereas recombinant AMPA receptors display deactivation time constants in the range of a few milliseconds, deactivation time constants for recombinant NMDA receptors are in the range of hundreds of milliseconds up to seconds, depending on which NR2 subunit is used to form the receptor. Furthermore it is worth mentioning that other factors than subunit composition can influence functional properties of both AMPA and NMDA receptors. Thus, there is growing evidence that *in vivo* receptor localisation (extrasynaptic versus synaptic) and auxiliary proteins and interactions with scaffolding complexes mediate and modulate signalling during neuronal development, synaptic plasticity and disease [7]. Desensitization of NMDA receptors is more complex than of AMPA receptors. At least three different forms have been described, all of which are mediated by the NR2 subunit.

The two kainate receptor subunits GluR5 and GluR6 undergo posttranscriptional modification similar to AMPA receptors. These two subunits also contain a Q/R site that is modified by RNA editing [3]. The Q/R site seems to have a strong influence on the functional properties of kainate receptors, similar to what has been observed in AMPA receptors. The GluR6(Q) subunit shows strong inward rectification whereas GluR6(R) does not rectify. And, like in AMPA receptors, the inward rectification of GluR6(Q) channels is most likely due to blocking of the channel by intracellular polyamines. But in contrast to AMPA receptors, where the GluR-B subunit is almost completely Q/R site-edited, significant proportions of the kainate subunits remain unedited. No editing occurs on the KA1 and KA2 subunit mRNAs, which carry a Q at the Q/R site. Editing of the Q/R site has a strong influence on single-channel conductance. Homomeric channels formed by edited subunits have a smaller single-channel conductance than homomeric channels formed by unedited subunits or heteromeric channels containing unedited subunits. Such a larger single-channel conductance for unedited receptors compared to edited receptors has also been observed for AMPA receptors. Desensitization and recovery from desensitization are different compared to other glutamate receptors. Whereas

desensitization of kainate receptors is very fast, recovery from desensitization is very slow.

Drugs

Changes in the physiological function of glutamate are thought to contribute to the pathogenesis of neurological diseases. Derivatives of quinoxaline-2,3-diones have long been shown to have an antagonistic effect on AMPA, kainate and NMDA receptor channels [4]. Representative examples of this group acting on AMPA receptors are 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) and 2,3-dihydroxy-6-nitro-7-sulfamoylbenzo(f)quinoxaline (NBQX). In addition to being glycine-site antagonists for NMDA receptors they have also been shown to be competitive antagonists for AMPA and kainate receptors, with a much higher affinity for AMPA and kainate receptors than for the glycine binding-site of the NMDA receptors. The advent of these compounds allowed the study of the mechanism of fast synaptic transmission by AMPA receptors as well as of their potential in neuroprotection. But due to their nephrotoxic side effects and their poor solubility in water they are of limited therapeutic importance.

NMDA receptors play key roles not only in synaptic plasticity, but also in neurological diseases such as epilepsy and neurodegeneration. NMDA hypofunction has been proposed to underlie some behavioural symptoms in schizophrenia. Their ability to participate in excitotoxic events is due to the high Ca^{2+} permeability, their high affinity for glutamate and their relative lack of desensitization. This has prompted extensive research for selective NMDA receptor antagonists [4]. Different types of antagonists have been developed, in part acting on different parts of the receptor. Compounds such as dizocilpine (MK-801), aptiganel, phencyclidine and ketamine are activity-dependent channel blockers. They need channel opening in order to bind to and block the receptor. Therefore, they are noncompetitive antagonists. Antagonists of the glutamate- and glycine-recognition site have also been developed. Antagonists against the glycine-recognition site such as kynurenic acid are of special interest because glycine is a coagonist at the NMDA receptor, but glutamate acts as the neurotransmitter. In contrast, glycine plays a more modulatory role, since it is always present in the extracellular fluid. Therefore, these antagonists would limit the level of NMDA receptor activation, but still allow for a certain physiological activation. Another approach taken is the development of subunit-selective compounds. One compound of this group of antagonists is ifenprodil and its derivatives Ro 25-6981 and CP-101,606 (traxoprodil). It is selective for the NR2B subunit and has a much lower affinity on receptors containing NR2A, C or D subunits. The action of ifenprodil is not only subunit-specific, but also state-dependent. It binds to the activated and desensitized receptor with a higher affinity than to a

receptor without a bound ligand, in this way exerting a stronger blockade on receptors continuously activated in a disease state whereas leaving normal fast synaptic transmission largely unaffected. A recently developed competitive antagonist for the NR2A-subunit in NVP-AAM077 that has been used to study the contribution of the NR2A subunit in synaptic plasticity and neurological diseases [8].

Antagonists selective for kainate receptors are not available yet. The non-NMDA receptor antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) blocks AMPA as well as kainate receptors. Nevertheless, compounds like GYKI 53655, which acts as a noncompetitive antagonist of AMPA receptors and completely blocks AMPA receptor function at certain concentrations at which no antagonistic effect on kainate receptors is discernible, has been used to demonstrate the kainate receptor-mediated currents in neurons.

Cambridge, UK

Synonyms

Inositol 1,4,5-trisphosphate receptor

Definition

Inositol 1,4,5-trisphosphate (IP₃) receptors are intracellular cation channels. They are expressed in most cells and predominantly within the membranes of the endoplasmic reticulum. They mediate release of Ca²⁺ from intracellular stores by the many receptors that stimulate IP₃ formation.

Basic Mechanisms

Ca²⁺ Signalling

Ca²⁺ is an intracellular messenger used by all eukaryotic cells. It regulates cellular activities through every stage of the lifecycle, from fertilization, through growth and differentiation, to controlling the specialized behaviours of differentiated cells, and ultimately in controlling cell death [1]. The ability of cells actively to extrude Ca²⁺ from their cytosol – a property that probably evolved in parallel with the use of ATP as an energy currency – provides steep Ca²⁺ concentration gradients across both the ER membrane and the plasma membrane. Controlled opening of Ca²⁺ permeable channels in either membrane then allows Ca²⁺ to flow rapidly down its electrochemical gradient, generating the increase in cytosolic Ca²⁺ concentration that ultimately regulates cellular activity.

Ionotropic Receptors (Channel-linked)

A number of agonists can act through several receptor classes, e.g., ion channels and ▶G-protein-coupled receptors. To set receptor subtypes permanently linked to ion channels (▶ligand-gated ion channels) apart

The versatility of these Ca²⁺ signals derives largely from their complex spatial and temporal organisation. Different Ca²⁺ channels, by delivering their Ca²⁺ to different subcellular domains, can selectively regulate distinct Ca²⁺ sensitive processes. Cellular responses may also be tuned to respond to the frequency of the ▶Ca²⁺ spikes from which these Ca²⁺ signals are often built. Information is thus encoded in both the spatial and temporal organisation of Ca²⁺ signals. Both aspects depend upon interplay between Ca²⁺ channels targeted precisely to specific subcellular locations.

Whether Ca²⁺ signals remain local, regulating only proteins closely associated with active ▶Ca²⁺ channels, or become global and so potentially regulate Ca²⁺ sensors throughout the cell, depends upon both the intensity of the initiating stimulus and the extent to which the Ca²⁺ signal propagates regeneratively across the cell. Signals detected at the plasma membrane may either directly stimulate Ca²⁺ channels within the plasma membrane (e.g., voltage-gated Ca²⁺ channels, NMDA receptors) or, via intracellular signals, cause activation of intracellular Ca²⁺ channels. The latter include IP₃ receptors, their relatives the ▶ryanodine receptors (RyR), and the less thoroughly understood receptors for NAADP (nicotinic acid adenine dinucleotide phosphate). Each of these channels can contribute to initiation of Ca²⁺ signals, but stimulation of IP₃R

and RyR by cytosolic Ca²⁺ endows these channels with an additional ability to regeneratively propagate intracellular Ca²⁺ signals by ▶Ca²⁺ induced Ca²⁺ release (Fig. 1). [1]

IP₃Rs open only when they bind IP₃: their ability to initiate and propagate Ca²⁺ signals therefore depends upon formation of IP₃, catalysed by ▶phospholipases C which hydrolyse phosphatidylinositol 4,5-bisphosphate to IP₃ and diacylglycerol. Many receptors, responding to many different stimuli, lead to activation of phospholipase C and so to release of Ca²⁺ from intracellular stores via IP₃R. The same receptors almost invariably also stimulate Ca²⁺ entry across the plasma membrane, an essential response if Ca²⁺ signals are to be sustained because IP₃R within the ER have access to only a limited source of Ca²⁺. The links between these receptors and Ca²⁺ entry, and the nature of the Ca²⁺ entry pathway itself are diverse, but a common accompaniment of IP₃-evoked Ca²⁺ release is the activation of ▶store-operated Ca²⁺ entry channels. These channels are formed from oligomeric assemblies of ▶Orai proteins, which are activated by ▶STIM proteins within the ER when the Ca²⁺ content of the ER falls allowing Ca²⁺ to dissociate from the luminal ▶EF-hand of the STIM protein. IP₃Rs, therefore, not only initiate Ca²⁺ signals in response to the many receptors that stimulate IP₃ formation, they can regeneratively propagate the signals across the cell (Fig. 1), and they also, by depleting the ER of Ca²⁺, stimulate the store-operated Ca²⁺ entry required for sustained Ca²⁺ signalling.

IP₃ Receptors. Figure 1 Interplay between Ca²⁺ channels. Ca²⁺ signals are initiated when an extracellular stimulus (red) directly opens a Ca²⁺ channel in the plasma membrane or indirectly, via a signalling pathway (green), opens an intracellular Ca²⁺ channel. Ca²⁺ signals may then be propagated across the cell by Ca²⁺-induced Ca²⁺ release mediated by IP₃R or RyR.

Structure of IP₃ Receptors

IP₃R are expressed in almost all animal cells, from *Caenorhabditis elegans* to man. They are found predominantly, though not exclusively, within the ER membrane. In vertebrates, three genes (and their splice variants) encode three distinct, but closely related, subunits of the IP₃R (IP₃R1–3) each comprising a large protein of about 2700 residues (~300 kDa). Functional IP₃R are tetramers: homotetramers in those species (e.g., insects and *C. elegans*) with only a single IP₃R subtype, but homo- or heterotetramers in vertebrates [2]. The essential properties of all IP₃R are broadly similar, but the subtypes differ in their distributions and in the finer details of their regulation. Here we concentrate on the key shared features, focussing primarily on IP₃R1, the most thoroughly studied subtype.

Each IP₃R subunit can be structurally divided into three regions: a single IP₃-binding site lying towards the N-terminal, a large central modulatory region, and six transmembrane domains (TMD) lying close to the C-terminus (Fig. 2). Residues 224–578 form the IP₃-binding core (IBC) and its crystal structure in complex with IP₃ shows IP₃ cradled at the corner of the L-shaped

IP₃ Receptors. Figure 2 Key structural features of IP₃ receptors. The key domains are shown in the central block. The upper structures show the suppressor domain (PDB accession code, 1XZZ) and the IBC (1N4K) with its (red) and β (blue) domains. A proposed structure for the pore region is shown below, with the selectivity filter shown in red; only two of the four subunits are shown. The lowest panel shows reconstructed 3D structures of IP₃R1 viewed (left to right) from ER lumen, the cytosol and in cross-section across the ER membrane (reproduced with permission from [4]).

structure formed by the α and β domains of the protein (Fig. 2) [3]. This binding cleft is lined by several key arginine and lysine residues that coordinate the three phosphoryl groups of IP₃. The 4- and 5-phosphates of IP₃ are essential for activity and while their major contacts are with the β and α domains, respectively, each makes some contacts with both domains. These interactions are consistent with a notion that activation of the IP₃R may be initiated by IP₃ drawing the α and β domains together into a more rigid structure. The 1-phosphate, by contrast, improves affinity, but it is not essential, and it makes far fewer contacts with the IBC. The N-terminal of the IP₃R comprises the so-called “suppressor domain” and its structure has also been resolved (Fig. 2) [4]. The suppressor domain is likely to be involved in coupling IP₃ binding to channel gating, but we do not yet know the relative dispositions of the IBC and suppressor domain in the native IP₃R structure. Towards the C-terminal of each subunit, there are

thought to be six helical TMDs; these target IP₃R to the ER, contribute to oligomerization, and form the cation-selective pore. The pore is formed by the last pair of TMD (TMD5–6) and the intervening luminal loop from each subunit. Its structure is thought to be similar to the pore of K⁺ channels, with the two TMD and a pore helix holding a relatively conserved selectivity filter (Fig. 2). Negatively charged residues flanking the luminal loop may contribute to the modest selectivity of the IP₃R pore for Ca²⁺ over monovalent cations (~sevenfold selective) by concentrating Ca²⁺ around the pore. A large cytoplasmic region (~1700 residues) separates the IP₃-binding domain from the TMDs. This region contains many (though certainly not all) sites through which IP₃R are modulated; it is often described as the “modulatory domain” [2]. It includes Ca²⁺-binding sites, sites to which ATP bind, sites for phosphorylation by several protein kinases, and sequences that mediate interaction with proteins like

calmodulin. Nothing is known of the structure of the modulatory domain.

At present only low resolution ($>30\text{\AA}$) structures, all derived from single particle analysis of images from electron microscopy, are available for the entire IP_3R . These structures differ in their details, but all show a roughly square structure with fourfold symmetry and lateral dimensions of about 20 nm (Fig. 2).

Regulation of IP_3 Receptors

IP_3 is the essential regulator of IP_3R : the pore opens only when the IP_3R has IP_3 bound. But IP_3 alone does not stimulate opening, rather it tunes the sensitivity of the IP_3R to Ca^{2+} by causing a stimulatory Ca^{2+} -binding site to become accessible and an inhibitory site to be occluded. Binding of Ca^{2+} to the stimulatory site then causes channel opening [5]. This interplay between IP_3 binding and Ca^{2+} regulation leads to biphasic effects of cytosolic Ca^{2+} on steady-state responses to IP_3 : modest increases in cytosolic Ca^{2+} promote channel opening, while more substantial increases are inhibitory. This pattern of regulation plays an essential part in the regenerative behaviour of IP_3R (Fig. 1). The identities of the essential Ca^{2+} -binding sites remain unclear. The stimulatory site is likely to reside on the IP_3R itself; while inhibition may be mediated by an accessory protein: **calmodulin** is a potential, albeit controversial, candidate.

IP_3 and Ca^{2+} are the essential regulators of IP_3R gating, but many additional signals and accessory proteins modulate their responses. Phosphorylation by a host of protein kinases, ATP, redox state, calmodulin, cytochrome c, and many additional proteins have all been shown to modulate IP_3R behaviour. IP_3Rs thus serve to integrate many different signals. These signals then tune the sensitivity of the IP_3R to IP_3 and Ca^{2+} , and so allow the IP_3R effectively to process information coming from many different signalling pathways before returning the output to the cytosol as a Ca^{2+} signal. IP_3 receptors are signal integrators.

How Does IP_3 Binding Lead to Opening of the Pore?

At present we can only speculate on the mechanisms that link IP_3 binding to the IBC to opening of the pore. IP_3 binding causes a large conformational change to the N-terminal region, perhaps initiated by a closure of the gap between the α and β domains of the IBC as IP_3 binds and cross-links the two domains. But how does IP_3 binding cause exposure of the essential stimulatory Ca^{2+} -binding site? A speculative possibility is that a cluster of acidic residues lying close to the hinge around which IP_3 is proposed to pull the α and β domains together might be re-arranged by that movement into a functional Ca^{2+} -binding site. The suppressor domain is essential for IP_3 to cause channel gating and may communicate directly with the pore region. We further

speculate that IP_3 and Ca^{2+} binding to the IBC free it from its interaction with the suppressor domain allowing it to then signal onwards to the pore, possibly by interacting directly with the cytosolic loop linking TMD4 and 5. Movement of that loop might then, in analogy with K^+ channels, physically gate the channel.

Pharmacological Intervention

No ligands of IP_3R have yet found clinical application. Most agonists of IP_3R are either modifications of IP_3 or derived from adenophostin A. The only known antagonists of IP_3R (e.g., heparin, 2-APB) are very poorly selective.

IPC

Ischemic Preconditioning.

IPSP (Inhibitory Postsynaptic Potential)

An inhibitory postsynaptic potential is a local hyperpolarizing potential at a postsynaptic membrane, which is elicited by the release of an inhibitory neurotransmitter via an inhibitory postsynaptic current.

- ▶ Synaptic Transmission
- ▶ GABAergic System

IRAG

IP₃ receptor associated cGMP kinase substrate of 130 kDa that is present in all smooth muscles and platelets. It's phosphorylation decreases calcium release from intracellular IP₃-sensitive stores.

► Smooth Muscle Tone Regulation

IRAK Family

IL-1 receptor associated kinase family-A with Toll-like receptor signalling. There are four members in this group to date: IRAK-1,2,4 and M. They can phosphorylate among themselves, as well with other proteins involved in signalling such as ► TRAF-6.

► Toll-like Receptors

Iron Chelator

A molecule that binds iron through coordinating moieties (e.g., carboxylates or amines). They are used to inhibit iron-catalyzed free radical reactions or to treat iron overload conditions. Desferrioxamine and deferoxiprone are two widely used iron chelators.

Irreversible Antagonists

According to Michaelis–Menten kinetics, ligands have affinity for receptors determined by their rate of offset from the binding domain divided by their rate of onset to the binding domain. Reversible ligands occupy different proportions of receptor sites according to this ratio and the concentration present in the receptor compartment. Irreversible ligands have negligible rates of offset (i.e., once the ligand binds to the receptor it essentially stays there) therefore receptor occupancy does not achieve a steady-state but rather increases with increasing time of exposure of the receptors to the ligand. Thus, once a receptor is occupied by an

irreversible antagonist, it remains inactivated throughout the course of the experiment.

► Affinity

► Drug–receptor Interaction

Irritable Bowel Syndrome (IBS)

Irritable bowel syndrome (IBS) is an exceedingly common condition in all societies, characterized by abdominal discomfort or pain in association with altered bowel habit or incomplete stool evacuation, bloating and constipation or diarrhoea. easily go undetected and do not show up with common tests such as blood tests or x-rays. The estimated prevalence in the community is about 10%. Irritable bowel syndrome and its variants, collectively called functional gastrointestinal disorders, constitute 40–50% of all the patients seen by gastroenterologists in Western countries.

► Serotonergic System

Isaacs' Syndrome

Isaacs' syndrome (an acquired neuromyotonia) is caused by autoantibodies directed against 4-aminopyridine or α -dendrotoxin-sensitive K⁺ channels (Kv1.1 and Kv1.6) in motor and sensory neurons. The syndromes include muscle twitching during rest, cramps during muscle contraction, impaired muscle relaxation, and muscle weakness due to hyperexcitability of peripheral motor nerves.

► K⁺ Channels

Ischemic Preconditioning (IPC)

IPC is the endogenous cellular protective mechanism in the heart by which brief periods of ischemia induce protection against infarction due to subsequent longer periods of ischemia.

► ATP-dependent K⁺ Channels

Ischemic Stroke

An episode of acute regional ischemia in the brain leading to neuronal death. It is usually caused by thrombi or emboli from atherosclerotic plaques.

► Atherosclerosis

Isopeptide Bond

An amide bond formed between a carboxyl group of one amino acid and an amino group of another, where either group occupies a position other than α .

Isoprenoid

Isoprenoids are intermediates and products of the biosynthetic pathway that starts with mevalonate and ends with cholesterol and other sterols.

► Lipid Modifications

Isoprenylation

► Lipid Modifications

ITAM

Immunoreceptor based activation motif. The classical ITAM motif comprises the consensus sequence YxxI/Lx(6–12)YxxI/L (where Y stands for tyrosine, I stands for isoleucine, L stands for leucine, and x can be any amino acid). Kinases containing tandem SH2 domains, as for example ZAP-70 or SYK, recognize the phosphorylated ITAMs, thereby initiating downstream signaling events.

► T Cell Receptors

Itch

(Itchy homolog E3 ubiquitin protein ligase) As revealed by cDNA cloning, the *itch* gene encodes 854 amino acids with a molecular weight of 113 kDa. As a regulatory E3 ubiquitin ligase, *itch* is composed of an N-terminal protein kinase, C-related C2 domain, four WW protein–protein interaction domains, and a C-terminal HECT ubiquitin ligase domain, and is a member of the HECT domain-containing E3 Ub protein ligases.

JAK-STAT Pathway

THOMAS MEYER¹, UWE VINKEMEIER²

¹Abteilung Psychosomatische Medizin und Psychotherapie, Universität Marburg, Germany

²School of Biomedical Sciences, University of Nottingham Medical School, Nottingham, UK

Definition

The *Janus kinase-signal transducer and activator of transcription* (JAK-STAT) signaling pathway is activated in response to a large number of ► **cytokines**, hormones, and growth factors. As their name implies, the ► **STAT** proteins exhibit the dual function of transducing signals from the cell surface into the nucleus as well as activating transcription of target genes, thus converting extracellular stimuli to a wide range of appropriate cellular responses [1, 2]. STATs have been identified as important regulators of a multitude of cellular processes, such as immune response, antiviral protection, and proliferation.

Basic Characteristics

The JAK-STAT pathway is widely used by members of the cytokine receptor superfamily. Upon ligand binding and oligomerization of the cognate receptor chains, the receptor-associated ► **JAKs** themselves become tyrosine phosphorylated and consecutively phosphorylate critical tyrosine residues on the cytoplasmic domain of the receptors, thereby generating docking sites for STAT proteins and other intracellular signaling molecules. The STATs are recruited to specific phosphotyrosine-containing motifs located in the cytoplasmic part of the receptor via their Src-homology-2 (SH2) domain and in turn are phosphorylated by activated JAKs at a single tyrosine residue in their C-terminus. Tyrosine phosphorylation induces conformational changes in the dimeric STAT molecules by virtue of reciprocal SH2–phospho-tyrosine interactions. The phosphorylated STATs are capable of binding to nonameric palindromes with relaxed sequence specificity in the promoter regions of cytokine-inducible genes, termed GAS (The gamma activated site is a

STAT binding site in the promoter region of cytokine-responsive genes. It is nonameric palindrome with relaxed sequence specificity.) sites, to regulate gene expression. ► **Tyrosine phosphatases** located in the nucleus then dephosphorylate STAT molecules (Fig. 1).

Physiological Functions of JAKs

The mammalian JAK family of protein tyrosine kinases consists of four members (JAK1, JAK2, JAK3, and TYK2), which are characterized by the possession of a kinase and an adjacent pseudokinase domain. JAKs have a molecular mass of approximately 130 kDa and are composed of seven JAK homology domains. The essential role of JAKs in mediating signal transduction via members of the cytokine receptor superfamily became apparent from studies of knockout mice. Targeted disruption of the mouse JAK1 gene results in perinatal lethality, obviously caused by defective neural function, and altered lymphoid development. JAK2-deficient mice exhibit an embryonic lethal phenotype caused by a block in definite erythropoiesis but show intact lymphoid development, demonstrating the obligatory and nonredundant roles of JAKs in cytokine-induced biological responses. Mutant mice lacking JAK3 are viable but display severe defects in both cellular and humoral immune responses with profound reduction in mature B and T cells, resembling the clinical symptoms of patients suffering from an autosomal-recessive form of severe combined immunodeficiency in which inactivating mutations in the JAK3 gene have been identified.

Roles of STAT Proteins in Cytokine-Inducible and Constitutive Gene Induction

In mammalia, seven different members encoded by distinct genes have been identified, all of which are activated by a distinct set of cytokines. Diversity in signaling is provided by variants of STAT proteins derived from either alternative splicing of RNA transcripts or proteolytic processing (e.g., STATs 1, 3, 4, and 5) and the ability of certain STATs to form both homodimers and heterodimers with each other. In response to ► **interferon- γ** monomeric STAT1 dimerizes, while upon interferon- α stimulation a heterotrimeric complex consisting of STAT1 and STAT2 with associated

JAK-STAT Pathway. Figure 1 Activating and inhibitory mechanisms of the JAK-STAT pathway.

p48 is formed, known as the ISGF3 ▶ **transcription factor**. Major structural features in STAT proteins are the N-terminal region involved in cooperative DNA binding of multiple STAT dimers, the central DNA-binding domain, the dimerization region containing the SH2 domain and the site of tyrosine phosphorylation, and the C-terminal transcriptional transactivation domain. Phosphorylation of a critical serine residue within the transactivation domain is necessary for maximal transcriptional activity of some STAT family members.

STAT1 knockout mice exhibit selective signaling defects in their response to interferon, including an impaired expression of MHC class II, complement protein C3, the MHC class II transactivating protein CIITA, interferon regulatory factor-1, and guanylate-binding protein [3]. STAT3 activated through binding of IL-6, leptin, EGF, PDGF, LIF, or other ligands to their cognate receptors appears to have important roles in preventing apoptosis and promoting proliferative processes. A deficiency in STAT3 causes embryonic

lethality in mice, indicating the essential role of STAT3 in growth regulation, embryonic development, and organogenesis. STAT4 is activated in T cells in response to IL-12 and stimulates the development of T_H1 cells. The two ubiquitously expressed STAT5 proteins (STAT5a and 5b) are encoded by distinct genes and share more than 90% sequence identity. They are activated by many growth stimulatory cytokines, including interleukins, GM-CSF, GH, prolactin, EGF, as well as erythropoietin, and exert critical roles in antiapoptosis and proliferation. STAT6 functions in response to IL-4 and IL-13 signaling to induce T_H2 cell development, CD23 and MHC class II expression, immunoglobulin class switching, and B- and T-cell proliferation.

Originally discovered as DNA-binding proteins that mediate interferon signaling, recent data demonstrated that STAT1 can also exert constitutive functions in the nucleus, which do not require STAT activation with tyrosine phosphorylation. Cells lacking STAT1 are

resistant to apoptotic cell death induced by tumor necrosis factor due to an inefficient expression of caspase genes, while reintroduction of STAT1 in these cells restores protease expression and sensitivity to apoptosis. For the transcription of certain target genes a phosphorylation of the critical tyrosine residue 701 is not necessary, suggesting that unphosphorylated STAT1 can also bind to DNA. Recent data indicate that unphosphorylated STAT1 can either positively or negatively regulate the constitutive expression of a wide range of different genes. It was shown that tyrosine phosphorylated and unphosphorylated STAT1 molecules shuttle between the cytoplasm and the nucleus via independent pathways to distinct sets of target genes.

Besides the cytokine receptors that lack intrinsic kinase activity but have associated JAK kinases, STAT proteins can be activated by a variety of G-protein coupled receptors and growth factor receptors with intrinsic tyrosine kinase activity (for example EGF, PDGF, CSF-1, and angiotensin receptor). Increasing evidence suggests a critical role for STAT family members in oncogenesis and aberrant cell proliferation. Constitutively activated STATs have been found in many transformed cell lines and a wide variety of human tumor entities. Numerous non-receptor tyrosine kinases and viral oncoproteins, such as v-Src, v-Abl, v-Sis, and v-Eyk, have been identified to induce DNA-binding activity of STAT proteins.

Mechanisms negatively regulating the JAK-STAT pathway have been identified. Besides the dominant-negative effects of naturally occurring STAT variants lacking the transactivation domain, ►PIAS proteins (*protein inhibitor of activated STAT*) have been shown to interact with STATs and to suppress their DNA-binding activity. The ►SOCS proteins (*suppressor of cytokine signaling*), also named as CIS (*cytokine inducible src homology 2-domain containing protein*), JAB (*JAK-binding protein*) or SSI (*STAT-induced STAT inhibitor*), are induced by cytokine signaling and act in a negative feedback loop to inhibit JAK kinase activity. Another important negative regulatory mechanism involves the recruitment of tyrosine phosphatases containing tandem SH2 domains (SHP-1 and SHP-2) to the intracytoplasmic portion of receptor complexes, where they dephosphorylate and thus inhibit JAK activity.

Drugs

Components of the JAK-STAT signaling pathway represent novel targets for pharmacological interventions [4]. Recently, a specific and orally active JAK3 antagonist was identified from screening of a chemical library for inhibitors of *in vitro* JAK3 kinase activity. The most effective compound, CP-690,550, was shown

to significantly suppress immune reactions and prevent allograft rejection in animal organ transplantation [5]. The JAK3 inhibitor significantly prolonged survival in a murine model of heart transplantation and in cynomolgus monkeys receiving kidney transplants. Moreover, typical side effects associated with established immunosuppressive therapies were not reported, suggesting a potential role for CP-690,550 or derivatives thereof in the prevention and treatment of transplant rejection and other clinical conditions of desirable immunosuppression.

Other interesting targets for pharmacological therapies include the STAT proteins. Drugs specifically blocking dimeric STAT molecules are of promising value in the treatment of cancer, because of the high levels of STAT activation in tumor cells. Structural targets for the development of novel therapeutics within the STAT molecule include the SH2 domain responsible for dimerization and recruitment to the receptor, the DNA-binding domain as well as the recently discovered nuclear import signal for activated STAT1.

JNKs

c-jun N-terminal kinases. Group of three kinases (JNK1, JNK2, JNK3) which belongs to the family of mitogen-activated protein (MAP) kinases and phosphorylate c-Jun on Ser63 and Ser73. JNK1 and JNK2 are widely expressed, whereas JNK3 is primarily found in the nervous system and the testes. JNKs are activated by various stress signals like cytokines, ultra-violet irradiation or osmotic shock.

►MAP Kinase Cascades

K_{ATP} Channel

- ▶ ATP-dependent K⁺ Channel

K_{NDP} Channel

- ▶ NDP-dependent K⁺ Channels

K⁺ Channel Openers

Typical KCO members are diazoxide, pinacidil, cromakalim, and nicorandil. KCOs activate K_{ATP} channels by binding to SUR subunits. Diazoxide and nicorandil are clinically used in treatment of PHHI and angina pectoris, respectively.

- ▶ ATP-dependent K⁺ Channels

K Channels

K Channels belong to a class of membrane proteins that form highly K-selective pores in membranes. All known K Channels are composed of several (usually four) pore forming alpha subunits and auxiliary beta subunits. K Channels play an essential role in cellular excitability, being involved in repolarization of Action Potentials and setting the cell resting potential as well as contributing to potassium homeostasis.

- ▶ Potassium Channels

K_D

The dissociation constant for the drug–receptor complex. It is a measurement for the affinity of a drug to a receptor. The lower the value, the higher the affinity.

K⁺ Homeostasis

Potassium homeostasis refers to the maintaining and regulating of a relatively stable and mostly internal (intracellular) potassium balance (concentration), although more generally it refers to the maintenance of potassium balance in any compartment (e.g. in the blood).

- ▶ K⁺ Channels

k_{off}

k_{off}, or the dissociation constant of a drug, refers to the rate at which the drug–receptor complex dissociates into separate drug and receptor units.

Kainate Receptor

Kainate receptors are a subtype of ionotropic glutamate receptors that are permeable to Na⁺, K⁺ and Ca²⁺ ions.

- ▶ Ionotropic Glutamate Receptors

Kallidin, Lysyl-Bradykinin

- ▶ Kinins

Kallikrein

- ▶ Kinins

KCNQ-Channels

KCNQ-channels are assembled from KCNQ α -subunits. Mutations in the KCNQ1 gene are associated with heart arrhythmia and deafness (LQT1 syndrome, Romano–Ward Syndrome, Jervell–Lange Nielsen Syndrome). Mutations in KCNQ2 and KCNQ3 genes are associated with a benign form of juvenile epilepsy (BFNC). Mutations in the KCNQ4 gene are associated with deafness.

KDEL Receptor

Interaction of the KDEL-receptor with soluble luminal proteins bearing the tetrapeptide KDEL at their carboxy-terminus retrieves these proteins back from the Golgi to the endoplasmic reticulum.

- ▶ Intracellular Transport

KELL Blood Group Antigen

KELL blood group antigen is a plasma membrane protein isolated from red cells homologous to zinc-binding glycoproteins with neutral endopeptidase activity.

Ki Values

The K_i value is the dissociation constant of an enzyme-inhibitor complex. If $[E]$ and $[I]$ are the concentrations of enzyme and its inhibitor and $[EI]$ is the concentration of the enzyme-inhibitor complex, there is an equilibrium of complex formation and detachment as follows:

Under these circumstances, K_i can be defined as:

$$k_i = \frac{[E][I]}{[EI]}$$

Kinase

A kinase is an enzyme that catalyzes the transfer of the terminal phosphate of a nucleotide to suitable substrates. Protein and lipid kinases play important roles in signaling. The kinase domain is a two lobed structure with an ATP binding site and a substrate-binding site. Protein kinases can be tyrosine kinases (e.g. receptor tyrosine kinases (RTKs)), serine/threonine kinases (e.g. protein kinase C – PKC) or dual specificity kinases (e.g. MEK). Kinases that can phosphorylate histidine and arginine residues have been identified in lower organisms.

Definition

Kinins are a group of peptide hormones of 8–11 residues that act locally as proinflammatory agents, often through the release of powerful downstream effectors such as nitric oxide and/or prostaglandins.

Basic Characteristics

Liberation of Kinins

Typically, kinins are locally produced at injured or inflamed tissues sites where they act through a combined endocrine/paracrine mode. In a first step, the high-molecular weight inactive kinin precursor proteins, the kininogens, are targeted to the inflamed site where the kinins are eventually proteolytically liberated from the kininogens by specific kininogenases, the kallikreins. In humans, two types of kininogens exist, termed high-molecular-weight (H-)kininogen (H-kininogen) and low-molecular-weight (L-)kininogen (Fig. 1.) Both types of kininogens are encoded by distinct mRNAs generated by alternative splicing from a single kininogen gene. A third type of kininogen, T-kininogen, appears to be unique for rats and is not found in humans or other mammals. Kininogens are predominantly expressed by hepatocytes and secreted into the human plasma via constitutive routes. Kidney and secretory glands are among the prominent extrahepatic sites of kininogen production.

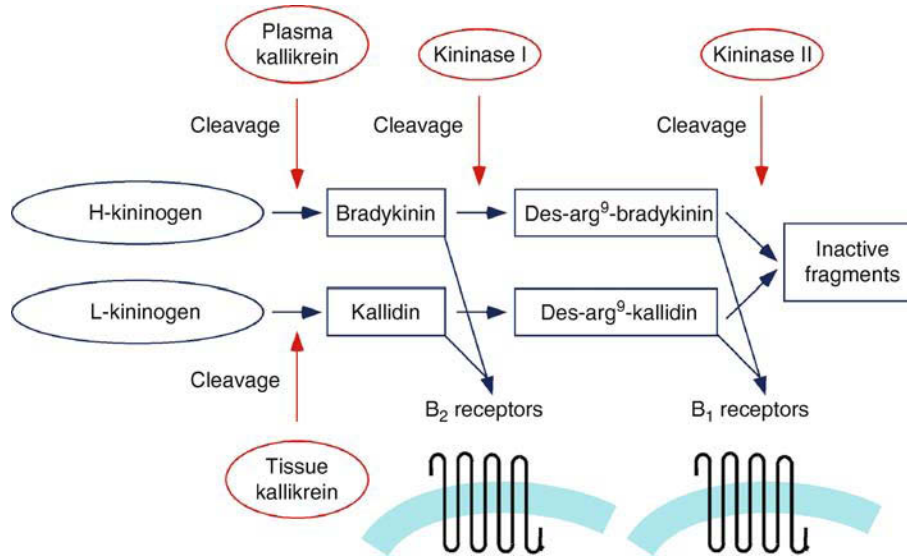

The most common kinin-liberating enzymes are kallikreins, a group of serine proteases that are found in glandular cells, ▶neutrophils and biological fluids such as plasma and urine. In humans, two classes of kinin-liberating kallikreins exist i.e. tissue kallikrein and plasma kallikrein, that differ by their structural, immunological and functional characteristics [1]. In some mammalian species, tissue kallikrein preferentially utilizes L-kininogen as the substrate to produce kallidin, whereas plasma kallikrein acts on H-kininogen to generate bradykinin (Table 1). Kinins can also be released by common proteases such as trypsin, elastase or cathepsin D, however the biological significance of these kinin-liberating processes is unknown. Apart from human kininogenases, a large number of proteases derived from pathogenic microorganisms has been found to liberate kinins from kininogens.

Kinins are extremely short-lived peptide hormones (plasma half live <15 s) that are rapidly proteolytically converted and inactivated. For instance, bradykinin and kallidin are cleaved at their carboxy-terminal ends by carboxypeptidases of the N and M type, collectively referred to as kininases type I, to form desArg⁹-bradykinin and desArg¹⁰-kallidin, respectively (Table 1). Because bradykinin and kallidin act on B₂ receptors, and desArg⁹-bradykinin and desArg¹⁰-kallidin bind exclusively to B₁ receptors, the proteolytic conversion of the kinins “switches” the relative binding affinity for the two kinin receptors, B₁ and B₂ receptor, respectively (Fig. 1.) Both types of agonists are rapidly degraded and inactivated by the action of the dipeptidylpeptidase angiotensin-converting enzyme, also known as kininase type II, and neutral endopeptidase which inactivate kinins by trimming the kinin peptides at their carboxy-terminal ends (Table 1).

In humans as well as in other but not all mammalian species, kininogens are modified by posttranslational hydroxylation of a single proline residue of their kinin sequence, i.e. position 3 in bradykinin or position 4 in kallidin. Hydroxylation appears not to affect the specificity, affinity or intrinsic efficacy of the kinins.

Kinins in Biological Fluids

The quantification of kinins in human tissues or body fluids has been limited due to the inherent difficulties in accurately measuring the concentration of ephemeral peptides. Today HPLC-based and RIA/capture-EIA measurements are established to determine kinins in human plasma, liquor or urine. Serine protease inhibitors need to be added to prevent rapid degradation of the kinins *in vitro* during sample preparation. Kinins and their degradation products have been studied in various biological milieus such as plasma/serum, urine, joint fluids, kidney, lung and skeletal muscle [2]. Under normal conditions, the concentration of kinins in these compartments is extremely low; for

Kinins. Figure 1 Scheme of kinin liberation, turnover and action.

instance kinin levels in human plasma are in the femtomolar and lower picomolar range. Plasma concentration of kininogens is in the micromolar range, i.e. the ratio of effector to precursor concentrations is maintained at an extremely low level of 10^{-6} to 10^{-9} , and therefore kinin release must be extremely tightly controlled. Kinin levels, however, can considerably rise in patients prone to diseases such as hereditary angioedema. In more severe complications such as ►sepsis and ►septic shock, kinin levels correlate with the severity of the disease state.

Receptors

The pathophysiological kinin functions are mediated by their interaction with specific receptors. In humans, two types of kinin receptor have been identified, namely B₁ and B₂ receptors [1]. The two receptors are coded by two genes on closely opposed loci of human chromosome 14q32 that likely arose from a common progenitor, though their sequence identity is limited. The two proteins belong to the large family of G protein-coupled receptors characterized by seven transmembrane-spanning helices. Unlike B₂ receptors that are constitutively expressed

in many cell types and tissues, the expression levels of B₁ receptors are very low under non-stimulated conditions. However, inflammatory or noxious stimuli boost the biosynthesis of the B₁ receptor. Several ►cytokines such as interleukin IL-1 β , as well as ►growth factors and bacterial ►lipopolysaccharides can up-regulate the transcription of the B₁ gene. B₁ and B₂ receptors are predominantly coupled to the ►pertussis toxin-insensitive G_q type of G protein leading to phospholipase C activation, mobilization of intracellular calcium by inositol-1,4,5-trisphosphate (IP₃) and activation of ►protein kinase C (Fig. 2.) Kinin receptors are vigorous stimulators of the biosynthesis of potent downstream effectors such as ►prostaglandins and ►leukotrienes due to ►phospholipase A₂ activation, and of ►nitric oxide via stimulation of the endothelial isoform of ►nitric oxide synthase (eNOS).

Kinin Receptor-Deficient Mice

Mice that are homozygous for a disrupted B₁ or B₂ receptor gene are healthy, fertile and normotensive. In B₁-deficient mice, bacterial lipopolysaccharide-induced ►hypotension is diminished and the recruitment of polymorphonuclear leukocytes to the sites of tissue injury is impaired, and the animals show signs of ►hypoalgesia. Deletion of the B₂ gene in mice leads to salt-sensitive hypertension and altered ►nociception.

Kinins. Figure 2 Intracellular signaling cascades triggered by kinins. Following binding of kinins to the receptor the associated heterotrimeric G protein complex dissociates. The α subunit stimulates phospholipase C (PLC) which in turn catalyses the breakdown of phosphatidylinositol-4,5-bisphosphate (PIP₂) into 1,2-diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP₃). IP₃ reacts with Ca²⁺ channels in the endoplasmic reticulum (ER) releasing Ca²⁺ into the cytosol. The increase in intracellular Ca²⁺ levels activates protein kinase C (PKC), which translocates to the plasma membrane, anchoring to DAG and phosphatidylserine.

B₂ knockout embryos subjected to salt stress *in utero* show suppressed renin expression and an abnormal kidney phenotype and develop early postnatal hypertension. Consistently, although basal bradykinin formation is defective tissue kallikrein-null mice have normal blood pressure however suffer from cardiovascular abnormalities. However suggesting a function of kinin signaling during development.

Biological Functions and Clinical Implications of the Cardiovascular System

Kinins are implicated in many physiological and pathological processes including the induction of pain and hypotension, contraction of smooth muscles, regulation of local blood flow, stimulation of electrolyte fluxes, activation of sensory neurons and increase of vascular permeability. Many of these effects are triggered at least in part via the major downstream effectors ►prostaglandins, leukotrienes, the small GTPase Cdc42 and ►nitric oxide.

In rare cases of a systemic release, kinins have the potential to cause severe hypotension. Uncontrolled activation of the contact system (Fig. 3) is thought to trigger a massive formation of kinins under certain pathological conditions [3]. For instance, this situation is seen in patients with underlying diseases such as systemic inflammatory response syndrome (SIRS) due to sepsis or trauma. SIRS progression is accompanied by depletion of contact system factors and low levels of H-kininogen and plasma kallikrein are indicative of a

Kinins. Figure 3 Activation of the contact system on negatively charged surfaces. Upon perturbation or damage, endothelial cells change their properties from a non-thrombogenic to a thrombogenic state, thereby initiating pro-coagulative and pro-inflammatory cascades. The contact system contributing to this conversion comprises four factors, i.e. three inactive proteinases, factor XII (F XII, Hageman factor), factor XI (F XI), plasma prekallikrein (PK), and a single non-enzymatic co-factor, H-kininogen (HK). Under physiological conditions, these proteinases circulate as zymogens. The contact system associates with glycosaminoglycans of cell surface proteoglycans exposed by many cell types of the cardiovascular system, such as platelets, leucocytes and endothelial cells.

fatal outcome, as often found in sepsis [4]. Other diseases associated with a massive, often systemic release of kinins are hereditary angioedema and pancreatitis. Kinins are also generated during allergic and non-allergic rhinitis and ▶asthma. Notably, kinins are important endogenous mediators exerting acute protective effects in the ischemic myocardium via ▶nitric oxide-dependent mechanisms. On the other hand, stable synthetic kinin homologues, which efficiently open the endothelial barrier, are utilized in cancer therapy. These kinin receptor agonists facilitate penetration of chemotherapeutic drugs from the blood into adjacent tissues.

In injured arterial vessels reciprocal activation of FXII and plasma prekallikrein results in a local accumulation of active kallikrein which in turn cleaves its substrate H-kininogen and releases bradykinin (BK). Active FXII triggers the intrinsic pathway of coagulation via its substrate factor XI. Although FXII is activated by a variety of polyanions, including constituents of subendothelial matrix (glycosaminoglycans, collagens, sulfatides, and nucleosomes) and non-physiological materials (glass, ellagic acid, kaolin, silica) the mechanism(s) responsible for FXII activation *in vivo* are not completely understood. Induction of fibrin clot formation through contact activation-mediated activation of FXII is the basis of the activated partial thromboplastin time (aPTT) assay, a commonly used method for the global assessment of plasma coagulation in clinical settings. Deficiency of contact proteins H-kininogen, plasma kallikrein or FXII severely prolongs the aPTT but does not cause bleeding in patients. Although FXII-mediated fibrin formation plays no significant role for hemostasis, FXII-deficient mice are protected from arterial and venous thrombus formation and ischemia-reperfusion injury in models of ischemic stroke [5].

Drugs

Aprotinin (Trasylol[®]) was the first drug to be used in the clinic to prevent the formation of kinins. More recently this potent serine protease inhibitor has received much attention in cardiac surgical practice as a pharmacologic intervention to improve the hemostatic derangement associated with cardiopulmonary bypass. Interestingly, aprotinin isolated from bovine lung not only inhibits contact activation but also impinges on a number of interrelated pathways, thereby providing an antifibrinolytic effect, attenuating platelet dysfunction and down-regulating inflammatory responses. As a drug, aprotinin is also used to reduce blood loss and transfusion requirements in patients with a risk of hemorrhage, though the underlying molecular mechanisms responsible for the beneficial effects of aprotinin are still obscure. However, due to aprotinin's anaphylactic potential, the use of Trasylol has raised serious

concerns worldwide. Recently, a specific inhibitor of active plasmakallikrein (DX88[®]) was introduced for treatment of attacks of hereditary angioedema. Alternatively, a peptide based inhibitor of B₂ receptors (icatibant[®]) is used in clinical trials to prevent life threatening swellings hereditary angioedema and in severe scernings.

In addition to this inhibitor, a large number of specific B₁ and B₂ receptor antagonists has been developed. Some of them are orally available and are resistant to proteolytic degradation. Kinin antagonists have been tested in clinical trials and it appears that they have sepsis, effects on the survival in patients with severe systemic inflammatory response syndrome and sepsis and in patients suffering from severe traumatic brain injury. Kinin antagonists are drug candidates for diseases such hyperalgesia and angioedema, and the use of kinin agonists in the treatment of brain tumors is anticipated.

Angiotensin-converting enzyme (ACE) inhibitors represent a class of drugs that have proven anti-hypertensive and anti-proteinuric effects. They delay the progression of renal disease in conjunction with the ability to reduce systemic blood pressure. Furthermore they have been shown to reduce mortality and morbidity in myocardial infarction associated with chronic heart failure. The cardioprotective effect of ACE inhibitors is a combined result of the diminished conversion of angiotensin I and of the attenuated kinin breakdown leading to kinin accumulation in ischemic myocardia. Given their pleiotropic effects, ACE inhibitors may well use alternative mechanism(s) to exert their beneficial roles, e.g. through the resensitization of kinin receptors, however, the precise modes of action remain to be determined.

Kir Channels

Kir Channels are a class of potassium channels generated by tetrameric arrangement of one-pore/two-transmembrane helix (1P/2TM) protein subunits, often associated with additional beta subunits. Kir Channels serve to modulate cell excitability, being involved in repolarization of Action Potentials, setting the resting potential of the cell and contributing to potassium homeostasis.

Knockout Mice

Knockout mice are mice carrying a mutation leading to the disruption of a certain gene. Using a molecular genetic technique called “gene targeting,” a gene is rendered nonfunctional in totipotent embryonal stem cells in culture. These mutant cells are then used to generate mice carrying the mutation in the germ line, thus leading to the establishment of an animal colony with a loss of function of the desired gene.

Kvβ -Subunits

Kvβ -subunits are auxiliary subunits of Shaker-related Kv-channels, which belong to the Kv1 subfamily of voltage-gated potassium channels. Kvβ -subunits may function as chaperones in Kvα -subunit assembly and may modulate the gating properties of Kv-channels. In particular, some Kvβ -subunits may confer a rapid inactivation to otherwise non-inactivating Kv-channels.

- ▶ Voltage-gated K⁺ Channels

Kv-Channels

Kv-channel is an abbreviation of voltage-gated potassium channels. K stands for potassium and v for voltage.

- ▶ Voltage-gated K⁺ Channels

KvLQT1-Channels

The subunits of KvLQT1-channels were cloned by positional cloning from mutant human DNA obtained from patients suffering from a hereditary LQT1 (long QT) syndrome associated with heart arrhythmia and deafness. The corresponding gene is abbreviated as KCNQ1. KCN stands for K-channel, Q for the K-channel subfamily, and 1 indicates it as the first member of the KCNQ subfamily. Relatives of this channel (KCNQ2-KCNQ5) underlie the M-channels in the nervous system.

Kynurenine Pathway

The kynurenine pathway accounts for most of the non-protein tryptophan metabolism in most tissues. Several metabolites produced by this pathway have been shown

to be biologically active. Kynurenic acid produced via kynurenine has been shown to be an antagonist at N-methyl D-aspartate (NMDA), kainate and α -amino-5-methyl-3-hydroxy-4-isoxazole propionic acid (AMPA) receptors. It can block glutamate receptors in various species in distinguish subpopulations of kainate

receptors. 3-hydroxykynurenine can produce neuronal damage by generating radicals. Quinolinic acid, another metabolite produced by the kynurenine pathway, functions as an agonist at NMDA receptors.

► Iontropic Glutamate Receptors

L-NAME

L-NAME (N-nitro-L-arginine methyl ester), like L-NMMA, is a structural analogue of L-arginine and competes with L-arginine for NO-synthase, which uses L-arginine as a substrate for the formation of NO. L-NMMA and L-NAME are very effective NO-synthesis inhibitors, both in vitro and in vivo.

Centre d'Ingenierie des Protéines, University of Liège,
Liège, Belgium

Synonyms

Wall peptidoglycan inhibitors

Definition

►β-Lactam antibiotics are bicyclic or monocyclic azetidinone ring-containing compounds (Fig. 1). They kill bacteria by preventing the assembly of (4–3) peptidoglycans. These covalently closed net-like polymers form the matrix of the cell wall by which the bacteria can divide and multiply, despite their high internal osmotic pressure.

Mechanism of Action

►Peptidoglycans of the (4–3) and (3–3) types (Fig. 2) are comprised of glycan chains made of alternating β-1,4-linked *N*-acetylglucosamine and *N*-acetylmuramic acid residues [1]. The *D*-lactyl groups on carbon C₃ of the muramic acids are substituted by *L*-alanyl-γ-*D*-glutamyl-*L*-diaminoacyl-*D*-alanine stem tetrapeptides. In the (4–3) peptidoglycans, peptides borne by adjacent glycan chains are cross-linked through direct linkages or cross bridges (comprising one or several intervening

amino acid residues) that extend from the *D*-alanine residue at position 4 of a stem peptide to the ω-amino group at position 3 of another stem peptide. Lipid II (Fig. 3) is the immediate biosynthetic precursor. A disaccharide bearing an *L*-alanyl-γ-*D*-glutamyl-*L*-diaminoacyl-*D*-alanyl-*D*-alanine stem pentapeptide (the diamino acid residue of which can be either free, i.e., unsubstituted, or substituted by one or several amino acid residues, i.e., branched) is exposed on the outer face of the plasma membrane, linked to a C₅₅-undecaprenyl via a pyrophosphate. From this precursor, the formation of polymeric (4–3) peptidoglycans relies on glycosyl transferases ensuring glycan chain elongation and acyl transferases ensuring peptide cross linking. Acyl transferases of the SXXK superfamily (►SXXK Acyl Transferases, also called DD-transpeptidases, with X denoting a variable amino acid residue) are implicated in cross linking and they exhibit a specific bar code in the form of three motifs, SXXK, SXN (or analogue) and KTG (or analogue), occurring at equivalent places and roughly with the same spacing along the polypeptide chains [2]. As a result of the polypeptide folding, the motifs are brought close to each other at the immediate boundary of the catalytic centre between an all-α domain and an α/β domain. SXXK acyl transferases identify *N*-acyl-*D*-alanyl-*D*-alanine sequences as carbonyl donors, produce a *N*-acyl-*D*-alanyl moiety linked as an ester to the serine residue of the invariant SXXK motif and transfer the peptidyl moiety onto an amino group (transpeptidation) or a water molecule (carboxypeptidation). SXXK acyl transferases identify penicillin (used as a generic term for β-lactam antibiotics) as a suicide carbonyl donor. Because the serine-ester linked penicilloyl enzyme that SXXK acyl transferases produce is rather stable, they are immobilized, at least for a long time, in the form of penicillin-binding proteins, in short PBPs. The inactivation reaction can be written

where E-OH is the enzyme, with –OH the hydroxyl group of its active-site serine residue. Kinetically, the interaction is described by a 3-step model

β-Lactam Antibiotics. associated SXXK acyl transferase modules are positioned in an active conformation within the morphogenetic apparatus where they need to be. Binding of β-lactam antibiotics to the SXXK acyl transferase modules of the PBP fusions leads to the formation of Henri–Michaelis complexes that exhibit ligand- and enzyme-specific hydrogen bonding networks. *Escherichia coli* is killed in a number of ways; via cell lysis as a result of the selective inactivation of the class A PBP1a and PBP1b (which can substitute for each other) by cephaloridine and cefsulodin; via transformation of the cells into round bodies as a result of the selective inactivation of the cell-cycle subclass B2 PBP2 by mecillinam and thienamycin; via cell filamentation as a result of the selective inactivation of the cell-cycle subclass B3 PBP3 by mezlocillin, cefaperazone, cefotaxime, cefuroxime, cephalothin and aztreonam; or via different combinations of these morphological alterations by ampicillin, benzylpenicillin, carbenicillin and cefoxitin.

β-Lactamase-Mediated Resistance

► SXXK free-standing PBPs are peptidoglycan-hydrolyses of one kind or another. Loss of these auxilliary cell-cycle proteins causes varying morphological aberrations, but is not fatal at least in the laboratory environment. Similarly, conversion of free-standing PBPs into β-lactam antibiotic-hydrolysing enzymes, with loss of peptidase activity and conservation of the polypeptide fold, gives rise to the SXXK β-lactamases. There are three classes of SXXK β-lactamases A, C and D, which are easily distinguished on the basis of their primary structures, although the tertiary structures are

clearly similar and also related to those of the acyl transferase modules of PBPs. In particular, in addition to the characteristic SXXK, motifs reminiscent of the bar code SXN and KTG groups are found in nearly superimposable positions. The catalytic pathway of β-lactamases follows the 3-step model shown above but with good substrates, the k_3 value can be higher than 1000 s⁻¹ [4].

The class A enzymes have M_r values around 30,000. Their substrate specificities are quite variable and a large number of enzymes have emerged in response to the selective pressure exerted by the sometimes abusive utilization of antibiotics. Some of these “new enzymes” are variants of previously known enzymes, with only a limited number of mutations (1–4) but a significantly broadened substrate spectrum while others exhibit significantly different sequences. The first category is exemplified by the numerous TEM variants whose activity can be extended to third and fourth generation cephalosporins and the second by the NMCA and SME enzymes which, in contrast to all other SXXK β-lactamases, hydrolyse carbapenems with high efficiency. Despite these specificity differences, the tertiary structures of all class A β-lactamases are nearly superimposable.

The class C enzymes have M_r values of 39,000 and exhibit more uniform properties. They hydrolyse benzyl- and phenoxymethyl penicillin relatively well (turn-over numbers of 20–70 s⁻¹), ampicillin and amoxicillin 10- to 20-fold less rapidly and extremely poorly the other penicillins (generally due to low k_3 values). The early cephalosporins (cephalothin,

β -Lactam Antibiotics. Figure 3 Lipid II precursor (bottom) and polymeric (4–3) peptidoglycan of *Escherichia coli* and *Mycobacterium tuberculosis*. Glycosyl transferase and acyl transferase-catalysed reactions. G: *N*-acetylglucosamine. M: *N*-acetylmuramic acid. A₂pm: *meso*-diaminopimelic acid. (3–3) Peptidoglycan cross linking (Fig. 2) may proceed via the formation, in a penicillin-resistant manner, of a *N*-acyl-L-diaminoacyl moiety linked as an ester to the serine residue and the transfer of the peptidyl moiety to the ω -amino group of the diamino acid residue of another peptide.

cephalexin, cefazolin) are well hydrolysed but the later generation compounds also exhibit low to very low k_3 values, as do imipenem and aztreonam. A few mutations are known to extend the spectrum of some enzymes but the most currently utilized bacterial strategy is overproduction by deregulation of the biosynthetic control mechanism, so that the MICs of poor or even very poor substrates can increase significantly [5].

Class D enzymes (M_r of about 27,000) exhibit a high activity versus isoxazolyl penicillins, such as oxacillin and are referred to as the OXA-family. Surprisingly, the amino group of the SXXK lysine residues is carboxylated in the most active forms of the enzymes. Penicillins are generally better substrates than cephalosporins but mutations have been found which confer extended activity spectra to these enzymes.

Inactivators of class A β -lactamases (clavulanate, sulbactam, tazobactam) are themselves β -lactams and act as suicide substrates. They can be used in

combination with β -lactamase sensitive compounds (ampicillin, amoxicillin) but are not clinically useful against class C and class D producers. Some TEM mutants have also been selected that exhibit reduced sensitivity to these inactivators.

The class B metallo- β -lactamases have emerged more recently as a clinical problem but they are particularly dangerous since many of them hydrolyse all known β -lactams, with the exception of monobactams. In particular, they hydrolyse the suicide substrates mentioned above, as well as carbapenems that usually escape the activity of all the SXXK enzymes, with the exception of the NMCA group.

Three subclasses B1, B2 and B3 can be distinguished on the basis of the sequences. B1 and B3 enzymes are optimally active with 2 Zn²⁺ ions, while the B2 enzymes are inhibited by the second Zn²⁺. These B2 enzymes also exhibit a very narrow activity spectrum and only hydrolyse carbapenems. The 3D structures of representative members of each subfamily have been

solved and they highlight a typical αββα fold, completely unrelated to that of the SXXK enzymes.

The production of β-lactamases can be inducible or constitutive and the genes carried by the chromosome or plasmids, some genes being parts of integrons. Several clinical strains produce up to three distinct enzymes.

PBP-Mediated Resistance

There are at least two modes of intrinsic resistance to β-lactam antibiotics. Determinants conferring a decreased susceptibility to β-lactam antibiotics evolve by the accumulation of point mutations in genes that code for essential PBP fusions of classes A and/or B. The shuffling and capture of DNA sequences from commensal *Streptococci* having a reduced susceptibility to the drug, give rise to *Streptococcus pneumoniae* pathogens in which mosaic genes code for mosaic PBP fusions of classes A and/or B of decreased affinity for the drug. Mosaic and wildtype PBP fusions of the same class (and the same subclass) differ by up to 15% amino acid residues. Mosaic PBPs occur also in *Neisseria meningitidis* and *Neisseria gonorrhoeae* strains.

Other strategies leading to an increased resistance are the transfer of a complete gene encoding a resistant PBP from a non-pathogenic related species to yield the Methicillin Resistant *Staphylococcus aureus* (MRSA) and the overproduction by *Enterococci* of a pre-existing but minor resistant PBP, which can further mutate to even more resistant forms. Some bacteria can also manufacture a (3–3) peptidoglycan (Fig. 2) with the help of a penicillin-resistant LD-transpeptidase, which is not an SXXK enzyme. Indeed, a low proportion of (3–3) cross links have been found in the walls of *Enterococcus faecium*, *Mycobacterium tuberculosis* and *Mycobacterium leprae*. The quantitative influence of these cross links on the resistance level remains to be determined but the synthesis of (3–3) peptidoglycan, combined with that of a set of relatively resistant SXXK PBPs and the limited permeability of the mycolic acid layer might explain the lack of efficiency of β-lactam antibiotics as therapeutic agents against tuberculosis and leprosy [6].

Outer Membrane Permeability and Active Efflux Systems

In Gram-negative bacteria, diffusion of β-lactam antibiotics into the periplasm (where the activity of PBPs takes place) occurs via the channels that porins create in the outer membrane. The number and properties of the porin molecules are such that diffusion is relatively rapid in *E. coli* but much slower in *Enterobacter* and *Pseudomonas*. Mutants can be selected after the permeability of porin channels or their number has been decreased. A slow diffusion into

the periplasm becomes a particularly important factor when it is combined with the presence of a β-lactamase (even in low concentration or when poorly active) in the same cellular compartment. Note that in *Mycobacteria*, the mycolic acid layer plays a role similar to that of the outer membrane in Gram-negatives. Finally, β-lactams bearing a hydrophobic side-chain can be ejected from the periplasm by the active efflux systems AcrAB-TolC in *E. coli* and *Salmonella typhimurium* and MexAB-OprM in *Pseudomonas*. Overexpression of these proteins can significantly increase the level of resistance.

Clinical Use

Because the SXXK PBPs are specific to the prokaryotes, the β-lactam antibiotics have a high selective toxicity without marked side effects except for possible allergic reactions. Resistance is a problem of great concern. The use of antibiotics fuels the continuing emergence and spreading of novel β-lactamases and intrinsic resistance determinants among bacterial pathogens.

Lateral Hypothalamic Area

The lateral hypothalamic area has been identified as a feeding centre by studies involving electric stimulation and discrete lesions. Neurons in the lateral hypothalamic area and the neighbouring perifornical area express neuropeptides that stimulate feeding when injected into cerebral ventricles (orexins 1 and 2, melanin-concentrating hormone (MCH)).

- ▶ Appetite Control

Laxatives

Laxatives, also called purgatives or cathartics, are substances used to hasten the transit of food through the intestine. Laxatives function by different mechanisms. Bulk laxatives, like methylcellulose or bran, contain agents like polysaccharide polymers, which are not fermented by the normal processes of digestion. They retain water in the gut lumen and promote bowel movements. Osmotic laxatives consist of poorly absorbable solutes such as salines containing magnesium cations or phosphate anions or non-digestible sugars and alcohols (glycerin, lactulose, sorbitol or mannitol). Osmotic laxatives retain an increased volume of fluid in the lumen of the bowel by osmosis, which accelerates the transfer of the bowel contents. Faecal softeners alter the consistency of the faeces. They are also called emollients and contain surface-active compounds similar to detergents, like docusate salts. Stimulant laxatives/purgatives increase the motility of the gut (peristalsis) and stimulate water and electrolyte secretion by the mucosa. Stimulant laxatives, which can cause abdominal cramps and deterioration of intestinal function, include diphenylmethane derivatives (bisacodyl, phenolphthalein), anthraquinone laxatives (derivatives of plants such as aloe, cascara or senna) and ricinoleic acid.

Leptin

The cytokine leptin is secreted by adipocytes (fat cells) in proportion to the size of the adipose depot and circulates via the bloodstream to the brain, where it ultimately affects feeding behavior, endocrine systems including reproductive function and, at least in rodents, energy expenditure. The major effect of Leptin is on the hypothalamus, where it suppresses appetite and hence food intake. Leptin exerts its effects via binding to the leptin receptor in the brain (specifically in the hypothalamus), which activates the JAK-STAT Pathway.

- Appetite Control
- Adipokines

Lethal Dose

The lethal dose (LD₅₀) is a measure of the toxicity of a compound. In an LD₅₀ toxicity test, various doses of a drug are administered to groups of animals, and the mortality in each group is determined. The lethal dose 50 is the dose, which is lethal for 50% of a group of animals.

Leucin Zipper

A leucine zipper is a structural motif present in a large class of transcription factors. These dimeric proteins contain two extended alpha helices that “grip” the DNA molecule much like a pair of scissors at adjacent major grooves. The coiled-coil dimerization domain contains precisely spaced leucine residues which are required for the interaction of the two monomers. Some DNA-binding proteins with this general motif contain other hydrophobic amino acids in these positions; hence, this structural motif is generally called a basic zipper.

Leukotrienes

ALAN R. LEFF, NILDA M. MUÑOZ
Department of Medicine, University of Chicago,
IL, USA

Synonyms

►Cysteinyl leukotrienes; B-leukotriene

Definition

Leukotrienes belong to a large family of lipid mediators, termed eicosanoids, which are derived from arachidonic acid (AA) and released from the cell membrane by phospholipases. AA is subsequently converted by the enzyme, 5-lipoxygenase (5-LO) and a protein cofactor, ►5-lipoxygenase activating protein (FLAP), into two bioactive classes of leukotriene (LT): (i) LTB₄ and (ii) ►cysteinyl leukotrienes (cysLTs), LTC₄, D₄, and E₄. Leukotrienes do not exist in the state preformed in cells. These compounds play a significant role in allergic responses and contribute variably to the bronchoconstrictor response in human ►bronchial asthma, and possibly, chronic obstructive pulmonary disease.

Basic Characteristics

Synthesis and Metabolism

The site of synthesis of leukotrienes is largely or completely in the nuclear membrane. LTs are produced from cell membrane phospholipid-associated arachidonic acid (AA), which is liberated by 85 kDa cytosolic group IVAPLA₂ (cPLA₂) (Fig. 1) or phospholipase C (not shown) in response to cell activation. The secretory phospholipase group V PLA₂ (gVPLA₂) also is capable of inducing leukotriene synthesis, probably from phosphatidylcholine-rich membrane hydrolysis at both plasma or perinuclear membrane [1]. AA is converted to 5-HETE and subsequently to an unstable epoxide LTA₄ ([5(s)-trans-5,6-oxido-7,9-trans11,14-cis-eicosatetra- nonic acid]), a central intermediary in LT biosynthesis. LTs are synthesized in the cells by 5-LO which acts in concert with FLAP, a protein essential for 5-LO to function enzymatically in intact cells. In neutrophils, LTA₄ is transformed by LTA hydrolase to dihydroxy LTB₄, whereas in ►eosinophils, macrophages, basophils, and mast cells that express LTC₄ synthase, the terminal enzyme involved in cysLT synthesis, LTA₄ is conjugated with the tripeptide glutathione to form LTC₄. Outside of the cell, LTC₄ is rapidly converted by γ -glutamyltranspeptidase into LTD₄. LTD₄ is converted more slowly into LTE₄ by a dipeptidase, which is secreted into the urine and is sometimes used (controversially) as a marker for cysLT synthesis. Leukotriene B₄, a noncysteine

Leukotrienes. Figure 1 Schema representing cellular biosynthesis of cysteinyl leukotrienes (cysLTs) and BLT at the nuclear membrane. In this schema, cPLA₂ has migrated from the cytosol to the nuclear envelope and 5-LO is secreted from the nucleus to bind with FLAP and produce the metabolite, LTA₄, which is synthesized by 5-LO from 5-HPETE (not shown) in two steps. LTA₄ is converted by LTC₄ synthase which after LTC₄, is converted rapidly to LTD₄ outside of the inflammatory cell. Note that a specific hydrolase (LTA₄ hydrolase) also catalyzes the formation of LTB₄, a non-cysLT, which has its own receptor. See text for details.

containing dihydroxy leukotriene, binds to its own BLT receptor. The cysLTs are characterized by a side chain containing 3, 2, or 1 amino acid(s) (cysteine is always present); there are two or more specific cysLT receptors in tissues at various sites including airway smooth muscle, vascular smooth muscle, and inflammatory cells themselves. Both cysLT receptors have been characterized and cloned. LTD₄ binds to high affinity CysLT₁ receptor while CysLT₂ receptor is most preferred target for LTC₄.

Recent investigations have suggested that cysLT may also be synthesized in the cytosol in lipid bodies that are formed during cellular activation in eosinophils [2]. It has been suggested that all enzyme and transport systems essential to cysLT synthesis exist in these lipid bodies, and hence synthesis could occur without translocation of cPLA₂ to the nuclear envelope. Likewise, it has been suggested that 5-LO is not stored within the nucleus, but rather is an enzyme dispersed throughout the cytosol, which migrates to the perinuclear membrane and cytosolic lipid bodies upon cellular activation. Recently, the role of 14 kDa secretory PLA₂ in leukotriene synthesis has been explored in human granulocytes [1]. Studies demonstrated that gVPLA₂ is capable of causing AA synthesis and subsequent LT secretion by both cPLA₂-dependent and -independent pathways. Among the secretory enzymes, gVPLA₂ is unique because it can bind cell membranes by two distinct mechanisms: (i) cell surface proteoglycan through a cluster of cationic residues at the carboxy terminus of the enzyme and (ii) direct interfacial binding to membrane phosphatidylcholine. In eosinophils, gVPLA₂ is internalized and binds to perinuclear membrane to generate AA and subsequent

translocation of cytosolic 5-LO to perinuclear membrane. Accordingly, LTC₄ secretion caused by gVPLA₂ in eosinophils does not involve ERK-1/2 mediated cPLA₂ phosphorylation. By contrast, LTB₄ secretion caused by gVPLA₂ in neutrophils is mediated through activation of the cPLA₂ pathway. These novel pathways for gVPLA₂ are fully established in granulocytes; however, the role of other 14 kDa sPLA₂ isoforms in LT synthesis *in vitro* remains an area of considerable interest. sPLA₂s have been identified in the bronchoalveolar lavage fluid of asthmatic subjects.

Leukotriene Receptors

There are two distinct receptor types for LTB₄ (BLT₁ and BLT₂ receptors) and two for cysLTs (CysLT₁ and CysLT₂ receptors). Classification is based mainly on functional data as derived from recent cloning and biochemical characterization. For LTB₄, high affinity BLT₁-receptor shows high degree of specificity for LTB₄ (Kd 0.15–1 nM) and is only expressed in inflammatory cells. Recently identified low affinity BLT₂-receptor has a higher Kd value for LTB₄ (23 nM) and is expressed ubiquitously, in contrast to BLT₁, in leukocytes.

The cysLTs are a family of potent bioactive lipids that act through two structurally divergent G protein coupled CysLT₁ and CysLT₂ receptors. mRNA expression demonstrates the CysLT₁ gene, which is located on the X chromosome and is identified in macrophages, smooth muscle cells, leukocytes, lung, and spleen. The CysLT₁ receptor was originally identified on the basis of its contractile properties for bronchial smooth muscle. The agonist for the CysLT₁ receptor are

LTD₄ > LTC₄ > LTE₄. The second receptor, CysLT₂, binds equally to LTD₄ and LTC₄; mRNA is expressed in heart, leukocytes, spleen, brain, placenta, and lymph nodes. To date, the functional role of CysLT₂ receptor remains unclear. The current nomenclature is summarized in Table 2, together with order of potency of the LTs, names of some selective antagonist drugs and expression in human and mouse tissues/cells.

Role of Leukotrienes in Inflammatory Diseases

LTB₄, a B-leukotriene, is a potent chemotaxin for neutrophils and T-cells and a weak chemotaxin for human eosinophils. In human neutrophils, LTB₄ causes translocation of intracellular calcium that initiates an autocrine pattern of stimulated cellular activity. It promotes the adhesion of neutrophils to the vascular endothelium and enhances the migration across the endothelial wall into the surrounding tissues. LTB₄ also causes the release of toxic oxygen radicals, lysosomal enzymes, and chemokines/cytokines from proinflammatory cells. Some studies have shown that LTB₄ may cause contraction of both human bronchus and guinea pig parenchymal strips *in vitro*; however, blockade of LTB₄ receptor has little or no therapeutic action in human asthma.

The cysLTs were formerly known as SRS-A (slow reacting substance of anaphylaxis) because of the slow, sustained contraction of airway smooth muscle that resulted from the secretion of this substance(s) upon mast cell activation. Human bronchi may have a homogenous population of CysLT₁ receptors, whereas guinea pig trachea have both CysLT_{1/2} receptors. Although originally identified in tissue mast cells, eosinophils, and mast cells, both have substantial cysLT synthetic capacity. Because the eosinophil is ubiquitous in asthma and allergic disease and because it is capable of cysLT synthesis, this cell has generally been regarded as primary mechanism for sustained cysLT secretion in allergic states (Table 1). However, recent publications have suggested the eosinophil secretion is relatively minimal compared to mast cell secretory capacity for cysLTs.

Asthmatic exacerbations are associated with chemotaxis of eosinophils from the peripheral blood across endothelial membranes into the parenchyma and lumen of the conducting airways of the lung. This process is facilitated by the upregulation of β_1 - and β_2 -integrins, which bind to counterligands of the immunoglobulin supergene family on the endothelial surface. Diapedesis is facilitated by the presence of these ligands on both sides of the endothelium (luminal and parenchymal). The migration of eosinophils from the peripheral blood to human airways provides a continuous reservoir for leukotriene synthesis in allergic and asthma reactions. The 85 kDa cPLA₂ that catalyzes the first steps of leukotriene synthesis also serves as a messenger protein for cellular adhesion, likely by the synthesis of lysophospholipid, which is the by-product of membrane hydrolysis in which AA is also synthesized.

Leukotrienes play a role in both allergy and asthma [5]. While cysLTs are highly efficacious bronchoconstricting agents when administered exogenously to human asthmatics (Fig. 2) (1000-fold the potency of histamine), a substantial role for cysLT in asthmatic bronchoconstriction has not been established. Amelioration of inflammatory response by corticosteroids in both asthma and allergic reactions is highly efficacious and does not appear to result from blockade of leukotriene synthesis. No other chronic inflammatory disease has been linked directly to cysLT secretion despite the capacity for these compounds to cause edema and inflammatory cell migration.

Drugs

The effects of leukotrienes can be blocked at several levels. Inhibitors of FLAP or 5-LO inhibit LT synthesis at all levels. However, FLAP antagonists developed to date have been too hepatotoxic for human use. Zileuton, a 5-LO synthase inhibiting drug, also demonstrated some hepatotoxicity in a small percentage of patients, which was nonetheless entirely reversible. However, the short half-life of this compound requires four times daily

Leukotrienes. Table 1 Pharmacologic actions of the leukotrienes

LTB ₄	CysteinyI LTs (LTC ₄ , LTD ₄ , LTE ₄)
PMN aggregation	Airway smooth muscle contraction
PMN chemotaxis	Constriction of conducting airways
Nuclear transcription	Contraction of guinea pig parenchyma
Exudation of plasma	Secretion of mucus
Translocation of calcium	Fluid leakage from venules

administration, and accordingly, this compound is rarely prescribed. The most widely used antiLT drugs are the ►leukotriene receptor antagonists (LTRAs; see Table 2), which were synthesized before the cloning of the CysLT₁ receptor. These include pranlukast, which is widely

Leukotrienes. Figure 2 Relative airway responses of asthmatic patients to inhaled cysteinyl leukotrienes versus histamine. CysLTs have up to 1,000-fold greater potency in causing bronchoconstriction than histamine. Reprinted with permission from (2).

used in Japan, and zafirlukast and montelukast, which are used in the USA, Europe, and Asia. In controlled studies in human asthmatics, these compounds cause 5–8% improvement in bronchoconstriction as measured by the forced expiratory volume in 1 s (FEV₁). LTRAs have been shown to reduce the need for inhaled corticosteroids (ICS) and β-adrenoceptor agonists in human asthma. Additional studies have suggested that addition of LTRA to ICS or β-adrenoceptor agonists augments the improvement in FEV₁. Nonetheless, LTRAs are fairly expensive and substantially less efficacious than either long-acting β-adrenergic agonists (LABA) or ICS, particularly when LABA and ICS are used in combination. Accordingly, the use of LTRAs is often relegated to either mild asthma or as supplemental therapy for patients failing to respond to other drugs.

There are few definitive data to substantiate the efficacy of LTRA therapy in refractory asthma, except for patients with “aspirin-sensitive asthma.” This is a fairly uncommon form of asthma that occurs generally in adults who often have no prior (i.e., childhood) history of asthma or ►atopy, may have nasal polyposis, and who often are dependent upon oral corticosteroids for control of their asthma. This syndrome is not specific to aspirin but is provoked by any inhibitors of the cyclooxygenase-1 (COX-1) pathway. These patients have been shown to have a genetic defect that causes

^aPartial agonist in some tissues.

overexpression of the enzyme LTC₄ synthase. However, the mechanism by which bronchoconstriction is provoked by COX-1 inhibition remains unexplained. In such patients, LTRAs are specifically indicated. There is limited evidence suggesting that patients with aspirin-sensitive asthma can use selective COX-2 inhibitors safely; however, COX-2-specific analgesics still are not recommended for use in aspirin-sensitive asthma by the FDA in the USA and may themselves be cardiotoxic.

Although some studies have shown no change in the excretion of LTE₄ in the urine of patients treated with corticosteroids, other investigations indicated that corticosteroids inhibit cPLA₂ translocation to the nuclear membrane in inflammatory cells, thus attenuating stimulated synthesis of cysLTs. This would suggest that oral and possibly inhaled corticosteroids may also inhibit production of cysLTs both directly (see above) and indirectly by causing necrosis and apoptosis of eosinophils.

In the USA, LTRAs have largely replaced theophylline as the incremental drug for the treatment of moderate and severe asthma, where LABA plus ICS alone do not provide adequate control. For patients with mild persistent asthma, LTRAs have been designated as a suitable substitute for low dose ICS by the National Asthma Education Panel Program (NAEPP) of the National Heart and Lung Institute (National Institutes of Health). However, inhaled ICS are more efficacious.

Therapeutic Response to Antileukotriene Drugs

When given acutely to patients who have no prior exposure to LTRA therapy, FEV₁ increases measurably within 30 min and results in a maximal improvement of about 8% in 1 h. For short acting drugs (e.g., zileuton), this response returns rapidly to baseline, and the drug must initially be administered in four doses daily. In this regard, the initial effects of 5-LO inhibition are more like bronchodilators than disease modifying agents. However, with prolonged use (>60 days), there is little difference between peak and trough response in FEV₁, even if zileuton administration is decreased to twice daily. This acquired, longer acting effect has been suggested to imply a disease modifying effect of antileukotriene therapy. In some studies, even acute administration of LTRAs has caused a modest decrease in eosinophil migration into asthmatic airways and the presence of the cysLT receptor, which has been recently identified on eosinophils, suggests a possible mechanism for this action. Other recent studies indicate that the LTRA, montelukast, if infused intravenously causes rapid incremental increase in FEV₁ in patients seeking treatment for acute asthma. The reason for the improved efficacy by intravenous infusion is unclear, but further investigations are examining the future role of LTRAs as potential rescue drugs in acute asthma.

LTRAs are extremely safe for patient use. However, the present generation of LTRAs is only modestly efficacious. Many patients show no clinically meaningful response, and current recommendations suggest a 1 month trial period to determine if patients will benefit from these drugs. With the exception of aspirin-sensitive asthmatics, there is currently no means for predicting which patients or under what circumstances antileukotriene therapies will be effective.

Lewy Bodies

Lewy bodies are typical in neuronal degeneration, which is accompanied by the presence of these eosinophilic intracellular inclusions of 5–25 μm diameter in a proportion of still surviving neurons. Lewy bodies contain neurofilament, tubulin, microtubule-associated proteins 1 and 2, and gelsolin, an actin-modulating protein.

Liddle's Syndrome

Liddle's syndrome is an autosomal dominant disorder that is caused by persistent hyperactivity of the epithelial Na channel. Its symptoms mimic aldosterone excess, but plasma aldosterone levels are actually reduced (pseudaldosteronism). The disease is characterized by early onset arterial hypertension, hypokalemia, and metabolic alkalosis.

Disease-causing mutations are found in the cytoplasmic regulatory region of the β and γ subunits of the epithelial sodium channel (ENaC) genes. In general, patients with Liddle's syndrome can be treated successfully with the ENaC inhibitor amiloride.

Ligand

A ligand can be an antagonist or agonist that binds to a receptor.

Ligand-Gated Ion Channels

Ion channels that are opened by binding of a neurotransmitter (or drug) to a receptor domain on extracellular sites of the channel protein(s) are defined

as ligand-gated. Nicotinic acetylcholine, glutamate, γ -aminobutyric acid_A (GABA_A) and glycine receptors are examples of this type of receptor-linked ion channel.

Linkage Disequilibrium (LD)

Polymorphisms in the human genome are often not independently transmitted; i.e., a polymorphism is associated with particular variants present on the same chromosome. Recombination erodes this association, but for physically close polymorphisms (e.g., within a gene), the correlation, known as LD, persists over time.

Lipid-lowering Drugs

Lipid-lowering drugs are drugs that affect the lipoprotein metabolism and that used in therapy to lower plasma lipids (cholesterol, triglycerides). The main classes of

drugs used clinically are statins (HMG-CoA reductase inhibitors), anion exchange resins (e.g. cholestyramine and cholestipol), fibrates (bezafibrate, gemfibrozil or clofibrate) and other drugs like nicotinic acid.

Definition

Covalent attachment of lipid moieties to proteins plays important roles in the cellular localization and function of a broad spectrum of proteins in all eukaryotic cells. Such proteins, commonly referred to as lipidated proteins, are classified based on the identity of the attached lipid (Fig. 1). Each specific type of lipid has unique properties that confer distinct functional attributes to its protein host. *S*-acylated proteins, commonly referred to as palmitoylated proteins, generally contain the 16-carbon saturated acyl group palmitoyl attached via a labile thioester bond to cysteine residue(s), although other fatty acyl chains may substitute for palmitoyl group. *N*-myristoylated proteins contain the saturated 14-carbon myristoyl group attached via amide bond formation to amino-terminal glycine residues. *S*-prenylated proteins contain one of two ▶ **isoprenoid** lipids, either the 15-carbon farnesyl or 20-carbon geranylgeranyl. The fourth major class of lipidated proteins is those containing the glycosylphosphatidylinositol (GPI) moiety, a large and complex structure of which the lipid component is an entire phospholipid.

Basic Mechanisms

S-acylated proteins include many GTP-binding regulatory proteins (G proteins), including most α subunits of ▶ **heterotrimeric G-proteins** and also many members of the Ras superfamily of monomeric G proteins, a number of G protein-coupled receptors, several non-receptor ▶ **tyrosine kinases**, and a number of other signaling molecules. *S*-acylation is posttranslational and reversible, a property that allows the cell to control

Lipid	Structure	Position of modification
<i>N</i> -myristoyl		Amino-terminal glycine
<i>S</i> -acyl (<i>S</i> -palmitoyl)		Cysteine, no defined consensus
<i>S</i> -prenyl (farnesyl)		Cysteine at/near carboxyl-terminus
<i>S</i> -prenyl (geranylgeranyl)		Cysteine at/near carboxyl-terminus
GPI anchor	Complex structure includes phosphatidylinositol and sugars	Carboxyl-terminus

Lipid Modifications. Figure 1 Major classes of lipid-modified proteins.

the modification state, and hence the localization and biological activity, of the protein [1]. The lipid substrates for *S*-acylation are ►acyl-CoA molecules. The molecular mechanism of *S*-acylation is only recently being elucidated; the first identified acyltransferase specifically involved in the process being the product of the *Skinny Hedgehog (Ski)* gene in *Drosophila*. *Ski* orthologs have also been identified in mammalian genomes. This acyltransferase appears to specifically process secreted proteins, in particular a molecule important in development termed Hedgehog.

The process by which cytoplasmic proteins are subject to *S*-acylation is also becoming clarified. The breakthrough in this arena came from genetic screens in yeast, in which two related *S*-palmitoyltransferases were uncovered that are termed Erf2 and Akr1. These two gene products share a common sequence referred to as a DHHC (aspartate-histidine-histidine-cysteine) motif, and a large number of genes encoding DHHC-motif proteins can be identified in all eukaryotes for which genome information is available. Although biochemical details of the enzymatic function of DHHC-motif proteins are still rather limited, the available evidence is consistent with the DHHC domain playing a direct role in the protein acyltransferase reaction.

In addition, nonenzymatic acylation of cysteine thiols on proteins incubated in the presence of acyl-CoA has been described, although the biological importance of this process is still unclear.

N-myristoylated proteins include select α subunits of heterotrimeric G proteins, a number of nonreceptor tyrosine kinases, a few monomeric G-proteins, and several other proteins important in biological regulation [2]. There is some overlap between *S*-acylated and *N*-myristoylated proteins such that many contain both lipid modifications. Such “dual lipidation” can have important consequences, most notably the localization of the dually modified species to distinct membrane subdomains termed ►lipid rafts or ►caveolae. *N*-myristoylation is a stable modification of proteins. The myristoyl moiety is attached to the protein cotranslationally by the enzyme myristoyl CoA: protein *N*-myristoyltransferase (NMT); the lipid substrate is myristoyl-CoA. NMT has been extensively studied in regard to substrate utilization and kinetic properties, and crystal structures of fungal enzymes are available. There are two distinct but closely related genes encoding NMTs in mammalian cells, *NMT1* and *NMT2*, although differences between the two isoforms have not yet been described.

S-prenylation is the most recent of the four major types of lipid modifications to be described. As with *S*-acylation, *S*-prenylation is posttranslational. The lipid substrates for these modifications are farnesyl diphosphate and geranylgeranyl diphosphate. The mechanism

involves attachment of the isoprenoid lipid to cysteine residues at or near the carboxyl terminus through a stable thioether bond [3]. Two distinct classes of *S*-prenylated proteins exist in eukaryotic organisms. Proteins containing a cysteine residue fourth from the carboxyl terminus (the so-called CaaX-motif) can be modified by either the 15-carbon farnesyl or 20-carbon geranylgeranyl isoprenoid by one of two closely related termed protein farnesyltransferase (FTase) and protein geranylgeranyltransferase type 1 (GGTase-1); these enzymes are collectively referred to as CaaX prenyltransferases [4]. FTase and GGTase-1 are $\alpha\beta$ heterodimers; the α subunits of the enzymes are identical while the β subunits are the products of distinct, but related, genes. The identity of the “X” residue of the CaaX motif dictates which of the two enzymes recognize the substrate protein. Following prenylation, most CaaX-type proteins are further processed by proteolytic removal of the three carboxyl-terminal residues (i.e., the -aaX) by the Rce1 CaaX protease and methylation of the now-exposed carboxyl group of the prenylcysteine by the Icmt methyltransferase. A number of *S*-prenylated proteins are also subject to *S*-acylation at a nearby cysteine residue to produce a dually lipidated molecule, although this type of dual modification does not apparently target the protein to the same type of membrane subdomain as the dual acylation noted above.

The second class of *S*-prenylated proteins is a member of the Rab family of proteins, which is involved in membrane trafficking in cells. These proteins are geranylgeranylated at two cysteine residues at or very near to their carboxyl-terminus by protein geranylgeranyltransferase type 2 (GGTase-2), also known as Rab GGTase [5]. GGTase-2 is also a $\alpha\beta$ heterodimer and its subunits show significant sequence similarity to the corresponding subunits of the CaaX prenyltransferases [6]. However, unlike the CaaX prenyltransferases, monomeric Rab proteins are not substrates for GGTase-2. In order to be processed by the enzyme, newly synthesized Rab proteins first bind and form a stable complex with a protein termed Rep, and it is the Rab–Rep complex that is recognized by GGTase-II. The enzyme acts in a processive fashion, attaching both geranylgeranyl groups to closely spaced cysteine residues at or near the carboxyl-terminus of the Rab proteins. All three of the protein prenyltransferases (FTase, GGTase-1, GGTase-2) have been extensively characterized in regard to substrate recognition, mechanism, and structure.

GPI-anchored proteins constitute a quite diverse family of cell-surface molecules that participate in such processes as nutrient uptake, cell adhesion, and membrane signaling events [3]. All GPI-linked proteins are destined for the cell surface via trafficking through the secretory pathway, where they acquire the

preassembled GPI moiety. The entire procedure, which involves assembly of the GPI moiety from ►**phosphatidylinositol** and sugars and proteolytic processing of the target protein to expose the GPI addition site at the carboxyl-terminus of the protein, involves a number of gene products. Many of the genes associated with GPI biosynthesis have been cloned by complementation of GPI-deficient mammalian cell lines and temperature-sensitive yeast GPI mutants. The precise mechanisms through which these enzymes work in concert to produce a GPI-anchored protein are just now beginning to be elucidated.

Pharmacological Intervention

Since the mechanisms of protein *S*-acylation are so poorly understood, there is little in the way of good pharmacological agents that target this process. One compound that has been used with modest success is cerulenin, which apparently mimics the acyl-CoA substrate in the reaction catalyzed by the putative *S*-acyltransferase that acts on intracellular proteins. In contrast, there has been substantial effort to identify and characterize specific inhibitors of *N*-myristoylation [2]. Genetic and biochemical studies have established NMT as a target for development of anti-fungal drugs. The enzyme is also a potential target for the development of antiviral and antineoplastic agents. Both peptidic and nonpeptidic inhibitors of NMTs, particularly fungal NMTs, have been described.

There has been enormous effort in the past 10 years to develop pharmacological agents targeting the *S*-prenylation by CaaX prenyltransferases, especially FTase [4]. This is primarily due to the interest in one subset of *S*-prenylated proteins, the Ras proteins, due to the important role of Ras in ►**oncogenesis**. Ras proteins are modified by the 15-carbon farnesyl isoprenoid, and farnesylation of these proteins is indispensable for both normal biological activity and oncogenic transformation. Selective inhibitors of FTase, termed FTIs, can reverse Ras-mediated oncogenic transformation of cells, and several are in clinical development as anticancer therapeutics. Literally hundreds of potent inhibitors of FTase, and many of GGTase-1, have been identified using several strategies, including design of analogs of the CaaX peptide and isoprenoid substrates and by high-throughput screening of natural product and compound libraries. These compounds can be placed into four distinct categories: mimics of CaaX tetrapeptides, mimics of FPP, ►**bisubstrate analogs**, and organic compounds selected from natural product and chemical libraries. There has been relatively little development of pharmacological agents targeting GGTase-2. It is likely, however, that some of the isoprenoid analogs that show activity against GGTase-1 will also have inhibitory activity on GGTase-2 given that both enzymes use the same isoprenoid substrate.

There is also increasing interest in developing pharmacological agents targeting the biosynthesis of GPI-anchored proteins [3]. Such proteins are particularly abundant on the surface of a number of protozoan organisms. Several devastating tropical diseases such as African sleeping sickness and Chagas disease are caused by protozoan parasites that rely heavily on cell-surface GPI-anchored proteins for both inhabiting their host and escaping immune detection. In studies primarily involving gene disruption approaches, several of the enzymes involved in GPI biosynthesis have been identified as attractive targets for development of antiparasitics. To date, there is very little publically available information on specific inhibitors of the enzymes involved in GPI biosynthesis and attachment, but it is likely that such information will be forthcoming.

Lipid Phosphate Phosphohydrolases

Lipid phosphate phosphohydrolases (LPPs), formerly called type 2 phosphatidate phosphohydrolases (PAP-2), catalyse the dephosphorylation of bioactive phospholipids (phosphatidic acid, ceramide-1-phosphate) and lysophospholipids (lysophosphatidic acid, sphingosine-1-phosphate). The substrate selectivity of individual LPPs is broad in contrast to the related sphingosine-1-phosphate phosphatase. LPPs are characterized by a lack of requirement for Mg²⁺ and insensitivity to *N*-ethylmaleimide. Three subtypes (LPP-1, LPP-2, LPP-3) have been identified in mammals. These enzymes have six putative transmembrane domains and three highly conserved domains that are characteristic of a phosphatase superfamily. Whether LPPs cleave extracellular mediators or rather have an influence on intracellular lipid phosphate concentrations is still a matter of debate.

Lipid Rafts

Lipid rafts are specific subdomains of the plasma membrane that are enriched in cholesterol and sphingolipids; many signaling molecules are apparently concentrated in these subdomains.

Plasma lipid transfer proteins

Definition

Plasma lipid transfer proteins, which include the cholesteryl-ester-transfer-protein (CETP; previously known as lipid transfer protein I, LTP-I) and the phospholipid-transfer-protein (PLTP; previously known as lipid transfer protein II, LTP-II) mediate the transfer of lipids (cholesteryl esters, triglycerides and phospholipids) between lipoproteins present in human plasma. These proteins significantly affect plasma lipoprotein concentration and composition.

Basic Characteristics

Gene and Protein Characteristics

The genes coding for CETP and PLTP belong to one gene family, which also includes lipopolysaccharide-binding-protein (LBP) and bactericidal/permeability-increasing-protein (BPI). This common descent not only becomes clear from a considerable sequence similarity (45–65% homology at the cDNA level), but also from substantial conservation of exon/intron transitions.

The gene encoding CETP is located on the long arm of chromosome 16 (16q12-21), spans approximately 25 kbp and harbors 16 exons and 15 introns. The molecule mass of its mature protein product is 74 kDa. Major sites of CETP gene expression in humans are the

liver, spleen and adipose tissue, with lower levels of expression in the small intestine, adrenals, kidney and heart. CETP present in human plasma seems to originate predominantly from the liver and adipose tissue, although data that have assessed this directly in man are lacking. The majority of human plasma CETP (~90%) is bound to ►high-density lipoprotein (HDL) particles. An important regulatory factor of CETP gene expression is hypercholesterolemia, which induces gene transcription. Sequences necessary for this cholesterol-responsiveness are located in the natural flanking regions of the human CETP gene, upstream of the transcription start site. This regulatory sequence concerns an element of two direct repeats separated by four nucleotides (DR4 element). This element enhances CETP gene expression following activation through a heterodimer, containing the transcription factors Liver X Receptor (LXR) and Retinoid X Receptor (RXR). In order to enhance gene transcription, these transcription factors require activation through ligands, which include cholesterol and its oxysterols.

The gene coding for PLTP has been mapped to chromosome 20 (20q12-13.1), where also the genes for LBP and BPI are situated. The PLTP gene contains 13.3 kbp, with similar organization as compared to CETP (16 exons-15 introns). Purified PLTP has a molecule mass of 81 kDa. PLTP is expressed in a variety of tissues including placenta, pancreas, lung, kidney, heart, liver, adipose tissue, skeletal muscle and brain. Macrophages also express PLTP and may contribute significantly to plasma PLTP activity levels. PLTP gene expression can be upregulated by cholesterol in a similar way as described for CETP. In addition, PLTP gene expression is subject to regulation via response elements for the peroxisome proliferator activated receptor (PPAR) alpha and the farnesoid X-activated receptor (FXR).

Detailed protein structures have been reported for BPI and CETP. Given the aforementioned similarities within this gene family, these protein structures serve as a likely model for the protein structure of PLTP. CETP and BPI are elongated molecules, shaped like a boomerang. There are two domains with similar folds, and a central beta-sheet domain between these two domains. The molecules contain two lipid-binding sites, one in each domain near the interface of the barrels and the central beta-sheet.

Function

In humans, CETP and PLTP are directly involved in the transfer of lipids between different ►lipoprotein classes. Through their action, these lipid transfer proteins have major effects on the concentration and composition of HDL. This section further describes the physiological function of CETP and PLTP in humans.

CETP mediates the exchange of cholesteryl esters and triglycerides between HDL and the proatherogenic,

apoB-containing lipoprotein fractions, predominantly ▶**very-low density lipoprotein** (VLDL). Specifically, triglycerides are transported from VLDL to HDL, with cholesteryl esters transferred in the opposite direction. It is generally acknowledged that CETP itself has no preference for the type of lipoprotein in its substrate specificity. The VLDL–HDL axis is likely to result from the presence of plasma lipid transfer inhibitor protein (LTIP), which is associated almost exclusively with ▶**low-density lipoprotein** (LDL) and inhibits the CETP-mediated transfer of cholesteryl esters and triglycerides. LTIP suppresses the involvement of LDL, thereby directing the CETP activity towards the remaining lipoprotein fractions, VLDL and HDL. The CETP-mediated lipid exchange is an equimolar and energy neutral process. The exchange seems to occur by a shuttle mechanism, rather than by the formation of a complex between CETP and donor and acceptor lipoproteins. In addition to LTIP, composition and concentration of lipoprotein substrates are important regulatory factors of the CETP-mediated exchange activity, and under physiological conditions, the net mass of VLDL-triglycerides may be rate limiting. The relevance of CETP for human lipid metabolism became evident after the identification of humans with partial or near complete loss of CETP activity due to the presence of a mutation in one or both alleles of the CETP gene. In these subjects, who predominantly live in Japan, (partial) loss of plasma CETP reduces the ability of cholesteryl esters to be transported out of HDL. This results in a net increase in plasma HDL cholesterol (HDL-C) levels, with the appearance of HDL particles that have increased in size. This change is paralleled by increased concentrations of ▶**apolipoprotein A-I** (apoA-I), which results from delayed catabolism of these large sized HDLs. In some cases of severe CETP deficiency, the reduced transfer of cholesteryl esters from HDL to VLDL furthermore gives also rise to mildly decreased levels of LDL cholesterol (LDL-C), which originates from VLDL. Recently, the first Caucasian family was described with partial CETP deficiency due to a novel splice site mutation in the CETP gene.

PLTP is responsible for the majority of phospholipid transfer activity in human plasma. Specifically, it transfers surface phospholipids from VLDL to HDL upon lipolysis of triglycerides present in VLDL. The exact mechanism by which PLTP exerts its activity is yet unknown. The best indications for an important role in lipid metabolism have been gained from knockout experiments in mice, which show severe reduction of plasma levels of HDL-C and apoA-I. This is most likely the result of increased catabolism of HDL particles that are small in size as a result of phospholipid depletion. In addition to the maintenance of normal plasma HDL-C and apoA-I concentration, PLTP is also involved in a process called HDL conversion. Shortly summarized, this cascade of processes leads to fusion of HDL

particles into larger particles, with a concomitant release of lipid-poor apoA-I. This newly formed lipid-poor apoA-I is a pivotal particle in the uptake of free cholesterol from peripheral cells via efflux through ABCA1. This is a potentially antiatherogenic function of PLTP, but – surprisingly – overexpression of human PLTP in mice results in increased susceptibility for diet-induced atherosclerosis and a reduction of plasma HDL-C, again due to hypercatabolism of apoA-I. At present, no reports exist on genetic PLTP deficiency in humans. Therefore, any hypothesis on the relevance of PLTP activity for human lipid metabolism remains to be confirmed. When it comes to humans, plasma PLTP activity is increased in insulin-resistant individuals with high plasma triglycerides and low HDL-C, as well as in patients with diabetes mellitus. In patients with type 2 diabetes, PLTP activity is positively associated with intima-media thickness, which is a surrogate measure for the risk of atherosclerotic disease. In addition, elevated PLTP activity is decreased by statin treatment.

Drugs

Plasma HDL-C concentration is negatively associated with occurrence of cardiovascular disease, independent of age, gender, LDL-C and other established risk factors. Consequently, there is great interest for pharmacological interventions to raise HDL-C. Among the drugs that are currently available, statins, fibrates and nicotinic acid exert such an increasing effect on plasma HDL-C concentrations. These drugs, however, are limited in their HDL-C raising efficacy (statins: +3% to +9%, fibrates: +0% to +11%, nicotinic acid: +7% to +23%) or exhibit significant side effects (nicotinic acid: flushes). The high levels of HDL-C observed in case of CETP deficiency have led to the development of strategies to raise HDL-C by inhibition of CETP activity in humans. Two such strategies are currently in advanced stage of development, i.e., vaccine-induced inhibition and inhibition of CETP activity through small-molecule compounds. Among these, the latter has attracted most attention. The effects of CETP inhibition through small-molecule compounds parallel those observed in genetic CETP deficient subjects to a large extent: increase of plasma HDL-C and apoA-I concentration, with the occurrence of large sized HDL particles due to cholesteryl ester enrichment. In case of potent CETP inhibition, plasma levels of LDL-C and apoB are also decreased. With respect to the effects on cardiovascular disease exerted by these lipoprotein changes, data from epidemiological studies might justify optimism. However, clinical trials assessing the consequences of CETP inhibition on surrogate and clinical cardiovascular endpoints are required. One such trial has recently been terminated due to an increased number of lethal cardiovascular events occurring in the CETP-inhibition group. At the moment,

it remains to be established whether this relates to intrinsic characteristics of the study drug or to the mechanism of CETP-inhibition in general.

Due to the absence of human models for PLTP deficiency, our knowledge about the relevance of plasma PLTP activity for human lipid metabolism is still incomplete. No investigational drugs are available that specifically target the activity of this protein.

Synonyms

Lipid metabolism; Cholesterol metabolism

Definition

► **Lipoprotein** metabolism is the process by which hydrophobic lipids, namely triglycerides and cholesterol, are transported within the interstitial fluid and plasma. It includes the transport of energy in the form of triglycerides from intestine and liver to muscles and adipose, as well as the transport of cholesterol both from intestine and liver to peripheral tissues, as well as from peripheral tissues back to the liver.

Basic Mechanisms

Lipoproteins are large macromolecular complexes, which transport triglycerides and cholesterol within the blood. Triglycerides are a key component of energy transport and metabolism, and cholesterol is an essential component of all cells and required for steroidogenesis. The structure of lipoproteins is a hydrophobic neutral lipid core consisting of triglycerides and cholesteryl esters, surrounded by amphipathic phospholipids and specialized proteins known as ► **apolipoproteins**. Phospholipids serve to permit interaction with the aqueous environment, and apolipoproteins are required for the structural integrity of lipoproteins and direct their metabolic interactions with enzymes, lipid transport proteins, and cell surface receptors. The five major families of lipoproteins are ► **chylomicrons**, ► **very-low-density lipoproteins (VLDL)**, ► **intermediate-density lipoproteins (IDL)**, ► **low-density lipoproteins (LDL)**, and ► **high-density lipoproteins (HDL)**. Chylomicrons are the largest and most lipid-rich lipoproteins, whereas HDL are the smallest lipoproteins and contain the least amount of lipid. In the exogenous pathway of lipid transport (Fig. 1), dietary fat and cholesterol are absorbed by intestinal enterocytes and incorporated into chylomicrons, which contain the major structural apolipoprotein B-48. Chylomicrons are initially secreted into lymph thus bypassing the hepatic first pass effect. Once they gain entry into the systemic circulation they bind to ► **lipoprotein lipase (LPL)** on the luminal surface of the capillary endothelium of tissues (► **endothelial lipase**), especially muscle and adipose tissue. The LPL hydrolyzes the triglycerides (apolipoprotein C-II on the chylomicron surface is a required cofactor for LPL). The free fatty

Lipoprotein Metabolism. Figure 1 Exogenous pathway of lipoprotein metabolism.

Lipoprotein Metabolism. Figure 2 Endogenous pathway of lipoprotein metabolism.

acids enter the tissue to be used for energy (muscle) or storage (adipose) and the triglyceride-depleted chylomicron remnant (CMR) is released. CMRs are taken up by the liver by binding of apolipoprotein E to the LDL receptor and the LDL receptor-related protein (LRP). In the endogenous pathway of lipid transport (Fig. 2), the liver synthesizes triglycerides and cholesteryl esters and packages them into VLDL, which contain the major structural apolipoprotein B-100. VLDLs are hydrolyzed by LPL to form intermediate density lipoproteins (IDL). IDL can be taken up by the liver via binding of apolipoprotein E to the LDL receptor or LRP. Alternatively, the triglyceride and phospholipid in IDL can be hydrolyzed by ▶hepatic lipase (HL) within the hepatic sinusoids to form LDL. LDL can be taken up by peripheral cells or by the liver by the binding of apolipoprotein B-100 to the LDL receptor.

The pathways of HDL metabolism and reverse cholesterol transport are complex (Fig. 3, [1]). HDL and its major apolipoprotein apoA-I are synthesized by both the intestine and the liver. A second major

HDL protein apoA-II is made only by the liver. Nascent HDL interacts with peripheral cells to facilitate the removal of excess free cholesterol through a process that is facilitated by the cellular protein ATP-binding cassette protein A1 (ABCA1). Some of the acquired free cholesterol is esterified to cholesteryl ester on the HDL particle by the action of the enzyme ▶lecithin-cholesterol acyltransferase (LCAT) and the nascent HDL particle becomes the larger HDL₃. HDL acquires further cholesteryl ester by continued LCAT action and eventually becomes the even larger HDL₂. HDL₂ can selectively transfer both cholesteryl ester and free cholesterol to the liver via an HDL receptor in the liver called scavenger receptor BI (SR-BI). Cholesteryl esters can also be transferred from HDL₂ to apoB-containing lipoproteins such as VLDL and LDL via the action of the ▶cholesteryl ester transfer protein (CETP) and then returned to the liver by hepatic uptake of LDL. HDL₂ triglycerides and phospholipids can be hydrolyzed by HL and endothelial lipase (EL) to remodel it to HDL₃. Cholesterol derived from HDL contributes to the hepatic cholesterol pool used for bile acid synthesis and the cholesterol is eventually excreted into the bile and feces as bile acid or free cholesterol.

Disorders of lipoprotein metabolism involve perturbations which cause elevation of triglycerides and/or cholesterol, reduction of HDL-C, or alteration of properties of lipoproteins, such as their size or composition. These perturbations can be genetic (primary) or occur as a result of other diseases, conditions, or drugs (secondary). Some of the most important secondary disorders include hypothyroidism, diabetes mellitus, renal disease, and alcohol use. Hypothyroidism causes elevated LDL-C levels due primarily to downregulation of the LDL receptor. Insulin-resistance and type 2 diabetes mellitus result in impaired capacity to catabolize chylomicrons and VLDL, as well as excess hepatic triglyceride and VLDL production. Chronic kidney disease, including but not limited to end-stage

by mutations in the gene *ABCA1*. ABCA1 facilitates efflux of cholesterol from cells to lipid-poor apoA-I, and in its absence apoA-I is not appropriately lipidated and is rapidly cleared from the circulation. LCAT deficiency causes markedly low levels of HDL-C, establishing the importance of cholesterol esterification by LCAT in the maintenance of normal HDL metabolism. Finally, CETP deficiency causes markedly elevated levels of HDL-C, establishing the importance of cholesteryl ester by CETP in the maintenance of normal HDL metabolism. Again, all of these gene products are targets of new HDL-based therapies.

Pharmacologic Relevance

LDL Cholesterol Reduction

Disorders of lipoprotein metabolism are important risk factors for atherosclerotic vascular disease (ASCVD). Thus the field of lipoprotein metabolism has been a fertile area for the development of drugs that modulate the levels of plasma lipoproteins. Intervention with drugs to reduce ►LDL cholesterol has been proven to decrease the risk of cardiovascular events [2]. Intervention with drugs to reduce triglycerides or raise HDL-C has not yet been definitively proven to reduce cardiovascular events. The early clinical trials for LDL-C reduction utilized niacin, bile acid sequestrants, and even the surgical approach of partial ileal bypass to reduce serum cholesterol levels. However, the bulk of the data supporting LDL-C reduction comes from the clinical outcome trials with ►HMG CoA-reductase inhibitors (statins). Early studies focused on patients with preexisting CHD, including the Scandinavian Simvastatin Survival Study (4S), the Cholesterol and Recurrent Events (CARE) study, and the Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID) trial and established the efficacy of statin therapy in reducing cardiovascular events in patients with CHD. Early primary prevention trials included the West of Scotland Coronary Prevention Study (WOSCOPS) and the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) and confirmed that the benefits of LDL cholesterol reduction extend to the primary prevention setting. Subsequent studies have expanded downward the range of baseline LDL-C levels for which statin therapy is beneficial as well as the target LDL that is effective [2], and include the Heart Protection Study (HPS), the Anglo-Scandinavian Cardiac Outcomes Trial Lipid-lowering Arm (ASCOT-LLA), the Collaborative Atorvastatin Diabetes Study (CARDS), the Treat to New Targets (TNT) trial, and the Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE-IT) study. These studies strongly support the “lower is better” approach to reducing LDL-C as applied to high-risk patients.

Thus drug therapy for LDL-C reduction is widely used. Statins are the cornerstone of LDL-C reducing drug therapy. By inhibiting cholesterol biosynthesis in the liver, statins lead to increased hepatic LDL receptor expression. There are six statins currently available: lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, and rosuvastatin. There is wide interindividual variation in the initial response to a statin, but once a patient is on a statin, the doubling of the statin dose produces a very predictable 6% further reduction in LDL-C. Some patients treated with statins develop muscle fatigue or pain, and severe myopathy and rhabdomyolysis have been reported. The risk of statin-associated myopathy is increased by the administration of drugs that interfere with the cytochrome P450 metabolism of statins [3]. Due to both inadequate reduction of LDL-C in some patients as well as statin intolerance in others, there is a clinical need for LDL-reducing drug therapy beyond statins. The most commonly used class is that of cholesterol absorption inhibitors; currently ezetimibe is the only drug in this class clinically available. Ezetimibe binds to and inhibits the function of NPC1L1, a major cholesterol transporter in the intestinal enterocyte responsible for absorption of luminal cholesterol derived both from diet as well as from bile. The inhibition of intestinal cholesterol absorption reduces hepatic cholesterol content and results in upregulation of hepatic LDL receptor expression. Ezetimibe at the 10 mg dose reduces cholesterol absorption by about 60% and reduces LDL-C levels by about 18% on average as monotherapy, and to a similar extent when used in combination with a statin. Ezetimibe is used in combination with statins to further reduce LDL-C levels and in patients who are statin-intolerant. In some cases, a third class of LDL-lowering drugs, bile acid sequestrants, is needed. Bile acid sequestrants bind bile acids in the intestine, prevent their reabsorption, and accelerate their loss in the feces. In order to maintain an adequate bile acid pool, the liver diverts cholesterol to bile acid synthesis, resulting in decreased hepatic cholesterol and upregulation of hepatic LDL receptor expression. Cholestyramine and colestipol are insoluble resins that must be suspended in liquid and colesevalam is available as large tablets, and relatively large amounts of bile acid sequestrants must be used to achieve effective LDL reduction.

Inability to achieve LDL-C goals with existing drug therapy remains an important unmet medical need. Advances in our understanding of the molecular regulation of LDL metabolism have generated new pharmacologic targets. These include the following: (i) inhibition of squalene synthase, another important enzyme in the cholesterol biosynthetic pathway; (ii) inhibition of MTP, which reduces VLDL production

and has been shown to reduce LDL-C levels; (iii) inhibition of apoB production using an antisense oligonucleotide approach; (iv) inhibition of PCSK9 based on the persuasive genetic data reviewed above.

The data supporting reduction in triglycerides or raising of HDL-C are much less abundant [4]. Fibrates and nicotinic acid are the most effective drugs in lowering TGs and raising HDL-C. Fibrates are agonists of PPAR α and are most effective as triglyceride lowering drugs, with modest effects in raising HDL-C. Fibrates lower triglycerides by activating PPAR α to stimulate \blacktriangleright LPL (enhancing triglyceride hydrolysis) and reduce hepatic apoC-III synthesis (enhancing clearance of TG-rich lipoproteins). A limited number of clinical trials with fibrates support the concept that they may reduce cardiovascular risk, particularly in patients with the phenotype of insulin-resistance. Increasingly, fibrates are being used in combination with statins. Nicotinic acid, or niacin, is a B-complex vitamin that in high doses lowers triglycerides and raises HDL-C levels. Niacin acutely reduces free fatty acid levels through inhibition of adipocyte triglyceride lipolysis, an effect now known to be mediated by the niacin receptor GPR109A, a G protein coupled receptor primarily expressed on adipocytes. Whether this mechanism accounts for the triglyceride lowering and HDL-C raising associated with niacin therapy is uncertain. The clinical use of niacin is limited by prostaglandin-mediated cutaneous flushing which is also mediated by GPR109A expressed on dermal macrophages. Data that niacin reduces cardiovascular risk is limited, but are consistent with a cardioprotective effect. Patients with combined hyperlipidemia may achieve their LDL-C goal with a statin alone, but frequently have persistently elevated triglycerides and often do not achieve their non-HDL-C goal. In this situation, the addition of either niacin or a fibrate to the statin can be highly effective in reducing the triglycerides and non-HDL-C levels. The therapy of low HDL-C is a major unmet medical need and new therapies designed to raise HDL-C levels or promote HDL function are under active development [1].

Lipoproteins

The main transport form of lipids in the circulation. They are spherical macromolecules of 10–1200 nm diameter composed of a core of neutral lipids (mostly cholesterol ester and triglycerides) surrounded by an amphipathic shell of polar phospholipids and cholesterol. Embedded in the shell of lipoproteins are apolipoproteins that are essential for assembly of the particles in tissues that secrete lipoproteins, and for their recognition by target cells.

Local Anaesthetics

MICHAEL BRÄU

Abteilung Anaesthesiologie und Operative
Intensivmedizin, Universitätsklinikum,
Justus-Liebig-Universität, Gießen, Germany

Definition

Local anaesthetics are drugs that reversibly interrupt impulse propagation in peripheral nerves thus leading to autonomic nervous system blockade, analgesia, anaesthesia and motor blockade in a desired area of the organism.

Mechanism of Action

Impulse propagation in the ►peripheral nervous system depends on the interplay between ion channels selective to potassium and sodium. Briefly, few voltage insensitive potassium channels allow diffusion of positively charged potassium ions from the internal side of the axon to the exterior. This leaves a negative charge at the internal side that is called resting potential and amounts to approximately -80 mV over the ►axonal membrane. Upon a small depolarisation of the membrane, ►voltage-gated Na^+ channels open (activate) and conduct positively charged sodium ions from the exterior to the interior of the axon that depolarises the membrane to about $+60$ mV (action potential). After a few milliseconds the channels close spontaneously (inactivation) terminating the action potential and thus giving it an impulse like character. The action potential spreads electrotonically to neighbouring sodium channels that also open to produce an action potential. In this way, the impulse is propagated along the nerve to (afferent) or from (efferent) the central nervous system. Local anaesthetics inhibit ionic current through voltage gated sodium channels in a concentration dependent and reversible manner therefore directly blocking the impulse propagation process in either direction [1]. The interaction between the local anaesthetic molecule and the sodium channel is complex. The binding affinity is low for resting channels, but dramatically increases when the channel is activated. Thus, at high stimulus frequency sodium current block increases (use-dependent block). Use-dependent block is not important for conduction block during local anaesthesia since very high concentrations are reached locally producing complete and sufficient block. However, when local anaesthetics such as lidocaine are applied intravenously, lower systemic concentrations may already induce use-dependent block and thus reduce excitability in electrically active cells. This mechanism is important for the successful use of lidocaine as an antiarrhythmic or analgesic drug.

The putative binding site for local anaesthetic molecules at the sodium channel has been identified as two amino acids in the sixth membrane-spanning segment of domain IV [2]. This binding site is located directly underneath the channel pore and can only be reached from the internal side of the membrane. Because local anaesthetics are applied exterior to the nerve fibre, they have to penetrate the axonal membrane before they can bind to the channel.

Besides sodium channels, other ion channels such calcium- and potassium channels as well as certain ligand-gated channels are affected by local anaesthetics. However, this plays only a minor role for nerve block but may have more impact on adverse effects induced by systemical concentrations of these drugs.

Structure Activity Relation

Local anaesthetics comprise a lipophilic and a hydrophilic portion separated by a connecting hydrocarbon chain (Fig. 1). The hydrophilic group is mostly a tertiary amine such as diethylamine; the lipophilic group is usually an unsaturated aromatic ring such as xylylidine or para-aminobenzoic acid. The lipophilic portion is essential for anaesthetic potency whereas the hydrophilic portion is required for water solubility. Both groups are important for binding the drug molecule to the sodium channel. The connecting hydrocarbon chain usually contains an ester or an amide, in rare cases also an ether, and separates the lipophilic and hydrophilic portions of the molecule in an ideal distance for binding to the channel. Local anaesthetics are classified by the nature of this bond into ester or amide local anaesthetics. This bond is also important for metabolism of the drugs and to adverse reactions such as allergic reactions. Clinically relevant local anaesthetics have an efficacy of 100%, i.e. at high concentrations they completely abolish the sodium current. Their blocking potencies range from a few micromolar to millimolar half-maximal blocking concentration and are highly dependent on lipid solubility. To a smaller amount potency also depends on the structure of the molecule and on the type of bonding

Local Anaesthetics. Figure 1 Common structure of local anaesthetics. A lipophilic moiety on the left, an aliphatic spacer containing an ester or amide bond in the middle and an amine group on the right are the typical structural elements for local anaesthetic drugs.

(Table 1). Further determinants of blocking potency are the membrane potential and the state in which the sodium channel is in (resting, activated, inactivated). The tertiary amine group can be protonated giving most local anaesthetics a pK_a of about eight so that a larger amount of the drug is in the hydrophilic form when injected into tissue with physiological pH. However, only the unprotonated lipophilic form is able to penetrate the

Local Anaesthetics. Table 1 Examples of clinically used local anaesthetics

Name	Structure	Relative potency	Mean blocking duration [h]	Lipid solubility log[P]	Molwt. [g/mol]	pKa
Procaine		1	0.5–1	1.92	236	9.1
Tetracaine		8	2–3	3.73	264	8.6
Lidocaine		2	1–2	2.26	234	8.2
Prilocaine		2	1–2	2.11	220	7.9
Mepivacaine		2	1.5–2	1.95	246	7.9
Ropivacaine		6	3–5	2.90	274	8.2
Bupivacaine		8	4–6	3.41	288	8.2

The ending “caine” stems from cocaine, the first clinically employed local anaesthetic. Procaine and tetracaine are ester-linked substances, the others are amides. Amide bonded local anaesthetics usually contain two i's in their name, ester-bonded only one. In the structure drawings, the lipophilic portion of the molecule is depicted at the left, the amine at the right. The asterisk marks the chiral centre of the stereoisomeric drugs. Lipid solubility is given as the logarithm of the water:octanol partition coefficient, log(P).

axonal membrane, which is required before binding to the sodium channel can occur. In a very acidic environment, like inflamed tissue, local anaesthetics are highly protonated, therefore cannot penetrate the axonal membrane and have little effect.

Toxicity

Local anaesthetics interfere with all voltage-gated sodium channel isoforms in an organism and thus with all electrically excitable cells in organs such as brain, heart and muscle. The major unwanted effects of local anaesthetics are thus disturbances of brain and heart function occurring during systemically high concentrations after overdosing or after accidental intra-vascular injection. Cerebral convulsions, general anaesthesia as well as dysrhythmias up to asystolic heart failure or ventricular fibrillation are feared as rare but most harmful complications. Other adverse effects can be allergic reactions. This occurs especially with ester-bonded local anaesthetics because their metabolism produces para-aminobenzoic acid that may serve as a hapten. As a special case, the local anaesthetic prilocaine is metabolised to o-toluidine, which may induce methemoglobinemia, especially in patients that have a glucose-6-phosphatase deficiency. The ►**S-stereoisomers** of the piperidine local anaesthetics bupivacaine and ropivacaine have now been introduced into clinical practise to reduce side effects. Their blocking potencies are minimally lower compared to their R-counterparts but their therapeutic index is wider.

Clinical Use

Local anaesthetics are mainly employed to induce regional anaesthesia and analgesia to allow surgical procedures in a desired region of the organism. Nerve block result in autonomic nervous system blockade, analgesia, anaesthesia and motor blockade. The patient normally stays awake during surgical procedures under regional anaesthesia, but regional anaesthesia can also be combined with general anaesthesia to reduce the requirement of narcotics and analgesic drugs. Local anaesthetics have to be injected locally into the circumference of a peripheral nerve, which gives sufficiently high concentrations to achieve conduction block. Certain injection techniques and procedures such as single nerve block as well as spinal, ►**epidural**, or intravenous regional anaesthesia have evolved to achieve the desired nerve block. It is also possible to place a catheter adjacent to a nerve and continuously apply local anaesthetics to receive long-term analgesia. Low concentrations of lipophilic local anaesthetics may be used for differential nerve block, i.e. only block of sympathetic and nociceptive fibres whereas somatosensory and motor fibres are less affected. Differential nerve block for example is useful in labour analgesia or for analgesia after surgical procedures of the extremities.

After local anaesthetic injection, onset of nerve block and duration depends mainly on lipid solubility and on the region in where the drug is injected. In some formulations adrenaline is added to prolong the blocking action by inducing regional vasoconstriction and hereby reduce absorption and metabolism.

The amide local anaesthetic lidocaine may also be used as an antiarrhythmic for ventricular tachycardia and extrasystoles after injection into the blood circulation. Drugs with high lipid solubility such as bupivacaine cannot be used for these purposes because their prolonged binding to the channel may induce dysrhythmias or asystolic heart failure [3]. Systemically applied lidocaine has also been used successfully in some cases of ►**neuropathic pain syndromes** [4]. Here, electrical activity in the peripheral nervous system is reduced by used-dependent but incomplete sodium channel blockade.

Locus

A specific region within a DNA sequence.

►**Pharmacogenomics**

Locus Ceruleus

The locus ceruleus is a structure located on the floor of the fourth ventricle in the rostral pons. It contains more than 50% of all noradrenergic neurons in the brain, and projects to almost all areas of the central nervous system.

The locus ceruleus is important for the regulation of attentional states and autonomic nervous system activity. It has also been implicated in the autonomic and stress-like effects of opiate withdrawal. A noradrenergic pathway originating from the locus ceruleus which descends into the spinal cord is part of the descending inhibitory control system, which has an inhibitory effect on nociceptive transmission in the dorsal horn.

Long-Chain Fatty Acids

Long-chain fatty acids (LCFAs) are aliphatic compounds with a terminal carboxyl group and with a chain length greater than 12 carbon atoms (e.g., lauric acid). Very long-chain fatty acids are fatty acids with more than 18 carbon atoms (e.g., stearic acid).

► Fatty Acid Transport Proteins

Long-QT Syndromes

Long-QT syndromes (LQTS) are potentially fatal inherited cardiac arrhythmias characterized by prolonged or delayed ventricular repolarization, manifested on the electrocardiogram as a prolongation of the QT interval. LQTS can be caused by mutations of at least six genes including KCNQ1 for LQT1, KCNH2 for LQT2, SCN5A encoding a cardiac sodium channel for LQT3, KCNE1 for LQT5 and MiRP1 for LQT6. LQT4 is linked to the mutations located in chromosome 4q25–27. Blockade of HERG channels is the most commonly identified drug-induced LQT.

Long-Term Depression

Long-term depression (LTD) is a synaptic plasticity phenomenon that corresponds to a decrease in the synaptic strength (decrease in the post-synaptic response observed for the same stimulation of the pre-synaptic

terminals) observed after a specific stimulation of the afferent fibres. This decreased response is still observed hours after its induction.

► Metabotropic Glutamate Receptors

Long-Term Potentiation

LTP

Definition

Long-term potentiation (LTP) is a synaptic plasticity phenomenon that corresponds to an increase in the synaptic strength (increase in the post-synaptic response observed for the same stimulation of the presynaptic terminals) observed after a high frequency stimulation (tetanus) of the afferent fibres. This increased response is still observed hours and even days after the tetanus. The phenomenon is often observed at glutamatergic synapses and involves, in most cases, the activation of the *N*-methyl *D*-aspartate (NMDA) subtype of ionotropic glutamate receptors.

Low-density-lipoprotein-cholesterol

LDL is the major carrier of cholesterol to the periphery and supplies the cholesterol essential for the integrity of nerve tissue, steroid hormone synthesis, and cell membranes. The association between elevated plasma cholesterol carried in LDL and the risk of coronary heart disease has been well established. LDL is also sometimes called the “bad” cholesterol.

Synonyms

Low-density lipoprotein receptor-related proteins; LRP

Definition

The low-density lipoprotein (▶LDL) receptor gene family encompasses a group of structurally related endocytic receptors that are expressed in many mammalian and nonmammalian cell types. The receptors mediate cellular binding and uptake of a variety of diverse macromolecules including lipoproteins and lipid-carrier-complexes, proteases and protease inhibitors, signaling factors, as well as viruses and toxins. Gene family members play crucial roles in many biological processes ranging from lipid homeostasis, to signal transduction, to cell migration.

Basic Characteristics Receptor-Mediated Endocytosis

Endocytic receptors are cell surface proteins that transport macromolecules into cells through a process known as receptor-mediated ▶endocytosis. In this process, a receptor on the cell surface binds a specific ligand from the extracellular space, internalizes via specialized in-tucked regions of the plasma membrane called clathrin-coated pits, and moves to an intracellular vesicle (▶endosome) to discharge its cargo. From endosomal compartments, ligands are further directed to lysosomes for catabolism, while the unliganded receptor returns to the cell surface to initiate the next round of endocytosis. Endocytic receptors serve to regulate the concentration of ligands in the extracellular space and to deliver them to cells in need of these metabolites. Binding of some ligands to endocytic receptor may also trigger intracellular signaling cascades involved in regulation of important physiological processes such as embryonic patterning, neuronal cell migration, or synaptic plasticity.

Structural Organization of the LDL Receptor Gene Family

Much of our knowledge of the structure and function of endocytic receptors is based on the analysis of the LDL receptor gene family. Members of this extended gene family can be found in a variety of species ranging from roundworms to insects, to vertebrates. Ten receptors exist in mammalian organisms, all of which share common structural motifs required for receptor-mediated

endocytosis (Fig. 1). Among other modules, their extracellular domains are composed of clusters of ▶complement-type repeats, the site of ligand binding, as well as β-propellers, essential for pH-dependent release of ligands in endosomes. The cytoplasmic tails harbor recognition sites for cytosolic adaptor proteins involved in protein trafficking and signal transduction. All ectodomains share significant sequence similarity in line with the ability of the receptors to bind an overlapping spectrum of ligands. In contrast, their cytoplasmic domains are unique, indicating distinct cellular fates for macromolecules internalized by individual receptors [1].

Functions of the LDL Receptor Gene Family

Transgenic animal models with spontaneous or induced receptor gene defects have been instrumental in elucidating the physiological roles of the LDL receptor gene family. In addition, a number of human diseases have been identified that are caused by sporadic or inherited forms of receptor deficiency (Table 1).

LDL Receptor

The LDL receptor is the archetype receptor of the gene family. It is the major endocytic receptor responsible for cellular uptake of cholesterol-rich ▶lipoproteins from the circulation and extracellular body fluids. It binds lipoprotein particles that contain the ▶apolipoproteins B-100 (APOB-100) or APOE, and mediates their endocytic uptake. Particles internalized via the LDL receptor are delivered to lysosomal degradation where the apolipoproteins are broken down into amino acids while the lipids are released into the cytosol for further metabolism. The uptake of lipoproteins by the LDL receptor has a dual role in lipid homeostasis. It delivers cholesterol required for maintenance of cellular functions (e.g., formation of membranes, synthesis of steroid hormones, and bile acids), and it regulates the concentration of this lipid in the circulation. The importance of the latter function is underscored by pathological abnormalities observed in patients with LDL receptor gene defects; a syndrome designated familial hypercholesterolemia (▶FH). In humans with FH, lack of LDL receptor activity results in massive increase in circulating LDL. The mean plasma cholesterol levels are elevated approximately twofold in individuals with heterozygous and fourfold in patients with homozygous gene defects. As a consequence of fulminate ▶hypercholesterolemia, FH patients suffer from premature atherosclerosis and coronary artery disease. To date more than 150 different mutations have been identified in the human LDL receptor gene.

VLDLR and APOE2

Very low-density lipoprotein receptor (▶VLDLR) and APOE receptor-2 (▶APOE2) are two gene family members with redundant functions. They are expressed in neurons of the developing brain and act as cell

Low-density Lipoprotein Receptor Gene Family. Figure 1 The LDL receptor gene family. The figure depicts the structural organization of mammalian members of the LDL receptor gene family. APOER2 (apolipoprotein E receptor 2); LDLR (low-density lipoprotein receptor); LRP (LDL receptor-related protein); MEGF7 (multiple epidermal growth factor repeat-containing protein 7); sorLA (sorting protein-related receptor); VLDLR (very low-density lipoprotein receptor). Designations in brackets indicate alternative names for the respective receptors.

Low-density Lipoprotein Receptor Gene Family. Table 1 Human diseases of the LDL receptor gene family

Receptor	Type of mutation	Disease
LDL receptor	Loss-of-function (familial, autosomal dominant)	Familial hypercholesterolemia (impaired clearance of LDL)
VLDL receptor	Loss-of-function (familial, autosomal recessive)	Autosomal recessive cerebellar hypoplasia (ataxia, mental retardation)
LRP5	Loss-of-function (familial, autosomal recessive)	Osteoporosis-pseudoglioma-syndrome (reduced bone mass)
	Gain-of-function (familial, autosomal dominant)	High-bone-mass trait (increased osteogenic activity)
LRP6	Missense mutation (familial, autosomal dominant)	Autosomal dominant early coronary artery disease (hyperlipidemia, hypertension, diabetes)
LRP1B	Loss-of-function (sporadic)	Esophageal squamous cell carcinoma, nonsmall-cell lung cancer
LRP2/megalin	Loss-of-function (familial, autosomal recessive)	Donnai-Barrow syndrome (brain malformation, renal tubular deficiency, diaphragmatic hernia)
SorLA	Polymorphisms (sporadic)	Late-onset Alzheimer's disease

surface receptor for ►**reelin**, a secreted guidance factor for newborn neurons that migrate to their proper position in the laminating neocortex and cerebellum. Binding of Reelin to VLDLR and APOER2 initiates an intracellular signaling cascade that involves the cytoplasmic adaptor disabled-1 (►**DAB1**) bound to the receptor tails, and that ultimately leads to reorganization of the cytoskeleton and regulation of cell migration (Fig. 2a) [2]. Receptor gene defects in humans (Table 1) and in animal models result in abnormal layering of neurons in the brain, and in severe neuronal dysfunction (cerebellar dysplasia, ataxia).

LRP5/6

These receptors are integral components of the ►**wingless** (Wnt) signaling cascade by acting as coreceptors to ►**frizzled**. Simultaneous binding of Wnt ligands to

LRP5/6 and frizzled results in signal transduction through the canonical Wnt signaling pathway (Fig. 2b) [3]. The function of LRP6 seems most relevant for early embryonic patterning events, as loss of receptor function in fruit fly, *Xenopus*, and mouse causes aberrant pattern formation and early embryonic lethality. In contrast, LRP5 activity is mainly required for regulation of bone formation as judged from loss-of-function and gain-of-function syndromes in humans that result in low or high-bone-mass traits, respectively (Table 1).

LRP4

LRP4 is another receptor of the LDL receptor gene family involved in regulation of embryonic patterning, mainly controlling formation of limb structures. Loss of receptor activity in gene targeted mice or spontaneous mutation in bovine cause abnormal limb development and

Low-density Lipoprotein Receptor Gene Family. Figure 2 Signal transduction by members of the LDL receptor gene family. (a) The reelin signaling pathway in migrating neurons is initiated by binding of the guidance factor to its cognate receptors VLDLR and APOER2. Binding induces clustering of DAB1 on the cytoplasmic receptor tails, activating SRC family tyrosine kinases (SFKs) that in turn phosphorylate the adaptor. Phosphorylated DAB1 activates phosphatidylinositol-3-kinase (PI3K) and protein kinase B (PKB). PKB inhibits the activity of glycogen synthase kinase 3β (GSK3β), resulting in reduced phosphorylation of Tau (τ) and stabilization of microtubules. Lissencephaly 1 (LIS1) is another interaction partner of phosphorylated DAB1. It associates with α-subunits to a multimeric protein complex that also regulates microtubule dynamics (modified from [2]). (b) As part of the canonical Wnt signaling pathway, Wnt ligands bind to LRP5/6 and Frizzled resulting in phosphorylation of the LRP5/6 tail by membrane-associated casein kinase 1γ (CK1γ). Phosphorylation recruits scaffold protein Axin to the LRP tail domain, preventing Axin-induced destruction of β-catenin. Stabilized β-catenin enters the nucleus to interact with high-mobility group protein TCF to induce target gene transcription.

polysyndactyly. The molecular mechanisms of LRP4 actions remain unclear at present, but may also involve signaling through embryonic morphogen pathways.

LRP1 and LRP1B

In hepatocytes, LRP1 serves as backup pathway to the LDL receptor in hepatic clearance of ►**chylomicron remnants**, lipoproteins that transport dietary lipids from the intestine to the liver. In vascular smooth muscle cells, LRP1 likely acts as signaling receptor that suppresses the activity of the platelet-derived growth factor (►**PDGF**) receptor. Loss of local LRP1 expression in mouse models causes enhanced activation of the PDGF receptor pathway, resulting in smooth muscle cell proliferation and in marked susceptibility to atherosclerotic lesion formation [4]. LRP1B is also known as LRP-DIT (deleted-in-tumors) because of its original description as a gene frequently inactivated in lung cancer cell lines. A possible role as tumor suppressor gene remains yet to be established. LRP1B may share some functional redundancy with LRP1 as suggested from the close sequence similarity and overlap in expression pattern of both receptors.

LRP2

LRP2 (megalin, gp330) is the largest member of the LDL receptor gene family. Inherited *Lrp2* gene defects are the cause of Donnai-Barrow syndrome, characterized by brain malformation, renal dysfunction, and diaphragmatic hernia. Rather than acting as lipoprotein receptor such as the LDL receptor and LRP1, LRP2 functions as endocytic receptor for cellular uptake of lipophilic vitamins and steroid hormones bound to plasma carrier proteins [1]. Most notably, a role for the receptor in retrieval of filtered 25-OH vitamin D₃ bound to the vitamin D binding protein (►**DBP**) from the glomerular filtrate is appreciated. Renal uptake of vitamin/DBP complexes prevents uncontrolled urinary loss of this essential metabolite and it delivers to renal proximal tubular cells the precursor for conversion into 1,25-(OH)₂ vitamin D₃, the active hormone that controls systemic calcium and bone metabolism. Loss of receptor function results in excessive urinary excretion of vitamin D₃ metabolites, and consequently, in vitamin D deficiency and osteomalacia (softening of the bones).

SorLA

SorLA is a chimeric receptor that harbors protein modules not present in other members of the LDL receptor gene family (Fig. 1). As well as acting as endocytic receptor for extracellular ligands (such as PDGF), sorLA also regulates the intracellular trafficking of target proteins between secretory and endocytic compartments. In particular, the receptor acts as sorting receptor for the amyloid precursor protein (►**APP**), the etiologic agent in ►**Alzheimer's disease**. In neurons, SorLA directs APP into intracellular compartments less

favorable for proteolytic processing, thereby impairing breakdown of APP to the amyloid-β peptide, the principle component of senile plaques (a hallmark of Alzheimer's disease). Polymorphisms in the human *SorLA* gene are among the most important genetic risk factors of late-onset Alzheimer's disease, likely by determining the expression levels of this protective factor in the brain of individuals [5].

Drugs

Currently no drugs directly modulating the LDL receptor family are known. The possible use of drugs targeting the LDL receptor family or downstream signaling proteins may be derived from Table 1.

Definition

Lysophospholipids are small bioactive lipid molecules characterized by a single carbon chain and a polar head group. Two subgroups can be distinguished: molecules containing the sphingoid base backbone (lysosphingolipids) and molecules containing the glycerol backbone (lysoglycerophospholipids). The lysolipid structure renders these lipids more hydrophilic and versatile than their corresponding phospholipids. Lysophospholipids act as extracellular mediators activating specific ▶ **G-protein-coupled receptors (GPCRs)**, although some of them additionally play a role in intracellular signal transduction. ▶ **Sphingosine-1-phosphate (S1P)** and ▶ **lysophosphatidic acid (LPA)** have been characterized in greatest detail so far, and the concept of lysophospholipids as a group of mediators is supported by the high homology between S1P- and LPA-specific GPCRs. Other, less well characterized lysophospholipids are sphingosylphosphorylcholine (SPC), lysophosphatidylcholine (LPC), psychosine (galactosylsphingosine) and glucopsychosine (glucosylsphingosine); the latter two are lacking a phosphate group. Lysophospholipids are auto- or paracrine regulators of cell growth and survival, migration and chemotaxis, cytoskeletal architecture, cell-cell-contacts and adhesion, Ca^{2+} homeostasis and Ca^{2+} -dependent functions. By regulating these cellular functions, lysophospholipids play a role in angiogenesis, lymphocyte trafficking, development of the nervous system, cancer growth and metastasis, inflammation and arteriosclerosis. Relatives of the lysophospholipid family are platelet-activating factor and the ▶ **endocannabinoids**, arachidonyl ethanolamide and 2-arachidonyl glycerol.

Basic Characteristics

Metabolism and Occurrence

S1P is formed from sphingosine by ▶ **sphingosine kinases (SphKs)**. Degradation of S1P occurs either reversibly by lipid phosphate phosphohydrolases (LPPs) and S1P phosphatases (SPPs), or irreversibly by S1P lyase (SPL) (Fig. 1). The localization of S1P production is highly important since S1P plays a role both as extracellular mediator and as intracellular

second messenger (Fig. 1). Intracellular formation of S1P by SphKs is regulated by many diverse stimuli, among them GPCR agonists, ►growth factors, ►cytokines or depolarization. Some stimuli induce a translocation of SphK1 from the cytosol to the plasma membrane, which appears to enable S1P secretion and so-called “inside-out signalling”. Many cell types including mast cells and tumour cells can release S1P. ATP-binding cassette (ABC) transporters have shown to be involved in this process. S1P is furthermore stored in platelets and released upon platelet activation. Accordingly, it has been found in serum in higher concentrations (~0.5–0.8 µM) than in plasma (~0.2–0.4 µM). Plasma S1P is bound to albumin and ►lipoproteins, mainly high-density lipoproteins (HDL). Tissue S1P levels are significantly lower, and thus there is a plasma/tissue S1P gradient.

LPA, i.e. monoacyl-glycerol-3-phosphate, can be formed and degraded by multiple metabolic pathways (Fig. 1). Depending on the precursor molecule and respective pathway, the fatty acid chain in LPA differs in length, degree of saturation and position (sn-1 or sn-2), which has an influence on biological activity. LPA

analogs with ether-bound alkyl or alkenyl chains are quantitatively less abundant than those with ester-bound acyl chains. Extracellular LPA is generated to a large part by a lysophospholipase D named ►autotaxin. Autotaxin is an extracellular enzyme that acts as autocrine motility factor of tumour cells. LPA production by autotaxin is essential for embryonic development in mice and apparently contributes most of LPA in plasma. Alternatively, LPA can be produced from surface-exposed phosphatidic acid by phosphatidic acid-selective PLA₁ or secretory type-II PLA₂. Like S1P, LPA occurs in plasma (~200 nM), is formed during coagulation, and present in serum in micromolar concentrations. Differences in the fatty acid composition of plasma- and serum-LPA suggest that the sources of these LPA pools were different. LPA is produced by many cell types, e.g. fibroblasts, adipocytes and tumour cells.

Lysophospholipid Receptors

An overview of lysophospholipid GPCR is presented in Table 1. Presently best characterized are the receptors of the endothelial differentiation gene (EDG)

Lysophospholipids. Table 1 G-protein-coupled lysophospholipid receptors

+Receptor	Endogenous ligands	Main tissue distribution	Signalling	Main biological effects
S1P ₁	S1P (nM) SPC (µM)	Ubiquitous	G _{i/o}	Migration ↑, proliferation, survival, cell–cell-contacts, angiogenesis, lymphocyte trafficking
S1P ₂		Ubiquitous	G _{i/o} , G _q , G _{12/13}	Migration ↓, vascular development, differentiation of vascular smooth muscle cells
S1P ₃		Ubiquitous	G _{i/o} , G _q , G _{12/13}	Heart rate ↓, vascular development, NO-dependent vasorelaxation
S1P ₄		Lymphoid and haematopoietic tissue	G _{i/o} , G _{12/13}	Proliferation and cytokine secretion in T-cells ↓

OGR1	SPC	Proton	Inhibition of proliferation, osteoclastogenesis
GPR4	SPC, LPC		Migration, angiogenesis, impairment of endothelial barrier function
G2A	LPC, SPC		Migration, apoptosis, suppression of autoimmunity
TDAG8	Psychosine		Formation of multinuclear cells, apoptosis

family, S1P₁₋₅ and LPA₁₋₃. They had originally been named after EDG-1, now S1P₁, which was detected in 1990 as an orphan GPCR upregulated during the differentiation of endothelial cells. According to an IUPHAR committee, these receptors are now named after the primary natural ligand and numbered in order of identification. S1P₁₋₃ and LPA₁₋₃ are widely expressed and often found co-expressed within a single cell type. S1P₄ is predominantly expressed in lymphatic and haematopoietic tissues and S1P₅ in brain white matter and skin. The EDG family receptors couple via G_{i/o}, G_{q/11} and G_{12/13} proteins to inhibition of ►adenylyl cyclase, stimulation of phospholipase C and increase in [Ca²⁺]_i, stimulation or inhibition of ►mitogen-activated protein kinases (ERK, JNK and p38) and cell growth, activation of Akt and survival, activation or inhibition of Rho and Rac and rearrangement of the cytoskeleton, and finally stimulation or inhibition of cell migration (for details, see Biological Actions).

Much less is known about other lysophospholipid receptors. LPA₄ and LPA₅ couple via G_s to activation of adenylyl cyclase. GPR3, GPR6 and GPR12 have a high constitutive activity, thereby stimulating adenylyl cyclase, but appear to be further activated by S1P and/or SPC. GPR6 and GPR12 are strongly expressed in mouse brain, and SPC increased synaptic contacts in GPR12-expressing embryonic cortical neurons. GPR3 and GPR12 are expressed in mouse oocytes and mediate a signal that maintains the oocytes in meiotic arrest, a process that is dependent on high cAMP levels. A role for lipid ligands in meiotic arrest is likely

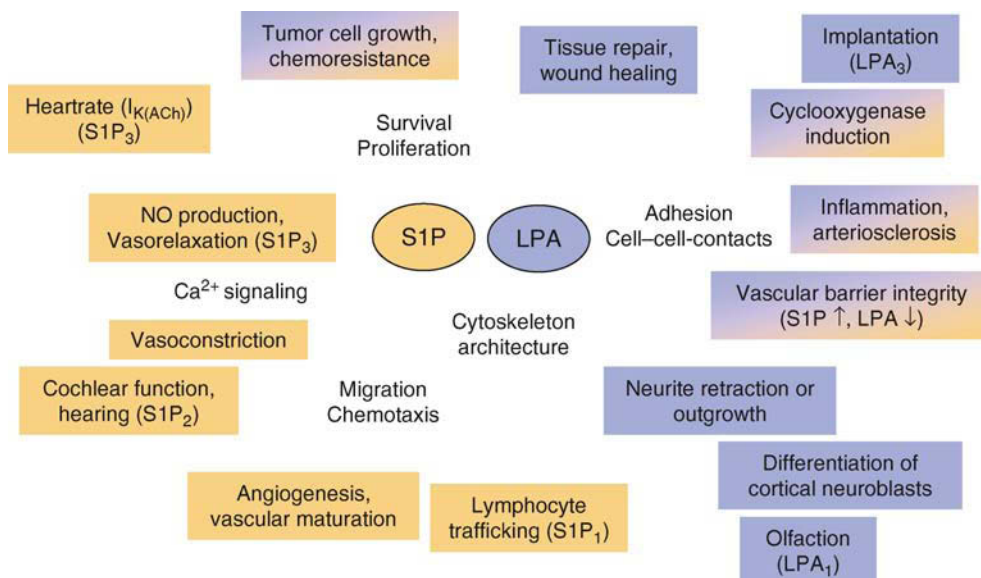

since spontaneous in vitro maturation of rodent oocytes was delayed by SPC and S1P.

Another group of putative lysophospholipid GPCR is highly controversial. OGR1, GPR4, G2A and TDAG8 form a cluster of homologous GPCRs that are candidate high-affinity receptors for SPC, LPC and psychosine (Table 1). SPC and LPC are the phosphocholine-containing analogs of S1P and LPA, respectively. Both lipids are normal constituents of plasma and serum. SPC acts also as a low-affinity or partial agonist at S1P₁₋₅. Contradictory studies have shown that the receptors of the OGR1 cluster can be regulated by lysophospholipids and/or by protons. Recent studies revealed that OGR1 was strongly induced during differentiation of bone marrow mononuclear cells into osteoclasts, and knockdown of OGR1 attenuated osteoclastogenesis. Endogenous GPR4 was required for SPC-stimulated migration of endothelial cells and endothelial tube formation. G2A and TDAG8 appear to play a functional role in migration and apoptosis of immune cells.

Finally, it has to be mentioned that LPA also has an intracellular target site, which is the nuclear transcription factor, peroxisome proliferator-activated receptor-γ (PPARγ). LPA competes for thiazolidinedione binding and activates PPARγ-dependent gene transcription. Thereby, LPA induced neointima formation in a rat carotid artery model.

Biological Actions

Cellular responses to S1P and LPA can be classified as growth-related (stimulation of cell proliferation and

Lysophospholipids. Figure 2 Functional roles of S1P and LPA.

survival, protection from apoptosis), cytoskeleton-dependent (shape change, migration, adhesion, chemotaxis) and Ca^{2+} -dependent (contraction, secretion). Some cellular responses are regulated in an opposite manner by different receptors. For example, the S1P_1 receptor mediates cell migration and chemotaxis, thereby regulating for example angiogenesis and lymphocyte trafficking. Growth factors such as platelet-derived growth factor need the S1P_1 receptor for signalling migration. On the contrary, this must be “and inhibits migration”. S1P_2 promotes cellular stress fibre formation and inhibits migration. Furthermore, the S1P_1 receptor does not increase $[\text{Ca}^{2+}]_i$ but rather inhibits $[\text{Ca}^{2+}]_i$ increases by other agonists, while S1P_2 and S1P_3 mediate $[\text{Ca}^{2+}]_i$ increases in response to S1P .

S1P is an important mediator in the cardiovascular system (Fig. 2). S1P stimulates proliferation, survival and migration of endothelial cells and induces formation of adherens junction assembly, decrease in vascular permeability and differentiation of endothelial cells into capillary-like networks. Expression of the S1P_1 receptor within endothelial cells is required for vasculogenesis. Mice lacking this receptor die during embryonic development from haemorrhages caused by a failure of pericytes to migrate around newly formed capillaries. S1P and LPA induce smooth muscle cell contraction and can cause vasoconstriction. S1P , via endothelial S1P_3 receptors, can also cause NO-dependent vasorelaxation. A lack of the S1P_2 receptor results in profound deafness in mice, apparently because the cochlear spiral artery does not appropriately contract in the absence of S1P_2 . The S1P_3 receptor mediates $I_{K(\text{ACh})}$ activation in atrial myocytes, leading to bradycardia. However, systemic cardiovascular parameters such as blood pressure or heart rate are marginally affected by intravenous S1P , consistent with a role of S1P as a local rather than systemic mediator. The importance of LPA in vascular development is illustrated by the phenotype of autotaxin deficiency, which is characterized by vascular defects early in development. LPA promotes surface expression of leukocyte adhesion molecules in endothelial cells. In contrast to S1P , LPA enhances vascular permeability. Of the two platelet-derived lysophospholipids, LPA but not S1P stimulates platelet aggregation. S1P , LPA and other lysolipids have been detected in lipoproteins and play a role in atherosclerosis. The major part of lipoprotein-bound S1P is associated with HDL, and many of HDL's beneficial vascular effects are mediated by S1P and S1P-GPCR . In contrast, LPA is produced during mild oxidation of low-density lipoproteins (LDL) and accumulates in atherosclerotic plaques where it acts proinflammatory and promotes thrombus formation.

The S1P_1 receptor and the gradient between lymphatic tissue (low S1P levels) and plasma (high S1P levels) are essential for lymphocyte trafficking. Deletion of S1P_1 , as well as pharmacological

downregulation of S1P_1 (see Drugs), inhibit lymphocyte emigration from lymphatic tissues. Inhibition of S1P lyase leads to elevated S1P tissue levels and also to lymphopenia. It appears likely that the S1P_1 receptor on the lymphocyte surface senses the S1P gradient and mediates lymphocyte trafficking.

LPA receptors play an important role in the nervous system (Fig. 2). The LPA_1 receptor was originally cloned from cerebral cortical neuroblasts and is highly expressed in the neurogenic ventricular zone of the embryonic cerebral cortex. In the adult nervous system, it is predominantly found in myelinating cells, i.e. oligodendrocytes and Schwann cells. Schwann cell morphology, adhesion and survival are regulated by LPA. LPA_1 and LPA_2 receptors mediate neuronal cell rounding and neurite retraction, while LPA_3 appears to stimulate neurite outgrowth. Deletion of the LPA_1 receptor in mice caused ~50% neonatal lethality. The surviving pups had a reduced size, craniofacial dysmorphism and impaired suckling behaviour. The defect in suckling behaviour caused malnutrition of the pups, leading to growth retardation and death, and was attributed to a defective olfaction. Deletion of LPA_2 in mice did not lead to obvious defects, while LPA_3 deficiency was accompanied by ~50% reduced litter sizes. This was caused by downregulation of cyclooxygenase-2 (►cyclooxygenases) in LPA_3 -deficient uteri during preimplantation, which delayed implantation and disturbed embryo spacing. The mice that were born were grossly normal.

Both S1P and LPA stimulate proliferation and migration of fibroblasts, while they inhibit proliferation and induce migration and differentiation of keratinocytes. LPA promotes wound healing *in vivo*. Thus, S1P and LPA interact in tissue repair. Many other tissues are responsive to S1P or LPA, including the respiratory tract (contraction of airway smooth muscle cells and cytokine release by S1P), kidney (diuresis by S1P), adipose tissue (preadipocyte proliferation by LPA), and others. Finally, S1P and LPA promote tumour cell growth, chemoresistance and metastasis (Fig. 2). The two mediators are produced by several tumour cells and occur for example in malignant ascites. The antiapoptotic action of S1P and LPA may protect the cells from chemotherapy or radiation. Furthermore, S1P and LPA stimulate tumour cell motility and invasiveness, although it has to be noted that motility of certain cancer cells (e.g. melanoma cells) is inhibited by S1P . S1P might also play a role in tumour angiogenesis. Its importance for tumour progression is further illustrated by the antitumour activity of SphK inhibitors and an anti- S1P antibody (see Drugs).

In summary, the lysophospholipids are local mediators that regulate development, tissue regeneration and homeostasis, but also play a role in inflammation, arteriosclerosis and cancer.

Drugs

In the field of S1P pharmacology, there is currently a novel immunosuppressive (►[immunosuppressive agents](#)) in clinical development for multiple sclerosis. FTY720 is a prodrug that, after being phosphorylated, acts as an agonist with low nanomolar affinity on S1P₁, S1P₃, S1P₄ and S1P₅, but not on S1P₂ receptors. SphK2 is required for effective phosphorylation of FTY720 in vivo. The immunosuppressive action of FTY720 is caused basically by activation and subsequent internalization of the S1P₁ receptor, which needs to be expressed on the lymphocyte surface to enable sensing of the plasma/tissue S1P gradient and to promote emigration of lymphocytes from lymphatic tissues. Since FTY720 does not generally impair T- and B-cell proliferation and functions, it presents a novel mode of immunosuppressive action, which might be useful in multiple sclerosis as well as transplantation or autoimmune diabetes. Activation of S1P receptor subtypes other than S1P₁ causes further, desired and undesired effects. For example, the bradycardia that occurs during the first days of FTY720 treatment is mediated by activation of S1P₃. Animal models show further effects of FTY720: it reduced the damage caused by ischemia-reperfusion in liver and kidney, inhibited angiogenesis, impeded tumour growth in a mouse model of melanoma, induced endothelial NO synthase activation and vasodilatation (via S1P₃) and reduced vascular permeability in vivo.

Other compounds acting on S1P-GPCR are only in the experimental stage. Several specific S1P₁ agonists have been described. SEW2871, that has been identified by high-throughput screening and lacks a phosphate group, induces lymphopenia in mice (in agreement with the role of S1P₁ in lymphocyte trafficking) but no bradycardia (in agreement with a lack of an effect on S1P₃). KRP-203 needs to be phosphorylated, like FTY720, but then activates specifically S1P₁ and produces effects similar to those of SEW2871. Interestingly, the S1P₁ receptor has a high constitutive activity which was reduced by an inverse agonist for S1P₁ (SB649146). A recently described S1P₁ antagonist did not induce lymphopenia but reversed immunosuppression induced by S1P₁ agonist, and furthermore enhanced capillary leakage. A putative S1P₃ receptor antagonist, BML-241, was identified by searching a three-dimensional compound database with a pharmacophore model of S1P, however, BML-241 has appears to have other, GPCR-independent effects. A specific S1P₂ receptor antagonist, JTE-013, has widely been used to analyse S1P₂ signalling pathways. This compound prevented for example S1P₂-mediated inhibition of cell migration and contraction of smooth muscle cells. Recently, a series of aryl amide compounds was presented which were more or less receptor subtype-selective. The lead compound, VPC23019, was a competitive antagonist at S1P₁ and S1P₃. K_i values for

VPC23019 in radioligand binding assays at S1P₁ and S1P₃ were in the low nanomolar range, and VPC23019 inhibited S1P-induced migration and Ca²⁺ mobilization. Small structural changes converted the molecule into an agonist. Furthermore, VPC23019 as all compounds of this series behaved as agonist at S1P₄ and S1P₅, but had no activity at S1P₂. Recently, an anti-S1P antibody was described. This antibody retarded the proliferation of various transplanted mouse tumours. Furthermore, it reduced tumour-associated angiogenesis and the ability of S1P to protect tumour cells from apoptosis. An antitumour activity was also observed with SphK inhibitors.

LPA-GPCR pharmacology is at the experimental stage. Dioctylglycerol pyrophosphate (DGPP 8:0) acts as a competitive antagonist preferentially at human LPA₃ receptors and inhibits at higher concentrations LPA₁, but not LPA₂. DGPP 8:0 specifically inhibited LPA-induced platelet activation. Furthermore, it blocked platelet activation by mildly oxidized low density lipoproteins and by homogenates of lipid-rich core isolated from soft arteriosclerotic plaques, illustrating the importance of LPA as a component of arteriosclerotic plaques. Fatty alcohol phosphates (FAP) with carbon chain lengths between 10 and 14 activate LPA₂ and inhibit LPA₃ in a competitive manner. Another LPA-GPCR antagonist is Ki16425, which was identified by high-throughput screening of 150,000 compounds for inhibition of LPA-induced [Ca²⁺]_i increases. This compound inhibited LPA₁ and LPA₃ at slightly lower concentrations than LPA₂, but was highly specific for LPA-GPCR. A similar preference for LPA₁ and LPA₃ was observed with VPC12249. O-methylphosphothionate (OMPT), a LPA₃-selective agonist, aggravated ischemia-reperfusion injury in mouse kidney, while the LPA_{1/3} antagonist, VPC12249, reduced the kidney damage. Since most compounds that interact with LPA-GPCRs, except Ki16425, have a phosphate group that can be subject to dephosphorylation, a novel strategy focuses on metabolically stabilized LPA analogues such as phosphonates, phosphorothioates, phosphonothioates and fluorophosphonates. These compounds affect LPA-GPCRs as well as LPA metabolizing enzymes.

Lysosphingolipids and Lysoglycerophospholipids

► Lysophospholipids

M-Channels

The M-channels (M for *muscarine*) are expressed in the peripheral sympathetic neurons and CNS. In the absence of acetylcholine, the M-channel opens at resting membrane potential and dampens neuronal responsiveness to synaptic inputs. Acetylcholine inhibits M-channel activity by activation of M1 receptor.

► K⁺ Channels

Macrolides

Macrolides are a group of antibiotics, produced in nature by many actinomycetes strains, that are composed of a 12- to 16-membered lactone ring, to which one or more sugar substituents is attached. They target the peptidyl transferase center on the 50S ribosomal subunit and function primarily by interfering with movement of the nascent peptide away from the active site and into the exit tunnel.

► Ribosomal Protein Synthesis Inhibitors

Macrophage

White blood cell preferentially located near potential entry sites for microbial pathogens and specialized for the uptake of particulate material by phagocytosis. Most macrophages originate from peripheral blood monocytes and are able to leave the circulation following stimulation by chemotactic agents.

► Interferons
► Immune Defense

Macula Densa

The macula densa is a dense aggregation of cells in the distal tubule of nephrons facing the glomerular tuft of capillaries. These cells sense the salt content of the distal tubular fluid and adjust glomerular perfusion and renin secretion accordingly.

► Renin–Angiotensin–Aldosterone System
► Diuretics

Major Histocompatibility Complex (MHC)

Group of transmembrane proteins engaged in the presentation of small peptide fragments to T-cells. Two classes of Major histocompatibility complex (MHC) molecules exist both of which are encoded by a highly polymorphic gene cluster. MHC class I and class II proteins present peptide fragments to CD8⁺ and CD4⁺ T-cells, respectively. The human MHC is also known as “HLA,” the murine MHC as “H-2” complex.

► Immune Defence

Malaria

Malaria remains a major public health problem in many parts of the world, including Southeast Asia, sub-Saharan Africa and Latin America where an estimated 300–500 million people are infected. 1–3 million die of malaria every year. The etiologic agents of malaria are protozoan parasites of the genus *Plasmodium*. Of the four pathogens that can cause malaria in humans (*Plasmodium falciparum*, *P. vivax*, *P. ovale*,

P. malariae), *P. falciparum* is responsible for the most severe form. At particular risk of developing severe malaria-associated pathology are the non-immune, including tourists and, in endemic areas, children and pregnant women during first pregnancy.

Malarial parasites feature a complex life cycle alternating between vertebrate and invertebrate hosts. The life cycle begins with the bite of an infected *Anopheles* mosquito and the injection of sporozoites into the blood stream. Sporozoites enter the liver and infect hepatocytes where they replicate and produce merozoites. Upon rupture of an infected hepatocyte, merozoites are released. The merozoites infect erythrocytes to establish the erythrocytic developmental cycle. The clinical symptoms of malaria are largely associated with the intraerythrocytic stages and include intermittent fever followed by shaking chills, headache, muscle pain, nausea, vomiting and diarrhoea. Infections with *P. falciparum* can cause life-threatening complications including cerebral malaria and multi-organ failure.

► Antiprotozoal Drugs

Malignant Hyperthermia (MH)

Malignant hyperthermia (MH) is an autosomal-dominant pharmacogenetic disorder that is triggered by exposure to inhalation of general anesthetics, such as halothane. In susceptible individuals, these drugs can induce tachycardia, a greatly increased body metabolism, muscle contracture and an elevated body temperature (above 40°C) with a rapid rate of increase. Many cases of MH are linked to a gene for type 1 ryanodine receptor (RyR1).

Synonyms

Serine/threonine protein kinase phosphorelay modules

Definition

Mitogen activated protein ► kinase (MAPK) cascades are three kinase modules activated by ► phosphorylation. The three kinase modules are composed of a MAPK, a MAPKK, and a MAPKKK. There are multiple members of each component of the MAPK cascade that are conserved from yeast to human. Activation of selective MAPK modules by specific stimuli regulates cell functions such as gene expression, adhesion, migration, differentiation, and apoptosis.

Basic Characteristics

Characteristics of MAPK Cascades

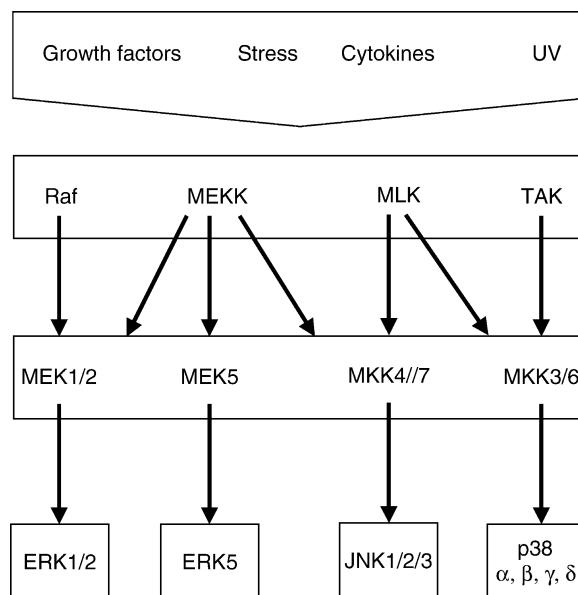

MAPK cascades are signaling modules that serve as important mediators of signal transduction from the cell surface to the nucleus [1, 2]. MAPK modules are activated by diverse stimuli including growth factors, hormones, ►cytokines, bacterial products such as lipopolysaccharide (LPS), and stresses to the cell including gamma and ultraviolet irradiation, heat and cold shock, hyperosmolarity, and oxidative stress. Activation of MAPK signaling by these stimuli contributes to the regulation of many different cell functions including growth, differentiation, survival, ►apoptosis, cytokine production, migration, and adhesion [2].

MAPK cascades are composed of three cytoplasmic kinases, the MAPKKK, MAPKK, and MAPK, that are regulated by phosphorylation (Fig. 1) [1, 2]. The MAPKKK, also called MEKK for MEK kinase, is a serine/threonine kinase. Selective activation of MAPKKKs by upstream cellular stimuli results in the phosphorylation of MAPKK, also called MEK for MAP/ERK kinase by the MAPKKK. MAPKKK members are structurally diverse and are differentially regulated by specific upstream stimuli. The MAPKK is phosphorylated by the MAPKKK on two specific serine/threonine residues in its activation loop. The MAPKK family members are dual specificity kinases capable of phosphorylating critical threonine and tyrosine residues in the activation loop of the MAPKs. MAPKKs have the fewest members in the MAPK signaling module. MAPKs are a family of serine/threonine kinases that upon activation by their respective MAPKKs, are capable of phosphorylating cytoplasmic substrates as well as

translocating to the nucleus where they phosphorylate transcription factors and thus regulate gene expression. MAPKs are divided into four main subfamilies including the extracellular signal-regulated kinases (ERKs) 1 and 2, ERK5, Jun amino-terminal kinases (JNKs), and p38 kinase members. This review will focus on four of the best characterized MAPK cascades including ERK1/2, ERK5, JNK, and p38 kinase.

Characteristics of the ERK1/2 Pathway

Extracellular signal-regulated kinase (ERK) 1 and ERK 2, also called p44 MAPK and p42 MAPK respectively, are nearly 85% identical. ERK1 and 2 are involved in the regulation of cell growth, differentiation, survival, and cell cycle progression. While ERK1 and 2 are ubiquitously expressed in mammalian tissues, the majority of their functions and biological properties have been characterized in the context of fibroblasts [2]. Similar to other MAPKs, ERK1 and ERK 2 are terminal components of a three kinase signaling module. Extracellular stimuli (such as growth factors, cytokines and serum) or events (such as cell adhesion) promote the activation of Raf kinases (MAPKKKs), which proceed to phosphorylate MAPK/ERK kinase (MEK) 1 and MEK2 (MAPKKs). Activation of ERK1/2 is accomplished by the MEK1- or MEK2-mediated dual phosphorylation of threonine and tyrosine of the conserved threonine–glutamate–tyrosine (TEY) motif present in the catalytic domains of ERK1/2 [1]. Once activated, ERK1/2 phosphorylate cytosolic substrates, including ribosomal S6 kinase (p90^{rsk}), phospholipase A₂ (PLA₂), and microtubule associated proteins (MAPs). Additionally, activated ERK1 and ERK2 are capable of translocating to the

MAP Kinase Cascades. Figure 1 Organization of MAPK cascades. See text for details.

nucleus where they phosphorylate a number of transcription factors (Elk1, Ets1, Sap1a, and c-Myc) and, thereby, increase their transcriptional activities [2]. Downregulation of ERK1/2 is achieved chiefly through the dephosphorylation of their TEY motifs by a family of MAPK ► **phosphatases** (MKPs) [1].

The biological functions of ERK1 and ERK2 have been further defined by mouse models in which the genes coding for these proteins have been knocked out. ERK1 knockout mice appear to be grossly phenotypically normal and fertile but have defects in thymocyte proliferation and maturation. However, ERK2 knockouts are not viable and die early in embryogenesis (day E7.5) as a result of defects in placental development. Raf-1, an upstream activator of ERK1/2, has also been knocked out in mice and displays similar placental defects leading to embryonic mortality. Knockouts of other upstream activators of ERK1/2, including the MAPKKK B-Raf and the MAPKK MEK1, are also embryonic lethal and have vascular and angiogenic defects [2]. Thus, from these studies important roles for ERK1/2 in cell proliferation, migration, differentiation, and angiogenesis can be inferred.

Characteristics of the ERK5 Pathway

The MEK5/ERK5 pathway is a more recently identified MAPK signaling module [1, 2]. The MAPK ERK5, also known as Big MAP kinase (BMK1) possesses a TEY activation motif similar to ERK1/2 and is activated by growth factor stimulation, albeit with slightly different kinetics than ERK1/2. Stimulation of cells with epidermal growth factor (EGF) promotes ERK5-dependent cell proliferation and cell-cycle progression. In addition to being responsive to growth factors, ERK5 is also activated by cell stress stimuli including oxidative stress and hypersosmolarity similar to the MAPK members JNK and p38 kinase. Although ERK5 is stimulated by activators common to other MAPK members, ERK5 is activated by a unique upstream MAPKK termed MEK5 that is not utilized by other MAPKs [1, 2]. MEK5 is activated by the MAPKKKs MEKK2 and MEKK3. Additionally, the structure of ERK5 is significantly different from other MAPK members. ERK5 possesses a unique, long C-terminal tail containing a nuclear localization signal and a distinct N-terminal domain that binds MEK5.

ERK5 is an important regulator of serum-induced immediate early gene expression. Active ERK5 has been shown to phosphorylate MEF2c, a member of the MEF2 transcription factor family, resulting in an increase in c-jun transcription, a gene required for cell proliferation. The essential role of MEK5 and ERK5 in blood vessel and cardiovascular development has been demonstrated in mice deficient for either ERK5 or MEK5. Embryos that lack either ERK5 or MEK5 die at embryonic day 10 due to placental, angiogenesis, and cardiovascular defects. Deletion of ERK5 in adult mice

results in the apoptotic death of endothelial cells, resulting in leaky blood vessels and hemorrhage. Thus, ERK5 plays an important biological role in the coordination of cell response to different stimuli and promotes cell growth in the vascular system of the both the developing embryo and the adult.

Characteristics of the JNK Pathway

The MAPKs termed Jun amino-terminal kinases (JNKs) are a subgroup comprised of three known members, JNK1, 2, and 3. This group of kinases is thus named due to their specific phosphorylation of the transcription factor c-Jun, a component of the AP-1 transcription complex. JNK pathway regulation of AP-1 activity is critical for transcriptional control of a number of gene products resulting from a variety of stimuli, ranging from growth factor receptor ligation, cytoskeletal changes, and cellular stresses like osmotic shock and irradiation. Indeed, JNKs were originally identified as stress-activated protein kinases (SAPKs) [1, 2]. Through the regulation of AP-1, JNKs influence the expression of genes as diverse as cytokines, growth factors, inflammatory mediators, and matrix ► **metalloproteinases**. Thus, JNK signaling is expected to play a key role in cellular survival and disease processes stemming from inflammation and cell death. These pathological conditions include diabetes, stroke, and Parkinson's disease. JNKs 1 and 2 are widely expressed, whereas JNK3 expression is limited to neuronal tissue and cardiac myocytes [2, 3].

JNKs are also classified by the presence of a threonine–proline–tyrosine motif in their activation loop. These residues are phosphorylated by the upstream dual-specificity MAPKKs MKK4 and MKK7 resulting in JNK activation. MKK4/7 are, in turn, phosphorylated by a number of upstream MAPKKKs, including MEKK1/2/3/4, MLKs, ASK1, TAO1 and 2, and TAK1 [1]. Several JNK pathway component knockouts have been produced by ► **homologous recombination**, and these tools are helping to define the biological function of JNK signaling. These studies have thus far shown JNK1 and 2 as having a role in immune cell function. Simultaneous deletion of both JNK1 and 2 results in death during midgestation due to failure of neural tube closure and additional brain defects. All JNKs seem to regulate cell survival. For example, JNK1/2 double knockout fibroblasts show increased resistance to radiation [1, 3].

Characteristics of the p38 Kinase Pathway

p38 kinases are members of the mitogen-activated protein kinase (MAPK) family of serine/threonine kinases that phosphorylate and regulate both cytoplasmic proteins and transcription factors, thus regulating gene transcription [1]. Several investigators have independently identified p38 kinase during experiments designed to isolate kinases involved in cell responses to cellular stresses. Four isoforms of p38 kinase have been isolated:

α , β , γ , and δ . These isoforms have been classified as p38 kinases based on both the presence of a conserved threonine–glycine–tyrosine (TGY) sequence in their activation loop and a high amino acid identity. For example, p38 α and β are 60% identical to p38 γ and δ , further suggesting p38 kinases as a subfamily of MAPKs [2]. Stimuli including heat and cold shock, osmotic shock, irradiation, LPS, and cytokines have been shown to activate p38. The MAPKKs activated upstream of p38 include MEKK3, MEKK4, ASK1, TAK1, and MLK3. These MAPKKs have been shown to activate the MAPKKs MKK3/MKK6 that phosphorylate p38 kinase on a highly conserved tyrosine and threonine residues in the activation loop. Phosphorylation of p38 kinase results in the nuclear translocation of this kinase where it can phosphorylate and activate transcription factors such as ATF-2 and ELK1. However, not all targets of p38 kinase are nuclear. p38 kinase also phosphorylates cytoplasmic proteins such as tau protein, MAPKAPK2, 3 and 5, and Mnk1/2.

Activation of p38 has been shown to affect multiple cell functions including development, growth, ►apoptosis, spreading, adhesion, cytokine production and cell-cycle progression. Embryos deficient for p38 α die midgestationally by embryonic day 12.5 due to defects in placental angiogenesis, whereas mice lacking p38 β , p38 γ , or p38 δ are viable, suggesting functional redundancy of these p38 isoforms. Gamma irradiation activates MKK6, stimulating p38 γ and blocking G2-M transition. Similarly, UV irradiation activates p38 α and β that may

serve as an early sensor of DNA damage. Finally, stimulation of cells with LPS activates p38 kinase, resulting in the production of the ►cytokines IL-1 and TNF α and leading to increased inflammation. p38 further increases inflammation through the stabilization of mRNAs containing AU repeats such as TNF α and COX2. Disruption of the p38 pathway would therefore be useful clinically in the arrest of the inflammatory response and in the treatment of inflammatory diseases [3].

Drugs

To date, no compounds have been identified that directly and specifically inhibit either ERK1 or ERK2. However, a number of inhibitors have been developed that affect the activities of the kinases upstream of ERK1/2. The most useful compounds for the inhibition of ERK1/2 activity have been the MEK1/2 inhibitors PD98059 and UO126 (Table 1). These compounds have high specificity for MEK1 and MEK2, and at low concentrations, do not cause appreciable inhibition of MAPK pathways other than ERK1 and ERK2. Both PD98059 and UO126 bind to MEK1 and MEK2 at sites distinct from the ATP-binding pocket, but cause allosteric changes in the proteins that render them unable to activate ERK1/2. However, neither of these two inhibitors is suitable for clinical use due to unfavorable pharmacological properties. A second-generation compound, PD184352, has been developed and found to successfully reduce elevated levels of ERK1/2 activity in colon carcinoma cells and reduce tumor growth in mice (Table 1) [3]. PD184352

MAP Kinase Cascades. Table 1 Pharmacological Inhibitors of MAPK Cascades

Kinase	Inhibitors	Mechanism of Action	Biological Consequences
Raf	Bay 439006	ATP-competitive	Reduces MEK1/2 activity and tumor growth.

was withdrawn from clinical trials due to poor efficacy, likely resulting from poor solubility, high metabolic clearance, and poor bioavailability [4]. More recently, PD0325901 and ARRY-142886 have entered clinical trials [4]. In addition to inhibitors of MEK1/2, a Raf-1 inhibitor, Bay439006, has shown promise as an inhibitor of ERK1/2-mediated cancer cell growth and ▶*metastasis* and is in Phase II and III trials in patients with many different tumor types including melanoma and colorectal cancer [4].

Selective inhibitors of ERK5 have not been described. However, studies of MEK1/2 inhibitors have detected effects on MEK5, the upstream activator of ERK5. In addition to inhibition of MEK1/2 activation of ERK1/2, both PD98059 and U0126 have been shown to partially reduce EGF and hydrogen peroxide activation of the ERK5 pathway in mammalian cell lines (Table 1). Inhibition of the ERK5 pathway occurs at the level of MEK5, however the precise mechanism is unknown. Similarly, the MEK1/2 inhibitor PD184352 also inhibited EGF-stimulation of the MEK5/ERK5 pathway, but a 10-fold higher concentration of inhibitor was required relative to that required for MEK1/2 inhibition (Table 1). Additionally, low doses (2 μm) of PD184352 that completely block ERK1/2 activity were shown to prolong activation of ERK5 in response to EGF and hydrogen peroxide. The additional effects of MEK1/2 inhibitors on MEK5/ERK5 signaling alters the interpretation of results related to studies of these inhibitors on ERK1/2 signaling [3]. Although selective inhibitors of MEK5/ERK5 are yet to be identified, the ability of ERK5 signaling to promote cell proliferation makes it a potentially useful clinical target for inhibitors.

The recent development of the JNK-specific inhibitor SP600125 will likely aid efforts to define the biological significance of JNK signaling (Table 1). SP600125 is an anthrapyrazolone that competes with ATP for the nucleotide-binding site in the JNK catalytic domain [3]. Importantly, as JNK activity is necessary for expression of some extracellular proteinases linked to invasiveness, JNK inhibition may represent an avenue by which to affect tumorigenesis, cancer ▶*metastasis*, and inflammatory immune response. Further, manipulation of JNK activity may potentially allow alleviation of cell death-mediated pathologies, such as ischemic injury and myocardial infarction.

The most extensive development of pharmacological inhibitors of MAPK cascades members has been for p38 (Table 1) [3]. Small-molecule inhibitors have been developed for two p38 isoforms (α and β). Pyridinyl imidazole compounds have been known to block inflammation since the early 1970s. Structural analyses have revealed that p38 kinase inhibitors binds to the ATP-binding pocket of p38 thereby acting as competitive inhibitors. The p38 kinase inhibitor SB202190 is able to bind both the low-activity nonphosphorylated

form and the high activity phosphorylated form of p38 suggesting that the inhibitor is able to disrupt the activation of p38 (Table 1) [3]. Several p38 inhibitors have been in development for the treatment of inflammatory diseases like rheumatoid arthritis, Crohn's disease, and psoriasis [5]. However, Vertex 745 and BIRB-796 were withdrawn due to effects on the central nervous system and liver enzymes, respectively [5]. Second-generation inhibitors like Vertex 702 and Vertex 850 are in Phase II clinical trials. In addition to reducing inflammation, p38 inhibitors like SCIO-469 and second generation inhibitor SCIO-323 are in clinical trials for the reduction of dental pain associated with inflammation [5].

MMPs

Definition

Matrix metalloproteinases (MMPs) are zinc-dependent endopeptidases and belong to a larger family of proteases known as the metzincin superfamily. MMPs are a major group of enzymes that regulate cell–matrix composition. They require a zinc ion in their active site for catalytic activity and are critical for maintaining tissue allostasis. MMPs are active at neutral pH and can therefore catalyze the normal turnover of ► **extracellular matrix** (ECM) macromolecules. Members of the MMP family include the “classical” MMPs (extracellular proteolytic enzymes), the membrane-bound MMPs (MT-MMPs), the ADAMs (a disintegrin and metalloproteinase; adamylsins), and the ADAMTS (a disintegrin and metalloproteinase with thrombospondin motif).

Basic Characteristics

MMP genes show a highly conserved modular structure. They were first detected in vertebrates (1962), and human beings, but have since been found in invertebrates and plants as well. The MMP family

consists of zinc-dependent proteolytic enzymes, which comprise at least 24 different members so far [1] (Table 1). Although all of them exhibit a broad substrate spectrum, they are divided based on their main substrate into collagenases, gelatinases, stromelysins, matrilysins, metalloelastase, membrane-type MMPs (MT-MMPs), and others. MMPs are secreted as zymogens and become activated by cleavage of their propeptide. Figure 1 (Domain structure) depicts an overview of the domain organization of different MMPs. They have several structural features in common that include a propeptide domain containing the “cysteine switch,” the catalytic zinc-binding domain with the sequence HEXGHXXGXXHS, and a hemopexin-like domain. Although each MMP exhibits substrate specificity toward individual matrix proteins, there is considerable overlapping within the whole family. Collectively they are capable of degrading all kinds of ECM proteins, such as the interstitial and ► **basement membrane** collagens, proteoglycans (e.g., aggrecan, decorin, biglycan, fibromodulin, and versican) as well as accessory ECM proteins such as fibronectin. MMPs can also process a number of bioactive molecules. They are involved in the cleavage of cell surface receptors, the release of apoptotic ligands (such as the ► **FAS ligand**), and ► **chemokine** (in-)activation. They also play a major role on cell proliferation, migration (adhesion/dispersion), differentiation, ► **angiogenesis**, ► **apoptosis**, and host defense.

The enzymatic activity of these potentially harmful enzymes is tightly controlled. Once transcribed into protein, MMPs are expressed as inactive zymogens and require distinct activation processes to convert them into active enzymes. After secretion, MMP-activity is regulated by the noncovalent binding of tissue inhibitors of metalloproteinases (► **TIMPs**) as shown in Fig. 2 for MMP-2 and TIMP-2. Four TIMPs have been identified so far: TIMP-1, TIMP-2, TIMP-3, and TIMP-4. All known MMPs can be inhibited by at least one of the four known TIMPs. Nevertheless, individual differences with regard to bond strength and thus the magnitude of inhibition of a particular MMP do exist.

Drugs

Ample evidence exists on the role of MMPs in normal and pathological processes, including tissue remodeling associated with various physiological and pathological processes such as morphogenesis, embryogenesis, angiogenesis, tissue repair, inflammation, cirrhosis [2], arthritis, cancer, and metastasis. The gelatinases MMP-2 and MMP-9 are thought to be important, e.g., in metastasis and MMP-1 in rheumatoid and osteoarthritis.

MMP inhibitor development constitutes an important branch of research in both academic and industrial settings and advances our knowledge on the structure–function relationship of these enzymes. Targeting

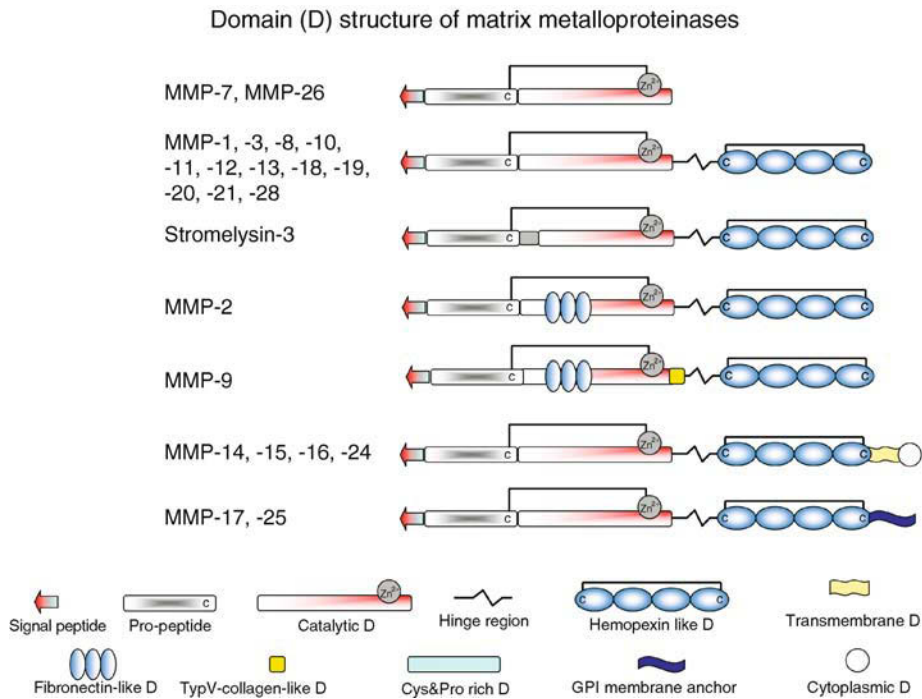

Matrix Metalloproteinases. Table 1 MMPs and their genes known so far

Gene	Name	Location	Comments
<i>MMP-1</i>	Interstitial collagenase	Secreted	One of three collagenases that can degrade the interstitial collagens, types I, II, and III
<i>MMP-2</i>	Gelatinase-A, 72 kDa gelatinase	Secreted	
<i>MMP-3</i>	Stromelysin 1	Secreted	
<i>MMP-7</i>	Matrilysin, PUMP 1	Secreted	Smallest member of MMPs
<i>MMP-8</i>	Neutrophil collagenase	Secreted	
<i>MMP-9</i>	Gelatinase-B, 92 kDa gelatinase	Secreted	<i>MMP-9</i> plays a regulatory role in angiogenesis not only through proteolytic activity but also through other downstream angiogenic factors
<i>MMP-10</i>	Stromelysin 2	Secreted	
<i>MMP-11</i>	Stromelysin 3	Secreted	<i>MMP-11</i> shows more similarity to the MT-MMPs, is convertase-activatable and is secreted therefore usually associated to convertase-activatable MMPs.
<i>MMP-12</i>	Macrophage metalloelastase	Secreted	
<i>MMP-13</i>	Collagenase 3	Secreted	
<i>MMP-14</i>	MT1-MMP	Membrane-associated	Type-I transmembrane MMP
<i>MMP-15</i>	MT2-MMP	Membrane-associated	type-I transmembrane MMP
<i>MMP-16</i>	MT3-MMP	Membrane-associated	Type-I transmembrane MMP
<i>MMP-17</i>	MT4-MMP	Membrane-associated	Gglycosyl phosphatidylinositol-attached
<i>MMP-18</i>	Collagenase 4, xcol4, xenopus collagenase	–	No known human orthologue
<i>MMP-19</i>	RASI-1, occasionally referred to as stromelysin-4	–	
<i>MMP-20</i>	Enamelysin	Secreted	
<i>MMP-21</i>	X-MMP	Secreted	
<i>MMP-23A</i>	CA-MMP	Membrane-associated	Type-II transmembrane cysteine array
<i>MMP-23B</i>	–	Membrane-associated	Type-II transmembrane cysteine array
<i>MMP-24</i>	MT5-MMP	Membrane-associated	Type-I transmembrane MMP
<i>MMP-25</i>	MT6-MMP	Membrane-associated	Gglycosyl phosphatidylinositol-attached
<i>MMP-26</i>	Matrilysin-2, endometase	–	
<i>MMP-27</i>	MMP-22, C-MMP	–	
<i>MMP-28</i>	Epilysin	Secreted	Discovered in 2001, given its name due to have been discovered in human keratinocytes. Highly expressed in lung, placenta, salivary glands, heart, uterus, skin

MMPs for therapeutic interventions is complicated by the fact that MMPs are indispensable for normal development and physiology and by their multifunctionality, possible functional redundancy or contradiction, and context-dependent expression and activity. This complexity was revealed by previous efforts to inhibit MMP activity in the treatment of cancer patients that yielded unsatisfactory results. Doxycycline, at subantimicrobial doses, inhibits MMP activity, and has been used in various experimental systems for this purpose. It is used clinically for the treatment of

periodontal disease and is the only MMP inhibitor that is widely available clinically.

A number of rationally designed MMP inhibitors have shown some promise in the treatment of pathologies, which MMPs are suspected to be involved in. However, most of these, such as Marimastat (BB-2516), a broad spectrum MMP inhibitor, or trocade (Ro 32–3555), an MMP-1 selective inhibitor, have performed poorly in clinical trials. The failure of Marimastat was partially responsible for the folding of British Biotech, which developed it. The failure of

Matrix Metalloproteinases. Figure 2 ProMMP-2-TIMP-2 structure (adopted from [4]). TIMP-2 cartoon and transparent surface structure is shown in blue, MMP-2 in red. The C-terminal ends of both molecules are marked as spheres.

these drugs has been largely due to toxicity (particularly musculo-skeletal toxicity in the case of broad spectrum inhibitors) and failure to show expected results (in the case of trocade, promising results in rabbit arthritis models were not replicated in human trials). The reasons behind the largely disappointing clinical results

of MMP inhibitors are still unclear, especially in light of their activity in animal models. New evidence suggests that MMPs may also generate angiogenesis inhibitors [3]. Because of this dual role in tumor tissue, it is important to identify correctly the MMPs involved in function, activity, and origin as a prerequisite to

creating highly selective MMP inhibitors as potential therapeutics.

Development of MMP null mice carrying specific MMP deletions has provided an opportunity to explore the role of MMPs in normal development as well as in such diverse conditions and diseases as skeletal dysplasias, coronary artery and heart disease, arthritis, cancer, and brain disorders.

Matrix-assisted Laser Desorption/Ionization Mass Spectrometry

Matrix-assisted laser desorption mass spectrometry (MALDI-MS) is, after electrospray ionization (ESI), the second most commonly used method for ionization of biomolecules in mass spectrometry. Samples are mixed with a UV-absorbing matrix substance and are air-dried on a metal target. Ionization and desorption of intact molecular ions are performed using a UV laser pulse.

Maturity-Onset Diabetes of the Young (MODY)

MODY is a type of non-insulin-dependent diabetes mellitus caused by rare autosomal-dominant mutations. Presently there are six known forms of the disease which are all due to ineffective insulin production or

release. Mutations are localized in the following genes: hepa-tocyte nuclear factor 4alpha (HNF4alpha, MODY 1); glucokinase (MODY 2); HNF1alpha (MODY 3); insulin promoter factor-1 (MODY 4); HNF1beta (MODY 5); neurogenic differentiation 1 (MODY 6). MODY 2 and MODY 3 are the most common forms. As a rule, in MODY clinical phenotype is similar to mild type 1 diabetes.

Multidrug resistance proteins

Definition

Multidrug **ABC transporters** are integral membrane proteins that can cause cross-resistance to several cytotoxic agents in human tumors and in cellular model systems. These transporters belong to the so-called ATP-Binding Cassette (ABC) protein family. The human genome encodes 48 ABC proteins that can be grouped into seven subfamilies (ABCA–ABCG). Only three of the 48 ABC transporters, ABCB1 (**P-glycoprotein**, Pgp, MDR1), ABCC1 (**MRP1**), and **ABCG2** (MXR, BCRP) have unambiguously been shown to cause cellular **multidrug resistance** (MDR) [1]. Few other members of the ABC family are also thought to be capable of drug extrusion. Although ABC transporter proteins were discovered and are still referred to as MDR transporters, their major physiological function is to provide general protection against hydrophobic **xenobiotics** [2]. The human (mammalian) multidrug transporters are plasma membrane pumps, exporting compounds from the cytosol to the extracellular space. Transported substrates include cytotoxic drugs, detoxified metabolites, toxins, and carcinogens found in food products, as well as endogenous compounds.

Basic Characteristics

Structure

ABC transporters are large integral membrane proteins consisting of transmembrane domains (TMDs) and nucleotide binding domains (NBDs). Secondary structure predictions and membrane topology models indicate that the NBDs are intracellular globular units, whereas in most cases the TMDs are composed of six membrane spanning helices. According to a general consensus, all functionally active ABC transporters contain a minimum of two ABC units and two TMDs. These four elements may be encoded by a single polypeptide chain (“full transporters,” such as the MDR1/Pgp/ABCB1 protein). In contrast, “half transporters,” such as the members of the ABCG family, possess only a single ABC and a single TMD and they form homodimers or heterodimers to generate a functional ABC transporter (Fig. 1). In each case, the tandem repeat of TMDs and ABCs fold into a single transporter with a pseudo-twofold symmetry, in which the transmembrane helices define a “pore” for substrate translocation, and the nucleotide binding cassettes harvest the energy of ATP binding and hydrolysis.

The NBD unit harbors several conserved sequence motifs (Walker A and B, ABC-signature motifs), which

MDR-ABC Transporters. Figure 1 Membrane topology models of the ABCB1 (MDR1/Pgp), the ABCC1 (MRP1), and the ABCG2 (MXR/BCRP) proteins. The models were constructed on the basis of sequence analysis and experimental data. TMD, transmembrane domain; NBD, nucleotide binding domain; L₀, linker region between TMD₀ and TMD₁ in ABCC1.

play a role in harvesting the energy of ATP. Crystallized ABC domains show a unique, L-shaped fold, in which the secondary structure elements form a characteristic assembly only seen in ABC-ATPases. Structural information, together with experimental data has convincingly demonstrated that the two ABC subunits minimally required for a functional ABC transporter cooperate during the transport. The two ABC domains complement each other's active sites, forming two composite catalytic centers per protein.

In all MDR-ABC transporters, the sites interacting with the transported substrates are most probably located within the TMDs. As of today, high resolution structures are not available for mammalian ABC transporters. Therefore, only structural data of bacterial ABC transporters and homology models can serve as a basis of structure predictions for the human MDR-ABC proteins. Recent structural studies of the bacterial multidrug ABC-transporter Sav 1866 indicate a relatively large drug-binding pocket within the transmembrane regions. The transmembrane helices form a cone-shaped chamber, which is lined with hydrophobic side chains, and has a wide opening from the intracellular side. The two ABC domains are in contact with the transmembrane helices thus providing the structural basis of the ATP-coupled transport mechanism.

Mechanism of Action

The MDR ABC proteins are primary **▶ active transporters**. As such, they utilize the energy of cellular ATP for the promotion of vectorial, transmembrane movement of drugs or xenobiotics. These ATP hydrolytic enzymes (ATPases) interact with two different types of substrates: the energy donor substrate and the transported substrate. The energy donor substrate is the intracellular Mg-ATP complex, and the chemical energy for the active transport of substrates is provided by the binding and hydrolysis of ATP within the NBD units. In a phenomenological sense, the transported substrates are bound to intracellular (or in some cases probably intramembrane), high affinity "on" sites and are unloaded at extracellular, low affinity "off" sites. While ABC transporters most likely recognize hydrophilic substrates and drug conjugates in the cytosol, hydrophobic substrates that are expected to freely diffuse into the cells are recognized in the context of the plasma membrane, before they reach the cytoplasm ("hydrophobic vacuum cleaner" model).

Anticancer Drug Resistance

Despite recent developments, effectiveness of **▶ chemotherapy** is still rather limited for most types of cancer, including tumors of the colon, lung, kidney, pancreas, and liver. Why some cancers respond better than others may be explained by factors relating to the anatomy and physiology of the cancer-ridden organ or

the pharmacokinetics of the drugs used to combat the disease. In addition, tumors may resort to cellular mechanisms, which may prevent the accumulation of cytotoxic drugs in the cancer cells. Of the 48 human ABC transporters, ABCB1 (MDR1/Pgp), several members of the ABCC subfamily (the MRPs) and the **▶ ABCG2** protein qualify for the MDR-ABC protein status [3–5]. MDR transporters can export most neutral and cationic hydrophobic compounds, and cancer cells readily co-opt this mechanism as a primary shield against chemotherapy (Fig. 2). This "first-line" defense is reasonably successful, as most of the routinely used agents of the current chemotherapy regimens are MDR transporter substrates.

Although *in vitro* models clearly show that MDR transporters can protect tumor cells, their relevance in clinical oncology remains controversial. As is the case for most potentially useful cancer biomarkers, no universally embraced guidelines for analytical or clinical validation of MDR transporters exist. Evidence linking ABCB1 Pgp/MDR1 expression with poor clinical outcome is most conclusive for breast cancer, sarcoma, and certain types of leukemia. The relevance of the other MDR transporters in clinical MDR is still unclear. The prognostic implication of ABCC1/▶MRP1 remains controversial and very little is known clinically about ABCG2.

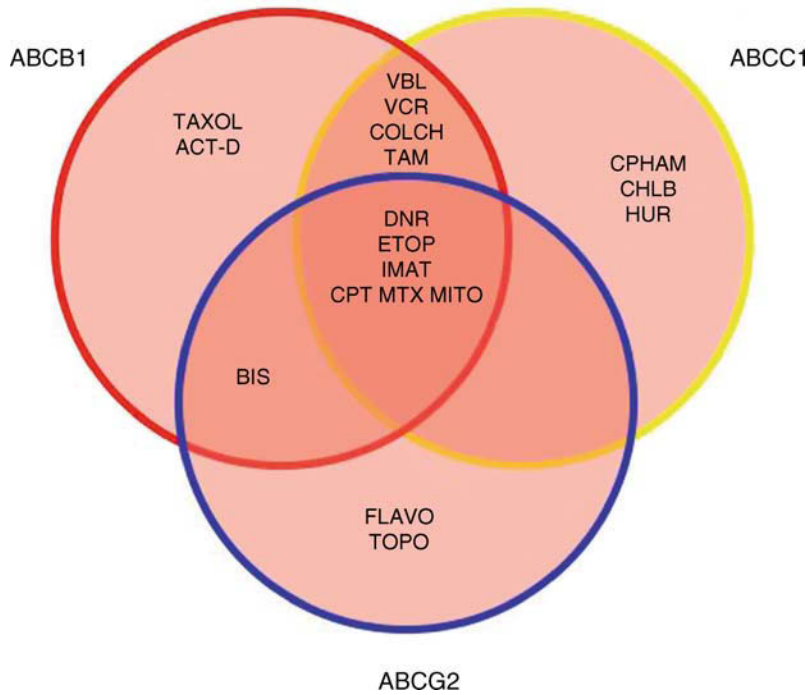

Pharmacological Interventions

Since ABC transporters mediate resistance to a whole array of drugs, they should be an attractive target for the improvement of anticancer therapy. Despite promising *in vitro* results, successful modulation of clinical MDR through the chemical blockade of drug efflux from cancer cells remains elusive, due to the parallel inhibition of MDR transporters residing in **▶ pharmacological barriers**. Modulators are unlikely to improve the therapeutic index of anticancer drugs unless agents that lack significant pharmacokinetic interactions are found.

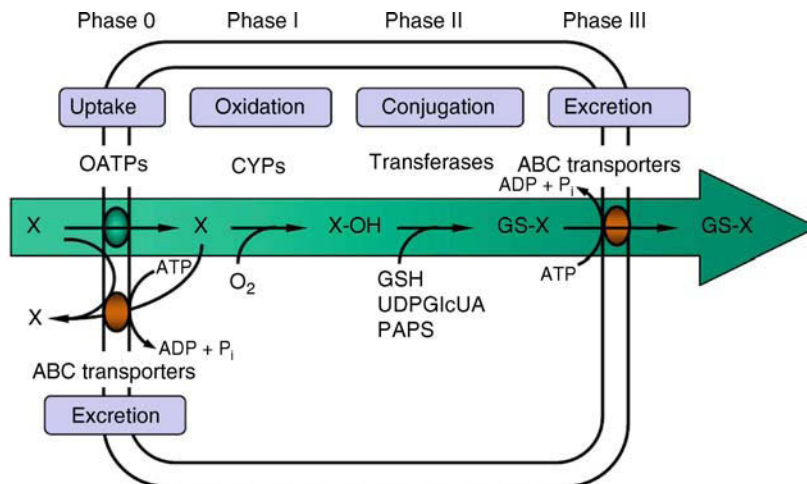

Role of MDR Transporters in Pharmacology

MDR1/Pgp confers resistance to a vast array of clinically and toxicologically relevant compounds, including but certainly not limited to anticancer drugs, HIV-protease inhibitors, antibiotics, antidepressants, antiepileptics, and analgesics. MDR-ABC transporters show high expression in cell types forming different **▶ physiological barriers** such as epithelial cells lining the gastrointestinal tract, proximal tubule cells of the kidney, hepatocytes, epithelial cells in the choroid plexus, and capillary endothelial cells in the brain and the testes.

▶ Cellular defense mechanisms against toxins (A multistep mechanism for elimination of toxic metabolites and xenobiotics. It involves various transport, oxidation, and conjugation steps.) are usually divided into several steps as it is visualized on Fig. 3. Organic anion transporting proteins (OATPs) are responsible for the cellular uptake of endogenous compounds and

xenobiotics, whereas MDR-ABC proteins hinder the cellular uptake of these substances (Phase 0). Should toxins enter the cells, they are subject to oxidation (Phase I), and subsequent conjugation (Phase II). As a result of Phase I–II metabolism, toxins become more hydrophilic and are expelled from the cells via

mechanisms that involve certain MDR-ABC transporters (Phase III).

Crucial data regarding the physiological relevance of MDR transporters came from knockout mice studies. Surprisingly, loss of these genes does not result in an obvious phenotype: MDR knockout mice are viable and

fertile, almost indistinguishable from their wild-type littermates. These results are usually interpreted to suggest that pharmacological modulation of human MDR1 transporters is a feasible strategy to treat multidrug resistant cancer.

However, the high expression in pharmacological barriers in organs that regulate drug distribution, as well as the hypersensitivity of the knockout mice to xenobiotic toxins suggest a major physiological role in the protection of the organism against orally ingested natural toxins. MDR transporters influence drug distribution in three ways: they limit drug absorption in the gastrointestinal tract, they promote drug elimination in the liver, kidney, and intestine, and they regulate drug uptake into cells, tissues, or pharmacological compartments. The gastrointestinal tract, which represents the first line of defense against orally ingested toxins and drugs, is well equipped with a range of ABC transporters that play a prominent role in restricting the passage of hydrophobic compounds that would otherwise cross these barriers by passive diffusion.

Since selective modulation of MDR transporters in cancer cells is difficult to achieve, attempts to circumvent MDR will have to face the profound effects on the distribution of concomitantly administered drugs.

Melanocortins

STEPHEN J. GETTING
Department of Human and Health Sciences, School of Biosciences, University of Westminster, London, UK

Synonyms

Melanocortins; Melanocyte stimulating hormones

Definition

Melanocortin peptides have been proposed as potent modulators of many pathologies including inflammatory (asthma, arthritis) and cardiovascular disease. They have been shown to be directed against resident cells within tissue such as macrophages, endothelial cells and also circulating leukocytes (neutrophils and lymphocytes). Therefore harnessing their therapeutic potential could lead to the development of novel therapeutics.

Basic Characteristics

History

Melanocortins were identified in common ancestors of lampreys and gnathostomes over 700 million years ago and are little changed throughout evolution. They

are derived from a larger precursor molecule known as the ►**pro-opiomelanocortin (POMC)** protein which contains three main domains: the N-terminus region which contains γ -MSH, the central highly conserved ACTH_{1–39} sequence, with α -MSH at its N-terminus and the C-terminal β -lipotropin, which can be cleaved to generate β -endorphin. Proteolytic cleavage by prohormone converting (PC) enzyme and carboxypeptidases between two pairs of basic amino acids residues (-Lys-Lys-, -Arg-Lys-, -Arg-Arg-, -Lys-Arg-) leads to the generation of biologically active fragments. Identification of their biological potential was first demonstrated by Philip Hench at the Mayo clinic in the 1950's with the parent hormone ACTH_{1–39} being used clinically for the treatment of rheumatoid (RA) and gouty arthritis. However, due to side effects such as adrenal gland suppression, it is no longer in clinical use [1].

Melanocortin Receptors

Melanocortins exert their biological effects by binding to G-protein-coupled seven transmembrane receptors (GPCR's). To date five ►**melanocortin receptors (MCR)** have been identified and termed MC1–5R and shown to display high sequence homology with 60% between MC4R and MC5R and 38% between MC2R and MC4R. All MCR are positively coupled to adenylyl cyclase leading to cAMP accumulation within the target cell. Cloning of them has enabled a greater understanding of their biological roles and identification that a common amino acid sequence His-Phe-Arg-Trp (HFRW) is required for activation [2].

MC1R has many different functions including pigmentation, anti-pyretic and anti-inflammatory actions. It is expressed on an array of cells including melanocytes, macrophages, monocytes, neutrophils, endothelial cells, fibroblasts, mast cells and lymphocytes. α -MSH is the most potent peptide followed by ACTH_{1–39} while β -MSH and γ -MSH cause weak activation. Truncated peptides ACTH_{4–10} and ACTH_{1–10} do not activate MC1R, suggesting that the amino and carboxyl-terminal ends of α -MSH (ACTH_{1–13}) are important for full biological activation of the MC1R.

MC2R is solely activated by ACTH_{1–39} and expressed on the adrenal gland leading to release of steroids by the adrenal cortex. A single study has shown that murine adipocytes show expression something not observed in humans; these findings suggest that MC2R may play a potential role in metabolism.

MC3R is expressed both within the periphery and central nervous system (CNS) with detection in immune cells, gut, placenta but no detection in the adrenal gland or melanocytes. Unlike other MCR, most melanocortins (ACTH_{1–39}, α -, β - and γ -MSH) display equipotent binding and full biological activity with truncated peptides, ACTH_{4–10} and ACTH_{1–10}. MC3R

has been postulated to play a role in modulating food intake and energy metabolism, acute inflammation and ischaemic-damage in the heart. This would suggest that MC3R could be an endogenous control mechanism for modulating these pathologies.

MC4R is solely expressed within the CNS, including the hypothalamus, spinal cord and cortex and binds peptides in a similar fashion to the MC1R. The receptor has been shown to be involved in mediating erectile dysfunction, pain and controlling food intake and energy expenditure and could be an exciting target for controlling obesity.

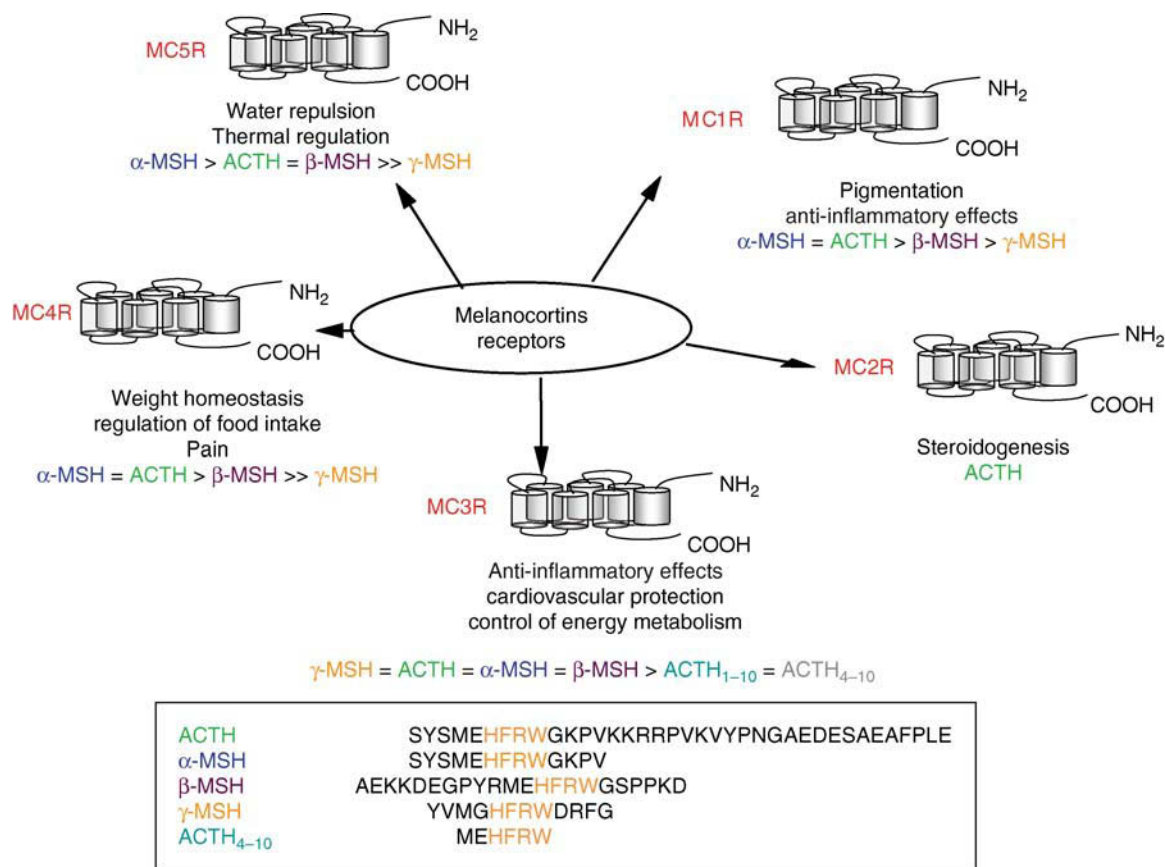

MC5R displays similar binding to MC1R and identified in liver, lung, thymus, testis, ovary, mammary glands, fat cells, bone marrow, skin, skeletal muscle, stomach and duodenum. An interesting observation is its expression in B lymphocytes and in T lymphocytes suggesting a role in immune regulation (Fig. 1).

Drugs

Historically the only melanocortin peptide to be used clinically is the parent hormone from which all these peptides are derived from namely ACTH (see above). It has also been used in the treatment infantile spasms for epilepsy, where it is administered as an intramuscular injection only over a 2–12 weeks period. Obvious side effects include weight gain, puffy face, high blood pressure and an increased risk of infection and should never be administered to patients with diabetics, renal or heart failure. ACTH is also used as a stimulation test to measure adrenal cortex activity, i.e. production of cortisol and is used to ascertain whether someone has ►**Addison's disease**.

Peptides

The development of synthetic and non-peptide mimetics have allowed the unravelling of the biological functions of the MCR expressed in different tissues. This has proved difficult due to the high sequence homology between receptors however we are beginning to see compounds displaying a greater degree of selectivity which will aid scientists in understanding their physiological roles. One of the first synthesised analogues of α -MSH is [Nle⁴,D-Phe⁷]- α -MSH shown to be beneficial in inflammatory models. It is however difficult to imagine that a peptide of this length could have a therapeutic future due to cost to develop and produce, therefore the need to develop smaller compounds was undertaken. The cyclic heptapeptide MTII (chemical sequence: Acetyl-[Nle⁴,Asp⁵,D-Phe⁷, Lys¹⁰]-cyclo- α -Melanocyte Stimulating Hormone Amide Fragment 4–10) a potent MC3/4R agonist has been extensively shown to display anti-inflammatory effects with respect to inhibiting neutrophil migration and also the generation of cytokines/chemokines in models of gouty arthritis and also in controlling metabolic disorders. One of the major breakthroughs in

Melanocortins. Figure 1 Shows the melanocortin receptors, function and naturally occurring peptide sequences that activate them.

melanocortin pharmacology came with the development of SHU9119 which is a substitution of a bulky aromatic amino acid D-Nal(2) into position 7 of ACTH₁₋₃₉ leading to an antagonist at MC3/4R termed SHU9119 (Ac-Nle⁴-c [Asp⁵,D-Nal(2)⁷,Lys¹⁰]α-MSH (4-10)-NH₂). This has allowed many groups to dissect the role of the MC3R in diseases ranging from arthritis to cardiovascular and also in models of obesity. Development of selective MC3R agonists was further enhanced when dTRP⁸-γ-MSH (A highly selective melanocortin type 3 receptor agonist shown to modulate the host inflammatory response in models of experimental gouty arthritis.) was designed and shown to modulate urate crystal induced inflammation in two different rodent models. Other compounds synthesised include PG901 and PG911 developed by substitution of His(6) of the MC3/4R antagonist SHU9119 with Pro(6) or Hyp(6) leading to full agonists at the MC5R and full antagonists at the human MC3/4R these findings highlight that subtle changes of amino acids at discrete positions within the α-MSH sequence can lead to the development of increasingly more selective compounds. We are now entering an era where the Big Pharma has shown an interest in melanocortin biology with the development of non-peptide ligands. These have the

potential to have improved potency, receptor selectivity and bioavailability. The MC4R agonist THIQ (chemical sequence: (N-[(3R)-1,2,3,4-tetrahydroisoquinolinium-3-ylcarbonyl]-(1R)-1-(4-chlorobenzyl)-2-[4-cyclohexyl-4-(1H-1,2,4-triazol-1-ylmethyl)piperidin-1-yl]-2-oxoethylamine) developed by the Merck group displays efficacy in models of erectile dysfunction. In the field of inflammation the MC1R agonist (BMS-470539) developed by Bristol-Myers Squibb has been shown to modulate acute inflammation. BMS-470539 is active at 16.8 and 11.6nM in mice and human melanoma cells, respectively and shown to inhibit LPS induced TNF-α production in BALB/c mice. Palatin Technologies have a novel candidate drug (Bremelanotide formerly known as PT-141) in Phase 2 clinical trials for male and female sexual dysfunction and is believed to be devoid of cardiovascular side effects.

Role of Melanocortin Peptides in Disease Pathologies

Cardiovascular disease affects 2.7 million British people and is a major cause of mortality with circulating neutrophils being proposed as contributing factors in ischaemic damage, though damage can still occur *in vitro* in the absence of blood. Melanocortins have

demonstrated protective effects in myocardial ischaemic-injury (MI) models, where cytokines and neutrophils play a causal role. Short-term ischaemia (5 min) in rats caused by ligation of the left anterior descending coronary artery was reduced by ACTH₁₋₂₄ and the non-selective agonist NDP- α -MSH. Identification of the receptor involved in mediating the protective effects has focused on a panel of pharmacological tools with the selective MC1R agonist **▶MS05** being inactive whilst a potential role for MC3R has been proposed, since the MC3/4R antagonist SHU9119 blocked the protective effects of these compounds (ACTH₁₋₂₄ and NDP- α -MSH) within the heart. Recent studies have highlighted that MC3R is the cellular target with the MC3/4R agonist MTII exhibiting protective effects in a more chronic model of IR injury at 24 h post-reperfusion. Murine and rat hearts were shown to express message and protein for MC3R with expression unaltered following IR. These studies propose a previously unrecognised protective role for MC3R activation and may open up new avenues for therapeutic intervention against heart, and possibly other organ IR injury [3].

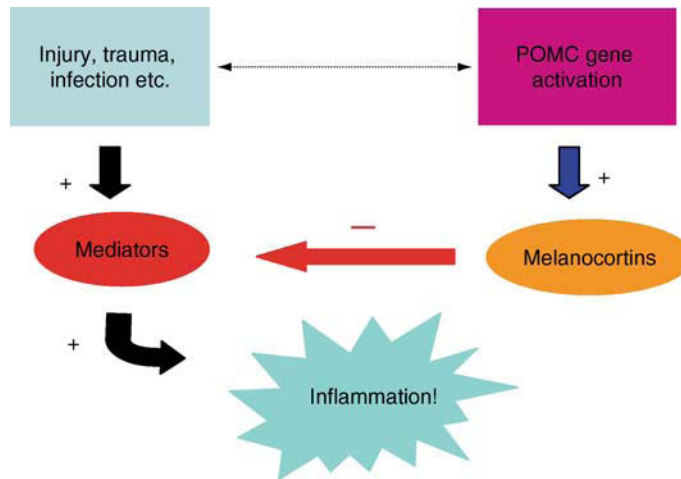

Rheumatoid arthritis (RA) is a complex pathology, which not only affects the joints but also the hearts of patients. There is a 40% mortality rate with RA patients due to cardiovascular complications, with RA patients having elevated cholesterol, blood pressure, diabetes and a tendency to be obese. Therapeutic intervention in RA can lead to some of these complications, with the non-steroidal anti-inflammatory drug Ibuprofen potentially causing a rise in blood pressure. Glucocorticoids can increase cardiovascular problems with acceleration in the development of arterial thickening and narrowing. Disease modifying drugs such as methotrexate have been shown to promote heart disease due to increases in homocysteine. Based on these findings and the fact that the elderly cannot tolerate drugs such as non-steroidals due to decrease in renal clearance, the development of novel naturally occurring therapeutics is essential. A potential alternative to existing therapies could be melanocortin peptides, as they have been demonstrated to possess an array of anti-inflammatory effects in models of arthritis and ischaemic-reperfusion injury.

A clinical study by Catania and colleagues [4] highlighted that α -MSH was elevated in the synovial fluid of patients with RA. An increase in α -MSH concentration was detected in the synovial fluid but not in the plasma suggest local production and potential for an endogenous anti-inflammatory loop within the joint to control the host inflammatory response. Elevation of α -MSH within the knee joint led to a lower degree of inflammation observed in patients. Further work has shown in a pre-clinical model of RA (adjuvant induced arthritis) that α -MSH, was able to modulate weight loss, arthritic score, joint damage and swelling, features

observed in the human pathology. More importantly was the fact that α -MSH caused an increased beneficial effect compared to the clinically used glucocorticoid prednisolone and inhibited glucocorticoid induced weight loss.

Gout: Gouty arthritis is a neutrophil driven pathology which is caused by shedding of urate crystals in the intraarticular and periarticular space of the knee joint resulting in an intense inflammatory response (erythema and oedema). More importantly with an increasing ageing and obese population – both risk factors in gout, we are potentially facing a financial and debilitating time-bomb. Melanocortin peptides have been shown to modulate neutrophil migration and release of pro-inflammatory cytokines and chemokines in a **▶corticosterone** independent manner. This inhibitory effect was due to blockade of inflammatory mediator release from macrophages via activation of MC3R. Further studies using the naturally occurring γ_2 -MSH, partially-selective synthetic peptide MTII and highly selective MC3R agonist **▶dTRP⁸- γ -MSH** have also highlighted the importance of MC3R in gouty arthritis. Recently MC3R null mice have been evaluated in models of gout and have shown an exacerbation in the host inflammatory response to urate crystals compared to wild types. This data further strengthens the hypothesis that MC3R is preferential in modulating the host inflammatory response compared to MC1R (Fig. 2).

Obesity and Energy Expenditure: Obesity is fast becoming a major epidemic within our society. A number of reasons have been attributed to this including a lack of exercise, an excess of readily available food and genetic factors; all these result in an inability to maintain a stable body weight. To restore homeostasis, a number of alterations to our lifestyle need to be addressed: more exercise, reduction in fast, readily available food or therapeutic intervention. The arcuate nucleus of the hypothalamus is a region where neurons contain the *POMC* gene. During periods of starvation or overeating, activation of POMC neurons is reduced or activated respectively, thus maintaining homeostatic balance and helping us control body weight. To mediate this effect, α -MSH derived from POMC stimulates the central MCR whilst antagonism occurs via AgRP. Fasting stimulates AgRP neurons whilst starvation causes inhibition; these effects occur *via* central MCR (MC3 and 4R) and maintain energy homeostasis. Utilisation of knock-out animals has allowed for the role of these receptors to be dissected. MC3R null mice have increased adipose tissue and are hypoactive, whilst POMC null mice are obese. The pharmaceutical industry has mainly focused on the MC4R as a major target for eating disorders. Chronic antagonism of MC3/4R using SHU9119 and/or AgRP results in obesity by increasing food intake and decreasing energy expenditure whilst MTII and α -MSH has the opposite effect. Therefore at present it would appear that MC3R is involved in regulating adiposity and

Melanocortins. Figure 2 Shows anti-inflammatory effect of melanocortin peptides.

Melanocortins. Figure 3 Melanocortins have the potential to restore homeostasis to tissue.

MC4R for feeding behaviour, targeting one or both of these receptors in addition to understanding the complex cross-talk within the CNS may lead to the development of melanocortin based therapeutics for the treatment of eating disorders [5].

Conclusion

Melanocortin peptides are potent anti-inflammatory agents displaying beneficial effects in diseases ranging from cardiovascular to arthritis to obesity to name a few. Within an inflammatory context, they have the ability to switch off early production of cytokines and at later stages they increase levels of anti-inflammatory proteins that lead to the resolution of the host inflammatory response potentially restoring homeostasis to the tissue. They could eventually be viewed as an alternative to glucocorticoids, as their mode of action often resembles that seen

with this widely used therapeutic but may be devoid of the side effects associated with continuous glucocorticoid therapy. The difficulty with peptide therapeutics is their short half-lives due to rapid clearance, in some respects this maybe of benefit as they will not accumulate within the body, thus reducing potential side effects. Development of non-peptide MCR agonists may hold the key and lead to the development of the first melanocortin based therapeutics (Fig. 3).

Melanocyte-stimulating Hormone

Melanocyte-stimulating hormones (α MSH, β MSH, γ MSH; also called melanocortins or melanotropins) are generated by proteolytic cleavage of proopiomelanocortin. MSH isoforms increase the synthesis of eumelanin by melanocytes and regulate body weight by activating anorexigenic pathways in the hypothalamus.

- ▶ Appetite Control
- ▶ Melanocortins

Melatonin

Melatonin is a hormone secreted by the pineal gland. Production of melatonin is regulated via signals from the suprachiasmatic nucleus, the seat of a mammal's circadian clock. Thus, melatonin levels are highest during the hours of darkness, and lowest during the day (i.e. light). Exogenously administered melatonin elicits a sleep promoting effect, although owing to interaction with the fluctuations of endogenous melatonin, this effect is highly dependent on the time of day the compound is ingested. Nevertheless, a synthetic compound that acts as an agonist at melatonin receptors (ramelteon) has been shown clinically to be useful as a *hypnotic*. Endogenously, in addition to its role in the circadian cycle, melatonin acts as an antioxidant and immunoregulator.

Mesangial Cells

Mesangial cells are the smooth muscle-like cells of the capillaries in the glomerulus of the kidney.

Mesolimbic System/Reward System

In 1954, experiments by Olds and Milner revealed that the brain has specialized "centers" for reward functions. In these studies electrical stimulation of certain brain sites was found to be highly rewarding in the sense that rats operantly respond for electrical stimulation of these brain sites, often to the exclusion of any other activity. A neurotransmitter system that is particularly sensitive to electrical self-stimulation is the mesolimbic dopamine projection that originates in the ventral tegmental area and projects to structures closely

associated with the limbic system, most prominently the nucleus accumbens shell region and the prefrontal cortex. Because of its ubiquitous involvement in the regulation of reward-related behavior this system has been characterized as a neurochemical substrate of reward.

Metabolic Syndrome

The metabolic syndrome (also called syndrome X) is characterized by several clinical features which are associated with an increased risk for cardiovascular diseases. Two classification systems by the National Cholesterol Education Program (NCEP) as well as by the World Health Organization (WHO) have been used to define the metabolic syndrome (see table). The most important features are abdominal obesity, insulin resistance with impaired glucose regulation, dyslipidemia (high triglyceride and low HDL cholesterol plasma levels), and hypertension. The prevalence of the metabolic syndrome is increasing dramatically worldwide. It is generally believed that the increase in adipose tissue is the primary and most important mechanism underlying the development of the metabolic syndrome. There is good evidence that an increase in the visceral fat is linked to insulin resistance. Potential mechanisms linking obesity to insulin resistance and the development of type 2 diabetes are an increase in the circulating levels of free fatty acids which decrease insulin sensitivity as well as the altered production of

adipokines such as adiponectin or resistin. While adiponectin has beneficial effects on insulin sensitivity of peripheral organs, resistin can induce insulin resistance. In patients with metabolic syndrome, adiponectin plasma levels are reduced whereas resistin levels are increased. The increased availability of free fatty acids derived from adipose tissue results in an accelerated synthesis of very low-density lipoproteins containing triglycerides in the liver of patients with metabolic syndrome. High triglyceride concentrations in ApoB-containing lipoproteins are typically accompanied by a decrease in HDL cholesterol levels due to a decreased exchange of triglycerides and cholesterol esters between ApoB-containing lipoproteins and HDL particles via the cholesterol ester transfer protein (CETP). There is also evidence that hyperinsulinemia can result in arterial hypertension due to increased sodium retention and an increase in the activity of the sympathetic nervous system as well as by direct vascular effects. Recently, evidence has emerged that obesity is accompanied by a chronic inflammatory process in the fat tissue resulting in increased expression of TNF α and other cytokines which may contribute to the systemic insulin resistance and which may further promote the chronic inflammatory processes underlying the development of atherosclerosis. Thus, the metabolic syndrome comprises a variety of symptoms and processes which are interconnected in a complex manner and eventually promote the development of atherosclerotic processes resulting in an increased cardiovascular morbidity.

Synonyms

G-protein coupled glutamate receptors

Definition

► **Glutamate** is the transmitter of most fast excitatory synapses in the central nervous system. To excite (depolarize) the post-synaptic neuron, glutamate activates various types of receptor channels (the ► **ionotropic glutamate (iGlu) receptors**) known as the NMDA, AMPA and kainate receptors (Fig. 1). Glutamate also acts on receptors called the ► **metabotropic glutamate (mGlu) receptors** that are coupled to heterotrimeric G proteins to activate intracellular pathways. Eight mGlu receptors have been identified in mammals and all play important roles in the fine-tuning of most glutamatergic as well as other synapses [1].

Basic Characteristics

The mGlu Receptor Family

The mGlu receptors were first identified as receptors responsible for the glutamate stimulation of phospholipase C (PLC) in neurons. Latter, other mGlu receptors were shown to inhibit ► **adenylyl cyclase (AC)**. Molecular cloning and the sequencing of mammalian genomes identified eight genes encoding mGlu receptors [1]. Additional mGlu receptor subtypes exist due to alternative splicing of the mRNA encoding mGlu1 (splice variants a, b and d are the best characterized), mGlu5 (a and b), mGlu7 (a and b) and mGlu8 (a and b). All these splice variants differ in the sequence of their carboxy-terminal intracellular tail. These receptors can be classified into three groups based on their sequence similarity, their pharmacology (see below) and their transduction mechanism [1]. The sequence similarity is ~60–70% between members of a given group, and drops to 40% between receptors of two distinct groups. The group-I is composed of mGlu1 and mGlu5 receptors, which are both coupled to the stimulation of PLC. The mGlu2 and mGlu3 receptors form the group-II, whereas the mGlu4, mGlu6, mGlu7 and mGlu8 constitute the group-III. Both group-II and group-III mGlu receptors can inhibit AC in transfected cells.

Metabotropic Glutamate Receptors. Figure 1 The mGlu receptors and the fine tuning of glutamatergic synapses. Release of glutamate from nerve terminals activates the iGlu receptors (the NMDA and AMPA subtypes) in the post-synaptic element, leading to neuronal excitation. The group-I mGlu receptors (mGlu1 or mGlu5) located on the side of the post-synaptic element regulates the activity of Ca^{2+} and K^{+} channels as well as of iGlu receptors via intracellular pathways. The group-II mGlu2 and mGlu3 receptors regulate not only the release of glutamate when located on the pre-synaptic terminal, but can also participate in the glutamate response when located in the post-synaptic element. Most group-III mGlu receptors (4, 7 and 8) are located in the pre-synaptic release zone where they inhibit glutamate release. Inserted in the left top corner is a dendrogram of the mGluR family, illustrating the three groups of mGluRs.

Transduction Mechanism and Function of mGlu Receptors

Group-I mGlu receptors are mainly found on the side of the post-synaptic element (Fig. 1). By activating PLC, they stimulate the formation of inositol triphosphate leading to the release of Ca^{2+} from intracellular stores. This Ca^{2+} signal can then regulate the activity of enzymes such as protein kinase C and phospholipase A2. Group-I mGlu receptors can also regulate the activity of various channels, including Ca^{2+} channels. They also inhibit or activate K^+ channels leading either to a decrease or to an increase in neuronal excitability. Group-I mGlu receptors also modulate (mainly positively) the activity of the iGlu receptors of the AMPA and NMDA types, and can therefore modulate the excitatory effect of glutamate. NMDA receptors are known to be responsible for the ►excitotoxic effect of ►glutamate and to play an important role in synaptic plasticity including ►long-term potentiation (LTP) and long-term depression (LTD). It is therefore not surprising that antagonists of group-I mGlu receptors have neuroprotective effects and can inhibit synaptic plasticity such as LTP and LTD. By stimulating the release of endocannabinoids from the post-synaptic element, activation of group-I mGluRs can also have indirect pre-synaptic effect, inhibiting glutamate release.

The mGlu1 receptors are expressed at high density in the Purkinje neurons in the cerebellum where they are involved in a synaptic plasticity phenomenon important for the control of eye movements. These receptors are also found in the thalamus, the olfactory bulb and in some neurons of the hippocampus. The mGlu5 receptors are highly expressed in the pyramidal neurons of the hippocampus where they regulate a LTP phenomenon important for spatial memory. The mGlu5 receptors are also found in glial cells, but their function in these cells is still not yet fully elucidated. Both group-I mGlu receptors are expressed in many other brain regions and as such are involved in many processes such as the central response to pain, the control of movements via the extrapyramidal motor circuit. Group-I mGlu receptors are also found outside the central nervous system, such as in the sensory terminals in the skin where they can be at the origin of the inflammatory pain sensation. These various observations help in understanding the anxiolytic, antiparkinsonian and analgesic effects, as well as the decrease in the development of cocaine dependence observed with a mGlu5 receptor antagonist (MPEP (2-Methyl-6-(Phenylethynyl) Pyridine)) [2]. In addition neuroprotective and antiepileptic effects have been observed with an mGlu1 receptor antagonist (BAY367620).

Group-II mGlu receptors have been observed in pre-synaptic as well as in post-synaptic elements. These receptors can inhibit AC activity, but their main action

in neurons is to regulate the activity of various types of channels, including inhibition of Ca^{2+} channels (and as such they can inhibit the release process at the pre-synaptic level). In the brain, mGlu2 receptors are highly expressed in Golgi cells in the cerebellum and in the dentate granule neurons of the hippocampal formation where they are involved in a LTD phenomenon. The other group-II mGlu receptor, mGlu3, is found not only in neurons, but also in astrocytes where its role is not yet elucidated. The mGlu3 receptor is mainly expressed in the reticular nucleus of the thalamus. Group-II mGlu receptors are also expressed in many other brain areas, and the recent development of selective and systematically active group-II mGlu receptor agonists (such as LY354740) reveal the potential use of such compounds for the treatment of anxiety, schizophrenia and drug dependence [3].

Group-III mGlu receptors are mostly found in the pre-synaptic element within the synaptic release site (Fig. 1), except the mGlu6 receptor, which is responsible for the post-synaptic action of glutamate on the ON bipolar cells in the retina. These receptors are therefore considered as autoreceptors controlling the glutamate release process. The mGlu7 and 4 receptors are also found in GABA-ergic terminals where they inhibit the release of the inhibitory transmitter GABA. Like group-II receptors, group-III mGlu receptors can inhibit AC activity, but their main action is the inhibition of Ca^{2+} channels leading to the inhibition of the release process. Due to their localization at the synaptic vesicle release site, it is likely that group-III mGlu receptors can directly control the release machinery.

The mGlu7 receptor type is widely expressed in the brain and is activated by high concentration of glutamate (100–1,000 μM). It may serve to prevent over-activity of glutamatergic synapses, and accordingly, the deletion of its gene in mice leads to the rapid development of general epilepsy and death. The mGlu4 receptor is mostly expressed in the cerebellum and the olfactory bulb, but also in other areas. It has been shown to play a role in certain types of absence epilepsy. The mGlu8 receptor is expressed in some restricted areas in the brain and its physiological function is not yet elucidated, but the deletion of the mGlu8 gene result in increased anxiety and weight gain.

Original Structure and Activation Mechanism of mGlu Receptors

Alike any other G-protein coupled receptors (GPCRs), mGlu receptors have seven transmembrane helices, also known as the ►heptahelical domain (Fig. 2). As observed for all GPCRs, the intracellular loops 2 and 3 as well as the C-terminal tail are the key determinants for the interaction with and activation of G-proteins. However, sequence similarity analysis as well as specific structural features make these mGlu receptors different from many other

Metabotropic Glutamate Receptors. Figure 2 The original structure and activation mechanism of mGlu receptors. These receptors dimeric entities, each protomer (one in red and yellow, the other in blue) being composed of a Venus Flytrap (VFT) domain connected to a heptahelical domain via a cysteine-rich region. Binding of agonists in the VFT cleft stabilizes a closed state of the VFT. This is associated with a relative movement of the two VFTs in the dimer, as indicated with the double white arrow. Antagonists act by preventing closure of the VFT. Allosteric modulators interact in the heptahelical domain. These can either act as non-competitive antagonists (also called negative allosteric modulators) or facilitate agonist activation of the receptor (positive allosteric modulators).

GPCRs, and were the first members of the class C GPCRs. The main structural originality of these receptors is their large extracellular domain (Fig. 2) that contains the glutamate binding site [4]. The structure of this extracellular domain has been solved for both mGluR1, mGluR3 and mGluR7 [4]. It is composed of two lobes that are separated by a wide cleft in the absence of glutamate. Upon binding of the agonist within this cleft, the two lobes close like a Venus Flytrap trapping an insect. This domain is therefore often called the “Venus Flytrap” (VFT) domain (VFT domain), and is connected to the first transmembrane segment of the ▶heptahelical domain by a cysteine-rich domain that plays a critical role in transmitting the signal from the VFT (VFT domain) to the ▶heptahelical domain (Fig. 2). The second original feature of the mGlu receptors compared to other GPCRs is that they are always found as dimers in the brain. A disulfide bond linking the two VFTs stabilizes this dimeric structure. Today, only homodimers have been identified. This dimeric structure of mGlu receptors is probably critical for glutamate to activate the receptor. Indeed, the resolution of the structure of the extracellular domain of mGlu1 and mGlu3 revealed a dimer of VFTs, and a large change in the general conformation of the dimer is seen in the presence of glutamate. This change is such that the C-terminal ends of the two VFT modules become closer in the presence of agonists (Fig. 2). Because the C-terminal ends on the VFT modules are linked to the

heptahelical domain via the cysteine-rich region, such a change of conformation is likely to induce a change of the relative position of the two heptahelical domains leading to the activation of only one of them which in turn activate the G-protein.

As we will see below, this original and complex structure of the mGlu receptors offers multiple possibilities to develop drugs modulating their activity.

Drugs

All compounds identified so far acting at the glutamate binding site share a glutamate-like structure. Such compounds are either agonists or competitive antagonists (Fig. 2). Within the last 15 years a number of group-selective compounds have been characterized. However, due to the high conservation of the glutamate binding site between receptors of the same group, very few subtype selective compounds have been characterized [3]. By using systematic screening procedures, pharmaceutical industries have identified ▶allosteric modulators of several mGlu receptor subtypes [2, 5]. Such molecules have a structure very different from glutamate and do not bind to the VFT but rather in the heptahelical domain (Fig. 2). These can be either non-competitive antagonists [2] or positive ▶allosteric modulators [5] and are subtype selective. Such compounds offer new possibilities to modulate mGlu receptor activity in the brain. Most importantly, because compounds activating mGlu receptors are expected

to have multiple therapeutic applications (see above), positive allosteric modulators may be more efficacious than pure agonists since they are less likely to induce receptor desensitization. Moreover, in contrast to pure agonists that activate the receptor all the time and in every regions where the receptor is expressed, positive allosteric modulators only facilitate receptor activation by endogenous ligands. As such positive allosteric modulators maintain the normal biological activity of the receptor and its activation only where needed. As such, positive allosteric modulators are expected to have far less side effects, facilitating their use in a wider range of concentrations.

Group-I mGlu Receptor Compounds

Quisqualate was the first compound shown to activate group-I mGlu receptors. Although it is also active on the AMPA type of iGlu receptors, it remains the most potent group-I agonist. 1S,3R-ACPD was the first selective mGlu receptor agonist identified, but it activates group-I, group-II and some group-III mGlu receptors. ACPD (1-aminocyclopentane-1,3-dicarboxylic acid) is identified as the mGlu selective agonist. Within the four stereoisomers, 1S,3R-ACPD activates group-I and group-II mGlu receptors as well as some group-III receptors (mGlu8) at higher concentrations. The 1S,3S-ACPD isomer is one of the first selective group-II mGlu receptor agonists described. These molecules have been widely used to identify the possible physiological functions of mGlu receptors.

3,5-DHPG remains the best characterized selective group-I agonist, though it has a low potency (10 μ M). A few competitive group-I antagonists have been identified (the first was MCPG, which is also active on group-II receptors) such as LY367366 and LY393675, which are acting on both mGlu1 and mGlu5, and LY367385 which is mGlu1 selective, but all have a very low affinity. As mentioned above, non-competitive antagonists have been identified for group-I mGlu receptors that bind within the heptahelical domain. These are MPEP (2-Methyl-6-(Phenylethynyl) Pyridin), selective for mGlu5, and BAY367620, selective for mGlu1. These highly selective and potent compounds have helped in identifying the important physiological roles of group-I mGlu receptors mentioned above.

Other molecules also acting within the heptahelical domain of mGlu1 and mGlu5 have been shown to potentiate the action of glutamate and are therefore positive allosteric modulators. Such compounds have no effect on their own but increase both the efficacy and potency of agonists. These are Ro01-6128 and CPPHA for mGlu1 and mGlu5, respectively [5]. No behavioural effect has already been reported for these molecules but according to the known function of group-I mGlu receptors, positive action on cognition are expected.

Group-II mGlu Receptor Compounds

Potent and selective compounds have been identified for group-II receptors. The first one was DCGIV, but this compound also antagonizes group-III mGlu receptors and activates NMDA receptors limiting its usefulness in *in vivo* studies. LY354740 and its analogue LY379268 are actually the best group-II agonists, and, most interestingly, they are systemically active and have unravelled the various possible applications of group-II agonists described above. As for group-I mGluRs, positive allosteric modulators have been identified for mGlu2. These compounds also interact in the heptahelical domain and are very selective for mGlu2 (X). As observed with the group-II agonists, these modulators also have antipsychotic and anxiolytic activities, demonstrating that the behavioural effects of group-II agonists mostly result from the activation of mGlu2 receptors.

MCPG is the first described antagonist acting at group-II mGlu receptors but it is not selective, being also an antagonist of group-I and some group-III receptors. Today, the commonly used group-II competitive antagonists are derivatives of the non-selective mGlu agonist L-CCG-I: LY341495 > XE-CCG-I > PCCG4 > MCCG-I. However, LY341495 is active at all mGlu receptors, being more potent not only at group-II but also at most group-III receptors (mGlu6, 7 and 8). Moreover, the activity of the other compounds on group-III receptors remains to be characterized. Today, non-competitive antagonists acting in the heptahelical domain of group-II mGluRs have not yet been reported.

Group-III mGlu Receptor Compounds

L-AP4 and the natural compound, L-SOP, were the first identified group-III agonists. More recently, Z-CPrAP4, ACPT-I, (+)-PPG and DCPG were shown to be additional group-III agonists. DCPG, being 50–100 times more potent on mGlu8 than on the other group-III receptors, is proposed as a selective mGlu8 agonist. Among these molecules, ACPT-I was recently shown to pass the blood brain barrier, allowing easier *in vivo* studies, and demonstrating antiparkinsonian and antidepressant-like effect of this molecule. Modulators acting in the heptahelical domain of group-III mGluRs have also been identified. PHCCC was found to be a positive allosteric modulator selective for mGlu4 and display antiparkinsonian activity, and AMN082 was reported as an mGlu7 selective ligand. Although the latter also binds in the heptahelical domain of mGlu7, it directly activates the receptor even in the absence of glutamate.

Today, the number of group-III antagonists is rather limited. The only selective compounds are MAP4, MSOP and CPPG.

Currently, more group-selective and subtype selective compounds remain to be discovered. The recent demonstration of a possible action of new subtype selective

group-I modulators opens a new route for the discovery of such molecules for either group-II or group-III receptors. These will certainly be useful for the identification of the physiological roles of these different receptors and for the discovery of new therapeutic drugs.

Metabotropic Receptor

For differentiation of G-protein-coupled receptor subtypes from subtypes permanently linked to ion channels (ligand-gated ion channels) the terms metabotropic versus ionotropic receptors, respectively, are used. Prime examples of metabotropic receptors are given by the mGlu_{1–8} receptor family of G-protein-coupled glutamate receptors.

► Transmembrane Signaling

Metalloprote(in)ases

Metalloproteinases are a subgroup of proteinases. They are responsible for the cleavage of peptide bonds within a protein (proteolysis). Metalloproteinases contain a metal ion in the active center and are divided into four subclasses dependent on their mechanism of catalysis.

- Non-viral Peptidases
- Matrix Metalloproteases

Methicillin-resistant Staphylococci

Methicillin-resistant staphylococci are strains of staphylococci, which show resistance to a wide variety of antibiotics. They are named for their resistance to methicillin, a β -lactamase-resistant penicillin. Methicillin-resistant *Staphylococcus aureus* (MRSA) has become a serious problem particularly in hospitals.

N-Methyl D-aspartate Receptors

► Iontropic Glutamate Receptors

Methylating Agents

► Alkylating Agents

3,4-Methylenedioxymethamphetamine

3,4-Methylenedioxymethamphetamine (MDMA; ecstasy) is a synthetic analog of amphetamine that produces hallucinations, an elevation in mood, and a feeling of “emotional closeness”. This latter property has led to Ecstasy being referred to as the “hug drug”. The unique properties of Ecstasy as compared to the parent compound amphetamine are believed to be due to the more selective effects of Ecstasy in promoting transporter-mediated release of serotonin. The use of Ecstasy has become a part of the culture associated with “rave” style dance parties.

► Psychostimulants

2-Methyl-6-(phenylethynyl) Pyridine

MPEP (2-methyl-6-(phenylethynyl) pyridine) is the best characterized mGlu5 selective non-competitive antagonist. This compound was one of the first of the

allosteric regulators of the mGlu receptor identified as a non-competitive antagonist. MPEP is systematically active and has been very helpful in identifying the role of the mGlu5 receptor subtype, including its involvement in inflammatory pain, anxiety and the development of cocaine addiction.

► [Metabotropic Glutamate Receptors](#)

1-Methyl-4-Phenylpyridium

1-methyl-4-phenylpyridinium (MPP⁺), a permeant organic cation, is an excellent substrate for all organic cation transporters, but also for vesicular (VMAT) and some neuronal (e.g. DAT, NET) monoamine transporters. It is a potent neurotoxin and produces Parkinson's disease-like symptoms. It is generated in vivo from MPTP (1-methyl-4-phenyl-tetrahydropyridinium).

► [Organic Cation Transporters](#)

1-Methyl-4-Phenyl-1,2,3,6-Tetrahydropyridine

1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is a toxic agent which selectively destroys nigrostriatal neurons, but does not effect dopaminergic neurons elsewhere. MPTP is converted to its toxic metabolite, MPP⁺, by the enzyme monoamine oxidase. MPP⁺ is taken up via dopamine transporters and acts selectively on dopaminergic neurons by inhibiting mitochondrial oxidation reactions, which eventually results in the destruction of the cell. MPTP produces a severe form of Parkinson disease in primates.

Methylxanthines

Methylxanthines are naturally occurring drugs, including theophylline, theobromine and caffeine. Methylxanthines at relatively high doses inhibit phosphodiesterases, which results in an increase in intracellular cAMP

levels. Inhibition of phosphodiesterase may be responsible for the tachycardia and relaxation of smooth muscles observed in response to methylxanthines. Already at lower doses, methylxanthines act as antagonists on adenosine receptors. The latter effect is believed to be responsible for the psychomotor stimulant effects of methylxanthines. Theophylline is used clinically as an anti-asthmatic drug, due to its strong bronchodilator effects.

Michaelis–Menten Kinetics

In 1913 L. Michaelis and M.L. Menten realized that the kinetics of enzyme reactions differed significantly from the kinetics of conventional chemical reactions. They put the reaction of substrate plus enzyme yielding enzyme plus substrate into the form of the equation: reaction velocity = (maximal velocity of the reaction × substrate concentration) / (concentration of substrate + a fitting constant K_m). This latter constant characterized the tightness of the binding of the reaction between substrate and enzyme or the concentration at which the reaction was half the maximal value. This equation is formally identical to the Langmuir adsorption isotherm that relates the binding of a chemical to a surface. Both of these models form the basis of drug–receptor interaction, thus the kinetics involved are referred to as “Michaelian,” or “Langmuirian” in form.

Definition

A method to study the activity of a large numbers of genes simultaneously. This method uses high speed robotics to precisely apply tiny droplets containing biologically active material (DNA, proteins, chemicals) to glass slides. In Functional Genomics DNA microarrays are used to monitor gene expression at RNA level, to identify genetic mutations and to discover novel regulatory regions in genomic sequences. Protein or chemical arrays are used to monitor protein expression and to identify protein–protein or drug–protein interactions. Typically tens of thousands of genes or interactions can be monitored in a single experiment.

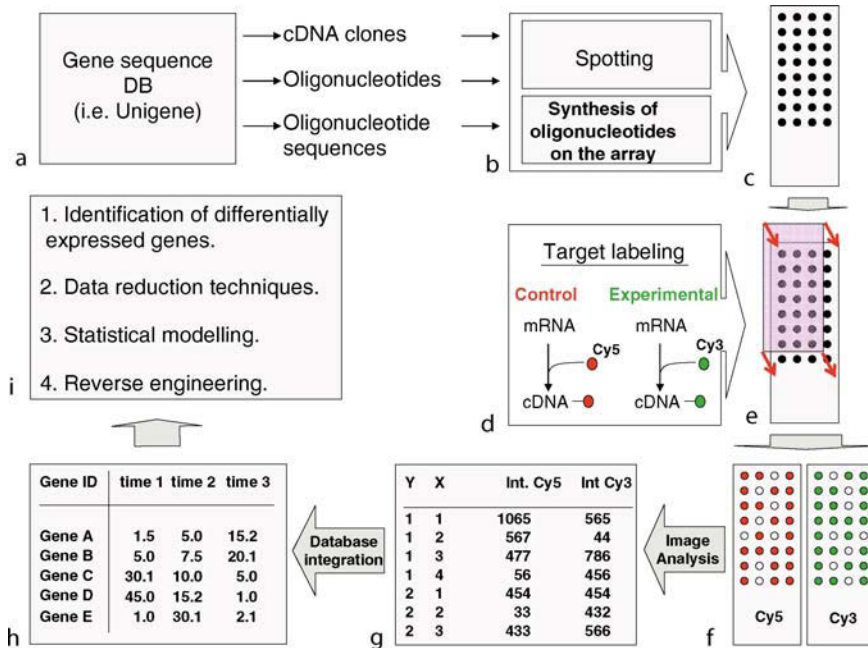

Description Gene Expression Profiling

The most common application of microarray technology is in monitoring gene expression (gene expression profiling).

The principle: The technique is based on a classic molecular biology procedure called reverse Northern blot. mRNA is extracted from a biological sample and reverse transcribed in the presence of a radioactive or fluorescent precursor. The reaction produces a pool of labeled complementary DNA copies (cDNAs) representative of the original mRNA pool and it is defined here as ▶target. The expression of an individual gene is quantified by hybridizing the target to the gene specific cDNA (defined as ▶probe) which has been previously spotted on a solid surface. The amount of radioactive or fluorescent signal associated to the spot is proportional to the amount of gene specific RNA originally present in the cell. Multiple cDNAs can be spotted in an ordered pattern (▶array) allowing the quantification of multiple genes. Before the advent of microarray technology researchers were employing low complexity nylon-based arrays, manufactured using manual devices. The technology subsequently evolved with the introduction of robotics which made possible to generate reproducible high density nylon filters (50 spots per square centimeter). This technology employed large membranes with up to 50,000 DNA spots, required several milliliters of hybridization solution and furthermore was relatively time consuming. The introduction of high-precision and high-speed robotics brought to a further miniaturization of the technology with the production of microarrays (up to 10,000 DNA spots per square centimeter).

Because of the high density of signals in the processed arrays the conversion of the radioactive or fluorescent emissions in a numeric value is performed by sophisticated image analysis software which identifies the position of every spot in the array, determines the spot and the local background intensities, and derives a number representing a spot-specific signal (Fig. 1h). Spot coordinates are then associated to a gene identities within the image analysis program or in a specific gene expression profiling database (Fig. 1i). Differentially expressed genes are identified comparing two or more arrays derived from different biological samples. When a gene is represented by multiple spots in an array or replicated hybridizations are available, statistical tests can be used to assess the significance of the observed differences. Furthermore, data mining techniques are used to identify groups of genes with similar expression profiles across different samples (Fig. 1j).

Array types: There are two main types of arrays: (i) oligonucleotide and (ii) cDNA arrays. In the first type short 20–25mers are synthesized on a silica chip

Microarray Technology. Figure 1 Microarray technology applied to gene expression profiling. The figure summarizes the process from the construction of the microarray to data analysis. (a) This panel describes the first step in manufacturing a microarray for gene expression profiling: the choice of the cDNA clones or the oligonucleotide sequences to represent the genes of interest. Clones or sequences are selected from sequence databases such as Unigene. (b) cDNA clones are PCR amplified and spotted on a slide, whereas oligonucleotides can be synthesized and spotted or synthesized in situ. (c) The result is an array of DNA samples representing several thousands of genes. Thousands of arrays can be manufactured from micrograms of DNA. (d) This panel represents the basic protocol to synthesize a labeled target. In this example, mRNAs derived from experimental and a control samples are differentially labeled, mixed, and (e) hybridized on an array. Typically the hybridization reaction is performed under a coverslip (marked in pink). (f) After hybridization the array is washed and scanned. Two images are produced for each array. (g) An image analysis program identifies the spots and derives a numerical value representing the intensity of the signal subtracted by the local background. The panel represents the output of a typical image analysis software. X and Y are spot coordinates. Int. Cy5 and Int. Cy3 are the signal intensities for each spot in the two channels. (h) Database integration associates a gene identity to each spot and integrates data from different arrays within the experiment. The example refers to a time course. Gene expression intensities for genes A–E are reported for time 1, time 2, and time 3 of a hypothetical experiment using three arrays. Each value is expressed as a ratio between the experimental and the control sample (i) Result of bioinformatics analysis applied to the data is summarized in panel i.

using photolithography (Affymetrix arrays, ►www.affymetrix.com), or using an ink-jet based technology (Rosetta Inpharmatics, ►www.rii.com). Alternatively presynthesized oligonucleotides can be printed onto glass slides. In the second type nucleic acids (usually in a form of PCR products) are robotically printed on glass slides as spots in defined locations. The first glass-based high density cDNA arrays were developed in Pat Brown's laboratory at Stanford University, USA [1]. cDNA arrays are now a very common choice in academic institutions because they offer a great degree of flexibility in the choice of the arrayed elements. Manufacturing them, however, requires a considerable infrastructure. The process needs liquid handling workstations to work with large collection of cDNA clones and to support the production of the purified probes and, of course, it requires robotics for the production of the

proper microarrays. More recently, several companies (Illumina ►<http://www.illumina.com>), PharmaSeq (►<http://www.pharmseq.com>), and SmartBead Technologies (►<http://www.smartbead.com>) have been producing nonplanar DNA microarrays that allow a higher level of miniturization and very high throughput. The illumina BeadArray™ technology is based on fibre optic strands bundled together. A “microwell” is etched into each fibre core, and this can be filled with oligonucleotide-functionalized microspheres, to which probe sequences are attached [2]. This technology offers a number of advantages over earlier arrays. The combination of the smallest individual feature sizes currently available and a high packing density, allows a greater number of probes and so a higher throughput. The small size of the array also allows smaller volumes to be examined, and improves detection.

The first step in designing a microarray is the choice of the cDNA clones or the determination of the oligonucleotide sequence which will represent the genes of interest. In both cases it is essential to use highly specific sequences to minimize cross-hybridization with related genes. An excellent source of gene information to design microarray probes are public domain expressed sequence databases such as Unigene, Genebank, dbEST. The Unigene database ([▶www.ncbi.nlm.nih.gov/UniGene/](http://www.ncbi.nlm.nih.gov/UniGene/)) is a collection of sequence clusters which represents the large majority of transcribed genes in a variety of species. It is also an excellent source of general information because it provides links to functional and genetics data, to scientific literature and indicates the source of the physical cDNA clones (Fig. 1a–c).

Because of the high gene coverage achievable with this technology it is possible to design arrays which cover the entire transcriptional capacity of an organism. For some species genome-wide arrays are already available. These are mainly bacteria and yeast open reading frame (ORF) based arrays. Human arrays covering the majority of the expressed genes are also available but it is still unpractical to design human arrays that cover all the possible splicing variants encoded in the genome. With the amount of effort dedicated to the annotation of the human genome it is expected that more comprehensive arrays will be soon available.

The target: In the last few years more methods to synthesize a labeled target have been introduced. The new methods are still based on a reverse transcription reaction but diverge in the way the fluorescent dye is incorporated in the target. For example, Genechip™ technology developed by Affymetrix uses a reverse transcription step followed by an RNA in vitro transcription reaction to produce a biotinylated target. The detection of the target, after hybridization, is achieved with a streptavidin-bound single fluorescent dye. Targets derived from different biological samples are always hybridized to multiple arrays. In the case of spotted arrays, two or more samples (typically experimental and control sample) can be compared on a single array. This is possible because the targets are labeled by direct incorporation of different fluorescent dyes (e.g., Cy3 and Cy5). After labeling, the targets are mixed and hybridized to the same array, resulting in competitive binding of the target to the sequences on the array (Fig. 1d,e). With both methods, after hybridization and washing, the slides are scanned using one (Affymetrix) or multiple (spotted arrays) wavelengths corresponding to the dyes used (Fig. 1f).

A relatively large amount of RNA needs to be labeled with fluorescent dyes in order to obtain satisfactory results (20–100 µg of total RNA or 1–2 µg of mRNA). These requirements could make microarrays incompatible with the very limited RNA yields obtained from some

type of biopsy or microdissected samples. To bypass these limitations several amplification methods have been developed. PCR-based amplification methods are quite straightforward but they introduce a bias in the gene representation due to the exponential amplification of the original mRNA molecules. Slightly more complex protocols are based on linear in vitro transcription. Although more reliable than PCR-based methods, they also introduce some bias. An alternative strategy to amplification methods has been developed by Genisphere Inc. ([▶www.genisphere.com](http://www.genisphere.com)). The target is synthesized using a reverse transcriptase reaction that introduces a sequence tag at the 3' end of every cDNA. A large agglomerate of oligonucleotides containing several hundreds of fluorescent dyes (dendromere) and containing a tag complementary to the cDNA tag is hybridized to the target to form a labeled cDNA which can be hybridized to the microarray. The large number of fluorophores attached to each cDNA molecule results in a 200-fold signal enhancement.

Amplification based methods can be used with as little as nanograms of total RNA (corresponding to <1000 cells) whereas the dendromer-based methods need at least one microgram of total RNA.

With the decrease in costs associated to synthesis of large collections of oligonucleotides, oligo-based arrays are becoming the technology of choice. Most established model organisms have oligo arrays (e.g., Affymetrix) readily available but this is not the case for less well studied organisms. cDNA arrays are still an important choice for non-model species [2].

Data analysis: The rapid spread of microarray gene expression profiling has created an unprecedented situation in biology. An incredibly large amount of genome-wide gene expression data has been rapidly produced creating the need for appropriate data analysis tools. Many applications have been produced in academic groups and many others are available through commercial providers. Briefly, there are four levels of analysis which have been applied to gene expression profiling. The first uses statistical tests to identify genes differentially expressed between two or more samples. The second utilizes data reduction techniques to simplify the complexity of the dataset by identifying clusters of genes with similar expression profile across different experimental conditions. One of the most common data reduction methods is called Cluster analysis. This method is based on a correlation measure that assigns a high score to genes that have very similar expression profiles. Using this matrix a roadmap displaying the degree of similarity between the genes in the array is built and visualized in a form of a hierarchical tree. The most correlated genes being on very close branches. Even the simple visual inspection of the tree is usually sufficient to identify meaningful associations. The third level involves the use of statistical modeling to link the molecular state of a cell

or tissue with its physiology. A statistical model may be a classifier to identify genes predictive of sample classes (for example tumor vs. normal tissue) or to the expression of an interesting biomarker. An example of the former is the *nearest centroid* classifier. In this method the molecular profile of an unknown sample is compared to the average profile of each class. The sample is then assigned to the class that it is closest to. In statistical modeling it is important to assess the accuracy of the model. A classic approach to this problem is the *holdout* method. In this approach, the correct class labels are known and the data is split into a training and test set. A model is constructed using the training set. The test set provides a group of samples previously unseen by the model, and these can then be used to test if the model correctly predicts their class membership on an independent population. It is desirable to construct such models using a small number of the total genes in the data set, and so a method of gene selection is required. Genes may be tested individually (*univariate gene selection*), or in association (*multivariate selection strategies*). The fourth level of analysis uses reverse engineering algorithms to infer the structure of transcriptional pathways within the cell. This approach has been demonstrated to be very powerful and recently has shown to be robust to extensive experimental verification.

Other Applications

Genotyping of Human Single nucleotide polymorphism (SNPs): The human genome project has produced large amounts of genome sequence and polymorphism data which is extremely useful to investigate the genetic bases of human diseases. Among these, single nucleotide polymorphisms (SNPs) are the most frequent variant in the human genome since they occur once every 1 kb of genomic DNA. Identification of disease genes, however, requires linkage and association analysis of thousands of SNPs in thousands of individuals. This is an impossible task without a high throughput genotyping method. Microarray-based sequencing have been successfully used to genotype SNPs in human populations [3].

Microarray analysis of Chromatin Immunoprecipitation (Chip-on-chip): Protein–DNA interactions are key in the regulation of transcription, DNA replication, DNA repair, DNA recombination, and genome packaging. Discovering the location of these interactions at a genome level is therefore crucial in order to fully understand the mechanisms involved. The ChIP procedure starts by crosslinking growing cells using formaldehyde. Formaldehyde crosslinking causes DNA-bound proteins to be covalently attached to their DNA site. The crosslinked cell extracts are then immunoprecipitated with antibodies against the protein of interest. After this the DNA is purified, the relative amounts of different genomic regions can be amplified, labeled, and hybridized to a microarray. Regions bound in vivo by the

protein of interest will be represented by probes on the microarray that have a relatively high ratio of sample/control binding. In this way it is possible to determine the association of a protein across the whole genome (for a complete overview of this approach see [2]).

Protein arrays: The amount of steady-state RNA in a cell is not always reflecting the biological activity of an expressed gene. It is the protein translated from the RNA pool that exerts the function. It has been proven that mRNA and protein abundance are often not correlated. It follows that information about protein levels and their interactions are essential to understand the biological mechanisms. Microarray technology has been used to increase the throughput of classical protein detection methods and recently to study protein–protein interactions. Protein arrays are more complex than DNA arrays. The major issue is that proteins must bound to the slide while retaining their correct folding. In spite of these difficulties the field is rapidly expanding. Many companies are investing in developing and improving the technology. An excellent example of protein arrays and their applications is described by MacBeath et al. [4]. The authors have deposited 10,000 protein spots on a glass microscope slide and demonstrated that their arrays could detect protein–protein interactions, reveal interactions between enzymes and their substrates, and detect small molecules–protein interactions. Protein microarrays consisting of either printed antibodies or printed protein antigens are used to monitor, respectively, protein levels or antibody levels. With the effort now being concentrated in developing antibodies for the whole of the human proteome, the broad use of protein microarrays is not far in the future.

Pharmacological Relevance

The ability of microarray technology to describe the behavior of thousands of molecular markers is well suited to identify and characterize the effect of a drug in complex biological systems and provide insights into the mechanism of action of the drug, its toxicity, and the molecular basis of drug resistance. Below are some examples of the use of microarray technology in the pharmacology/drug discovery area.

Sensitivity to drugs: It is known that the expression of certain genes can influence the response to drugs. Misexpression or mutations in these genes can sometimes be responsible for treatment failure. This problem is particularly severe in anticancer therapy where resistant cell clones can expand very rapidly and generate secondary tumors which are completely unresponsive to therapy. A general method for the rapid identification of genes influencing drug sensitivity is therefore crucial for the development of future therapies. Uwe Scherf at the National Cancer Institute (NCI) in Bethesda (USA) has used a gene expression profiling based approach to identify genes responsible for influencing the response of

a panel of 60 human cancer cell lines (NCI-60 panel) to a number of anticancer drugs. The data were analyzed using a clustering-based method that relates gene expression in the tumor cell before drug treatment to its capacity to respond to the drug [5]. Interestingly, the authors identified a large number of significant correlations, many of them related to known mechanisms of drug resistance.

Drug mode of action studies (MOA): Conventional molecular and biochemical approaches to MOA studies are usually time consuming and resource demanding. A group of researchers from Rosetta Inpharmatica has recently developed a gene expression profiling based method to identify drug targets that may significantly speed up investigation in this area.

The principle is simple. The expression fingerprint of yeast cells treated with a compound with unknown MOA is compared with a reference set of transcriptional profiles representing 300 *Saccharomyces cerevisiae* gene knock out mutants. The mutant with the closest expression fingerprint to the compound-treated cells will most likely be mutated in a gene related to the drug target. Sequence homology to the identified yeast gene may then reveal the potential drug target in more broadly pharmaceutically relevant species (i.e., mouse, rat, and man). Interestingly the analysis of the expression profiles of yeast cells treated with the anesthetic drug dyclonine identified the human neuro-active sigma factor as a potential target. Although there are potential complications in a broader application of gene expression profiling to the analysis of a drug mode of action directly in mammalian cells several more studies have been reported [5].

Toxicology: Many companies are known to use gene expression profiling to assess the potential toxicity of lead compounds. This approach may require a database of reference compounds with known pharmacological and toxicological properties. Lead compounds can be compared to the database to predict compound-related or mechanism-related toxicity [5].

Pharmacogenomics: This rapidly expanding field examines the genetic basis for individual variations in response to therapeutics. Mutations in certain genes involved in drug metabolism make some populations unresponsive to a certain drug. Microarray technology can be used to genotype patients and predict their response to therapy. In this context pharmacogenetics promises to increase the success of pharmaceutical research by developing individualized medicines tailored to patients' genotypes [5].

Germany

Synonyms

Antibiotic resistance

Definition

A bacterial isolate is called resistant if it grows in a relatively high concentration of a specific antibacterial drug. Thus, it is insensitive. The sensitivity is measured with standardized methods as the ► **minimal inhibitory concentration** (MIC). Guidelines from institutions like the CLSI (Clinical and Laboratory Standards Institute, formerly NCCLS) and DIN (Deutsches Institut für Normung e.V.) define specific breakpoints above which MIC an isolate is regarded as resistant. This breakpoint usually is derived from microbiological and clinical experience and resistance is associated with a high likelihood of therapeutic failure (Fig. 1).

Basic Mechanisms

Bacteria can develop resistance to antimicrobial agents as a result of mutational changes in the ► **chromosome** or via the acquisition of genetic material (resistance genes carried on ► **plasmids** or ► **transposons** or the recombination of foreign DNA into the chromosome) (Fig. 2).

The basic biochemical mechanisms leading to bacterial resistance can be classified into three different categories.

Antibiotic Inactivation

A common means that causes resistance is the inactivation of the antibiotic before it reaches the target site. Antibiotics can be either enzymatically cleaved or modified. In both cases the antibiotic loses its capacity to bind to its target.

Microbial Resistance to Drugs. Figure 1 MIC-distribution showing the number of isolates of one species with a certain MIC. Some bacterial species are naturally resistant (intrinsic resistance) to drugs because their natural MIC is above the breakpoint. Naturally sensitive isolates as well as naturally resistant ones can acquire resistance and with that increase their MIC (acquired or secondary resistance).

Microbial Resistance to Drugs. Figure 2 Bacterial cells can obtain resistance genes in three ways: (i) Bacteria receive a plasmid or a conjugative transposon carrying resistance genes by a mechanism that involves direct cell-to-cell contact between donor and recipient cell (conjugation). (ii) A bacteriophage infects a bacterium carrying a resistance gene and transfers the gene to the recipient cell where it can be incorporated into the genome (transduction). (iii) Free DNA from dead cells in the vicinity of the recipient cell is taken up and integrated into the chromosome (transformation).

Enzymatic Cleavage

β -Lactamases are enzymes that hydrolyze the β -lactam ring of β -lactam antibiotics (penicillins, cephalosporins, monobactams and carbapenems). They are the most common cause of β -lactam resistance. Most enzymes use a serine residue in the active site that attacks the β -lactam-amid carbonyl group. The covalently formed acylester is then hydrolyzed to reactivate the β -lactamase and liberates the inactivated antibiotic. Metallo β -lactamases use Zn(II) bound water for hydrolysis of the β -lactam bond. β -Lactamases constitute a heterogeneous group of enzymes with differences in molecular structures, in substrate preferences and in the genetic localizations of the encoding gene (Table 1).

Another group of antibiotics that can be inactivated by hydrolysis are 14- and 15- membered macrolides [2]. Esterases cleave the lactone ring. The plasmid encoded *ere* genes are found in members of the *Enterobacteriaceae* and increase the intrinsic resistance. Furthermore, these esterases can also be found in some isolates of erythromycin resistant staphylococci.

Resistance to streptogramin type B antibiotics can be mediated in staphylococci and enterococci by plasmids carrying a *vgb* gene [2]. The Vgb enzyme is a lyase that linearizes the cyclic hexadepsipeptide by cleavage of the ester bond via an elimination reaction.

Chemical Modification

Several bacterial enzymes can modify antibiotics to inactive derivatives (Table 2).

Enzymatic modification is the most important mechanism of aminoglycoside resistance in gram-positive and gram-negative bacteria. There are three different types of enzymatic activities. *N*-acetyltransferases (AAC) use acetyl-CoA as a donor to modify amino groups in the aminoglycoside. ATP dependent *O*-adenyltransferases (ANT) and ATP dependent *O*-phosphoryltransferases (APH) modify hydroxyl residues. Numerous enzymes have been described. The nomenclature includes the regiospecificity of the group transfer (e.g. 3''), a roman numbering distinguishes between substrate specificities and an alphabetic prefix differentiates different genes. The localization of the genes can be chromosomal but is usually plasmidic and can often be found on transposable elements [3].

It has been shown that an AAC enzyme variant (AAC (6')-Ib-cr, cr for ciprofloxacin resistance) found in various *Enterobacteriaceae* is capable of *N*-acetylating fluoroquinolones with an unmodified piperazinyl substituent at the amino nitrogen. Although the increase in MIC is low, this plasmid encoded quinolone resistance determinant can augment further development of clinically relevant resistance.

Acetyl-CoA is also utilized as a cofactor to modify chloramphenicol by *O*-acetyltransferases (CATs). These enzymes have been found in many different bacterial genera and are usually plasmid encoded in clinical isolates. Furthermore, streptogramin type A antibiotics are acetylated by Vat enzymes that occur on plasmids in staphylococci and enterococci.

Microbial Resistance to Drugs. Table 1 Classification of β -lactamases [1]

Molecular class	Functional mechanism	Examples of enzymes ^a	Types ^b
Class A	Serine β -lactamases	SHV-1 penicillinase in <i>K. pneumoniae</i> , and Koxy with activity against certain third generation cephalosporins in <i>K. oxytoca</i>	BlaZ staphylococcal penicillinase; TEM, SHV, VEB, PER and CTX-M penicillinases and ESBLs (β -lactamases with activity against third generation cephalosporins and aztreonam) KPC, IMI/NMC and SME carbapenemases
Class B	Metallo β -lactamases	L1 enzyme of <i>S. maltophilia</i> ; enzyme of <i>Aeromonas</i> spp.; CcrA enzyme found in 1–3% of <i>B. fragilis</i> isolates. All enzymes are carbapenemases	IMP, VIM and SPM type carbapenemases
Class C	Serine β -lactamases	AmpC enzymes of <i>E. coli</i> , <i>Shigella</i> spp., <i>Enterobacter</i> spp., <i>C. freundii</i> , <i>M. morgani</i> , <i>Providencia</i> spp. and <i>Serratia</i> spp. cephalosporinases with wide spectrum of activity	CMY, LAT, BIL, MOX, ACC, FOX and DHA types. All genes are <i>ampC</i> genes that have been mobilized by transfer to plasmid DNA.
Class D	Serine β -lactamases	OXA enzymes (oxacillinases) of <i>Acinetobacter</i> spp. and some <i>Aeromonas</i> spp. Some OXA enzymes are carbapenemases	Most OXA types are chromosomal

^aEnzymes that are normally chromosomal and ubiquitous. Some are produced at low levels; mutations can lead to high-level production.

^bTypes that are plasmid- or transposon-mediated, generally produced at high levels.

Microbial Resistance to Drugs. Table 2 Antibiotic modifying enzymes [2, 3]

Enzymes	Substrates	Host	Gene localization
Acetyltransferases			
AAC	Aminoglycosides, fluoroquinolones	Gram-negative and gram-positive bacteria	Plasmid, transposon, chromosome
Vat	Streptogramin A	Staphylococci, enterococci	Plasmid
CAT	Chloramphenicol	Gram-negative and gram-positive bacteria	Plasmid, chromosome, transposon
Adenyltransferases			
ANT	Aminoglycosides	Gram-negative and gram-positive bacteria	Plasmid, transposon
Lnu	Lincomycin	Staphylococci, <i>E. faecium</i>	Plasmid
Arr	Rifampicin	Gram-negative bacteria	Plasmid
Phosphotransferases			
APH	Aminoglycosides	Gram-negative and gram-positive bacteria	Plasmid, transposon
Mph	Macrolides	<i>E. coli</i> , <i>S. aureus</i>	Plasmid
Glutathionetransferase			
Fos	Fosfomycin	Gram-negative and gram-positive bacteria	Plasmid

Nucleotidylation – the addition of adenylate-residues by Lnu enzymes – can also be the cause of resistance to lincosamide antibiotics in staphylococci and enterococci. A plasmid encoded ADP-ribosylating transferase (Arr-2) that leads to rifampicin resistance has been detected in various *Enterobacteriaceae* as well as in *Pseudomonas aeruginosa*.

O-phosphotransferases that modify macrolides are produced by highly macrolide resistant *E. coli* isolates. However, these enzymes have no clinical importance for macrolide resistance in gram-positive bacteria, and gram-negative ones are regarded as naturally resistant [2].

A minor percentage of fosfomycin resistance in gram-positive and gram-negative species is due to plasmids carrying a *fos* gene. The Fos protein, a glutathione-S-transferase, catalyzes the opening of fosfomycin followed by the addition of the tripeptide glutathione to the antibiotic.

Prevention of Access to the Target

The second general mechanism to cause resistance to antibacterial agents is to prevent the drug from reaching its target site. This is either achieved by altered rates of entry (reduced uptake) or by the active removal of the drug (active efflux) [4].

Reduced Uptake

The outer membrane of gram-negative bacteria is a permeability barrier that allows the passive diffusion of small hydrophilic antibiotics only through aqueous channels, the porins. Drugs larger than 800 Da are

excluded. Mutational changes that lead to a reduction in the number of porins or the size of their diameter slow down the penetration process. In combination with a second contributor, e.g. a β -lactamase, porin changes can have a pronounced effect on the MIC. Accordingly, carbapenem resistance has been described in clinical *Enterobacter* and *Citrobacter* isolates due to the loss of a major porin protein combined with a high-level production of an AmpC β -lactamase that is normally not able to confer resistance to carbapenems.

Furthermore, if the antibiotic passes membranes through a specific port of entry, its mutational loss leads to resistance. The lack of the outer membrane protein OprD in *P. aeruginosa* causes resistance to the β -lactam antibiotic imipenem. Fosfomycin passes the cytoplasmic membrane via an L- α -glycerol phosphate permease. This transport system is not essential for bacterial growth and therefore mutants with a reduced expression are frequently selected under therapy.

Active Efflux

Bacterial resistance can be caused by actively pumping antibiotics out of the cell and therefore decreasing the concentration at the target site. Drug efflux systems in bacteria are classified into four major groups based on their sequence homologies and functional similarities (Table 3).

ATP-binding cassette (ABC) transporters are efflux pumps that derive the energy needed for drug extrusion from the hydrolysis of ATP. Bacterial ABC antibiotic efflux transporter encoded on plasmids is a significant

Microbial Resistance to Drugs. Table 3 Examples of frequent bacterial efflux systems [4]

System	Substrates	Species	Gene location
ABC			
MsrA	14-, 15-Membered macrolides, streptogramin type B	Staphylococci	Plasmid
Vga, Vga(B)	Streptogramin type A	<i>S. aureus</i>	Plasmid
SMR			
Smr (QacC)	Quarternary ammonium compounds	<i>S. aureus</i>	Plasmid
MFS			
NorA	Fluoroquinolones	<i>S. aureus</i>	Chromosome
TetK	Tetracycline	<i>S. aureus</i>	Plasmid
QacA	Quarternary ammonium compounds	<i>S. aureus</i>	Plasmid
TetA	Tetracycline	<i>E. coli</i>	Plasmid
MefA	14-, 15-Membered macrolides	<i>S. pyogenes</i>	Chromosome
MefE	14-, 15-Membered macrolides	<i>S. pneumoniae</i>	Chromosome
RND			
AcrAB-TolC	Tetracycline, fluoroquinolones, chloramphenicol, β -lactams except imipenem, novobiocin, erythromycin, fusidic acid, rifampicin	<i>E. coli</i>	Chromosome
MexAB-OprM	Tetracycline, fluoroquinolones, chloramphenicol, β -lactams except imipenem, novobiocin, erythromycin, fusidic acid, rifampicin, trimethoprim, sulfamethoxazol	<i>P. aeruginosa</i>	Chromosome

contributor to the acquired resistance of staphylococci to macrolide and streptogramin antibiotics. The energy for the efflux mediated by the other three groups of bacterial transporters is provided by the proton-motive-force. Transporters of the SMR family (*Staphylococcus* multi-drug resistance) are plasmid encoded small cytoplasmic membrane proteins. The Smr transporter of *Staphylococcus aureus* pumps out quarternary ammonium compounds (e.g. benzalkonium chloride) and therefore confers resistance to these disinfectants. Within the MFS (major facilitator superfamily) group there are several pumps acting on different classes of antibiotics (Table 3). The respective genes are found on conjugative and non-▶conjugative plasmids or within the chromosome. They can be part of ▶conjugative transposons as seen with the *mef* genes. Transporters of the RND (resistance/nodulation/division) family are chromosomally encoded. These systems are typically tripartite. A pump protein is located in the cytoplasmic membrane and an “outer membrane protein” forms a transperiplasmic tunnel and a channel through the outer membrane. The contact between them is established by a “membrane fusion protein”. The efflux pumps of *P. aeruginosa* contribute significantly to the natural resistance of this species to a wide range of antibiotics. Furthermore, they can confer high levels of resistance when overexpressed as a result of mutations within regulatory genes.

Altered Target

A third general mechanism of bacterial resistance is to obtain an unsusceptible target. The affinity of the antibiotic to the target is diminished without impairing the physiological function of the target considerably. This can be either achieved by altering the usual target or by the acquisition of a new unsusceptible target [5].

Alteration of the Usual Target

One general mechanism is to exchange residues within the target molecule.

Resistance to fluoroquinolones is frequently mediated by amino acid changes within specific domains of the target proteins gyrase and topoisomerase IV. Mutations occur at hotspots in a quinolone resistance-determining region (QRDR) of the genes *gyrA* (coding for subunit A of gyrase) and *parC/grlA* coding for subunit A of topoisomerase IV.

One amino acid substitution within a specific region in the β -subunit of the RNA-polymerase, the target molecule of rifampicin, is necessary to establish high-level resistance to this antibiotic.

Macrolide, lincosamide and streptogramin B resistance (MLS_B phenotype) can be linked to specific nucleotide changes within the 23S rRNA of the large ribosomal subunit, mainly at position A2058 or neighbouring bases (*E. coli* numbering). This is the

major mechanism of macrolide resistance in *Helicobacter pylori*, a species that does not possess multiple but only two *rrn* operons.

The acquisition of a *vanA* gene cluster carried on a transposon is the major mechanism to confer glycopeptide resistance in enterococci (vancomycin resistant enterococci, VRE). Recently, few isolated cases of *vanA* gene clusters in clinical *S. aureus* isolates (VRSA) have also been reported. A coordinated expression of several *van* genes leads to the synthesis of modified peptidoglycan precursors: The D-alanyl-D-alanine moiety, the target of glycopeptides, is replaced by D-alanyl-D-lactate, which has a decreased affinity for vancomycin and teicoplanin.

A similar complex mechanism is responsible for the penicillin resistance of pathogenic *Neisseria* and *Streptococcus pneumoniae*. These bacteria are naturally competent, meaning they are able to take up free DNA. They alter the targets for penicillin, the penicillin binding proteins (PBPs), by recombining parts of their PBP genes with homologous DNA from related species. The resulting mosaic genes then encode PBPs with low affinity to penicillin.

A second mechanism that can be grouped into the category of alteration of the usual target is the overproduction of the target.

The enterococcal penicillin-binding-protein PBP5 binds penicillin with low affinity. The overproduction of this PBP is able to compensate the loss of the others which are inhibited by the drug.

Overproduction of the chromosomal genes for the dihydrofolate reductase (DHFR) and the dihydropteroate synthase (DHPS) leads to a decreased susceptibility to trimethoprim and sulfamethoxazol, respectively. This is thought to be the effect of titrating out the antibiotics. However, clinically significant resistance is always associated with amino acid changes within the target enzymes leading to a decreased affinity of the antibiotics.

A third common means to alter the target is its modification. A widespread mechanism, with high clinical relevance in staphylococci and streptococci, leading to a MLS_B phenotype encoded by *erm* genes, is mainly found on conjugative and non-conjugative transposons. The Erm enzymes add one or two methyl groups to the adenine residue A2058 of the 23S ribosomal RNA. This phenotype is either constitutive or inducible by macrolide antibiotics via a translational attenuation mechanism.

Resistance to tetracyclines is often caused by the acquisition of genes (e.g. *tetO* and *tetM*) coding for so-called ribosome protection proteins. These proteins bind to the ribosome and protect them from tetracycline action.

The enzymes gyrase and topoisomerase IV can be protected from fluoroquinolone inhibition by a small protein belonging to the pentapeptide-repeat family of

proteins, termed QNR. The *qnr* gene is plasmid encoded and its acquisition leads to a reduced susceptibility to fluoroquinolones (Hooper). Although *qnr* alone does not lead to clinical resistance, it can facilitate the selection of higher-level resistance.

Acquisition of New Unsusceptible Targets

Methicillin resistant *S. aureus* (MRSA) isolates produce an acquired new PBP with low affinity to almost all β -lactam antibiotics. It allows functional cell wall synthesis even if the normally occurring PBPs are inhibited. This PBP2a (or PBP2') is encoded by the *mecA* gene that is part of a region of foreign DNA (*mec* region) that has been integrated into the staphylococcal chromosome. MRSA is a major problem as these isolates also tend to display a multi-resistance phenotype to other classes of antibiotics.

Resistance to trimethoprim can be due to the acquisition of plasmid encoded non-allelic variants of the chromosomal DHFR enzyme that are antibiotic unsusceptible. The genes may be part of transposons that then insert into the chromosome. For instance, in gram-negative bacteria the most widespread gene is *dhfrI* on transposon Tn7.

Accessory DHPS enzymes confer resistance to sulfonamides. Two different types encoded by the genes *sullI* (located on transposons) and *sullII* (located on plasmids) have been described. These resistance determinants are often genetically linked to trimethoprim resistance genes. Therefore, the combination of sulfonamide antibiotics with trimethoprim does not prevent resistance selection.

Drug resistance in the defined sense, however, is not always the reason for treatment failures. The formation of biofilms may be as well regarded as a resistance mechanism. Cells within such a film withstand the antibiotic treatment. Some antibiotics (e.g. the aminoglycoside tobramycin) penetrate only slowly into the film. A further explanation is the existence of cells living in a non-growing, protected phenotypic state.

Furthermore, the inability of the drug to reach the focus of the infection or to reach bacteria with intracellular location may be a common reason for the failure of antibiotic treatment.

Pharmacological Relevance

The presence of a specific resistance mechanism in a bacterial isolate does not necessarily implicate that this isolate is resistant in clinical terms. However, an isolate expressing a resistance mechanism possibly will be eliminated less easily as compared to a susceptible one. In clinical practice, resistance mechanisms will be rarely identified. Usually the sensitivity of isolates will be determined and reported to the clinician by using the interpretive criteria which is sensitive, intermediate or resistant. Some bacteria harbouring resistance

mechanisms may show up as sensitive in the standard test, however, therapy will probably fail.

Microfilaments

- ▶ Cytoskeleton

Microtubule

A microtubule is a hollow tube of 25 nm diameter formed by 13 protofilaments. Each protofilament consists of polymerized α - and β -tubulin heterodimers. Microtubules are polarized and have a plus and a minus end.

- ▶ Cytoskeleton

Microtubule Associated Proteins

Microtubule associated proteins (MAPs) are attached to microtubules in vivo and play a role in their nucleation, growth, shrinkage, stabilization and motion.

- ▶ Cytoskeleton

Mineralocorticoids

The main endogenous mineralocorticoid is aldosterone, which is mainly produced by the outer layer of the adrenal medulla, the zona glomerulosa. Aldosterone, like other steroids, binds to a specific intracellular (nuclear) receptor, the mineralocorticoid receptor (MR). Its main action is to increase sodium reabsorption by an action on the distal tubules in the kidney, which is accompanied by an increased excretion of potassium and hydrogen ions.

Minimal Inhibitory Concentration

The minimal inhibitory concentration (MIC) is the concentration which is able to prevent 10^5 cells/mL from growing up to a visible density ($\sim 10^8$ cells/mL) under standardized conditions.

- ▶ Microbial Resistance to Drugs

MinK

This minimal K^+ channel (MinK) encoded by *KCNE1* consists of 130 amino acid residues and has a single transmembrane segment. A slowly activating K^+ current-induced MinK cRNA is expressed in *Xenopus* oocytes. Coexpression of KvLQT1 with MinK induced a current that has characteristics similar to cardiac slowly activating delayed-rectifier K^+ current, IK_S , in contrast to IK_R that has relative fast activation and is composed of hERG/MiRP1.

- ▶ K^+ Channels

MirP Subunits

MirP subunits are relatives of MinK subunits. The abbreviation means MinK related Protein. So far, four MirP subunits are known. The corresponding human genes are KCNE2 to KCNE5. MirP1 (KCNE2) may associate with HERG channels. Mutations in MirP1 have been associated with certain forms of the long QT syndrome.

- ▶ K^+ Channels

Mitochondrial Permeability Transition Pore

Mitochondrial permeability transition involves the opening of a larger channel in the inner mitochondrial membrane leading to free radical generation, release of calcium into the cytosol and caspase activation. These alterations in mitochondrial permeability lead eventually to disruption of the respiratory chain and depletion of ATP. This in turn leads to release of soluble intramitochondrial membrane proteins such as cytochrome C and apoptosis-inducing factor, which results in apoptosis.

- ▶ Apoptosis

Mitogen

Substances that cause cells, particularly lymphocytes, to undergo cell division. Mitogens are also referred to as polyclonal activators, since they stimulate proliferation of lymphocytes irrespective of their clonal origin. The best known mitogens are phytohemagglutinines isolated from certain plants.

Molecular Dynamics

► Molecular Modeling

Molecular Dynamics Simulation

The principle of the molecular dynamics simulation approach is the movement of atoms under the action of a force field.

This approach starts with an initial low-energy structure and the integrated Newton's equation of motion is solved for all atoms simultaneously. Often the protein is placed in a box, which is filled up with solute molecules, e.g., water. To avoid effects at the edges a trick is used, the so-called periodic boundary condition. At the beginning, a starting velocity is assigned to every atom. The velocities are selected to couple the system on a certain temperature bath e.g., 310 K. For every atom, the force which is acting on this particle by the surrounding atoms is calculated. With a given step, usually 1 femtosecond, the next position is calculated over time to obtain classical atomic trajectories, which define conformational motions.

Biocomputing; Molecular simulation; Molecular dynamics; Structural bioinformatics

Definition

Molecular modeling itself can be simply described as the computer-assisted calculation, modulation, and visualization of realistic 3D-molecular structures and their physical–chemical properties using ► [force fields/molecular mechanics](#).

Moreover, molecular modeling is one key method of a wide range of computer-assisted methods to analyze and predict relationships between protein sequence, 3D-molecular structure, and biological function (sequence–structure–function relationships). In molecular pharmacology these methods focus predominantly on analysis of interactions between different proteins, and between ligands (hormones, drugs) and proteins as well gaining information at the amino acid and even to atomic level.

Description

The constantly increasing amount of data coming from high throughput experimental methods, from genome sequences, from functional- and ► [structural genomics](#) has given a rise to a need for computer-assisted methods to elucidate sequence–structure–function relationships.

Sequence Similarity

Protein sequences encoded by genome sequences encode biological functions.

There are two different dimensions, breadth and depth, used to reveal sequence–structure–functional relationships by computational methods [1].

The aim of the first dimension breadth is to reveal sequence–function relationships by comparing protein sequences by sequence similarity. Simple bioinformatic algorithms can be used to compare a pair of related proteins or for sequence similarity searches e.g., BLAST (Basic Local Alignment Search Tool). Improved algorithms allow multiple alignments of larger number of proteins and extraction of consensus sequence pattern and sequence profiles or structural templates, which can be related to some functions, see e.g., under ► <http://www.expasy.ch/tools/#similarity>.

The aim of the second dimension depth is to consider protein 3D-structures to uncover structure–function relationships. Starting from the protein sequences, the steps in the depth dimension are structure prediction, homology modeling of protein structures, and the simulation of protein–protein interactions and ligand-complexes.

Protein Structure Predictions

Starting from the protein sequence (primary structure) several algorithms can be used to analyze the primary structure and to predict secondary structural elements like beta-strands, turns, and helices. The first algorithms from Chou and Fasman occurred already in 1978. The latest algorithms find e.g., that predictions of transmembrane

and coiled regions from the primary sequence are possible ([▶http://dodo.cpmc.columbia.edu](http://dodo.cpmc.columbia.edu)).

Approaches of de novo predictions, which try to calculate how the structural elements are folded into the 3D-structure (tertiary structure) of complete proteins are nowadays far away from reliable large-scale applications. On the other, hand this topic is under strong development indicated by recent successful results at the contest for structural prediction methods CASP4. With the fast growing number of experimentally solved 3D-structures of protein and new promising approaches like threading tools combined with experimental structural constraints, one can expect more reliable de novo predictions for 3D-protein structures in the future.

Homology Models of Protein Structures

The primary sequence of proteins, with identical function varies within different species by natural mutations of amino acids. With increasing distance in the evolutionary process the number of variations between the sequences of proteins increase.

In the protein structure database PDB ([▶http://www.rcsb.org/pdb](http://www.rcsb.org/pdb)), by X-ray crystallography and NMR spectroscopy, experimentally solved 3D-protein structures are available to the public. Homology model building for a query sequence uses protein portions of known 3D-structures as structural templates for proteins with high sequence similarity.

If the sequence of a protein has more than 90% identity to a protein with known experimental 3D-structure, then it is an optimal case to build a homologous structural model based on that structural template. The margins of error for the model and for the experimental method are in similar ranges. The different amino acids have to be mutated virtually. The conformations of the new side chains can be derived either from residues of structurally characterized amino acids in a similar spatial environment or from side chain rotamer libraries for each amino acid type which are stored for different structural environments like beta-strands or alpha-helices.

The discrepancies between homologous protein sequences occur predominantly at the surfaces and in the so-called loop regions. With decreasing sequence identities, insertions and deletions of loop chains or modeling of completely different loop chains are necessary. Segmentation of the loop in overlapping sequence fragments (3–10 residues) and searching for sequence similarity using BLAST or FASTA in the PDB database was proven to be most successful in loop modeling. Those fragments occurring several times in different protein structures with a common backbone conformation, have a high probability of adopting the same backbone conformation also in the query sequence. The overlap almost allows knowledge-based assembly of the fragments to a new loop conformation.

This segmentation strategy is also part of the successful algorithm, Rosetta ([▶http://depts.washington.edu/bakerpg/](http://depts.washington.edu/bakerpg/)) for predicting complete folds for new proteins.

Similar residues in the cores of protein structures especially hydrophobic residues at the same positions, are responsible for common folds of homologous proteins. Certain sequence profiles of conserved residue successions have been identified which give rise to a common fold of protein domains. They are organized in the smart database (simple modular architecture research tool) [▶http://smart.embl-heidelberg.de](http://smart.embl-heidelberg.de).

Natural mutation of amino acids in the core of a protein can stabilize the same fold with different complementary amino acid types, but they can also cause a different fold of that particular portion. If the sequence identity is lower than 30% it is much more difficult to identify a homologous structure. Other strategies like secondary structure predictions combined with knowledge-based rules about reciprocal exchange of residues are necessary. If there is a reliable assumption for common fold then it is possible to identify intra- and intermolecular interacting residues by search for correlated complementary mutations of residues by correlated mutation analysis, CMA (see e.g., [▶http://www.fmp-berlin.de/SSFA](http://www.fmp-berlin.de/SSFA)).

Predicting a likely conformation or fold of a particular region of a protein with less or no sequence similarity to protein structures recorded in the PDB, is the main challenges for homology modeling of proteins.

Sequence conservation is, in general, much weaker than structural conservation. There are proteins, which are clearly not related in sequence but are closely related in 3D-structure and fold, like hemoglobin and myoglobin, which have similar functions. In many proteins, fold elements like 4-helical bundles are repeated. Classifications of known structural folds of proteins are organized in the SCOP or CATH database see e.g., [▶http://scop.mrc-lmb.cam.ac.uk/scop/](http://scop.mrc-lmb.cam.ac.uk/scop/).

Taken together, the procedure to build a starting protein structural model for a protein combines similarity searches by sequences and by folds in different 3D-structure databases. Remaining unknown conformations are completed by information resulting from bioinformatic, knowledge-based approaches and overlapping segmentation of sequence fragments.

After the construction phase of a model follows the optimization of the geometrical structure by force fields.

Molecular Simulation

Simulation in general describes calculations with models, where different options and combinations of variables can be quickly played through. Molecular simulations allow the characterization of molecular properties during the motions of the molecular models, over time.

Force field or molecular mechanics calculations of molecular models are energy minimizations. Starting with an energy for an unfavorable molecular geometry the algorithm searches for the next local energy minimum at the energy hypersurface. Starting with different unfavorable geometries can lead to different conformations at other local energy minima. For larger molecular structures and especially for structural models build on templates with lower sequence identity, it is necessary to evaluate the geometrical stability.

Importantly, all biological procedures are operating at a temperature of 310 Kelvin, not at 0 Kelvin as the potential energy is calculated by the force fields. The kinetic energy must also be considered. Molecules and proteins at room temperature change the conformation at least at the surface and in loop region. ► **Molecular dynamics simulation** (MD) is an approach to tackle these kinetic and stability problems.

An approach to overcome the multi minima problem of proteins is ► **simulated annealing** (SA) run. Besides global molecular properties such as structural and thermal motions, functional properties of fast biological reactions can also be studied by MD.

Accuracy and Limitations

Molecular models are only an approximation to reality, but good models can often closely approach reality.

The margin of error of a final structural model depends on the sequence or fold similarity to the starting structural template.

An important measure for quality is the verification by MD or SA of the stability of a molecular model. Other programs (e.g., PROCHECK) can also be used to check the globular geometrical quality of a structure to avoid serious defects in the geometry of proteins.

Even the most elaborate models are worthless if there is no experimental examination at all.

Functional insights based on structural relationships can only rise to the level of hypotheses, and these hypotheses must be tested by direct functional experiments.

The strongest verification for a 3D-protein model comes from the experimental 3D-structure. This is the objective of the Critical Assessment of Techniques for Protein Structure Prediction, CASP (► <http://predictioncenter.org>), where the structural models are made in advance of the experimental structure of a particular protein.

In molecular pharmacology research an indirect proof of a structural model is possible by functional examinations, e.g., by molecular biological experiments. Well-selected site directed mutagenesis and their functional characterization allows confirmation or rejection of a molecular protein model. The process is organized as an iterative procedure, where the biological answer of suggested mutations is used to refine the model. The iteration continues until the model

is consistent with the biological experiments and the functional predictions of mutations are confirmed.

Pharmacological Relevance

In general the relevance of predictions of structure–function relationships based on molecular modeling and structural bioinformatics are threefold. First they can be used to answer the question of which partners (proteins) could interact. Second, predictions generate new hypotheses about binding site, about molecular mechanisms of activation and interaction between two partners, and can lead to new ideas for pharmacological intervention. The third aim is to use the predictions for structure-based drug design.

Common to all three aims is that silico-derived predictions can rationalize experimental efforts either by well-directed very specific molecular biological experiments like site directed mutations or e.g., by reducing the number of compounds to screen experimentally for drug design.

Structure–Function Prediction

From the human genome project it is known, that roughly 30,000 proteins exist in humans. Currently only the 3D-structures of few thousand human proteins or protein domains are known. Structures of membrane-bound proteins are several magnitudes rarer. Beside efforts to solve further structures like structural genomics, there is a challenge for computational approaches to predict structures and function for homologous proteins.

This is eminently necessary for large protein classes with important functions, e.g., the ► **G-protein coupled receptors** (GPCR) where several hundred different human GPCR are known. Out of this large family of seven transmembrane-helix proteins, there is only one structure known jet-rhodopsin. The rhodopsin structure is used as a template for homologous receptor models. Incorporation of further experimental results like scanning accessible cysteines, cross linking, spin labeling, ligand binding, and site directed mutations etc., allowed molecular modeling to predict successfully ligand binding sites and local activation mechanisms of diverse GPCR. In general the inactive conformation of GPCR is constrained by interaction of complementary residues in the interior side of the receptors which can be observed in the rhodopsin structure. Activation mechanisms of homologous GPCRs can be revealed by molecular simulations and characterized by molecular experiments as in the following example.

For the thyroid stimulating hormone receptor (TSHR) the homolog of glycoprotein hormone receptors and member of family A of GPCRs, a spatial and functional relationship between extracellular loop 2 (ECL2) and transmembrane helix 6 (TMH6) was suggested by homology modeling. In detail, side chain

interaction between Ile-568 and Ile-640, respectively was predicted to constrain the receptor in a conformation with low basal activity (Fig. 1). Subsequently, it was hypothesized that mutations on either side of the potential counterparts should disrupt, but complementary double mutation should rescue the dynamic interface between ECL2 and TMH6. Indeed, the single mutant Ile640Leu exhibits basal activity lower than wild type, its differently branched and bulkier side chain complements the reduced side chain bulk in Ile568Val, restoring wild type basal activity to the double mutant. This scenario is confirmed by the reciprocal double mutant Ile640Val/Ile568Leu [2]. Disruption of this critical interface between TMH6

and ECL2 by introduction of mutations in TSHR can either increase or decrease basal activity and indicates its pivotal role in intramolecular signal transduction and supports the established common mechanism of an activation-associated seesaw movement of TMH6 for family A of GPCRs (Fig. 2).

Structural similarity can sometimes be a very strong indicator of similar function, but does not mean, having similar function necessarily. More important structural similarity can show evolutionary links between proteins whose ancestors may have had similar functions.

Several different types of protein domains are known to function in binding to phosphotyrosine, including

Molecular Modeling. Figure 1 Molecular model image of the environment of ECL2 in the wild type TSHR. The homology model is based on the X-ray structure of inactive bovine rhodopsin (1F88, 1HZX, 1L9H). Considering for TSHR the ECL2 partial sequence similarity, the complementary of the environmental residues and the conserved disulfide bridge of ECL2-TMH3, a similar embedding of ECL2 into the TM bundle is feasible like in rhodopsin. Since the ECL2 sequence of TSHR is four residues shorter than the rhodopsin sequence the tip of ECL2 is slightly shortened and therefore enable an interaction between I568 (green bold) of ECL2 (red) and I640 (green bold) of TMH6 (violet), which was confirmed by mutation data. Color code of amino acids: green, hydrophobic; cyan, aromatic; yellow, cysteines; orange, hydrophilic serine and threonine; red, negatively charged; blue, positively charged.

Molecular Modeling. Figure 2 Schematic molecular mechanism for TSHR: ECL2 regulates the TMH6 adjustment and influences different activity states, which is concluded from modeling driven mutations. The generated mutants are reflecting an interface where TMH6 is gliding along ECL2 in a raster of three different receptor states. (a) in the activated state, the rather constrained basal state is released either by constitutive active mutants (CAM, E640V) with reduced side chain length/bulk or by a hormone-induced ECL2 shift (grey arrow). This is consistent to the established activation-associated see-saw movement of TMH6 (black arrows), enabling enhanced G-protein interaction for GPCRs of family A. (b) the hydrophobic side chain interaction of Ile-640 (TMH6) and Ile-568 (ECL2) is constraining the basal (partially active) conformation of wild type TSHR. (c) the decreased basal activity is provoked by a differently branched and bulkier side chain (I640L) at TMH6 by further interlocking with Ile-568, which likely causes a slight movement of TMH6 in the opposite direction to the activation conformation and diminishes G-protein interaction. For clarity only TMH6 and ECL2 of the heptahelical receptor are visualized.

►src homology-2 (SH2) domain and ►PTB domain. For example, the crystal structure of the amino-terminal domain from the human signaling protein Cbl revealed the presence of a cryptic SH2 domain followed by a C3HC4 ring finger domain. The sequence of this SH2 domain was so divergent that its existence had not been previously suspected. The conservation of unique and important structural elements in the X-ray structure, however, identified it clearly as a member of the SH2 family. A recently isolated E-cadherin binding protein called Hakai contained according to sequence similarity a C3H4 ring finger domain and a small portion of an incomplete SH2 domain. These are similar domains as in Cbl but with inverse order and the sequences around the incomplete SH2 domain were even more divergent from canonical SH2 domain and also from that of Cbl. Combination of sequence and fold similarity with structural alignments and functional investigation showed that Hakai is a Cbl-like protein where the SH2 domain and ring finger domain are in the same spatial arrangement. A two stranded beta-sheet identified in

the fibronectin structure by sequence similarity to Hakai replaced exactly the missing part in the incomplete SH2 fold. Although divergent to SH2 sequences the particular portion resembles exactly the corresponding SH2 fold. Moreover, an additional incomplete C2H2 Zn finger domain between ring finger and SH2 domain could be assigned to a complete Zn finger by its structural merging with the first helix of the SH2 domain, carrying the two missing histidines (Fig. 3). Mutations and functional characterization of the two histidines participating in Zn finger formation as well as the suspected arginine and serine for phosphotyrosine binding of SH2, confirmed the structural model of Hakai [3].

Simulation of Functional Properties

With growing computer power, the abilities to simulate functional properties and dynamics of fast biological reactions are increasing. Today molecular dynamics can be traced over a time range of about 1 ms. Relevant dynamics of fast biological processes (vision and

Molecular Modeling. Figure 3 Molecular model of Hakai based on structural bioinformatics, molecular modeling and biochemical experiments. Comparison of the structural model of Hakai, incomplete SH2 domain (magenta) with the SH2 domain X-ray structure of Cbl (white). The missing beta-strand fold $\beta 2$, $\beta 3$ at the incomplete SH2 sequence is exactly replaced by a beta-sheet fold found in Fibronectin (yellow) with similar sequence to Hakai in that portion. The SH2 like fold of Hakai is assembled by sequence- and fold similarity. An incomplete C2H2 Zn finger domain (blue) is completed by merging with helix $\alpha 1$ of the SH2 domain. Side chains H 185, H188 of the merged Zn finger domain and R199 and S201 of the P-Tyrosine binding site showed on mutations strong sensitive functional influences and confirm indirectly the proposed model at that region. Red, the preceding ring finger domain; green, putative phosphotyrosine peptide of E-cadherine.

photosynthesis) like electron transfer reactions, proton translocation (bacteriorhodopsin) and ion transport (potassium channels) in proteins have been studied. MD simulations can provide a realistic description of the actual reactive event.

Recently the dynamics and mechanisms of water permeation through biological membranes via pore proteins were studied using Aquaporin 1 (AQP1) and the homologous glycerol facilitator (GlpF). The selective pattern for transport of water at AQP1 and glycerol at GlpF could be identified. Also a fine-tuned water dipole rotation during the passage through the pores could be simulated by MD [4].

Critical examinations of dynamic effects showed that they are rather unlikely contribute to processes with significant activation barriers. Even in cases of ion channels it is found that the most important effects are associated with energies rather than dynamics [5].

The resulting insight of MD is crucial in studies of fast photo biological reactions and instructive in cases of slower processes. Very slow processes like folding of proteins cannot be traced by MD, because folding takes a time range between 20 ms and 1 h.

Definition

Ubiquitous mitochondrial monoamine oxidase [monoamine oxygen oxidoreductase (deaminating) (flavin-containing); EC 1.4.3.4; MAO] exists in two forms, namely type A and type B [► **monoamine oxidase (MAO) A and B**]. They are responsible for oxidative deamination of primary, secondary, and tertiary amines, including ► **neurotransmitters**, ► **adrenaline**, ► **noradrenaline**, ► **dopamine (DA)**, and ► **serotonin** and ► **vasoactive amines**, such as tyramine and phenylethylamine. Their nonselective and selective inhibitors (► **selective MAO-A and -B inhibitors**) are employed for the treatment of ► **depressive illness** and ► **Parkinson's disease (PD)**.

Reaction Mechanism of MAO

The role of MAO in terminating the action of the aminergic neurotransmitters and dietary amines has

been extensively studied and less attention has been paid to the functions of the products formed in the MAO reactions that include aldehyde and acidic metabolites.

Each of the products of this reaction may have important metabolic and signaling functions [1], but they are also potentially toxic at higher concentrations. The hydrogen peroxide resulting from MAO-catalyzed substrate oxidation has been shown to mimic the action of insulin, in adipocytes and cardiomyocytes and some other cell types, by increasing the number of glucose transporters at the cell surface, but the physiological significance of this is unknown [1]. It has been suggested that the aldehydes derived from serotonin and noradrenaline deamination may be involved in the regulation of sleep. On the other hand, aldehyde derived from dopamine, which never accumulates in normal brain, is thought to be highly toxic to dopamine neurons of substantia nigra in ► **Parkinson's disease**, where aldehyde dehydrogenase is almost absent in parkinsonian substantia nigra pars compacta and its ► **6-hydroxydopamine** model. Such aldehydes may also form adducts with amine groups, to yield compounds such as *N*-methyl-R-salsolinol and tetrahydropapaveroline and peptide adducts, which may have pathophysiological roles.

Basic Characteristics

MAO is an outer mitochondrial membrane enzyme, which possess mole/mole of enzyme, covalently bound ► **FAD (flavin adenine dinucleotide)** as cofactor. Although it had been shown that MAO was not a single enzyme, its differentiation into two forms was first identified by enzyme inhibitory sensitivity in the presence of different substrates. The irreversible propargylamine inhibitor, clorgyline, inhibits serotonin and noradrenaline metabolism at low concentrations in a sigmoidal fashion, although it is a poor inhibitor of benzylamine and phenylethylamine oxidation. However, with dopamine and tyramine a double sigmoidal inhibition is observed. This has been interpreted as representing two enzymes termed A and B, where

Monoamine Oxidases and their Inhibitors. Table 1 Substrate specificity of the two forms of rat liver and brain monoamine oxidase

Substrates of the A-form	Substrates of both forms	Substrates of the B form

clorgyline is an inhibitor of MAO type A and its substrates are serotonin and noradrenaline (Tables 1 and 2). By contrast the irreversible propargylamine inhibitor selegiline (*L*-deprenyl) is a potent inhibitor of Type B, which metabolizes benzylamine and phenylethylamine (Tables 1 and 2). MAO-A and -B have been cloned and shown to be different proteins with 70% homology of B form with that of the A form, but with the same cysteinyl-covalently bound flavin (Fig. 1). The propargylamine derived irreversible MAO-A and -B inhibitors bind covalently to the *N*-5 isoalloxazin moiety of the flavin covalently mole/mole of the enzyme (Fig. 2) [2, 3, 4].

Drugs

The differentiation of MAO employing clorgyline and selegiline has been employed to identify the presence of each form in different tissues and species (Table 3) [4, 5]. The same system has been employed with substrates of MAO-A and -B (Table 1) to identify selective and specific inhibitors (Table 4, Fig. 2) and substrates (Table 2). The selective propargylamine inhibitors (clorgyline, selegiline, rasagiline, *N*-(2-propynyl)-2-(5-benzyloxy-indolyl) methylamine, aliphatic *N*-methyl propargylamine) lose their selectivity at higher concentration both in vitro and in vivo. By contrast the reversible inhibitors (Table 4) appear to be relatively more specific in vitro and in vivo inhibition [1].

Neuropharmacology of MAOs and their Inhibitors

Acute treatment with nonselective MAO inhibitors (iproniazid, tranylcypromine, phenelzine), as a consequence of inhibiting both forms of the enzyme, increase brain levels of all monoamines (phenylethylamine, tryptamine, methylhistamine aminergic neurotransmitters (dopamine, noradrenaline, adrenaline and serotonin). By contrast MAO-A inhibitors (clorgyline) increase serotonin and noradrenaline, while MAO-B inhibitors (selegiline, rasagiline) increase brain levels

Monoamine Oxidases and their Inhibitors.

Figure 1 The crystal structure of human MAO-B. There are three functionally distinct domains, as shown. In red, the substrate domain contains two “cavities” shown in cyan. The outer space is the entrance cavity leading to the inner space, substrate binding cavity, closer to the flavin cofactor. The flavin-binding domain is shown in blue with the FAD molecule in yellow. In green, the C-terminal helical region which attaches the protein to the mitochondrial membrane. Rasagiline covalently links to the flavin via its propargylamine group (yellow arrow) and the indan ring extends into the substrate-binding cavity, blocking access for substrate.

of phenylethylamine and related amine. Neither class of the selective inhibitors affects brain levels of dopamine. Since the latter neurotransmitter is equally well metabolized by both enzymes. Thus when one form is inhibited, the other continues its degradation. A combination of MAO-A plus MAO-B inhibitors have the same effect as the nonselective inhibitors. Several studies in vitro and in vivo have shown that serotonin and noradrenaline are not strictly metabolized by

Monoamine Oxidases and their Inhibitors. Figure 2 Structures of MAO inhibitors. In the top row, the structural similarity between selegiline/l-deprenyl and methamphetamine is shown. Below are the aminoindan series of propargylamine compounds such as rasagiline. Next, the bifunctional MAO and cholinesterase inhibitors (ladostigil) and lastly, the iron chelator-MAO inhibitors.

MAO-A only. When concentration of these amines is high enough to satisfy the K_m of MAO-B for these amines, they can be metabolized by this enzyme form [4]. A similar picture is also seen in vivo. For this reason,

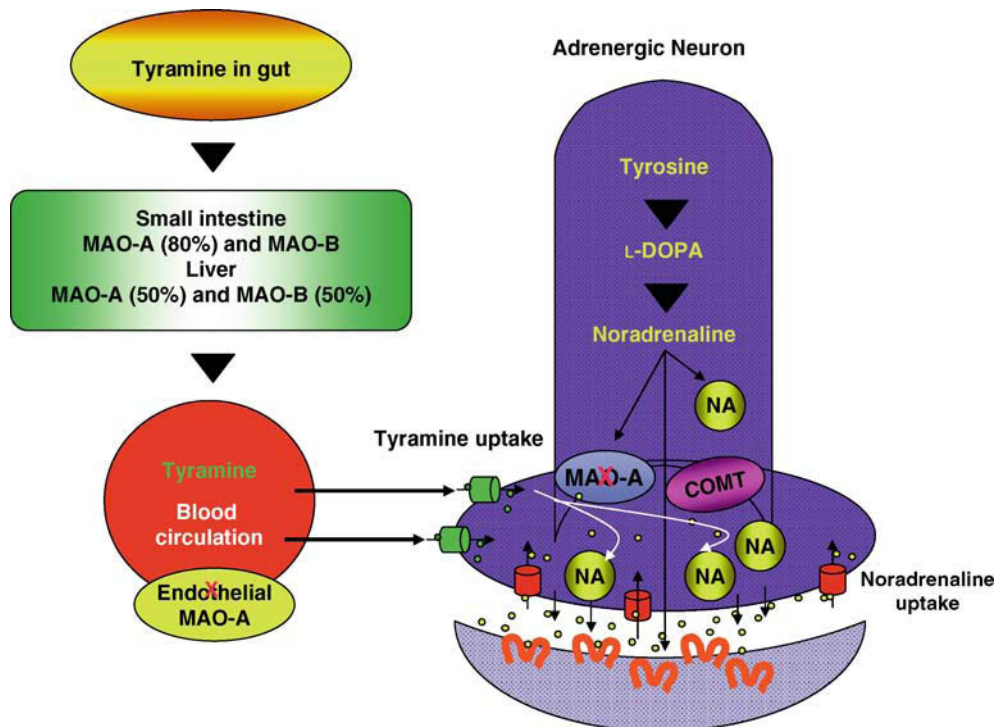

selective MAO-A inhibitors do not increase the brain levels of serotonin and noradrenaline to the same extent as nonselective inactivators [4, 5]. The acute effects of MAO inhibitors on amine neurotransmitter metabolism

are not mimicked on chronic treatment, since these amines cause a feed-back inhibition of the rate limiting synthetic enzymes, tyrosine hydroxylase (TH) and tryptophan hydroxylase. Furthermore, chronic treatment can result in increased release of noradrenaline and serotonin and inhibition of serotonin neuron firing, resulting from downregulation of presynaptic receptors alpha 2 receptors and desensitization of postsynaptic beta receptors, long term postsynaptic adaptive changes and subsensitivity of 5-HT₁ receptors. The mechanism of antidepressant actions of nonselective and MAO-A inhibitors has been linked to these effects and are seen 2–3 weeks of drug treatment, which is similar to time course of their clinical efficacy.

Cheese Reaction

Iproniazid was among the first psychotropic antidepressants to be discovered and introduced into the clinic. Although this inhibitor and others that followed

(tranylcypromine, phenelzine) demonstrated antidepressant activity, they exhibited a major side effect that came to be known as the “cheese reaction” [3, 4, 5]. The cheese reaction (Fig. 3) is induced by tyramine and other indirectly acting sympathomimetic amines present in food (most commonly in certain cheeses, hence the name) and fermented drink, such as beer and wine. Under normal circumstances, such dietary amines are extensively metabolized by MAO-A in the gut wall and in the liver and they are thus prevented from entering the systemic circulation. In the presence of an MAO inhibitor, this protective system is inactivated and tyramine or other monoamines and their amino acid precursor that can be decarboxylated, present in ingested food, enter the circulation without being metabolized. From here they have access to peripheral adrenergic neurons from which they induce a significant release of noradrenaline. The peripheral adrenergic neurons contain solely MAO-A, which is also

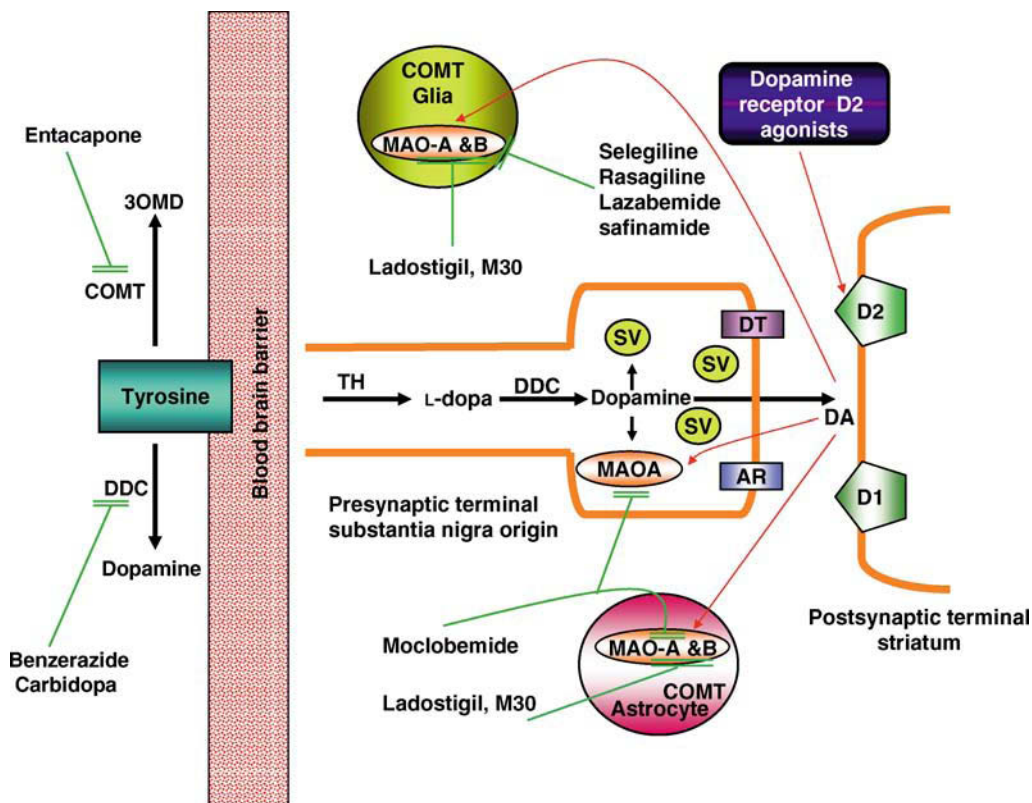

Monoamine Oxidases and their Inhibitors. Figure 3 The “cheese reaction” – potentiation of cardiovascular effects of tyramine (or other indirectly acting sympathomimetic amines) by irreversible inhibitors of MAO. Normally, dietary tyramine undergoes extensive “first pass” inactivation by the MAO-A and -B types in gut wall and then in the liver. The tyramine that survives to enter the systemic circulation is further inactivated by the MAO in vascular endothelial cells and lung (Bakhle, 1990). At the adrenergic neurone, uptake of tyramine initiates the release of noradrenaline, which accounts for the sympathomimetic effects of tyramine. Irreversible inhibition of MAO-A, the predominant form in the periphery adrenergic neurons, allows greatly increased tyramine entry in the systemic circulation and from there, adrenergic neurons, consequently increasing noradrenaline release and effect. By contrast, reversible inhibitors of MAO-A (RIMAs) are displaced from the enzyme by tyramine which is then metabolized normally by the enzyme. Thus, circulating tyramine never attains the high levels resulting from irreversible inhibition of MAO.

inhibited. The consequence of this release is a severe hypertensive response which can, in some cases, be fatal. These serious side effects stimulated a search for antidepressants that were not MAO inhibitors and led to their eventual replacement by the uptake inhibitors, the tricyclic antidepressants, and more recently the serotonin selective reuptake inhibitors (SSRI) such as Prozac. Better understanding of MAO-A and -B reactions and their distribution in peripheral adrenergic neurons had led to the demonstration that the cheese reaction is the property of irreversible MAO-A inhibition in the gut and peripheral adrenergic neurons, where this enzyme resides. The irreversible MAO-B inhibitors such as L-deprenyl (selegiline) and rasagiline (Azilect) do not induce cheese effect and have limited cardiovascular potentiation at their MAO-B inhibitory dosage. However, at inhibitor concentrations where this is lost and MAO-A is inhibited, the cheese reaction is

prominent. These studies resulted in the development of reversible MAO-A inhibitors (moclobemide) as ►**anti-depressant** that would not give a cheese reaction. The logistic being that tyramine taken up by adrenergic neurons can compete with the reversible MAO-A inhibitors at the active site of MAO, it can be metabolized before it can induce release of noradrenaline [3, 4].

MAO Inhibitors as Therapeutic Agents Parkinson's Disease

As early as 1961, the first generation of MAO inhibitors (iproniazid, isocarboxazide) were employed for the treatment of Parkinson's disease (PD). However, because of the severe side effects, such as "cheese reaction," they were abandoned. The realization that the basal ganglia (extrapyramidal region) of human brain contained mostly MAO-B, which metabolized

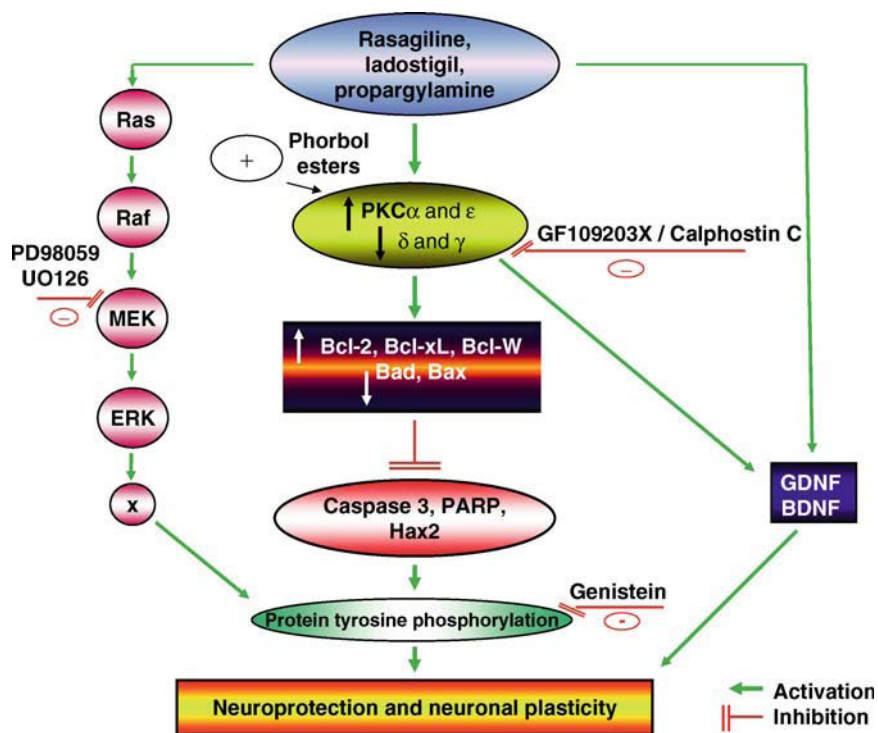

Monoamine Oxidases and their Inhibitors. Figure 4 Pathways of dopamine synthesis in dopaminergic neurons and metabolism by MAO-A and -B in the brain. Tyrosine passes through the blood–brain barrier and is hydroxylated by tyrosine hydroxylase (TH) to DOPA and then decarboxylated by DOPA decarboxylase (DDC) to dopamine (DA) within the neuron. Dopamine is taken up into synaptic vesicles (SV) or metabolized by neuronal mitochondria MAO-A. After release from the terminal, extracellular dopamine is cleared by uptake into astrocytes and glia also containing MAO-A and MAO-B. Selective inhibition of one MAO isoform allows the other to metabolize dopamine effectively and does not alter the steady state levels of striatal dopamine. On the other hand, nonselective inhibition of MAOs induces highly significant increase in striatal dopamine and in other brain regions, D1 and D2, dopamine receptors. On the other hand, in adrenergic and serotonergic neurons MAO-A and not MAO-B inhibition results in increased levels of these amines.

drugs upregulate ►**antiapoptotic** B-cell leukemia/lymphoma 2 (BCL2), while downregulating proapoptotic BCL2 family proteins (Fig. 5) and activate PKC-MAP kinase pathways (Fig. 6). The result is prevention of the demise of mitochondrial and its permeability transition and cell survival. This property has been directly linked to their propargyl moiety since propargylamine, which is devoid of MAO inhibitory activity, has similar effects. The suggestion that selegiline and rasagiline may be neuroprotective in PD, with their ►**disease modifying** action, has not been shown directly but is under investigation. However, a recent delayed-start study, in which rasagiline was given to two groups of parkinsonian subjects 6 months apart, has shown that subjects treated with rasagiline for 12 months showed less

functional decline than subjects whose treatment was delayed for 6 months. This has been suggested to indicate a disease modifying property. A major controlled study is under way to confirm this [4, 5].

Depressive Illness

Although it could be fatal, the cheese reaction seen with the first generation of MAO inhibitors as antidepressant was rather exaggerated. Not all patients that consumed food stuff containing sympathomimetic agents reacted in this manner. Nevertheless the irreversible MAO-AB inhibitors tranylcypromine and phenelzine are still in clinics, with caution taken that patients avoid certain food stuff containing tyramine. With the reversible MAO-A inhibitor, moclobemide (Fig. 4), this is unnecessary since it has highly limited capacity to induce the cheese reaction.

Monoamine Oxidases and their Inhibitors. Figure 6 The mechanism of neuroprotection and/or neurorescue by propargylamine MAO inhibitors. The propargylamine monoamine oxidase (MAO) inhibitors (such as rasagiline and ladostigil) activate the protein kinase C (PKC)-dependent mitogen-activated protein (MAP) kinase pathway 185,187 and mitochondrial B cell leukemia/lymphoma 2 (BCL2) family cytoprotective proteins, and down regulate proapoptotic BCL-associated death promoter (BAD), BCL2-associated protein X (BAX), caspase 3, poly (ADP-ribose) polymerase 1 (PARP1) and H2AX (a phosphorylated mammalian histone H2A)141. One direct consequence is the processing of amyloid precursor protein (APP) through the activation of α -secretase, resulting in increased release of the neuroprotective/neurotrophic soluble APP α (sAPP α). The activation of PKC α and PKC ϵ might explain the ability of these propargylamines to induce expression of glia cell line-derived neurotrophic factor (GDNF) and brain-derived neurotrophic factor (BDNF) mRNAs, and stimulate the release of GDNF. Inhibitors of PKC (such as GF109203X and calphostin C), extracellular signal-regulated kinase 1/2 (ERK1/2) (e.g., PD98059 and UO126) and tyrosine kinase (for instance, genistein) prevent APP processing and release of GDNF, and block BCL2-dependent neuroprotective pathways, supporting a mechanism by which propargylamines operate at different levels and suggesting a direct link between PKC and BCL2 family protein expression. MEK, MAP kinase; Raf, Ras, small G proteins; X represents a phosphorylated protein that activates tyrosine kinase.

Because of its mild antidepressant activity, it is generally considered to be more suitable for elder subjects, who react poorly to standard antidepressants [3, 4].

Mood-stabilising Drugs

In contrast to antidepressants (mood-elevating agents), mood-stabilizing drugs are not only effective in treating a state of depression, but can also control the manic phase of a manic-depressive (bipolar) illness. Mood-stabilizing drugs are often used prophylactically in bipolar depression. The most important mood-stabilizing agents are lithium salts which are able to prevent swings of mood in bipolar depression. In the acute phase, lithium is effective only in reducing mania, but not depression. It is currently not clear how lithium exerts its mood-stabilizing effects. Two main molecular mechanisms have been proposed. Lithium has been shown to inhibit inositol phosphatases. This results in a reduced

formation of free inositol, which is required for the formation of phosphatidyl inositols, serving as substrates for phospholipases (e.g. phospholipase- β). Lithium, thus, blocks the phosphatidyl inositol (PI) pathway resulting in the inhibition of agonist-stimulated inositol 1,4,5-triphosphate (IP₃) formation by a variety of receptors. Recently lithium has been shown to inhibit glycogen synthesis kinase-3 β (GSK-3 β), which is involved in various neuronal regulatory processes, including the Wnt-pathway.

Morphogens

Secreting signaling molecules with a pivotal role in organ development, particularly directing the positions of the specialized cell types in an organ. Examples of morphogens include transforming growth factor- β , fibroblast growth factor, and Wnt.

► Transforming Growth Factor-Beta

Morpholines

Morpholines are a chemical class of organic compounds with the six-membered ring tetrahydro-1,4-oxazine, as their basic structure.

► Antifungal Drugs

Motilin

Motilin is a 22-amino acid peptide hormone, secreted by the enterochromaffin cells of the small intestine,

which exerts a profound effect on gastric motility by inducing contractions of the antrum and duodenum. Motilin acts on a G-protein coupled receptor, which is expressed in a subset of interstitial cells of the human duodenum, jejunum and colon. Macrolide antibiotics like erythromycin and roxithromycin act as agonists on the motilin receptor.

Motor Proteins

Motor proteins move along microtubules or F-actin. The respective motor domains are linked to their cargoes via adaptor proteins. Kinesin motors move only to the plus and dynein motors only to the minus ends of microtubules. Myosin motors move along F-actin. When motors are immobilized at their cargo binding area, they can move microtubules or F-actin, respectively.

MPTP

Synonyms

N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine

Definition

A synthetic neurotoxin that causes parkinsonism in human and nonhuman primates, mice, gold fish, and dogs. MPTP is inert but metabolized by MAO-B to the neurotoxin MPP⁺ (1,2-dihydropyridine ion). This neurotoxin causes depletion of dopamine and degeneration of nigrostriatal dopamine neurons similar to what is observed in Parkinson's disease.

mRNA

Messenger RNA (mRNA) is the intermediate template between DNA and proteins. The information from a particular gene is transferred from a strand of DNA by the construction of a complementary strand of RNA through a process known as transcription. The amount of any particular type of mRNA in a cell reflects the extent to which a gene has been 'expressed'.

- ▶ Microarray Technology

MRP

Multidrug resistance related protein (MRP). Currently nine MRP proteins have been described in human. The MRP proteins belong to the C-branch of the ABC-transporter superfamily and are also involved in resistance against several anticancer drugs. MRP proteins transport a wide variety of endo- and exogenous compounds. For example, MRP2, which is expressed in the canalicular membrane of hepatocytes, eliminates bilirubin-glucuronide into the bile, and MRP4, 5, and 8 have been shown to eliminate cyclic nucleotides.

Muscarinic acetylcholine receptors

Definition

Muscarinic acetylcholine receptors (mAChRs) form a class of cell surface receptors that are activated upon binding of the neurotransmitter, acetylcholine. Structurally and functionally, mAChRs are prototypical members of the superfamily of G protein-coupled receptors. Following acetylcholine binding, the activated mAChRs interact with distinct classes of heterotrimeric G proteins resulting in the activation or inhibition of distinct downstream signaling cascades.

Basic Characteristics

The neurotransmitter acetylcholine (ACh) exerts its diverse pharmacological actions via binding to and subsequent activation of two general classes of cell surface receptors, the nicotinic and the mAChRs. These two classes of ACh receptors have distinct structural and functional properties. The ►nicotinic receptors,

which can be selectively activated by the alkaloid nicotine, represent ACh-gated ion channels. In contrast, the mAChRs, which can be selectively activated by the alkaloid muscarine, are members of the ►G protein-coupled receptor (GPCR) superfamily.

General Structural Features

Molecular cloning studies have revealed the existence of five molecularly distinct mammalian mAChRs (M_1 – M_5 ; Table 1; Fig. 1) [1, 2]. All five receptor subtypes are members of the so-called class I GPCR subfamily (rhodopsin-like receptors) with which they share about 20 highly conserved amino acids (Fig. 1). These highly conserved residues play important roles in proper receptor folding and receptor activation [1, 3]. The structural hallmark of mAChRs (and GPCRs in general) is the presence of seven α -helically arranged transmembrane domains (TM I–VII; Fig. 1), which form a tightly packed transmembrane core. The N-terminal portion of the receptor protein is located extracellularly, whereas the C-terminal segment protrudes into the cytoplasm. The seven transmembrane helices are linked by three intracellular (i1–i3; Fig. 1) and three extracellular loops (o2–o4; Fig. 1). A characteristic structural feature of the mAChRs is the presence of a rather large third intracellular loop (i3 loop; 157–240 amino acids in length), which, except for the N- and C-terminal segments, displays virtually no sequence homology among the different subtypes. The N- and C-terminal portions of the i3 loop play important roles in receptor/G protein coupling [1], whereas the central portions of the i3 loop are involved in the regulation of receptor activity (see below). The five receptor subtypes share the highest degree of sequence homology within the seven membrane-spanning domains (Fig. 1), which are known to be involved in ACh binding [1, 3].

Distribution and Physiological Functions of mAChRs

mAChRs are found in virtually all organs, tissues, and cell types. All five mAChRs are expressed in both the central nervous system (CNS) and the body periphery. Whereas the M_2 and M_3 receptor subtypes are the predominant mAChRs found in peripheral tissues, the M_1 and M_4 mAChRs are abundantly expressed in the CNS, specifically in higher brain regions. The M_5 mAChR is expressed at rather low levels in various central and peripheral tissues. Characteristically, most tissues or organs express multiple mAChR subtypes.

Peripheral mAChRs are known to mediate the well-documented actions of ACh at ►parasympathetically innervated effector tissues (organs) including heart, endocrine and exocrine glands, and smooth muscle tissues [2, 4]. The most prominent peripheral actions mediated by activation of these receptors are reduced heart rate and cardiac contractility, contraction of

Muscarinic Receptors. Table 1 Summary of key features of the five human mAChRs (M₁–M₅)

Receptor subtype	M ₁	M ₂	M ₃	M ₄	M ₅
Amino acids	460	466	590	479	532
Chromosomal localization	11q12	7q35–36	1q43–44	11p12–11.2	15q26
GenBank/EMBL Accession number	X15263	X15264 M16404	X15266	X15265 M16405	M80333
G protein-coupling selectivity	G _{q/11}	G _{i/o}	G _{q/11}	G _{i/o}	G _{q/11}
Subtype-preferring antagonists (examples) ^a	Pirenzepine	Tripitramine	Darifenacin	PD102807	— ^c
	MT7 ^b		MT3 ^b		

^aExcept for certain snake toxins, such as MT3 or MT7, the degree of subtype preference of so-called “subtype-selective” muscarinic antagonists is usually relatively small (for a summary of affinity values, see [2].)

^bMT3 and MT7 are toxins isolated from the venom of the green mamba (*Dendroaspis augusticeps*).

^cM₅ mAChRs are pharmacologically distinct in that they display very low affinity for antagonists such as AF-DX 116 and its derivatives [2].

smooth muscle tissues (e.g. smooth muscles of the eye, gastrointestinal system, lung, or urinary bladder), and stimulation of glandular secretion (e.g. lachrymal, salivary, and gastrointestinal glands). Whereas the cardiac muscarinic actions of ACh are mediated by M₂ receptors, the M₃ receptor subtype plays a major role in mediating ACh-dependent stimulation of glandular secretion and smooth muscle contraction [2, 4].

Central mAChRs are involved in modulating a very large number of behavioral, autonomic, sensory, and motor functions. For example, central muscarinic mechanisms play important roles in the control of body temperature, cardiovascular and pulmonary functions, learning and memory, emotional responses, arousal, attention, rapid eye movement (REM) sleep, and stress modulation. Moreover, increased or decreased muscarinic cholinergic neurotransmission has been implicated in the pathophysiology of several important disorders of the brain, including ►Alzheimer’s disease and ►Parkinson’s disease, depression, schizophrenia, and epilepsy. The roles of the individual mAChRs in mediating the diverse central muscarinic functions of ACh are not well understood at present, primarily due to the lack of muscarinic ligands endowed with a high degree of receptor subtype selectivity (see below). However, recent studies analyzing newly developed mutant mouse strains deficient in specific mAChR subtypes have led to many new insights into the physiological roles of the M₁–M₅ receptors [4].

Ligands and Mechanisms Involved in Ligand Binding

Various lines of evidence indicate that ACh binds to the M₁–M₅ receptors within a cleft enclosed by the ring-like arrangement of TM I–VII, about 10–15 Å away from the membrane surface [1, 3]. ACh binding induces as yet poorly understood changes in the arrangement of individual transmembrane helices. These conformational changes are then transmitted to the intracellular

surface of the receptor protein, enabling the receptor to productively interact with specific classes of ►heterotrimeric G proteins. The amino acids involved in ACh binding are located on different TM helices, primarily TM III, V, VI, and VII [1, 3]. Importantly, the positively charged ammonium head group of ACh (or the amino/ammonium head group of other classical muscarinic agonists or antagonists) is engaged in an ion–ion interaction with a TM III aspartate residue (shown boxed in Fig. 1), which is conserved among all ►biogenic amine GPCRs. This ion pair is surrounded by a cluster of aromatic amino acids, thus creating a charge-stabilized aromatic cage [1, 3].

The ACh-binding pocket partially overlaps with that of competitive muscarinic antagonists such as atropine, scopolamine, or quinuclidinyl benzilate. However, antagonists usually form additional strong interactions with hydrophobic receptor residues, thus stabilizing the inactive state of the receptor [1, 3].

The amino acids lining the ligand-binding cavity are highly conserved among the M₁–M₅ mAChRs. For this reason, the development of agonist or antagonist ligands able to interact with individual mAChR subtypes with a high degree of selectivity has proven to be a very difficult task. At present, agonists that display a high degree of selectivity for a particular mAChR subtype are not available [2]. Moreover, the degree of receptor subtype selectivity of so-called “selective” muscarinic antagonists, which are currently used to distinguish pharmacologically between different mAChR subtypes, is generally rather modest [2]. Such compounds include, for example, pirenzepine (M₁ receptor-preferring), tripitramine (M₂ receptor-preferring), darifenacin (M₃ receptor-preferring), or PD 102807 (M₄ receptor-preferring) [2]. Antagonists that preferentially bind to M₅ receptors are not available at present.

However, several snake toxins have been identified that display an unprecedented degree of mAChR

subtype selectivity. For example, the MT7 and MT3 toxins are highly selective antagonists for M_1 and M_4 mAChRs, respectively [2]. The binding of these polypeptide ligands appears to involve interactions with less well conserved amino acids present on the extracellular surface of the mAChRs.

The binding of muscarinic ligands to the primary recognition site can be modulated by so-called allosteric ligands which interact with a secondary (allosteric) site [2]. The best known ligands of this class are certain neuromuscular blocking agents including gallamine. Most allosteric ligands exhibit negative cooperativity with classical muscarinic agonists and antagonists. However, allosteric agents that display positive cooperativity with ACh or certain muscarinic antagonists at specific mAChR subtypes have also been identified [2]. The receptor-binding site for allosteric muscarinic ligands is thought to be located just “above” the classical ligand-binding pocket.

G Protein-Coupling Properties of mAChRs

Based on their G protein-coupling properties, the M_1 - M_5 mAChRs can be subdivided into two major functional subclasses [1, 2]. The M_1 , M_3 , and M_5 mAChRs are preferentially coupled to G proteins of the $G_{q/11}$ family, which mediate the activation of different isoforms of **phospholipase C β** resulting in the breakdown of phosphatidyl inositol and the generation of the second messengers, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol. In contrast, the M_2 and M_4 mAChRs are selectively linked to G proteins of the $G_{i/o}$ class, which, at a biochemical level, reduce the accumulation of intracellular cAMP via inhibition of **adenylyl cyclase**. However, the G protein-coupling selectivity of the individual mAChRs is relative rather than absolute, as has been observed with most other GPCRs. Mutagenesis studies have shown that amino acids located within the i2 loop and the membrane-proximal portions of the i3 loop play key roles in determining the G protein-coupling profile of the individual mAChRs [1].

Signaling Pathways Activated by mAChR Subtypes

At a cellular level, the activation of mAChRs leads to a wide spectrum of biochemical and electrophysiological responses [1, 5]. The precise pattern of responses that can be observed does not only depend on the nature of the activated G proteins (receptor subtypes) but also on which specific components of different signaling cascades (e.g. effector enzymes or ion channels) are actually expressed in the studied cell type or tissue. The observed effects can be caused by direct interactions of the activated G protein(s) with effector enzymes or ion channels or may be mediated by second messengers (Ca^{2+} , IP_3 , etc.) generated upon mAChR stimulation.

Activation of M_1 , M_3 , and M_5 mAChRs does not only lead to the generation of IP_3 followed by the mobilization of intracellular Ca^{2+} , but also results in the stimulation of phospholipase A2, phospholipase D, and various tyrosine kinases. Similarly, M_2 and M_4 receptor activation does not only mediate the inhibition of adenylyl cyclase, but also induces other biochemical responses including augmentation of phospholipase A2 activity. Moreover, the stimulation of different mAChR subtypes is also linked to the activation of different classes of mitogen-activated protein kinases (MAP kinases), resulting in specific effects on gene expression and cell growth or differentiation.

Stimulation of mAChRs also results in the activation or inhibition of a large number of ion channels [5]. For example, stimulation of M_1 receptors leads to the suppression of the so-called M current, a voltage-dependent K^+ current found in various neuronal tissues. M_2 receptors, on the other hand, mediate the opening of cardiac $I_{K(ACh)}$ channels, and both M_2 and M_4 receptors are linked to the inhibition of voltage-sensitive calcium channels [5].

Regulation of mAChR Activity

Like most other GPCRs, mAChRs are subject to desensitization, which is defined as diminished responsiveness of the receptor/effector signaling pathway upon prolonged exposure of the receptor to an activating ligand. The phenomenon of GPCR desensitization involves a complex series of events, including G protein uncoupling, receptor sequestration/internalization (removal of receptors from the cell surface), and receptor downregulation associated with the net loss of receptor protein [1]. Many of these processes are regulated by receptor phosphorylation catalyzed by various protein kinases including different members of the family of **GPCR kinases** (GRKs), casein kinase 1 α , or second messenger-dependent protein kinases. Phosphorylation occurs on threonine and serine residues located within the i3 loop and the C-terminal tail of the mAChRs. The individual mAChR subtypes differ in their ability to serve as substrates for phosphorylation by these various kinases. The rapid removal of mAChRs from the cell surface following agonist stimulation (referred to as receptor internalization/sequestration) occurs through multiple pathways, one of which involves the targeting of receptors to clathrin-coated pits.

Drugs

Current Clinical Uses of Muscarinic Drugs

Muscarinic agonists and antagonists are used for the treatment of a variety of pathophysiological conditions. For example, muscarinic agonists (pilocarpine, carbachol, or aceclidine) reduce intraocular pressure when

applied locally to the eye and are therefore widely used for the treatment of glaucoma. Moreover, muscarinic agonists (carbachol or bethanechol) are employed in certain cases of atonia of the stomach, bowel, or urinary bladder. The agonists pilocarpine and cevimeline are used to stimulate salivation under conditions where the function of the salivary glands is impaired. The antagonist, scopolamine, is highly effective in preventing motion sickness. Centrally acting muscarinic antagonists (e.g. trihexyphenidyl, procyclidine, or biperiden) are useful for the treatment of Parkinson's disease or Parkinson-like symptoms caused by the administration of antipsychotic drugs, probably due to their ability to reduce excessive striatal muscarinic neurotransmission resulting from the lack of striatal dopamine. Muscarinic antagonists are also of considerable value in the treatment of clinical disorders characterized by an increased tone or motility of the gastrointestinal and urogenital tract and in the local therapy of obstructive pulmonary diseases including chronic bronchitis and bronchial asthma. Antimuscarinic agents are widely used in ophthalmology to produce mydriasis and/or cycloplegia, are effective in the treatment of peptic ulcer disease (e.g. pirenzepine) and certain forms of cardiac arrhythmias, and can be used as part of routine preoperative medication, primarily to reduce reflex bradycardia and excessive bronchial secretion.

Potential Clinical Uses of Muscarinic Drugs

A major problem associated with the use of classical muscarinic drugs is the rather common occurrence of bothersome side effects, primarily due to the stimulation or blockage of cardiac, glandular, smooth muscle, or central mAChRs. It is likely that the development of muscarinic agonists and antagonists that can interact with individual mAChRs with a high degree of selectivity will lead to novel muscarinic drugs with reduced side effects and increased efficacy. For example, it has been proposed that selective activation of central M_1 receptors or selective blockage of presynaptic M_2 receptors mediating autoinhibition of ACh release may represent potentially useful strategies for the treatment of Alzheimer's disease. Such agents could offer therapeutic benefits by facilitating signaling through cortical and hippocampal M_1 mAChRs, which lack proper cholinergic innervation in patients with Alzheimer's disease. Selective M_3 receptor antagonists are likely to produce fewer side effects in the treatment of smooth muscle disorders including urinary urge incontinence, irritable bowel syndrome, and chronic obstructive pulmonary disease. The application of subtype-selective muscarinic drugs may also be beneficial in the management of pain (centrally active muscarinic agonists are potent analgesics) and in the treatment of schizophrenia [4].

Muscle Relaxants

Muscle relaxants reduce the tone of the voluntary muscles. Centrally acting muscle relaxants like benzodiazepines or baclofen reduce the background tone of the muscle without seriously affecting its ability to contract transiently under voluntary control. Baclofen is a selective agonist of presynaptic γ -aminobutyric acid_B (GABA_B)-receptors. Its antispastic action is due to the inhibition of the activation of motor neurons in the spinal cord. Peripherally acting muscle relaxants block neuro-muscular transmission. They either inhibit the synthesis of acetylcholine (e.g. hemicholinium) or inhibit acetylcholine release (e.g. botulinum toxin) or act postsynaptically as antagonists of the muscular nicotinic acetylcholine receptor (non-depolarising blocking agents; e.g. tubocurarine, pancuronium, vecuronium, atracurium, gallamine) or as agonists of the receptor (depolarizing blocking agents; e.g. suxamethonium). The peripherally acting relaxants are also called “neuromuscular blocking agents”.

Muscle Type Nicotinic Receptors

Nicotinic receptors (nicotinic acetylcholine receptors, nAChR) exist not only in the membrane of vertebrate skeletal muscle at the synapse between nerve and muscle (muscle-type nAChR) but also at various synapses throughout the brain, mainly at presynaptic positions (neuronal-type nAChR). Whereas the muscle-type nAChR is precisely composed of two α 1-subunits, one β -subunit, one γ -subunit and one δ -subunit (adult)

or one ϵ -subunit (embryonic), the neuronal receptors exist as homopentamers (e.g. $[\alpha 7]_5$) or heteropentamers comprising various combinations of $\alpha 2$ - to $\alpha 6$ - with $\beta 2$ - to $\beta 4$ -subunits or $\alpha 9$ - with $\alpha 10$ -subunits.

► Nicotinic Receptors

Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder caused by antibodies to nicotinic receptors of the skeletal muscle endplate. The antibodies block the receptors directly, for example by occupying the acetylcholine binding site. They also increase the rate of degradation of the receptors. Symptoms are muscle weakness and fatigue. Cholinesterase inhibitors such as physostigmine improve muscle strength by preservation of released acetylcholine, so that a greater number of still intact receptors is exposed to effective concentrations of the transmitter.

Myelin Basic Protein

Component of the myelin sheath surrounding the axons of nerve cells. Additional compounds of the myelin sheath are phospholipids, cholesterol, cerebroside, and specific keratins. The myelin sheath constitutes an isolating barrier during electrophysiological axonal signaling.

► Interferons

Myelosuppression

Myelosuppression is suppression of the production of blood cells by the bone marrow.

► Hematopoietic Growth Factors

Myocardial Infarction

An episode of acute cardiac ischemia that leads to death of cardiomyocytes. It is usually caused by a thrombotic atherosclerotic plaque.

► Atherosclerosis

Myosin Light Chain Kinase

Synonyms

MLCK

Definition

This kinase specifically phosphorylates the regulatory light chain of myosin after activation by calcium-calmodulin. Several isozymes of approximately 135 kDa exist.

► Smooth Muscle Tone Regulation

Myosin Phosphatase (MLCP)

Smooth muscle myosin phosphatase contains three subunits, a 110–130 kDa myosin phosphatase targeting and regulatory subunit (MYPT1), a 37 kDa catalytic subunit (PP-1C) and a 20 kDa subunit of unknown function.

► Smooth Muscle Tone Regulation

Myotonia

Myotonia is muscle stiffness, in which muscle relaxation after voluntary contraction is impaired. Mutations in several ion channel genes (Cl, Na, Ca, K channels) can cause myotonias, which can sometimes be differentiated clinically (e.g. paramyotonia is cold-sensitive). ClC-1 mutations cause 'pure' myotonia congenita which is not sensitive to temperature. Channel myotonia comes in a recessive (Becker type)

form and a dominant (Thomsen type) form. In myotonic dystrophy (due to mutations in a kinase gene), myotonia is one of the symptoms. In contrast to myotonic dystrophy, myotonia congenita is a nondystrophic, rather benign disorder in which the skeletal muscle is not dystrophic, but rather shows hypertrophy secondary to “exercise” by prolonged contractions.

Definition

The plasma membrane Na⁺/Ca²⁺ exchanger is a high-capacity and low affinity ionic transporter that exchanges three Na⁺ ions for one Ca²⁺ ion. When intracellular Ca²⁺ concentrations [Ca²⁺]_i rise and the

cells require the return to resting levels, this exchanger transport mechanism, couples the uphill extrusion of Ca²⁺ ions to the influx of Na⁺ ions into the cells down their electrochemical gradient. This mode of operation, defined as forward mode or Ca²⁺ efflux (corresponds to forward mode of operation) mechanism keeps the 10⁴-fold difference in [Ca²⁺]_i across the cell membrane. In other physiological or pathophysiological conditions when the intracellular Na⁺ concentrations [Na⁺]_i rise or membrane depolarization occurs, thus reducing the transmembrane Na⁺ electrochemical gradient, the Na⁺/Ca²⁺ exchanger mediates the extrusion of Na⁺ and the influx of Ca²⁺ ions. This mode of operation is defined as reverse mode or Ca²⁺ influx (corresponds to reverse mode of operation) mechanism. The mode of operation of the antiporter depends on: (i) the Na⁺ gradient, (ii) the Ca²⁺ gradient, and (iii) the membrane potential and therefore it is a major player in the regulation of physiological responses to increases of [Ca²⁺]_i and [Na⁺]_i [1–3].

Basic Characteristics

Molecular Biology and Topology

The molecular biology of NCX revealed that three genes coding for the three different NCX1, NCX2, and NCX3 proteins are present in mammals. These three genes appear to be dispersed, since *ncx1*, *ncx2*, and *ncx3* are localized in mouse chromosomes 17, 7, and 12, respectively. At the posttranscriptional level, at least 15 NCX1 and 5 NCX3 proteins are generated through an alternative splicing of the primary nuclear transcripts.

NCX1 protein is composed of ~938 amino acids having a theoretical molecular mass of 120 kDa and containing nine transmembrane segments named TMS 1–9. The amino terminus NCX is located in the extracellular space, whereas the carboxyl terminus is located intracellularly. The nine transmembrane segments can be divided into an N-terminal hydrophobic domain, composed of the first five: TMS 1–5, and into a C-terminal hydrophobic domain, composed of the last four: TMS 6–9. The NCX protein amino acid sequence found between TMS2 and TMS3 is called α-1 repeat, whereas the one found between TMS7 and TMS8 is named α-2 repeat. Both regions, α-1 and α-2 repeats, are located on the opposite site of the membrane. Since the

putative α -helices of the α -repeats are amphipathic, the hydrophilic faces of these helices may form a portion of the ion translocation pathway. Interestingly, the α -repeats form reentrant loops of NCX1 that interact within the protein. Interestingly, the center of α -2 repeat possesses the GIG amino acid sequence similar to the GYG sequence present in the P loop of K⁺ channels [2, 3]. These two hydrophobic domains are important for the binding and the transport of ions. The first five TMS 1–5 are separated from the last four TMS 6–9 through a large hydrophilic intracellular loop of 550 amino acids, named the f loop (Intracellular domain between transmembrane segments 5 and 6 of the sodium calcium exchanger) (Fig. 1).

Although the f loop is not implicated in Na⁺ and Ca²⁺ translocation, it is responsible for the regulation of NCX activity elicited by several cytoplasmic messengers and transductional mechanisms, such as Ca²⁺, Na⁺ and H⁺ ions, NO (►nitrenergic systems, NO-synthases), phosphatidylinositol 4,5 bisphosphate (PIP₂), protein kinase C (PKC), protein kinase A (PKA), and ATP. Furthermore, in the f loop, there are two Ca²⁺ binding domains named Ca²⁺ binding domain 1 (CBD1) [2, 3], containing an immunoglobulin-like fold with four Ca²⁺ ions bound and Ca²⁺ binding domain 2 (CBD2). CBD1 is the primary Ca²⁺ sensor and detects slightest increases in

cytosolic Ca²⁺ and the associated large structural changes activate the exchanger. In contrast, CBD2 undergoes comparably modest structural alterations and binds Ca²⁺ only at elevated Ca²⁺ concentrations. These two different sensitivity thresholds may enable NCX to function dynamically over a wide range of Ca²⁺ concentrations and permit high Ca²⁺ fluxes in excitable cells.

At the N-terminal end of the f loop, near the membrane lipid interface, there is an autoinhibitory domain, rich in both basic and hydrophobic residues and consisting of a 20-amino acid sequence (219–238). This amino acid sequence, named exchange inhibitory peptide (XIP), is involved in NCX activity regulation.

The other two isoforms NCX2 and NCX3 have a molecular topology similar to NCX1. They consist of 921 and 927 amino acids and are characterized by molecular masses of 102 and 105 kDa, respectively. NCX2 displays a 65% sequence identity with NCX1, whereas NCX3 possesses a 73% sequence identity with NCX1 and 75% sequence identity with NCX2. All three NCX gene products share the same membrane topology.

Distribution

Na⁺/Ca²⁺ exchanger activity is present in virtually every cell type examined. The NCX1 gene is expressed in several tissues, including brain, heart, skeletal

Na⁺/Ca²⁺ Exchangers. Figure 1 Molecular pharmacology of the Na⁺/Ca²⁺ exchanger. Topology and putative sites of the molecular action of drugs interfering with NCX activity (Reproduced from Annunziato L, Pignataro G, Di Renzo GF (2004) *Pharmacol Rev* 56:633–654).

muscle, smooth muscle, kidney, eye, secretory, immune system, and blood cells, whereas transcripts and proteins encoded by the NCX2 and NCX3 genes have been found exclusively in neuronal and skeletal muscle tissues. In addition, NCX1 and NCX3 give rise to several splicing variants that appear to be selectively expressed in different regions and cellular populations of the brain (Fig. 2).

Regulatory Factors

Several factors are involved in the regulation of Na⁺/Ca²⁺ exchanger activity: (i) the two transported cations, Na⁺ and Ca²⁺; (ii) the intracellular pH; (iii) the metabolic related compounds, ATP, PIP₂, PKA, and PKC; (iv) reactive oxygen species.

The site level at which [Ca²⁺]_i regulates NCX activity (CBD) is different from the one required for Ca²⁺ transport. Submicromolar concentrations (0.1–0.3 μM) of intracellular Ca²⁺ are needed to activate the antiporter through these Ca²⁺ binding site. The location of such regulatory site has been identified in the 134-amino acid-length region, situated in the center of the intracellular f loop [2]. (Table 1)

An increase in [Na⁺]_i can also regulate the Na⁺/Ca²⁺ exchanger. In particular, when intracellular Na⁺ increases, it binds to the transport site of the exchanger molecule, and after this Na⁺ influx, an inactivation process of the exchanger occurs. This inactivation process, very similar to the phenomenon occurring in voltage-dependent ionic channels, is named

Na⁺/Ca²⁺ Exchangers. Figure 2 Schematic diagram of NCX localization and function in a pre- and postsynaptic structure (Reproduced from Annunziato L, Pignataro G, Di Renzo GF (2004) *Pharmacol Rev* 56:633–654).

Na⁺/Ca²⁺ Exchangers. Table 1 Regulatory mechanisms of Na⁺/Ca²⁺ exchanger activity

Regulatory Factors	Effect
[Ca ²⁺] _i	Increase Na ⁺ /Ca ⁺ exchanger activity (Low affinity: 0.1–0.3 μM; high affinity: 20–50 nM)
[Na ⁺] _i	[Na ⁺] _i -dependent inactivation of outward Ca ²⁺ currents
NO	Stimulates Na ⁺ /Ca ²⁺ exchanger activity via cGMP
Redox Status	Oxidizing agents stimulate activity
PIP ₂	Elimination of the [Na ⁺] _i -dependent inactivation
ATP	↑ [Na ⁺] _o -dependent Ca ²⁺ efflux

PKA	↑ Activity in exon A-carrying splicing isoforms of the Na ⁺ /Ca ²⁺ exchanger
PKT	↑ Expression and activity of NCX1 and NCX3

Na^+ -dependent inactivation. There is a sequence of 20-aminoacids (219–238), located in the intracellular f loop near the membrane lipid interface, that seems to be involved in the Na^+ -dependent inactivation. This autoinhibitory 20-aminoacid sequence might interact with another portion of the f loop (562–679) producing NCX inhibition. In accordance with this view, the synthetic peptide provided with the same sequence of XIP region blocks NCX activity.

The intracellular pH can also regulate the exchanger. $[\text{H}^+]$ strongly inhibits NCX activity under steady-state conditions, in fact, reduction in $[\text{pH}]_i$ values, as little as 0.4, can induce a 90% inhibition of NCX activity. Such inhibitory action depends on the presence of intracellular Na^+ ions, hence, the action exerted by H^+ ions is pathophysiologically relevant with regards to brain and heart ischemia.

ATP, acting as a phosphoryl donor molecule, may increase the activity of the exchanger in a number of ways. Firstly, ATP directly participates in the NCX molecule phosphorylation process by PKA and PKC. Secondly, it increases PIP2 production. Finally, by activating G-protein-coupled receptors, via endogenous and exogenous ligands, ATP can stimulate the activity of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger through the pathway involving PKC or PKA activation. The mechanism underlying the phosphorylating effect on the exchanger is related to an increase in its affinity for both internal Ca^{2+} and external Na^+ and to a decrease in its inhibition by internal Na^+ . Each of the NCX isoforms has distinctive putative phosphorylation sites; ATP cellular depletion inhibits NCX1 and NCX2 but does not affect NCX3 activity. The other mechanism by which ATP can activate NCX occurs through the production of the lipid PIP2. In fact, this lipid binding the XIP region of the f loop eliminates NCX inactivation and stimulates NCX function. In addition, $\text{Na}^+/\text{Ca}^{2+}$ exchanger can be sensitive to reactive oxygen species, since modifications of the cellular redox state can cause an increase of NCX activity.

Pathophysiological Implications

In consideration of the relevant role played by the forward and reverse mode operation of NCX in the maintenance of $[\text{Na}^+]_i$ and $[\text{Ca}^{2+}]_i$ homeostasis in cells of the cardiovascular and central nervous system, alterations in gene structure, gene activation, protein expression, stability, and function may take part in the pathophysiology of several diseases. As matter of fact, homozygous overexpression of NCX1 in the heart results in mild cardiac hypertrophy and in a higher susceptibility to ischemia-reperfusion injury, whereas NCX1 gene deletion confers protection. In addition, NCX is widely recognized as a contributing factor to both impaired contractile performance and electrical instability like arrhythmia in human and experimental heart failure. It is

also hypothesized that in salt-dependent hypertension NCX1, operating in the reverse mode, may be involved in Ca^{2+} entry, thus resulting in vasoconstriction. Recently, a relevant role has been attributed to NCX during focal cerebral ischemia since a stimulation of NCX activity, promoting Ca^{2+} extrusion, may help neurons and glial cells that are not irreversibly damaged in the penumbral zone to survive, whereas antisense knocking-down of NCX1 and NCX3 transcripts, blocking produces a significant worsening of ischemic brain injury [4]. This evidence suggests that a pharmacological intervention aimed at increasing NCX expression and activity might be a promising perspective to reduce cerebral damage after ischemic insult.

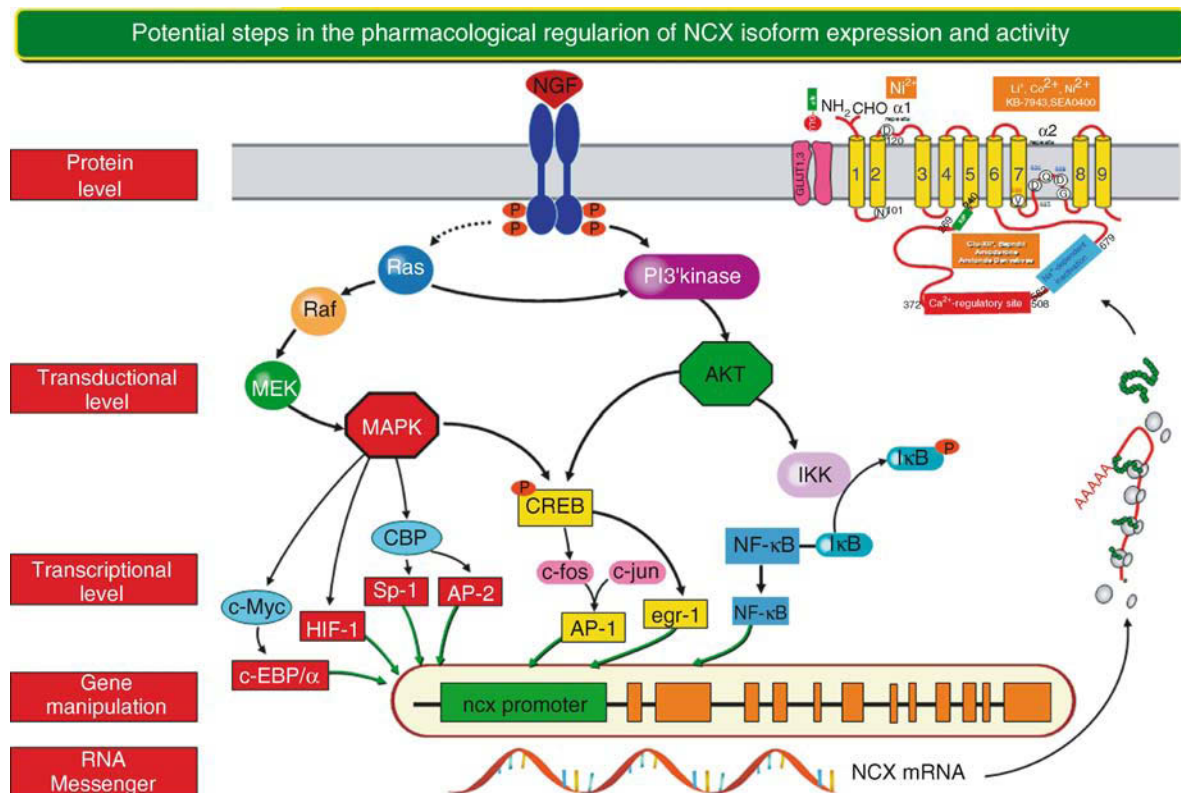

Drugs

Molecular Pharmacology of $\text{Na}^+/\text{Ca}^{2+}$ Exchanger

A great deal of interest has been devoted to the pharmacological modulation of NCX (Fig. 3). The reasons for this enormous interest lay in the hope of finding clinically effective drugs for those pathophysiological conditions such as cerebral ischemic disease, arrhythmias, heart failure, and hypertension in which a stimulation or an inhibition of the NCX might have achieved beneficial effects. In the last 35 years several inorganic and organic compounds have been reported to activate or to block NCX activity. (Table 2 and 3)

However, these compounds besides inhibiting NCX may also interfere with other cellular ion transporting mechanisms, i.e., Na^+ epithelial channels; K^+ channels; plasma membrane store-operated Ca^{2+} channels; VGCC-, NMDA-, and α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid/kainate receptor-operated channels; Na^+/H^+ exchanger; Na^+/K^+ ATPase; and plasma membrane Ca^{2+} ATPase. In addition, other aspects that should be taken in consideration in the pharmacological modulation of NCX activity are: (i) the existence of three different gene products NCX1, NCX2, and NCX3 that, although all share a high degree of aminoacid sequence homology, display a different pharmacological sensitivity; (ii) the existence of at least 15 splicing variants for NCX1 and 5 for NCX3, each of them might be selectivity modulated by various compounds; (iii) the double mode of operations of the exchanger, forward or reverse, that can be modulated in a differential manner by different drugs (Fig. 4). Thanks to site direct mutagenesis, a great advancement has been achieved in the last few years in the molecular pharmacology characterization of the domains, of the transmembrane segments, of the connecting loops, and finally of the single aminoacids responsible of drug action (Fig. 1).

Among the organic derivatives, amiloride analogs were the first to be described as powerful inhibitors of NCX activity when the antiporter operates either in the forward or the reverse mode of operation (Fig. 5). These

Na⁺/Ca²⁺ Exchangers. Figure 3 Potential steps in the pharmacological regulation of NCX isoform expression and activity. This scheme reproduces the potential levels at which drugs can interfere with the transduction, transcription, translation, and activity of NCX.

Na⁺/Ca²⁺ Exchangers. Table 2 Drug families inhibiting the Na⁺/Ca²⁺ exchanger

Pharmacological Class	Drugs
Amiloride derivatives	CB-DMB, DCB, DMB
Substituted pyrrolidines	Bepidil
Isothiourea derivatives	KB-R7943
Ethoxyanilines	SEA0400
Benzofuran derivatives	Amiodarone
Quinazolinone derivatives	SM-15811
Thiazolidine derivatives	SN-6
Phenoxy pyridine derivatives	JP11092454
Nicotinamide derivatives	YM-244769
Piperidine derivatives	YM-252077
Ylacetamide derivatives	YM-270951
Peptides	XIP, Glu-XIP, FMRFa, FRCRCF
Small interference RNA	siRNA-NCX1, siRNA-NCX1, siRNA-NCX3
Antisense oligodeoxynucleotides	AS-NCX1, AS-NCX2, AS-NCX3
Inorganic cations	Ni ²⁺ , La ²⁺ , Gd ²⁺

compounds are reversible blockers and the inhibition is competitive with respect to Na⁺ ions. The compounds of the amiloride family bearing substituents on the

terminal guanidino hydrogen atom behave as a specific NCX inhibitor but are devoided of any effect on other antiporters such as Na⁺/H⁺ exchanger.

Na⁺/Ca²⁺ Exchangers. Table 3 Compounds stimulating the Na⁺/Ca²⁺ exchanger

Pharmacological Class	Drugs
Redox agents	DTT, GSH, Fe ²⁺ , O ₂ ⁻ and of Fe ³⁺ , H ₂ O ₂
Organic compounds	Diethylpyrocarbonate (DEPC)
Inorganic cations	Li ⁺
Agonists of GPCRs	α, β Agonists, histamine, 5HT _{2c} agonists, endothelin-1, angiotensin-II
Peptides	Insulin, concanavalin A
Neurotrophic factors	NGF

Molecular properties of drugs interacting with NCX

Drug	IC ₅₀ (μM)	Mode selectivity	Site of action	Site of action at Aminoacid level	Isoform specificity
Bepidil	8.1	Forward > reverse mode	f loop	—————	—————
CB-DMB	7.3	Forward, reverse mode	Na ⁺ binding site	—————	NCX1=NCX3 >NCX2
KB-R7943	1–2.5 > 30	Reverse > forward mode	α-2 repeat	Ala809, Val820, Gln826, Gly833, Asn839	NCX3>NCX2 >NCX1
SEA0400	0.05–0.09	Reverse > forward mode	TMS5, α-2 repeat XIP region	Phe213, Gly833, Tyr224, Tyr226, Tyr228, Tyr231	NCX1>NCX2

Na⁺/Ca²⁺ Exchangers. Figure 4 Molecular properties of drugs interacting with NCX. Scheme summarizing the potency, the mode of selectivity, the molecular site of action and the isoform specificity of drugs interfering with NCX activity.

More recently, Shigekawa's group screening a compound library for the inhibitions of Na⁺-dependent Ca²⁺ uptake identified an isothiourea derivative named KB-R7943 which, in the low micromolar range, is able to block the reverse mode operation of the antiporter, whereas concentrations 30 times higher are needed to inhibit the forward mode. Another peculiarity of this isothiourea compound is the different ability to block NCX activity depending on the gene product involved. In fact, NCX3 inhibition requires concentrations that are threefold lower than those necessary to inhibit NCX2 and NCX1. KB-R7943 interacts with α-2 repeat of the exchanger molecule at the level of Ala809, Val820, Gln826, Gly833, and Asn839. In light of these peculiar pharmacological properties, in the last 7 years, KB-R7943 has aroused a great deal of interest among investigators working on NCX activity. However, recent reports have shown that KB-R7943 also exerts an inhibitory effect on several other transport

mechanisms such as L-type voltage gated Ca²⁺ channels, and receptor-operated NMDA channels (Fig. 6).

In 2001, a new compound belonging to the ethoxyanilines family, SEA0400, was reported as being the most potent NCX inhibitor available at the time, IC₅₀ = 5–92 nM, with a predominant activity on NCX1, a lower affinity for NCX2 and no effect on NCX3. However, the specificity of SEA0400 on NCX activity has recently been questioned, since it can also interfere with Ca²⁺ movement across the cell membrane. In 2002, by screening benzyloxyphenyl derivatives, Iwamoto's group discovered the new compound SN-6, which differs from KB-R7943 only in the substituent of phenyl moiety. The presence of this phenyl group confers to this antiporter inhibitor a more selective action on NCX1 rather than NCX3. Using chimeric analysis and subsequent site-directed mutagenesis some critical aminoacid residues responsible of SN-6 inhibition in the XIP region of the antiporter have

Target gene	Sequence
NCX1	5'-TGAGACTTCCAATGTGTT-3'
NCX2	5'-TCGGAGTAGCTTC-3'
NCX3	5'-GCCATACACAAGAC-3'

been identified. Interestingly, SN-6 preferentially acts on the exchanger under ATP-depleted conditions [5].

Very recently, the further screening of new benzyloxyphenyl derivatives revealed a highly potent NCX inhibitor, named YM-244769. This orally bioavailable compound is more potent inhibiting NCX3 than NCX1 and NCX2 in the reverse mode, but it is not active on the forward mode of operation of the three antiporter isoforms. (Table 4)

Recently, two more selective strategies able to inhibit each of the three NCX gene products, has been introduced as pharmacological tool. These strategies consist in the antisense oligodeoxynucleotide technique and small interference RNA directed against mRNA sequence of NCX1, NCX2, and NCX3. With this potentially therapeutic approach it has been possible to discriminate the role played by each of the three NCX gene products in preclinical models of pathological states in which this antiporter is involved.

NaCl Cotransporter

The thiazide sensitive NaCl cotransporter (NCC) is the major pathway of NaCl entry in the distal convoluted tubule. Like NKCC2, NCC contains 12 putative transmembrane domains and long intracellular amino- and carboxy-tails. NCC and NKCC as well as the KCl cotransporter KCC are members of the same gene family and have considerable homology.

Definition

Sodium–hydrogen ion exchangers (►NHEs) are a family of membrane proteins present in most living organisms, from simple prokaryotes to complex eukaryotes. They mediate the exchange of protons for sodium ions across the plasma membrane and possibly also across organellar membranes, and thereby play a role in the regulation of pH homeostasis, cell volume and transepithelial sodium transport. Not surprisingly, Na⁺/H⁺ exchangers are implicated in many pathological processes including hypertension, congenital secretory diarrhoea and ischemia-reperfusion injury. Within the human genome there are nine distinct genes (SLC9A1–9) encoding sodium–proton exchangers [1]. The proteins are made up of ~800 amino acid residues and share a highly homologous amino-terminal transmembrane domain, predicted to be composed of 12 transmembrane helices, and a more divergent cytoplasmic carboxy terminus, as shown in Fig. 1. There is between 20% and 70% homology amongst the various exchanger isoforms.

Basic Characteristics

The exchange of cations for protons occurs through the transmembrane domain, whereas regulation (fine-tuning) of the exchanger is largely exerted by the C-terminal domain. NHEs are believed to form homodimers in the membrane.

The exchange of sodium ions for protons occurs with a 1:1 stoichiometry, and is thus an electroneutral event. Transport is a passive, energetically downhill event, not

requiring direct investment of metabolic energy. Nevertheless, physiological levels of ATP are required for optimal function of the exchanger. In its normal physiological (forward) mode, the process is driven by the inward sodium gradient, which is generated and maintained by the ►Na⁺-K⁺-ATPase (Na⁺-K⁺ pump), an ATP-dependent enzyme. Plasmalemmal NHEs can also translocate other monovalent cations such as lithium and ammonium, though at a slower rate. Potassium is not transported measurably by the plasmalemmal exchangers, but the organellar exchangers may utilise this cation, as suggested for isoform NHE7. Kinetically, NHEs obey simple Michaelis–Menten kinetics, displaying a hyperbolic dependence on extracellular sodium concentration, indicative of a single binding site for sodium. In contrast, they show greater-than-first-order dependence on the intracellular hydrogen ion concentration, suggesting allosteric regulation. Indeed, it is generally believed that NHEs possess an intracellular allosteric modifier site responsive to protons, in addition to the proton transport site. This type of allosteric regulation has been documented only for a couple of the plasmalemmal NHEs and may not apply to all the isoforms.

The activity of the NHEs is markedly reduced when ATP levels are depleted, even if the sodium gradient is maintained. Truncation mutants of NHE1 in which all the known phosphorylation sites are removed, still retain at least a partial responsiveness to ATP depletion. This can be explained in part by the dependence and likely association of NHE1 with phosphatidylinositol 4,5-bisphosphate (►PIP₂), a plasmalemmal lipid. Upon ATP depletion, PIP₂ is gradually depleted, resulting in decreased NHE1 activity. This type of regulation may not apply to all isoforms, several of which reside in membranes with undetectable low levels of PIP₂.

NHE1. This isoform was identified in 1989 and because of its ubiquitous distribution is thought to perform ‘housekeeping’ functions, maintaining intracellular pH and cell volume homeostasis [2]. NHE1 is found on the plasma membrane of virtually all mammalian cells, where it can seemingly accumulate in microdomains. In some cells, however, NHE1 is not present throughout the entire cell surface, reflecting a more specialised role for this isoform in particular cell types, such as epithelia. Thus, NHE1 activity is required for the secretory function of parotid acinar cells. In addition to its housekeeping and secretory roles, NHE1 has been suggested to regulate cell proliferation, migration and adhesion, and to confer resistance to apoptosis. These extra properties of NHE1 may be achieved through remodelling of the cortical actin cytoskeleton. In this regard, NHE1 is known to interact with proteins of the ERM (ezrin, radixin and moesin) family.

NHE1-deficient mice survive into the postnatal period but develop growth retardation, progressive

Na⁺/H⁺ Exchangers. Figure 1 Prototypical structure and transmembrane disposition of NHE. The amino (N) and carboxy (C) termini of the molecule are indicated.

neurodegeneration with ataxia and seizures, and have a high mortality before weaning. This phenotype is associated with a reduced steady-state intracellular pH and hyperexcitability of hippocampal neurons, but the precise molecular mechanisms responsible for the phenotype are as yet unknown.

Acute over-activation of NHE1 results in a marked elevation in intracellular sodium concentration with a subsequent increase in intracellular calcium, via the Na⁺/Ca⁺⁺ exchanger. This in turn triggers a cascade of injurious events that can culminate in tissue dysfunction and ultimately apoptosis and necrosis. This is commonly seen in organs such as the heart, brain and kidneys as a consequence of ischemia-reperfusion.

The regulation of NHE1 is complex and involves multiple growth factors and hormones [3]. Phosphorylation of NHE1 by various protein kinases, including Erk 1/2, p160ROCK and p38 alters the set-point of the allosteric modifier site, enabling the exchangers to remain active at more alkaline pH. In addition to phosphorylation, NHE1 activity is regulated by association with ancillary proteins. In this manner, calmodulin and carbonic anhydrase II stimulate NHE1. The calcineurin B homolog proteins (CHP) also regulate NHE1. The CHP1 isoform is felt to be inhibitory, while CHP2 activates NHE1, which is required for optimal exchanger activity. CHP proteins are constitutively phosphorylated and associated with NHE1. Their dephosphorylation can

result in disassociation from the exchanger, with accompanying changes in exchange activity.

NHE2. NHE2 is found predominantly in the apical membrane of epithelial cells of the gastro-intestinal tract and also in the kidney, especially in the tubules. Although it regulates bicarbonate excretion in the distal convoluted tubule of the kidney, this isoform appears to contribute mainly to the secretory function of certain glands. NHE2 knockout mice have decreased parotid gland secretion plus a significant loss of gastric parietal and zymogenic cells, but no apparent intestinal or renal absorptive defects.

The regulation of NHE2 is multifactorial. Chronic exposure to nitric oxide and gamma-interferon decrease NHE2 activity, whereas metabolic acidosis and chronic stimulation with epidermal growth factor (EGF) increase activity.

NHE3. This isoform, with NHE1, has been most extensively studied. NHE3 is found mainly in the apical membrane of renal tubular epithelial cells, particularly those of the proximal tubule, and also in the gut. Of note, this isoform is not detectable in the basolateral membrane. In addition to its presence in the apical plasma membrane, NHE3 is found also in subapical vesicles that are thought to traffic to and from the membrane, thereby contributing to the acute regulation of exchange activity by altering the density of surface-exposed exchangers. Proximal tubular NHE3 is

responsible for approximately two thirds of sodium reabsorption in the kidney and contributes significantly to the ability of the kidney to concentrate urine. NHE3-deficient (knockout) mice have diarrhoea, alkalinised intestinal contents, increased urine output, mild acidosis, reduced blood pressure and elevated serum aldosterone levels. A rare, but severe, congenital secretory diarrhoea is believed to be due to decreased NHE3 activity in the intestinal brush-border in humans. Abnormal NHE3 activity is also implicated in the development of hypertension, though the exact pathophysiology is not yet known. Similarly the role of NHE3 in renal ischemia-reperfusion injury has still to be fully established.

Regulation of NHE3 involves many hormonal and physical mechanisms. Acutely, NHE3 activity is promoted by an increase in intracellular pH and this response is rapid. Furthermore, the increase in activity is proportional to the duration of acidification. Chronic acidification promotes recycling of NHE3 from subapical endosomes to the plasma membrane.

NHE3 is phosphorylated in the basal state. There are phosphorylation sites for both ►protein kinase A (PKA) and ►protein kinase C (PKC). Phosphorylation brings about a change in the rate of traffic between the subapical endosomes and the plasma membrane. However, acute changes in NHE3 activity can occur without changes in the surface expression of NHE3. Cyclic AMP (cAMP) for example inhibits NHE3 activity without reducing the surface expression of the exchanger. Parathyroid hormone and dopamine exert their effects by increasing cAMP.

NHE3 is also regulated by accessory proteins. Na⁺/H⁺ exchanger regulatory factors 1 and 2 (NHERF 1 and 2) are proteins that are believed to tether NHE3 to the actin cytoskeleton via an additional linker protein, namely ezrin. Unlike NHE1, disruption of the actin cytoskeleton decreases NHE3 activity and this is, at least in part, mediated by the small GTP-binding protein, RhoA, which is also a major organiser of the actin cytoskeleton. As in the case of NHE1, proteins that bind to regions of the cytoplasmic tail such as CHP1, also regulate NHE3. A role of lipid rafts in the acute regulation of NHE3 has been proposed.

Chronic up-regulation of NHE3 is stimulated by glucocorticosteroids, aldosterone, thyroxine, butyrate and chronic acidosis, amongst others. These factors stimulate transcription of the NHE3 gene. Less well documented are the mechanisms involved in chronic down-regulation of NHE3, though gamma-interferon is known to inhibit exchanger activity and this may account for its effect in inflammatory bowel disease.

NHE4. NHE4 is also located in the epithelial cells of the kidney and gut, but is seemingly basolateral rather

than apical. Little is known regarding the role and regulation of this isoform but it probably has some functional overlap with NHE1. Knockout mice have no obvious phenotype, except for a slightly decreased gastric acid secretion and an abnormal-looking gastric mucosa on biopsy. The effect of NHE4 ablation on kidney function has not been firmly established.

NHE5. The distribution of this isoform is distinct, being in neuronal-rich areas of the central nervous system. Low levels have also been found in testis, spleen and skeletal muscle. Like the preceding isoforms, NHE5 is found in the plasma membrane and is internalised by clathrin-associated endocytosis into recycling endosomes. The normal role of NHE5 is unknown but its malfunction is speculated to contribute to the development of neurodegenerative disease.

Stimulation of PKA and PKC inhibit NHE5 activity, as does hyperosmolarity, resembling the responsiveness of NHE3. NHE5 may also be regulated by the actin cytoskeleton, but further work is required to validate this notion and clarify the exact mechanism.

NHE6–9. NHEs 6–9 are all intracellular exchangers and they are distributed ubiquitously, though NHE8 differs slightly from the others in that it has higher levels in skeletal muscle and kidney. NHE6 is located in early and recycling endosomes, NHE7 in the trans-Golgi network, NHE8 in the mid- and trans-Golgi stacks and NHE9 in recycling endosomes [4]. These isoforms are thought to contribute to the maintenance of organellar pH and volume homeostasis, but little direct evidence exists for these proposed functions. Virtually nothing is known about proteins that associate with the endomembrane NHEs and whether they or other factors contribute to regulation of ion exchange.

Drugs

The first inhibitor of NHE, ►amiloride, was identified in 1982. This drug is a potassium-sparing diuretic that also inhibits the sodium–calcium exchanger and the conductive Na⁺ channel. Not all the NHE isoforms are inhibited equally by amiloride: NHE1 and 2 are responsive, NHE5 is partially responsive and NHE3, 4 and 7 are resistant. Other weak and non-specific inhibitors are clonidine and cimetidine.

Inhibition of NHE1 offered the potential to attenuate cardiac damage, particularly during ischemia-reperfusion and cardiac failure and, with this aim, several new molecules were derived from amiloride. By substituting the nitrogen of the 5-amino group, pyrazines were created that are more potent than amiloride, and although they are more selective for NHE1, they still have some effect on other isoforms. These drugs include DMA, EIPA, MIBA and HMA [5].

Further modifications of amiloride, replacing the pyrazine ring with a phenyl moiety, the 6-chloro with a sulfomethyl group and the 2-amino with a methyl group, or deleting it completely, has resulted in the generation of the bezoylguanidines, such as HOE-694, ►cariporide (HOE-642), eniporide and BIIB-513. These compounds have no effect on the Na⁺/Ca⁺⁺ exchanger or the Na⁺ channels. They are more selective for NHE1 and have no effect on NHE3 or NHE5.

Thereafter, molecules have been synthesised with a bicyclic ring, such as a quinoline or an indole, inserted. Many of these compounds like zoniporide and BMS-284640 are selective NHE1 inhibitors, but some inhibit also other isoforms. Most recently, an additional group of compounds with 4-substituted (benzo[b]thiophene-2-carbonyl) guanidines has been synthesised and these are potent NHE1 inhibitors. A structurally distinct compound, S-3226, was found to be the first selective NHE3 inhibitor.

The potency of the inhibitors is affected by the pH. Changes in pH affect the protonation state of the guanidine. In conditions of low pH, such as in ischemia-reperfusion, some drugs such as cariporide work more efficiently because they are on average more positively charged.

Animal studies on the effects of these drugs in ischemia-reperfusion have been very promising and this has led to a rapid progression from animal studies to human trials of the drugs. Unfortunately the drugs have been less effective in large-scale human trials, particularly after a myocardial infarction. This may be due to administration of the drug too late in the pathological process. It seems that NHE1 inhibition is most cardio-protective in the ischemia stage and, when drugs are administered post-infarction the ongoing reperfusion causes damage that they cannot effectively counteract. Supporting this concept are the better results obtained in patients undergoing coronary artery bypass graft surgery. When the inhibitor was administered pre-operatively, fewer patients went on to have myocardial infarction compared to those who received placebo. There is currently a large trial underway to further assess this effect. The use of NHE1 inhibitors in heart failure is also currently under evaluation. Animal studies also suggest a beneficial role for NHE1 inhibition in the prevention of cerebral ischemia-reperfusion injury.

Evaluation of inhibition of the other isoforms is still in the preclinical stages. Inhibition of NHE2 with prostaglandin E2 or with amiloride hastens the re-establishment of barrier function after intestinal ischemic damage in pigs and the use of S-3226 in rats with renal ischemia improved outcomes. Further work examining the effect of inhibition of the other isoforms is still required.

Na⁺- and K⁺ activated Adenosine 5'-Triphosphatase

► Na⁺/K⁺-ATPase

Na⁺/K⁺-ATPase

G. SCHEINER-BOBIS, W. SCHONER
Institute of Biochemistry and Endocrinology, Justus Liebig University Giessen, Giessen, Germany

Synonyms

Na⁺/K⁺-ATPase; sodium pump; Sodium- and potassium-activated adenosine 5'-triphosphatase; EC 3.6.1.37.

Definition

The Na⁺/K⁺-ATPase is an integral protein of the plasma membrane of animal cells that transports Na⁺ and K⁺ ions against their electrochemical gradients energized by ATP hydrolysis. For every ATP molecule hydrolyzed the Na⁺/K⁺-ATPase moves 3 Na⁺ ions from the cytosol to the extracellular space in exchange for 2 K⁺ ions that are taken up from the extracellular medium. This uneven transport of positive charge – 3 out versus 2 in – is coupled with various elementary functions of the cell: (i) It substantially contributes to the formation and maintenance of the membrane potential of the cell, (ii) It contributes to the osmotic regulation of the cell volume, (iii) In higher organisms it provides the basis for neuronal communication, and (iv) It provides in all animal cells the driving force for the Na⁺ gradient-coupled secondary active transport systems.

Basic Characteristics

The Subunit Composition of Na⁺/K⁺-ATPase

The Na⁺/K⁺-ATPase belongs to the P-type ATPases, a family of more than 50 enzymes that also includes the Ca²⁺-ATPase of the sarcoplasmic reticulum or the gastric H⁺/K⁺-ATPase. ►P-Type ATPases have in common that during ion transport an aspartyl phosphointermediate is formed by transfer of the γ -phosphate group of ATP to the highly conserved sequence DKTGS/T [1].

The Na⁺/K⁺-ATPase is an oligomeric protein that consists of α and β subunits. Four different isoforms of the α subunit ($\alpha 1$, $\alpha 2$, $\alpha 3$, and $\alpha 4$) have been identified with relative molecular masses varying between 100 and 113 kDa. They cross the membrane 10 times, forming transmembrane domains M1 to M10, and both amino and carboxy termini are localized on the cytosolic side [1]. The three β subunit isoforms ($\beta 1$, $\beta 2$, and $\beta 3$) identified thus far are highly glycosylated proteins of about 60 kDa, with the mass of the protein moiety ranging from 36–38 kDa. The β subunit crosses the membrane only once, and the amino terminus is localized on the intracellular side of the membrane. Next to the α and β subunits, which are absolutely required for catalytic activity, a third cytosolic peptide of 7–11 kDa, referred to as the γ subunit, appears in some tissues to be involved in regulating the activity of Na⁺/K⁺-ATPase by influencing its interactions with ATP, ouabain, and Na⁺ or K⁺ ions. The quaternary structure Na⁺/K⁺-ATPase with all three subunits has been recently resolved [2].

Na⁺/K⁺-ATPase Acts as a Sodium-Potassium Pump

The catalytic cycle of the Na⁺/K⁺-ATPase can be described by juxtaposition of distinct reaction sequences that are associated with two different conformational states termed E₁ and E₂ [1]. In the first step, the E₁ conformation is that the enzyme binds Na⁺ and ATP with very high affinity (K_D values of 0.19–0.26 mM and 0.1–0.2 μ M, respectively) (Fig. 1A, Step 1). After autophosphorylation by ATP at the aspartic acid within the sequence DKTGS/T the enzyme occludes the 3 Na⁺ ions (E₁-P(3Na⁺); Fig. 1a, Step 2) and releases them into the extracellular space after attaining the E₂-P 3Na⁺ conformation characterized by low affinity for Na⁺ ($K_{0.5}$ = 14 mM) (Fig. 1a, Step 3). The following E₂-P conformation binds 2 K⁺ ions with high affinity (K_D approx. 0.1 mM; Fig. 1a, Step 4). The binding of K⁺ to the enzyme induces a spontaneous dephosphorylation of the E₂-P conformation and leads to the occlusion of 2 K⁺ ions (E₂(2K⁺); Fig. 1a, Step 5). Intracellular ATP increases the extent of the release of K⁺ from the E₂(2K⁺) conformation (Fig. 1a, Step 6) and thereby also the return of the E₂(2K⁺) conformation to the E₁ATPNa conformation. The affinity of the E₂(2K⁺) conformation for ATP, with a $K_{0.5}$ value of 0.45 mM, is very low.

Drugs

The Na⁺/K⁺-ATPase as the Molecular Target for Cardiotonic Steroids (CTS) and Palytoxin

A vast number of toxins that specifically interact with the Na⁺/K⁺-ATPase and inhibit its catalytic activity have been isolated from various plants and animals (Fig. 2). The biggest group is constituted by substances referred to as cardiotonic steroids (CTS; also named cardiac glycosides or cardiac steroids) since their application, especially of digitalis and its congeners, help to treat chronic heart failure (NYHA II and IV), tachycardia, and dilatative cardiomyopathy. Treatment with low concentrations of digoxin significantly reduces mortality and hospitalization of patients with heart failure. This effect is believed to be due to a partial inhibition of Na⁺/K⁺-ATPase (Na⁺-lag hypothesis), possibly by indirectly inducing an elevation in the Ca²⁺ concentration in the myocardium. Nevertheless, other mechanisms are probable (see below).

The Na⁺/K⁺-ATPase is the only enzyme known to interact with CTS, which reversibly bind to the extracellular side of the Na⁺/K⁺-ATPase at the E₂-P conformational state [E₂-P* ouabain] and inhibit ATP hydrolysis and ion transport (Fig. 1b, step 4).

Besides CTS, the highly toxic palytoxin (LD₅₀ for rodents is 10–250 ng/kg), produced by corals of the genus *Palythoa*, is also a highly specific inhibitor of Na⁺/K⁺-ATPase (Fig. 2) [1]. Unlike the CTS, however, which stop ATP hydrolysis and ion flow, palytoxin, by binding to either the E₁ or the E₁-P conformation (Fig. 1c, steps 1 or 2, respectively), converts the sodium pump into an ion channel with a conductance of approximately 10 pS by arresting its natural ion-conducting structure in a permanently open conformation that allows K⁺ to flow down its concentration gradient out of the cell (Fig. 1c, step 3). Thus, the reason for the high toxicity of palytoxin might be associated with the outflow of K⁺, the collapse of the membrane potential, and the ensuing loss of basic cell functions. In addition, depolarization is a key event that affects numerous secondary systems. Thus, the concentration of Ca²⁺ becomes elevated in several organs through the opening of Ca²⁺ channels and leads to the production of inositol trisphosphate, the activation of phospholipase A₂ and metabolism of arachidonic acid, and numerous other physiological responses that all stem from the increased Na⁺ influx and the ensuing increase in the concentration of cytosolic Ca²⁺ that accompany the initial K⁺ outflow. The strong tumor-promoter activity of palytoxin might be associated with these events [3].

Na⁺/K⁺-ATPase Acts as Signal Transducer of Endogenous Cardiac Glycosides

The most popular assumption for the action of cardiac glycosides is that an inhibition or partial inhibition may induce inotropy of the heart by raising intracellular

cytosolic Ca²⁺ ([Ca²⁺]_i) via a coupling of Na⁺/K⁺-ATPase with the Na⁺/Ca²⁺ exchanger (NCX; Fig. 3). This Na⁺ lag hypothesis has been recently modified: It is assumed that an inhibition of the sodium pump by

cardiac glycosides may lead to a local increase of Na⁺ in a tiny reactive space between the plasmalemma and the endoplasmic/sarco-plasmic reticulum (ER/SR) in smooth muscle cells and astrocytes, which has been

Na⁺/K⁺-ATPase. Figure 1 (Continued)

Na⁺/K⁺-ATPase. Figure 1 (a) Reaction cycle of Na⁺/K⁺-ATPase. The enzyme binds Na⁺ and ATP in the E₁ conformational state (Step 1) and becomes phosphorylated at an aspartate residue by the γ-phosphate of ATP. This results in occlusion of 3 Na⁺ ions (Step 2) followed by their release to the extracellular space (Step 3). This new conformational state, termed E₂-P, with low affinity for Na⁺ and high affinity for K⁺ binds K⁺ (Step 4) and occludes the cation after dephosphorylation (Step 5). Binding of ATP with low affinity to the E₂(2K⁺) state leads to K⁺ being released to the cytosol (Step 6). The dashed box highlights the electrogenic steps of the catalytic cycle. (b) Binding of CTS to the sodium pump. CTS bind preferentially to the E₂-P conformation of the enzyme and inhibit ATP hydrolysis and ion transport. (c) Binding of palytoxin to Na⁺/K⁺-ATPase. Palytoxin (PTX) binds either to the E₁ or to the E₁-P conformation of the enzyme and arrests the natural ionophore of the sodium pump in a permanently open state (step 3), resembling the situation of an activated ion channel. Like the latter, the palytoxin-enzyme complex also allows Na⁺ or K⁺ cations to flow down their concentration gradients. The dotted line around the phosphate indicates that phosphorylation is not absolutely required.

named *plasmERosome* (Fig. 3) [4]. This may explain why a partial inhibition of the sodium pump isoforms α₂ and α₃ located here results in a small, transient increase in the sub-plasmalemmal Na⁺ concentration, which activates NCX1 and leads to a small local rise of Ca²⁺. This, in turn, stimulates the release of more Ca²⁺ from the ER/SR to the cytoplasm. In arterial smooth muscle cells this pathway is postulated to lead to arteriolar contraction and might be one of the reasons for essential hypertension.

Nevertheless, numerous recent investigations prove that interaction of CTS with the Na⁺/K⁺-ATPase located in caveolae at the plasma membrane leads to a series of events that trigger various intracellular signaling cascades. The same results are also obtained when CTS interact with nonpumping sodium pump mutants [5], indicating that a local [Na⁺] elevation followed by a [Ca²⁺]_i rise is not necessarily required for the induction of the signaling process. In addition, CTS-induced signaling events might differ depending upon the cell

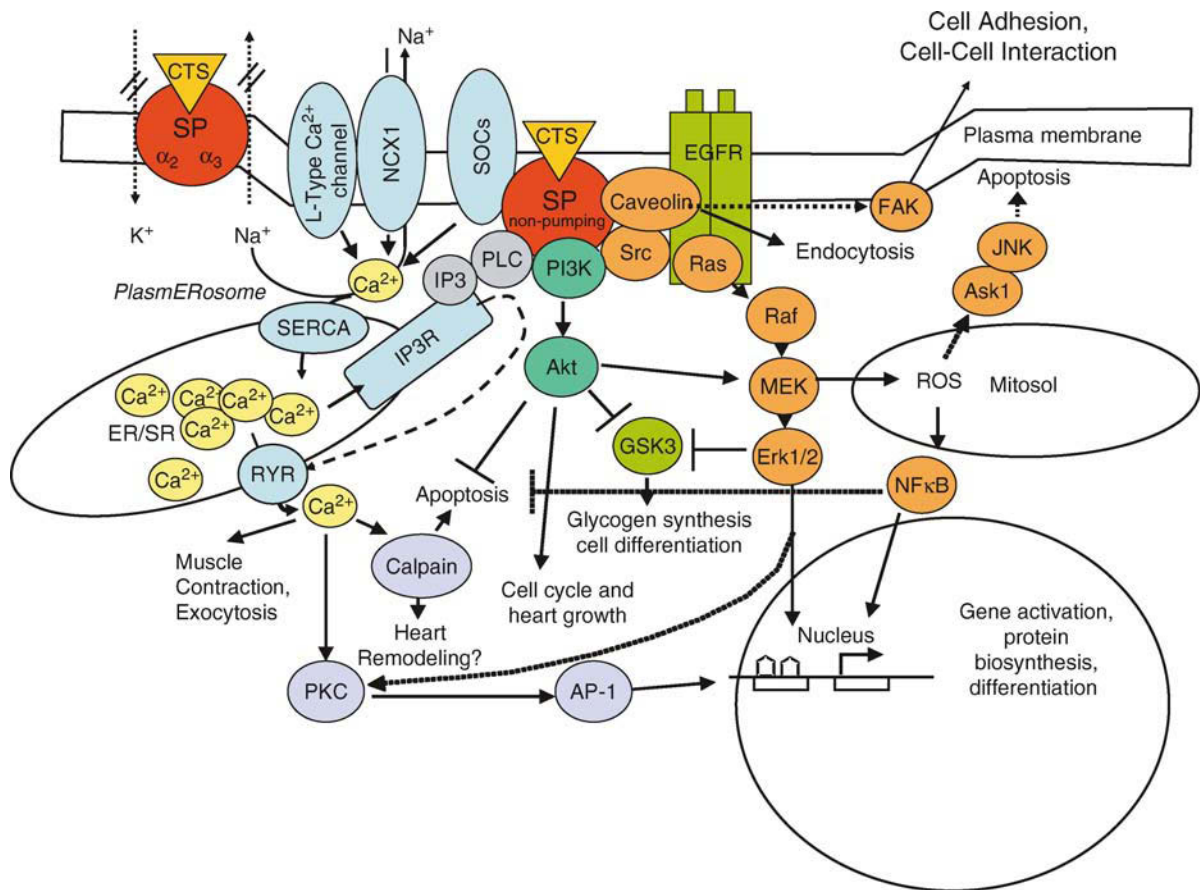

type and the nature of the CTS used. Figure 3 summarizes a series of signaling cascades proposed to explain the results from numerous investigations in various tissues. Thus, binding of CTS leads to a direct interaction of the amino-terminal end of the catalytic α subunit of Na⁺/K⁺-ATPase with the inositol trisphosphate (IP₃) receptor protein of the ER/SR and/or with phospholipase C (which raises IP₃ levels) leads subsequently to a rise of [Ca²⁺]_i. This promotes a positive inotropy of the heart, arterial smooth muscle contraction, exocytosis, and leads to **remodeling of the heart**. Additionally, such effects may be induced by direct interaction of Na⁺/K⁺-ATPase within the plasma membrane with L-type Ca²⁺ channels. Elevated [Ca²⁺]_i leads to an activation of protein kinase C (PKC), which activates cardiac genes via **transcription factor AP-1**. This may lead to cardiac hyperplasia. Besides these possibilities, CTS may activate via the Na⁺/K⁺-ATPase-Src-caveolin-epidermal growth factor complex the Ras-Raf-MEK-ERK1/2 pathway. CTS-induced

Na⁺/K⁺-ATPase. Figure 2 Specific Inhibitors of Na⁺/K⁺-ATPase. (a) Endogenous cardiac glycosides identified in mammals. Substances with a 5-membered lactone at position C17 of the steroid moiety are referred to as cardenolides, those with a 6-membered lactone as bufadienolides. (b) Palytoxin (C₁₂₉H₂₂₃N₃O₅₄) produced by corals of the genus *Palythoa*.

activation of the Ras-Raf-MEK-ERK1/2 pathway may also activate the formation of reactive oxygen species (ROS) in mitochondria that stimulate nuclear factor κB (NFκB). In kidney tubule and heart cells, activation of

genes by this route leads to differentiation of the tissue. In tumor cells, cardiac glycosides activate apoptosis via Ask1 and JNK, leading thereby to cell death, whereas in heart and kidney cells stimulation of ROS formation

Na⁺/K⁺-ATPase. Figure 3 Mechanism of action of exogenous and endogenous cardiac glycosides via the sodium pump in the plasmERosome and in the signalosome. The Na⁺ lag hypothesis assumes the existence of a sub-plasmalemmal space called the PlasmERosome. A cardioactive steroid (CTS)-dependent transient local rise of [Na⁺]_i in this compartment caused by stimulation of store-operated channels (SOC) or by CTS-dependent inhibition of α₂ and α₃ sodium pump subunits may subsequently lead to a local rise of [Ca²⁺]_i. This signal is amplified by filling up the sarco/endoplasmic reticulum (SR/ER) via the sarcoplasmic Ca²⁺-ATPase (SERCA) to a higher extent with Ca²⁺. Any agonist-stimulated Ca²⁺ release leads to an amplified Ca²⁺ release via the inositol tris-phosphate receptor (IP₃R) that stimulates the opening of the ryanodine Ca²⁺ channel (RYR), thus resulting in a higher degree of vasoconstriction. In a non-inhibited Na⁺/K⁺-ATPase Ca²⁺ in the PlasmERosome will be extruded by the Na⁺/Ca²⁺ exchanger (NCX1) and the plasmalemmal Ca²⁺-ATPase. When Na⁺/K⁺-ATPase acts as a signalosome in caveolae, endogenous and exogenous CTS induce various signal transducing pathways, even with a non-pumping enzyme. The abbreviations used are: AP-1 (activator protein 1), Ask-1 (apoptosis signal-regulating kinase 1), ERK 1/2 (extracellular signal-regulated kinases 1 and 2), FAK (focal adhesion kinase), GSK3 (glycogen synthase kinase 3), IP₃ (inositol (1,4,5) trisphosphate) IP₃R (IP₃ receptor), JNK (c-Jun N-terminal kinase), MEK (mitogen activated ERK-activating kinase, a MAP kinase), MKK (MAP kinase kinase), NCX1 (Na⁺/Ca²⁺ exchanger), NF-κB (nuclear factor κB), PI3K (phosphoinositide 3Y-kinase), PKC (protein kinase C), PLC (phospholipase C), Raf (Raf, a MAPK kinase kinase), Ras (a MAP kinase kinase), ROS (reactive oxygen species), SOC (store-operated Ca²⁺ channel), Src (sarcoma kinase), SP (sodium pump).

leads to the activation of NFκB and inhibition of apoptosis. The amino terminal end of the α subunit of Na⁺/K⁺-ATPase also interacts with phosphatidylinositol 3Y-kinase (PI3K). CTS binding to Na⁺/K⁺-ATPase may thus activate protein kinase B (Akt), which induces hypertrophy of the tissue and blocks apoptosis simultaneously. Akt also inactivates glycogen synthase kinase (GSK-3 α/β), which stimulates glycogen

synthesis and is a master switch in regulating cell fate, specificity, and tumorigenesis. Binding of CTS to the Na⁺/K⁺-ATPase-Src-caveolin-epidermal growth factor complex stimulates the focal adhesion kinase (FAK), which alters cell adhesion and cell-cell interactions but also induces the endocytosis of Na⁺/K⁺-ATPase. This may then lead to the degradation of CTS. It is unclear whether the sodium pump is able to be recycled.

Endogenous Cardiac Glycosides Act as Hormones

A great number of recent investigations have provided evidence for the existence of endogenous cardiac glycosides in animals that act as hormones at nanomolar concentrations [4]. Cardiac glycosides are steroid derivatives with an unsaturated lactone ring at the C17 position. Cardenolides and bufadienolides are generally considered to be of plant origin. However, bufadienolides have been known for a long while to be synthesized by amphibians. Recently, cardiac glycosides were isolated and identified in mammals (Fig. 1). The

Ouabain antagonist
Rostafuroxin (PST 2238)

Na^+/K^+ -ATPase. **Figure 4** Ouabain antagonist.

cardenolide ouabain was isolated from human blood and bovine adrenal glands and hypothalamus. Digoxin was isolated from urine of humans not being treated with this drug. The bufadienolides marinobufagenin, telocinobufagenin and 19 norbufalin were isolated from human fluids and tissues. There is a high probability that the zona fasciculata cells of the adrenal cortex, and possibly also the hypothalamus, are able to synthesize cardenolides. An adrenal tumor secreting ouabain and producing hypertension has been described. Na^+ -dependent release of ouabain, angiotensin II, endothelin, and catecholamines from cells of the midbrain may stimulate the release of endogenous ouabain from adrenal glands. An increase of sympathetic tone in stress and physical exercise leads to a rapid rise of endogenous ouabain and to a rapid fall after discontinuation. A constant and small rise of ouabain plasma concentrations (in the nanomolar concentration range, either from endogenous or exogenous sources) leads to arterial hypertension and remodeling of the heart and the arterial wall. Fifty percent of Caucasians with uncomplicated arterial essential hypertension and low plasma renin activity have been shown to exhibit elevated concentrations of endogenous ouabain. Possibly, endogenous digoxin, whose biosynthesis has

Na^+/K^+ -ATPase. **Figure 5** Cardiac glycosides and their derivatives with anti-cancer action.

also been demonstrated to take place in the adrenal gland, counteracts the secretion of endogenous ouabain from midbrain cells and lowers the sympathetic tone. This suppressive effect of digoxin could represent a very important mechanism for the therapeutic action of exogenously applied digoxin as well. There is good evidence that the secretion of the bufadienolide marinobufagenin from adrenal glands is activated via angiotensin II and catecholamines from the adrenal glands when the Na⁺ concentration increases in midbrain and hypothalamus. Marinobufagenin and telocinobufagenin are also elevated in essential hypertension. Contrary to the case with other cardenolides, marinobufagenin shows a natriuretic action on kidney tubular cells containing mainly the α_1 isoform of Na⁺/K⁺-ATPase [4].

Rostafuroxin, a Cardenolide Derivative with Antihypertensive Action

If 50% of Europeans with essential hypertension are affected by this disease because of an elevated secretion of endogenous ouabain, then there might be a chance to block its interaction at the cardiac glycoside binding site of Na⁺/K⁺-ATPase and thus lower blood pressure. This therapeutic approach seems to be successful. Recent studies provide evidence that the cardenolide analogue Rostafuroxin (PST 2238; Fig. 4) at very low concentrations can overcome the ouabain-induced rise of hypertension in experimental animals [6]. This compound has recently entered the phase I of clinical trials and is certainly a prototype of a new class of antihypertensive drugs.

Cardiac Glycosides as Anti-Cancer Agents

There is increasing evidence that proliferation of cancer cells is affected by cardiac glycosides and that the extent of this effect depends on the nature of the steroid derivative and on the cancer cell line used. Thus, digitalis or ouabain have been shown to induce apoptosis in human breast cancer or neuroblastoma cells, respectively, while bufalin and the class of the more hydrophobic cardenolides like digoxin, olean-drin, and the 2''-oxovoruscharin and its derivative UNSB1450 (Fig. 5) have been shown in vitro and in vivo to have anti-cancer activity primarily in leukaemia, lymphoma, melanoma, and ovarian and prostate cancer cells. These new investigations point toward new fields of research with the perspective of evaluating a potential introduction of CTS as anti-cancer agents in the treatment of malignancies. UNSB1450 seems especially to have a prospective benefit for cancer therapy. The compound has entered phase I clinical trials in Belgium [7].

Na⁺ K⁺ 2Cl⁻ Cotransporter

N

The bumetanide-sensitive Na⁺, K⁺, 2Cl⁻ cotransporter (NKCC) mediates the electroneutral uptake of chloride across epithelial cell membranes and is found in both absorptive and secretory epithelia (airways, salivary gland). NKCC exists in two isoforms, the secretory isoform NKCC1, and the absorptive isoform NKCC.

NKCC is a heavily glycosylated protein with 12 putative membrane-spanning regions. Thirty percent of the sodium that is filtered by renal glomeruli is reabsorbed by Na-K-2Cl cotransport in the ascending limb of Henle in the nephron. Na-K-2Cl cotransport is a target of all loop diuretics.

Narcolepsy

Narcolepsy is a chronic neurological disorder caused by the brain's inability to regulate sleep-wake cycles normally. At various times throughout the day, people with narcolepsy experience fleeting urges to sleep. If the urge becomes overwhelming, patients fall asleep for periods lasting from a few seconds to several minutes. The daytime sleep attacks are often accompanied by catalepsy, a sudden loss of muscular tone as usually observed during REM sleep, causing the patient to physically collapse. In a similar way, during the night, the patients have difficulty in maintaining *sleep continuity*. Thus, narcolepsy describes a disorder in which the affected individuals experience frequent and unpredictable transitions between wakefulness and sleep. The disorder has been linked to dysfunction in the *orexin* system, which in healthy individuals is (among other roles) responsible for stabilising the sleep/wake states.

Natriuretic Peptides

Natriuretic peptides are a family of peptide hormones. All of them contain a 17-amino acid long ring that is closed by a disulfide bond between two cysteine residues. ANP (atrial natriuretic peptide) is mainly expressed in the atria of the heart, whereas BNP (B-type natriuretic peptide) is synthesized in the ventricular myocardium. CNP occurs mainly in the endothelium and is thought to have a paracrine function. ANF and BNF lower blood pressure by a direct effect on smooth muscle and on the salt retention in the kidney. Natriuretic peptides bind and activate particulate guanylyl cyclases.

Natural Killer Cells

Large granular lymphocytes, not belonging to either the T- or B-cell lineage. Natural killer (NK) cells are considered part of the innate defense system since, in contrast to cytotoxic T-cells, they are able to kill certain tumor cells *in vitro* without prior sensitization. The basal activity of NK cells increases dramatically following stimulation with type I IFNs. In addition, NK cells display Fc-receptors for IgG and are important mediators of Antibody-Dependent-Cell-mediated-Cytotoxicity (ADCC).

Necrosis

Necrosis is a form of cell death, which involves multiple cells at the same time, all of which share a similar susceptibility. For example, blockage of an artery to an organ leads to anoxia to all of the cells of the tissue and leads to the death of these cells, which is called necrosis. Necrosis can also be seen in response to pharmacologic agents at very high doses, such as suicidal doses of acetaminophen. The process of cell death by necrosis can share some mechanisms with that of single cell death or apoptosis. For example, when similar cytotoxic drugs are given at much lower doses, single cells die by apoptosis rather than by necrosis. Another example is when the cell death process leads to depletion of ATP as it does with apoptosis and then extends to a secondary aggravation of the mitochondrial lesions leading to more extensive ATP depletion, which causes multiple cells to die synchronously; this is called necrosis.

Nephrogenic Diabetes Insipidus

In nephrogenic diabetes insipidus the kidney's ability to respond to AVP is impaired by different causes, such as drugs (e.g. lithium), chronic disorders (e.g. sickle cell disease, kidney failure) or inherited genetic disorders (X-linked or autosomal NDI). This type of diabetes insipidus can not be treated by exogenous administration of AVP or AVP analogues. Instead, diuretics (hydrochlorothiazide combined or not with amiloride) and NSAI (indomethacin) are administered to ameliorate polyuria.

Neuraminidase Inhibitors

Neuraminidase inhibitors are the major class of drugs to treat or to prevent the infection with influenza viruses. Currently, two neuraminidase inhibitors are available, zanamivir and oseltamivir, which block the release of new influenza virus from infected host cells and thereby stop the spread of infection. The enzyme neuraminidase is a surface glycoprotein present on all influenza viruses. There are nine influenza neuraminidase subtypes known of which subtypes N1 and N2 appear to be the most important ones. Neuraminidase inhibitors are effective against all neuraminidase subtypes. The activity of the neuraminidase is required for the newly

formed virus to detach from the host cell. To achieve that, neuraminidase cleaves terminal sialic acid residues from carbohydrate moieties on surface proteins of the host cell to which the newly formed virus particles are attached. This cleavage then results in the release of the viruses which are now able to infect other cells. Neuraminidase inhibitors are generally well tolerated. While zanamivir has to be administered by inhalation, oseltamivir can be given orally.

Neuregulin

Neuregulins are a complex family of factors consisting of neuregulins-1, -2, -3 and -4, that perform many functions during morphogenesis of various organs. Neuregulins exert their effects by activating the ErbB-family of receptor tyrosine kinases. While neuregulin-1 and -2 bind both ErbB3 and ErbB4, neuregulin-3 and -4 bind only ErbB4. Neuregulin-1 is also known as “neuro differentiation factor” or “heregulin” .

Neurodegeneration

Medical College of Georgia, Augusta, GA, USA

Synonyms

Neuronal cell deterioration; Neuronal cell death

Definition

Neurodegeneration refers to the processes whereby damaged neuronal cells deteriorate or degenerate and eventually die.

Since the body’s ability to replace lost neurons (i.e., such as via neurogenesis) is quite limited when compared to many nonneuronal cells, degenerative processes affecting neurons can be quite devastating.

Basic Mechanisms

The basic mechanisms underlying the neuronal cell degeneration and death observed in the neurologic disorders as diverse as Alzheimer’s disease and stroke have not been fully elucidated. However, a number of distinct factors and processes clearly contribute to neurodegeneration including increased oxidative stress and free radical damage, impaired mitochondrial function, excitotoxicity, immunologic and inflammatory mechanisms, impaired trophic factor support, and altered cell signaling. In the process of neuronal degeneration, cells eventually die as a result of one of two processes, apoptosis or necrosis.

Necrosis

Necrosis (sometimes referred to as cellular dissolution) occurs as a pathological response to cell injury most commonly resulting from trauma, ischemia, hypoxia, neurotoxins, or infection. Necrosis occurs when a cell is too severely damaged for the orderly energy-dependent process of apoptosis (see below) to occur. Following one or more of the insults listed above, neuronal degeneration or death occurs in groups of contiguous cells in a localized region and the initiation of inflammatory processes can be clearly observed in tissue sections [1]. In the process of necrosis, an initial swelling of the cell occurs (Fig. 1 and Table 1), little or no chromatin condensation is evident, mitochondria and other organelles swell and rupture, the plasma membrane lyses, and spillage of the cellular contents into the extracellular space follows. A general inflammatory response is then triggered and macrophages attack and phagocytize the cellular debris.

Apoptosis

Neuronal apoptosis (old Greek term for dropping off, like leaves in the fall) is triggered by a number of factors including lipid peroxidation (and membrane damage) induced by reactive oxygen species, genetic mutation, or DNA damage (or degradation) resulting from radiation or other destructive agents. A loss of trophic factor support, as well as some of the same factors that induce necrosis (see above) can also initiate apoptotic processes. Cell death by apoptosis also occurs extensively during the development of the mammalian nervous system and is required for the formation of appropriate connections between neurons and their

Neurodegeneration. Figure 1 Illustration of the major cellular changes observed in neuronal necrosis. A normal neuronal cell (a) when exposed to an insult (e.g., trauma, ischemia, hypoxia, neurotoxins, infection, etc.) initially swells (b), mitochondria and other organelles swell and rupture, the plasma membrane lyses (c), and spillage of the cellular contents into the extracellular space follows. A general inflammatory response (d) is then triggered and macrophages attack and phagocytize the cellular debris.

Neurodegeneration. Table 1 Comparison of necrosis and apoptosis

targets. The processes involved in apoptosis differ from necrosis (Table 1) in several important details, most notably, that neuronal death with apoptosis usually involves individual cells that are phagocytized before they can release their cytoplasmic contents and induce an inflammatory response in adjacent tissues, and

phagocytes are able to recognize dying or degenerating cells by their expression of death related cell surface epitopes. Furthermore, mitochondria are preserved until the late stages of apoptosis, whereas they swell and disintegrate early in necrosis. Figure 2 illustrates the major cellular changes observed in neuronal apoptosis. A normal neuronal cell (a) when exposed to specific triggers (e.g., lipid peroxidation, genetic mutation, DNA damage, excitotoxic injury, etc.) initially shrinks, chromatin becomes pyknotic (more dense) and condenses, then migrates to the nuclear membrane, DNA fragmentation and degradation occurs, and several organelles disappear (e.g., Golgi apparatus, endoplasmic reticulum). Afterwards, blebbing of the plasma membrane occurs (c), the cell then fragments into small apoptotic bodies that are subsequently phagocytosed and digested (d) without triggering inflammation.

As mentioned above, neuronal apoptosis serves a number of important roles in normal brain development and is a key mechanism by which defective or damaged neurons are removed from the brain. However, in a number of brain disorders including Alzheimer's disease, Dementia with Lewy bodies, and Parkinson's disease, inappropriate apoptosis may occur leading to accelerated neuronal loss and progressive disease symptoms. On the other hand in neural tumor cells, such as neuroblastoma and medulloblastoma cells, apoptotic pathways may be disabled and the cells become resistant to chemotherapeutic drugs that kill cancer cells by inducing apoptosis. Neuroblastoma and medulloblastoma are important pediatric solid tumors that arise in the sympathetic neuron lineage and cerebellum, respectively. Apoptosis may be accelerated or retarded by a variety of hormones, metabolic byproducts, electrolytes, and other endogenous substances. For example, altered serum levels of thyroid hormone or ammonia, altered plasma or extracellular levels of excitatory amino acids such as glutamate and aspartate, imbalances of calcium and other electrolytes, and lactic acidosis are all known to initiate or modify apoptotic processes. Apoptosis is also influenced by synaptic communication in both the central and peripheral nervous systems. For example, in transsynaptic degeneration, neurons deteriorate and often undergo apoptosis if they fail to be innervated (from the afferent side) due to the loss of presynaptic neurons. This process has been observed in the lateral genicular body after optic nerve lesions and in the inferior olivary nucleus after destruction of the central tegmental tract. Efferent, motor neurons degenerate if they fail to match with target muscle fibers or their muscle targets are lost, such as after amputation of a limb.

There is an increasing body of evidence that supports an apoptosis–necrosis cell death continuum. In this continuum, neuronal death can result from varying contributions of coexisting apoptotic and necrotic mechanisms [2]. Therefore the distinct designations

above (necrosis vs. apoptosis) are beginning to blur. [Table 1](#) provides an overview of the major differences between necrosis and apoptosis.

Regulation of Apoptosis

Apoptosis is regulated by a complex molecular cascade that controls the activation of a family of cysteine proteases known as caspase proteins (caspases 1–14). Caspases are responsible for breaking down vital structural and functional proteins, leading to the characteristic cytomorphology associated with apoptosis. While multiple molecular pathways (e.g., mitochondrial, death receptor, endoplasmic reticulum pathways) have been identified that lead to the activation of caspases, the mitochondrial (intrinsic) pathway is most associated with neuronal apoptosis. The mitochondrial pathway regulates caspase activity by controlling mitochondrial release of cytochrome *c* by pro- and antiapoptotic members of the Bcl-2 family of proteins. These proteins interact through dimerization in the mitochondrial membrane. The ratio of proapoptotic (e.g., Bax, Bad) to antiapoptotic (e.g., Bcl-2, Bcl-XL) protein levels is a key determinant in regulating cytochrome *c* release and subsequent caspase activation. For example, high Bax/Bcl-2 and Bax/Bcl-XL ratios promote cytochrome *c* release while low Bax/Bcl-2 and Bax/Bcl-XL ratios inhibit cytochrome *c* release. Downstream of mitochondria, cytochrome *c* forms a complex with caspase-9 and Apaf-1 to form the apoptosome. This complex cleaves procaspase-3 to form activated

caspase-3, which can initiate cellular disassembly. While caspase-3 is known as a downstream effector caspase, its activity can still be inhibited by members of the inhibitor-of-apoptosis (IAP) protein family (e.g., XIAP); XIAP is itself potentially inhibited by Smac/Diablo, a mitochondrial protein (reviewed [5] [3]).

As noted above, apoptotic activity can be triggered by a broad array of stimuli including oxidative stress (e.g., ischemia, hypoxia), proinflammatory cytokines, excitotoxicity, neurotrophin withdrawal, mitochondrial dysfunction, and abnormal intracellular calcium concentrations. A number of these stimuli can alter Bcl-2 family protein expression via potent regulatory genes such as *p53* and *par-4* in order to promote cytochrome *c* release and induce caspase-3 activation. Increased neuronal apoptosis has been demonstrated in classic neurodegenerative disorders including Alzheimer's disease. Interestingly, these disorders are also characterized by alterations in apoptotic regulatory proteins including several Bcl-2 family proteins and caspases. For example, Bcl-2 and caspase-3 are increased in Alzheimer's cortex. These increases are thought to be due to a compensatory upregulation in response to the neurodegenerative process. In contrast, lower Bcl-2 levels have been reported in frontal cortex in patients with autism, a classic neurodevelopmental disorder. Accumulating data suggest important roles for apoptotic pathways in the pathophysiology of a spectrum of neuropathological disorders (reviewed [5] [3]).

Localized Apoptotic Activity in Synapses and Neurites

Although caspase activation is often considered a precursor to rapid cell death, the emerging concept of synaptic or neuritic apoptosis suggests that apoptotic activation can be localized to synapses or distal neurites without inducing immediate neuronal death or involving the neuronal cell body ([Fig. 3](#)). Localized apoptotic mechanisms may lead to the release of cytochrome *c* from the mitochondria and an increase in the concentration of activated caspase-3 in a presynaptic terminal that is synapsing on a dendritic spine. Increased caspase-3 activity results in a localized breakdown of this nerve terminal and its synapse. Subsequently, the postsynaptic dendritic spine retracts and disappears. This process could also begin in the postsynaptic dendritic spine. Although mitochondria are usually not found in dendritic spines, dendritic mitochondria may release cytochrome *c* which can then diffuse into the dendritic spine. A dendritic spine-localized increase in caspase-3 activity could subsequently eliminate the spine. In Alzheimer's disease, this form of synaptic loss is thought to contribute to the initial cognitive decline that predates the onset of large-scale neuronal death. In the peripheral and central nervous systems, developmental and injury-induced synapse elimination has

Neurodegeneration. Figure 3 Illustration of synaptic (neuritic) apoptosis. A pyramidal neuron is depicted with cortical afferents synapsing on its dendrites. Localized apoptotic mechanisms lead to the release of cytochrome c from the mitochondria and an increase in the concentration of activated caspase-3 in a presynaptic terminal that is synapsing on a dendritic spine. Increased caspase-3 activity results in a localized breakdown of this nerve terminal and its synapse. Subsequently, the postsynaptic dendritic spine retracts and disappears (Figure modified from Glantz et al. [5] [3]).

been hypothesized to occur via axon retraction after the postsynaptic cell either withholds trophic support or actively promotes synaptic breakdown. Interestingly, caspase-3 activity has also been associated with normal physiological activity, including synaptic plasticity. For example, caspase-3 is involved with axonal regeneration associated with retinal growth cone formation, demonstrating roles in both local protein synthesis and degradation. Caspase activity has also been associated with long-term spatial memory storage (associated with behavioral training) in the rodent hippocampus and has been localized to dendrites, dendritic spines, and axon terminals in the rat forebrain. Collectively, these studies demonstrate that apoptosis localized to synapses and distal dendrites represents a potential mechanism underlying synaptic remodeling and elimination in both physiological and pathological conditions (reviewed [5] [3]).

Important Mediators of Neurodegeneration

Oxidative Stress

A variety of metabolic pathways generate highly reactive by-products known as free radicals including hydrogen peroxide, superoxide anions, and hydroxyl radicals. These substances can be used by various cells as part of the immune response to serve useful functions such as to combat infectious organisms and neoplastic cells, and to execute cells programmed for death during the normal course of development. In abnormal circumstances such as associated with traumatic and ischemic injury or neurodegenerative diseases such as Alzheimer's and Parkinson's disease, free radicals may be excessively

produced, aberrantly controlled, or inadequately scavenged. In such cases, free radicals cause injury as a result of membrane lipid peroxidation, DNA damage, iron accumulation, and protein nitrosylation. Excess free radicals are normally scavenged and inactivated by several endogenous substances such as vitamin E (α -tocopherol) which can quench lipid peroxidation, superoxide dismutase which scavenges superoxide radicals, and glutathione peroxidase which removes hydrogen peroxide and lipid peroxides. Therefore alterations or deficits in any of these endogenous substances can contribute to and/or initiate neurodegeneration.

Excitotoxic Amino Acids

Excitotoxic amino acids play a deleterious role in a number of neurologic diseases and are known to contribute to neurodegeneration. These compounds are released in response to a wide variety of insults to the CNS and include glutamate, aspartate, and several oxidation products of cysteine and homocysteine. For example, in stroke, excitatory amino acids are released in the penumbra of ischemic lesions and further released when perfusion is restored, and thus are believed to contribute significantly to reperfusion injury. These compounds are also released following traumatic brain injury, during prolonged seizures, and are thought to contribute to the neurotoxicity associated with the amyloid plaques observed in Alzheimer's disease. Over-activation of N-methyl-D-aspartate (NMDA) receptors (a subtype of glutamate receptor) by glutamate leads to alterations in a number of signal systems and ion channels activating apoptosis.

Energy Failure and Ion Dysregulation

Neuronal degeneration may result as a consequence of energy failure within mitochondria precipitated by ischemia, free radical damage, and several acquired and genetic disorders of metabolism. For example, mitochondrial energy disruption and neurodegeneration occur in Wernicke's encephalopathy, an acquired metabolic disorder resulting from ethanol abuse and/or thiamine deficiency. Similar neuropathology can be observed in Leigh's syndrome, an inherited neurometabolic disorder in which point mutations in mitochondrial DNA are evident. Friedrich's ataxia, the most common inherited ataxia, is an autosomal recessive disease in which protein aggregates appear to disrupt mitochondrial iron metabolism, leading to abnormal free radical formation and altered energy metabolism. In the cases highlighted above, specific irreversible processes lead to a decrease in high energy phosphates (e.g., ATP, creatine phosphate), possibly leading further to elevated acyl-CoA levels that inhibit multiple metabolic processes. Local electrolyte (ion) imbalances and/or ion channel dysfunction are also thought to contribute significantly to neurodegenerative processes. Ion changes are commonly among the early events in apoptosis and fact, alterations in calcium homeostasis are among the best-documented factors in neurodegeneration. Direct evidence of the importance of ion channels in neurodegeneration comes from genetic disorders that affect specific ion channels (i.e., channelopathies). Channelopathies may underlie certain forms of migraine, episodic ataxias, and epilepsy. Indirect evidence that ion dysregulation plays an important role in some forms of neurodegeneration comes from preclinical studies (i.e., stroke models in animals) in which calcium and sodium channel blockers reduce infarct size.

Inflammation

Several lines of evidence indicate that inflammatory processes contribute to the neurodegeneration found in a number of disease states. A common feature in neurodegenerative diseases is microgliosis. Microglia, in addition to releasing oxygen free radicals, also secrete a variety of compounds and substances known to stimulate local inflammation such as inflammatory cytokines, complement and coagulation proteins, as well as binding proteins. As an example, inflammatory factors found in degenerating sites in Alzheimer's disease brains include activated microglia, the cytokines interleukin Il-1 and Il-6, an early component of the complement cascade, Clq, as well as acute phase reactants such as C-reactive protein.

Neurotrophin Support and Altered Cell Signaling

A continuous supply of a variety of polypeptide molecules known as neurotrophic factors (or neurotrophins) is essential to the nervous systems of all vertebrates throughout development as well as in adult

life [4]. These important molecules interact with specific receptors and initiate a variety of cellular signaling systems. During the period of target innervation, limiting amounts of neurotrophic factors regulate neuronal numbers by allowing survival of only some of the innervating neurons, the remaining being eliminated by apoptosis. Increasing evidence indicates that several neurotrophic factors also influence the proliferation, survival, and differentiation of precursors of a number of neuronal lineages. In the adult, neurons continue to be dependent on trophic factor support, which may be provided by the target or by the neurons themselves. Altered trophic factor support and cell signaling as a result of excess free radicals or peroxynitrites has been implicated in the neurodegenerative processes associated with several neurologic diseases. Furthermore, the ability of neurotrophins to promote survival of peripheral and central neurons during development and after neuronal damage has stimulated the interest in these molecules as potential therapeutic agents for the treatment of nerve injuries and neurodegenerative diseases. Examples of important (therapeutically relevant, from a neurodegenerative disease standpoint) neurotrophins include nerve growth factor (NGF), and brain derived growth factor (BDNF) (see further discussion below).

Pharmacological Intervention

There are multiple mechanisms known to underlie the neuronal cell damage associated with injury or disease that at least theoretically could be targeted for pharmaceutical intervention. Currently however, there is no clinically available therapeutic agent that can reliably protect the brain from progressive neurodegenerative processes for sustained periods. Due to the extensive amount of preclinical research that has been conducted in recent years, there is a basis for optimism, however, it appears likely that some of these approaches will result in clinically effective therapeutic modalities in the near future. A short overview of some of the investigational approaches to combat neurodegeneration appears below.

Inhibitors of Inflammatory Processes

Inflammatory processes associated with neurodegenerative disease suggest a number of therapeutic targets, including inhibitors of complement activation or cytokines, free radical scavengers, and inhibitors of microglial activation. In retrospective studies, the use of nonsteroidal antiinflammatory drugs (NSAIDs) has been associated with a reduced incidence or slowed progression of Alzheimer disease, indicating a potential for therapeutic use of this class of agent.

Inhibitors of Apoptosis and Growth Factor like Molecules

As indicated earlier, apoptosis is inhibited by certain proteins, such as Bcl-2 and Bcl-x. In contrast, Bax and

the tumor suppressor protein, p53, have been shown to enhance the onset of apoptosis. Accordingly, drugs which have the ability to enhance the expression of Bcl-2 and Bcl-x or to inhibit the expression Bax and p53 could theoretically have the potential to reduce neurodegeneration [5]. Drugs that inhibit apoptosis-inducing enzymes including caspases may also have a role. The expression of Bcl-2 and other proteins in this family is also modulated by trophic factors such as NGF and basic fibroblast growth factor (FGF), endogenous neurotrophins which have been shown to block cell death and preserve the phenotype of various cells in the nervous system. NGF is well known to support basal forebrain cholinergic neurons, cells reproducibly ravaged in Alzheimer's disease and known to be critically important for many cognitive processes. Accordingly, there has been interest in using NGF as a therapeutic modality for Alzheimer's disease and potentially other conditions in which cholinergic deficits may be present (e.g., dementia with Lewy bodies). In other investigations, the potential role of trophic molecules in stroke has been evaluated. For example, in animal models of stroke, ischemic damage is reduced following treatment with FGF. Unfortunately, NGF, FGF, as well as most other peptide molecules fail to adequately penetrate the brain from peripheral administration and are thus considerably limited from a therapeutic standpoint. Recent interest has thus focused on low molecular weight growth factor like molecules or small organic molecules that increase the release of growth factors in the brain or increase the expression of growth factor receptors.

Inhibitors of Oxidative Stress

Human trials have evaluated vitamin E, selegiline, and other antioxidant molecules for their ability to prevent or slow the progressive neurodegeneration associated with several neurologic diseases. To date, the data have provided conflicting or equivocal results with some studies showing slightly positive effects and others showing little or no effect. A number of issues require further attention in this area such as the identification of optimal doses of the various antioxidant compounds as well as the evaluation of selected combinations of these agents. These issues are important since specific compounds are known to scavenge or inactivate specific oxidative agents, and thus a single compound would not intuitively be expected to combat free radicals originating from several sources.

Modulators of Glutamate Transmission

Several glutamate antagonists have been or are in the process of being evaluated both preclinically and clinically as neuroprotective agents. For example, MK-801, an NMDA antagonist, reduces the detrimental effects of excess glutamate (as well as other insults to neurons) in a variety of animal models. Unfortunately the

compound is too toxic for use in humans. However, memantine (another NMDA antagonist) is available adjunctively (to be administered with acetylcholinesterase inhibitors) for the treatment of moderate to severe Alzheimer's disease. Riluzole (a drug which inhibits glutamate release), is available clinically for the treatment of amyotrophic lateral sclerosis (ALS) and is somewhat effective in slowing progression. Riluzole has also been shown to reduce infarct size in stroke and brain injury after trauma in animal models and accordingly human studies are anticipated in the near future. Other agents that modulate glutamate receptors such as AMPA antagonists and compounds that interact allosterically at the polyamine and glycine receptor sites are also being evaluated.

Other Investigational Approaches

Other pharmaceutical and molecular therapies are currently being developed to antagonize neurodegenerative processes. For example, compounds designed to prevent toxic reactions of free radicals such as nitric oxide (NO) and reactive oxygen species (ROS), new calcium channel antagonists, as well as compounds that stimulate the expression of antioxidant enzymes such as superoxide dismutase are being developed. Further, the low incidence of cardiovascular disease in those who consume large amounts of omega-3 fatty acids and their known ability to protect cell membranes from a variety of insults has provided the impetus to evaluate these agents as potential neuroprotectants.

In summary, the steadily increasing size of geriatric populations in developed countries and the resultant increases in age-related diseases of the brain have provided the impetus for intensive study of the processes underlying neurodegeneration. A better understanding of these processes will likely lead to better methods of treatment not only for progressive memory disorders such as Alzheimer disease, but also for motor disorders such as amyotrophic lateral sclerosis, and cerebrovascular disorders such as stroke.

Neuroleptic-like Malignant Syndrome

Neuroleptic-like malignant syndrome is a serious but very rare adverse effect of some drugs, of e.g., neuroleptics, some anaesthetics and apparently tolcapone. Symptoms include hyperthermia, muscle deterioration, even dissolution.

- ▶ Neuroleptics

Neuroleptics

Neuroleptics or antipsychotics suppress the “positive symptoms” of schizophrenia such as combativeness, hallucinations and formal thought disorder. Some also alleviate the “negative symptoms” such as affective blunting, withdrawal and seclusiveness. Neuroleptics also produce a state of apathy and emotional indifference. Most neuroleptics block dopamine D₂-receptors but some, like clozapine, also block dopamine D₄-receptors or serotonin 5-hydroxytryptamine_{2A}-receptors.

Neuromedin B

- ▶ Bombesin-like Peptides

Neuromedin N

A six aminoacid neurotensin-like peptides synthesized in the same propeptide precursor as neurotensin.

- ▶ Neurotensin/Neuromedin N

Neuromedin U

Neuromedin U is a neuropeptide which is widely distributed in the gut and central nervous system. Peripheral activities of neuromedin U include stimulation of smooth muscle, increase in blood pressure, alteration of ion transport in the gut, control of local blood flow and regulation of adrenocortical function. The actions of neuromedin U are mediated by G-protein coupled receptors (NMU1, NMU2) which are coupled to G_{q/11}.

Neuromodulators

Mediators acting mostly at the pre-synaptic or pre-junctional level to control the release of neurotransmitters.

Neuromuscular Blocking Agents

- ▶ Muscle Relaxants

Neuromuscular Junction

Neuromuscular junction (NMJ) is the synapse or junction of the axon terminal of motoneurons with the highly excitable region of the muscle fibre's plasma membrane. Neuronal signals pass through the NMJ via the neurotransmitter ACh. Consequent initiation of action potentials across the muscle's cell surface ultimately causes the muscle contraction.

- ▶ Exocytosis

Neuropathic Pain

Neuropathic pain is initiated or caused by a primary lesion in the peripheral or central nervous system. The causative agent may be trauma, nerve-invading cancer, herpes zoster, HIV, stroke, diabetes, alcohol or other toxic substances. Neuropathic pain is refractory to most analgesic drugs. Altered sodium channel activity is characteristics of neuropathic pain states.

Neuropeptide FF

The octa-peptide neuropeptide FF is generated together with a related octa-peptide (neuropeptide AF) from a

common precursor protein. It is involved in nociception and in the modulation of opiate-induced analgesia, morphine intolerance and morphine abstinence. The effects of neuropeptide FF are mediated by G-protein coupled receptors (NPFF1, NPFF2).

Neuropeptide Y

MARTIN C. MICHEL

Academisch Medisch Centrum, Amsterdam,
The Netherlands

Synonyms

NPY

Definition

Neuropeptide Y (NPY) is a 36 amino acid polypeptide with tyrosine residues at both ends of the molecule. It is characterised structurally by a “PP-fold” consisting of an extended polyproline helix and an α -helix connected by a β -turn [1]. Based on structural and evolutionary criteria, NPY is closely related to ▶peptide YY (PYY) and ▶pancreatic polypeptide (PP).

Basic Characteristics

NPY is primarily (but not exclusively) synthesised and released by neurons, which in the peripheral nervous system are predominantly sympathetic neurons [1]. In most cases, NPY acts as a co-transmitter that is preferentially released upon high frequency nerve stimulation. NPY can be metabolised by the enzyme ▶dipeptidylpeptidase IV (also known as ▶CD26) to generate the biologically active fragment ▶NPY_{3–36}.

As to be expected from a peptide that has been highly conserved during evolution, NPY has many effects, e.g. in the central and peripheral nervous system, in the cardiovascular, metabolic and reproductive system. Central effects include a potent stimulation of food intake and ▶appetite control [2], anxiolytic effects, anti-seizure activity and various forms of neuroendocrine modulation. In the central and peripheral nervous system NPY receptors (mostly Y_2 subtype) mediate prejunctional inhibition of neurotransmitter release. In the periphery NPY is a potent direct vasoconstrictor, and it potentiates vasoconstriction by other agents (mostly via Y_1 receptors); despite reductions of renal blood flow, NPY enhances diuresis and natriuresis. NPY can inhibit pancreatic insulin release and inhibit lipolysis in adipocytes. It also can regulate gut motility and gastrointestinal and renal epithelial secretion.

In some cell types, e.g. in vascular smooth muscle cells, NPY appears to enhance cell growth.

NPY, PYY and PP act upon the same family of receptors, which are classified together as NPY receptors. Based on IUPHAR recommendations, the NPY receptors are designated by a capital Y and the various receptors within the family are designated by subscript numbers [3]. Five mammalian subtypes of NPY receptors have been cloned and are designated Y₁, Y₂, Y₄, Y₅ and y₆. Among the cloned receptors the Y₁, Y₂, Y₄ and Y₅ receptors represent fully defined subtypes, but no functional correlate of the cloned y₆ receptor has been established to date. The Y₄ receptor preferentially binds PP, whereas NPY (and PYY) are much less potent at the Y₄ receptor than at the other subtypes; hence, this PP-preferring subtype will not be discussed here. The y₆ receptor represents a non-functional pseudogene in humans and primates, is absent from the rat genome, and its pharmacological recognition profile remains controversial; hence, it will also not be discussed here.

Sequence comparisons show that receptors Y₁, Y₄ and y₆ are more closely related to each other than to the receptors Y₂ and Y₅. This is apparent not only from sequence identity but also from other features, such as cysteines believed to form disulfide bonds and the size of the third cytoplasmic loop, which is large in Y₅. The receptors Y₂ and Y₅ are equally distantly related to one another as to the Y₁/Y₄/y₆ group. In fact the Y₁/Y₄/y₆ group, the Y₂ and the Y₅ receptor are more distantly related to one another than any other G-protein-coupled receptors that bind the same endogenous ligand, despite the fact that Y₁, Y₂ and Y₅ each bind two distinct endogenous ligands, namely NPY and PYY. However, based on pharmacological recognition profiles, the receptors Y₁ and Y₅ are more similar to one another than to the receptor Y₄ (see below). Therefore, at present no formal division of NPY receptors into subfamilies is recommended.

- Y₁ receptors have been cloned from humans, rats, mice and from non-mammals such as *Xenopus laevis*. The genomic organisation of the Y₁ subtype gene has been determined in humans and mice, and the human gene has been located on chromosome 4q (31.3–32). Three splice variants in the 5' region of the human Y₁ receptor yield multiple promoters with tissue-specific expression patterns. Two splice variants of the murine Y₁ receptor have been described. While both variants bind NPY, the form with a shortened seventh transmembrane-spanning region and a lacking C-terminal tail does not appear to couple to signal transduction as efficiently as the full length form. Messenger RNA for the Y₁ receptor has been detected in a variety of human, rat and murine tissues including brain, heart, kidney and gastrointestinal tract.

- Y₂ receptors were originally cloned from human SMS-KAN cells. Later cloning studies in rats demonstrated that the cloned Y₂ receptor is also the molecular correlate of a previously proposed PYY-preferring receptor in the gastrointestinal tract. Messenger RNA for the Y₂ receptor has been detected in various parts of the CNS, whereas only low levels of Y₂ mRNA were found in human peripheral tissues.
- Y₅ receptors were cloned from humans and rats. Interestingly, the corresponding gene resides on human chromosome 4q in the same location as the human Y₁ receptor gene, but in opposite orientation. Messenger RNA for Y₅ receptors was detected by Northern blotting and in situ hybridisation in several rat brain areas, including those believed to be important for the regulation of food intake, as well as in testis.

All known NPY receptors belong to the large superfamily of **G-protein coupled receptors**. They appear to use similar signal-transduction pathways, and no clear and consistent alignment of a specific receptor type with a distinct transduction pathway has been identified. In almost every cell type studied (with the possible exception of some prejunctional receptors), NPY receptors act via pertussis toxin-sensitive **heterotrimeric GTP-binding proteins**, i.e. members of the G_i and G_o family. The typical signalling responses of NPY receptors are similar to those of other G_i/G_o-coupled receptors. Thus, inhibition of **adenylyl cyclase** is found in almost every tissue and cell type investigated and also with all cloned NPY receptor subtypes upon heterologous expression. Additional signalling responses that are restricted to certain cell types include inhibition of Ca²⁺ channels, e.g. in neurons, and activation and inhibition of K⁺ channels, e.g. in cardiomyocytes and vascular smooth muscle cells. Based on experiments with Ca²⁺ entry blockers, it has been postulated that NPY stimulates Ca²⁺ channels in the vasculature. In some cell types, members of the NPY family can mobilise Ca²⁺ from intracellular stores. While this appears to involve inositol phosphates in some cells, inositol phosphate-independent Ca²⁺ mobilisation has been postulated in other cell types. A sensitivity of certain responses to NPY to the cyclooxygenase inhibitor, indomethacin, indicates possible activation of a phospholipase A₂ by NPY receptors, but this has yet to be demonstrated definitively. Activation of a phospholipase D or of a tyrosine kinase, which can occur with some G_i/G_o-coupled receptors, has also not clearly been demonstrated. Thus, in general, Y receptors demonstrate a preferential coupling to pertussis toxin-sensitive G-proteins, i.e. the G_i and G_o family, which is followed by the responses typically under the control of these G-proteins.

Drugs

NPY receptors and NPY-induced responses were originally classified based on agonist orders of potency, but the advent of several subtype-selective antagonists has at least partly superseded the use of agonists for classification purposes. In some cases, however, particularly in vivo, agonists may still be required for receptor characterisation. This is based on the use of NPY, PYY, [Pro³⁴]-substituted analogues (which may or may not contain an additional [Leu³¹] substitution) and on C-terminal fragments of NPY and PYY (including the endogenous NPY_{3–36} and PYY_{3–36}).

Y₁ receptors are characterised by an agonist order of potency of NPY ≥ PYY ≥ [Pro³⁴]-substituted analogue >> C-terminal fragment > PP. C-Terminal fragments may act as partial agonists at Y₁ receptors and in some cell lines even as antagonists; whether such partial antagonism also occurs with intact tissues or in vivo remains to be determined. Y₁-selective antagonists include BIBO 3304 ((*R*)-*N*-[[4-(aminocarbonylaminoethyl)-phenyl]methyl]-*N*-(diphenylacetyl)-argininamide trifluoroacetate, K_i or K_B 0.2–1 nM), and BIBP 3226 ((*R*)-*N*-(diphenylacetyl)-*N*-[[4-(4-hydroxyphenyl)methyl]-arginine amide, K_i or K_B 1–10 nM), with BIBP 3435 ((*S*)-*N*-(diphenylacetyl)-*N*-[[4-(4-hydroxyphenyl)methyl]-argininamide) being a much less active stereoisomer, which can be used as an inactive control for the latter. Other Y₁ receptor antagonists include SR 120819A ((*R,R*)-1-(2-[2-2-naphthylsulphamoyl-3-phenyl-propionamido]-3-[4[*N*-(4-[dimethylaminomethyl]-*cis*-cyclohexylmethyl)amidinophenyl]propionyl]-pyrrolidine) or the polypeptide GR 231118 (also known as 1229U91 or GW1229, homodimeric Ile-Glu-Pro-Dpr-Tyr-Arg-Leu-Arg-Tyr-CONH₂), but the latter has also been reported to be an agonist at Y₄ receptors in some cases.

Y₂ receptors are characterised by an order of potency of NPY ≈ PYY ≥ C-terminal fragment >> [Pro³⁴]-substituted analogue > PP. BIIE 0246 ((*S*)-*N*-(1-[2-[4-[(*R,S*)-5,11-dihydro-6(6h)-oxodibenz[*b,e*]azepin-11-yl]-1-piperazinyl]-2-oxoethyl]cyclopentyl]acetyl)-*N*-[2-[1,2-di-hydro-3,5-(4H)-dioxo-1,2-diphenyl-3H-1,2,4-triazol-4-yl]ethyl]-argininamide) is a Y₂-selective antagonist with an affinity of 3 nM.

Y₅ receptors are characterised by an order of potency of NPY ≥ PYY ≈ [Pro³⁴]-substituted analogue ≈ NPY_{2–36} ≈ PYY_{3–36} >> NPY_{13–36}; rat PP had very low potency at the rat and human Y₅ receptor, while human and bovine PP had affinities similar to those of NPY and PYY. Y₅-selective antagonists include CGP 71683A (trans-naphthalene-1-sulfonic acid 4-[4-amino-quinazolin-2-ylamino]methyl]-cyclohexylmethylamide hydrochloride) with an affinity of 1 nM.

As additional tools, transgenic mice overexpressing NPY and knockout mice lacking NPY, Y₁ receptors or Y₅ receptors have been published.

Neuropeptides

The neuropeptides are peptides acting as neurotransmitters. Some form families such as the tachykinin family with substance P, neurokinin A and neurokinin B, which consist of 11 or 12 amino acids and possess the common carboxy-terminal sequence Phe-X-Gly-Leu-Met-CONH₂. Substance P is a transmitter of primary afferent nociceptive neurones. The opioid peptide family is characterized by the C-terminal sequence Tyr-Gly-Gly-Phe-X. Its numerous members are transmitters in many brain neurones. Neuropeptide Y (NPY), with 36 amino acids, is a transmitter (with noradrenaline and ATP) of postganglionic sympathetic neurones.

- ▶ Neuropeptide Y
- ▶ Opioid Systems
- ▶ Synaptic Transmission

Neuropilins

Neuropilins are transmembrane proteins which bind to class 3 semaphorins as well as to vascular endothelial growth factor. The two mammalian neuropilins NRP-1 and NRP-2 were originally identified as important receptors for the neuronal guidance factors of the class 3 semaphorin family. Recently, increasing evidence has emerged implicating neuropilins in the regulation of angiogenesis as well as in tumour progression.

- ▶ Plexins

Neurosteroids

Neurosteroids are neuroactive steroids, which are synthesized in the brain. Neurosteroids can bind to and modulate the activity of γ -aminobutyric acid_A (GABA_A) receptors.

- ▶ Benzodiazepines

Neurotensin/Neuromedin N

PATRICK KITABGI
INSERM U732/Université Pierre et Marie Curie,
Hopital St-Antoine, Paris cedex 12, France

Definition

Neurotensin (NT) is a neuropeptide predominantly expressed in the brain and the gut. The peptide exerts its effects through two G-protein-coupled receptors, NTS1 and NTS2, and through a single transmembrane domain protein, NTS3 or sortilin, that belongs to a small family of sorting receptors. In the brain, NT is predominantly expressed in neurons within discrete brain areas and nuclei where it modulates the activity of neuronal systems involved in behavioral responses such as locomotor activity, rewarding, drug seeking, eating and pain sensation. In the gut, NT is primarily produced in endocrine N cells scattered throughout the jejuno-ileal mucosa and regulates a number of processes including gastrointestinal motility, pancreatic and biliary secretion and growth of normal gastrointestinal tissues.

Basic Characteristics

Biosynthesis, Release and Inactivation

Like all neuropeptides, NT is synthesized as part of a larger precursor that also contains ▶neurotensin N (NN), a 6 amino acid ▶neurotensin-like peptide (Table 1). Pro-NT/NN is processed in the regulated secretory pathway of neuroendocrine cells by prohormone convertases PC1, PC2 and PC5-A that belong to a larger family of proprotein convertases. Due to differential cleavage specificity and tissue distribution of the convertases, pro-NT/NN processing gives rise to approximately a 1:1 and a 5:1 ratio of NT over NN content in the brain and gut, respectively. The peptides are stored in secretory vesicles and released from neuroendocrine cells in a Ca²⁺-dependent manner. NT and NN actions are terminated by desensitization of the

receptors they activate and by degradation mechanisms that take place in the extracellular space. NT degradation is ensured by three Zn metallo-endopeptidases, namely endopeptidases 3.4.24.11, 3.4.24.15 and 3.4.24.16, whereas NN degradation is mainly effected by aminopeptidase M, a Zn metallo-exopeptidase.

NT Receptors

NTS1

Agonist stimulation of ▶NTS1 receptor leads to ▶phospholipase C activation through the ▶heterotrimeric G-proteins Gq coupling in all systems examined. However, coupling to other G-proteins may occur in some systems. Thus, coupling to Gs leading to adenylyl cyclase activation in NTS1 receptor-overexpressing transfected cell lines and in the MIA PaCa-2 human pancreatic cancer cell line, and coupling to Gi/o leading to adenylyl cyclase inhibition in the N1E115 cell line or to ▶phospholipase A2 (PLA2) activation in transfected CHO cells have been observed. NTS1 stimulation also activates more distal transduction pathways such as the mitogen-activated protein kinase (▶MAPK) and serine/threonine protein kinase Akt pathways that are involved in the growth-promoting effects of NT in normal and ▶cancer tissues. NTS1 signaling properties are recapitulated in Table 2. Agonist binding to NTS1 induces internalization of receptor-ligand complexes into NTS1-expressing cells via clathrin-coated pits. Upon acute agonist exposure, internalized NTS1 receptors are targeted to lysosomes for degradation whereas under prolonged agonist exposure, NTS1 is routed towards the perinuclear Trans-Golgi recycling compartment.

Sanofi-Aventis has developed a nonpeptide NTS1 antagonist, ▶SR 48692 (Table 1), which binds with higher affinity to NTS1 than to ▶NTS2 and has proven extremely useful for probing the functions associated with NTS1. These studies and recent investigations in knockout mice that do not express NTS1 suggest that most of the known effects of NT are attributable to NTS1 (Table 2). Another nonpeptide NTS1 antagonist, SR 142948A, with higher affinity for both NTS1 and NTS2 and less selectivity for NTS1 than SR 48692 has also been characterized.

NTS2

NTS2 corresponds to the NT receptor originally described as having lower affinity for NT than NTS1 and as being selectively recognized by ▶levocabastine, a nonpeptide H1 histamine antagonist that has no affinity for NTS1. NTS2 shares about 60% homology with NTS1. It exhibits surprising species- and expression system-dependent pharmacological properties that are recapitulated in Table 2. Thus, in mNTS2-expressing *Xenopus* oocytes, NT, levocabastine and SR 48692 all behave as agonists. In CHO cells stably transfected with rNTS2, levocabastine and SR 48692 are agonists.

Neurotensin/Neuromedin N. Table 1 Structures and potential therapeutical uses of NT receptor ligands

Compound	Structure	Properties	Therapeutic potential
NT	pGlu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Ile-Leu-OH	Natural ligand of NT receptors	
NN	H-Lys-Ile-Pro-Tyr-Ile-Leu-OH	Natural ligand of NT receptors	
	[^{99m} Tc](NaHis)Ac-Lys-Ψ(CH ₂ NH)-Arg-Pro-Tyr- <i>t</i> -Leu-Leu-OH	Stable radiolabeled NT analog	Diagnostic and radiotherapeutic use in cancers
NT69L	NMe-Arg-Lys-Pro-L- <i>neo</i> -Trp- <i>t</i> -Leu-Leu-OH	Potent NT analog that crosses the blood-brain barrier	Antipsychotic; analgesic; anorectic
JMV 431	Boc-Arg-Arg-Pro-Tyr-Ψ(CH ₂ NH)Ile-Leu-OH	Selective ligand at NTS2 versus NTS1; inverse agonist at the constitutively active human NTS2	Analgesic
SR 48692		Nonpeptide antagonist at NTS1; agonist at NTS2	Inhibition of tumor growth; drug addiction treatment

NMe: *N*-methyl, *t*-Leu: *tert*-leucine, *L*-*neo*-Trp: (2*S*)-2-amino-3-(1*H*-4-indolyl)propanoic acid, Boc: *t*-butyl-oxycarbonyl, Ψ: pseudopeptide bond.

Neurotensin/Neuromedin N. Table 2 NTS1 and NTS2 signaling properties

Receptor subtype	Expression system	Transduction pathway	Agonist	Antagonist	Inverse agonist	
NTS1						
Rat and human	All systems	Coupling to Gq, phospholipase C activation,	NT	SR 48692		
		Increase in inositol phosphates and cytosolic [Ca ²⁺]	NN			SR 142948A
		Activation of MAPK pathway				
	Transfected cell systems with high expression levels	Coupling to Gs, stimulation of cAMP production				
Rat	Neuroblastoma N1E115 cell line	Coupling to Gi, inhibition of cAMP production				
	Stably transfected CHO cells	Coupling to Gi, production of arachidonic acid				
Human	Human pancreatic Mia PaCa-2 cell line	Coupling to Gs, stimulation of cAMP production				
NTS2						
Mouse	Xenopus oocyte	Activation of Ca ²⁺ -dependent Cl ⁻ conductance	NT			
			SR 48692			
			Levocabastine			
Rat	Stably transfected CHO cells	Increase in cytosolic [Ca ²⁺]	SR 48692			
			Levocabastine			
	Primary cultured cerebellar granule cells	Increase in cytosolic [Ca ²⁺]	SR 48692			
			Activation of MAPK pathway			NT
			Levocabastine			
Human	Stably transfected CHO cells	Increase in inositol phosphates, cytosolic [Ca ²⁺], arachidonic acid; activation of MAPK pathway	SR 48692	NT		
			SR 142948A	Levocabastine		
	Transiently transfected COS cells	Constitutive activity	SR 48692	NT	Levocabastine	
		Increase in inositol phosphates			JMV 431	

In primary cultured rat cerebellar granule cells that endogenously express rNTS2, SR 48692 is agonist on the Ca response while NT and levocabastine are agonists on the MAPK pathway. Finally, in CHO cells stably transfected with hNTS2, both SR 48692 and SR 143948A are agonists whereas NT and levocabastine are antagonists. Interestingly, in another hNTS2-expressing system, i.e., transiently transfected COS cells, constitutive NTS2 activity is detected and SR 48692, levocabastine and NT behave as agonist, inverse agonist and neutral antagonist, respectively. NTS2 efficiently internalizes upon agonist exposure and recycles back to the membrane.

NTS3

►NTS3, also termed sortilin, is a 100 kDa protein that shares homology with the yeast vacuolar sorting protein Vps10p and other mammalian sorting receptors. This family of proteins is characterized by a single transmembrane domain, a cystein-rich domain, a signal peptide, a furin cleavage site and a short cytoplasmic tail. Sortilin/NTS3 has been cloned from the human and rat. This receptor might be involved in protein sorting between and from the cell surface to intracellular compartments. Binding of NT to NTS3 was reported to elicit proliferative responses in a variety of cancer cell lines and to alter agonist-induced cellular trafficking and signaling of NTS1 in HT29 human colon cancer cells. The strongest evidence that NTS3 participates in NT signaling comes from the demonstration that NTS3 mediates NT-induced migration of human microglial cells by a mechanism dependent on the stimulation of both MAPK and ►PI3-kinase pathways.

Neurotensin–Dopamine Interaction

Centrally administered NT exerts a number of effects similar to those of neuroleptic drugs. There is at present unquestionable neuroanatomical, electrophysiological, neurochemical and behavioral evidence that NT modulates dopamine (DA) transmission in the nigro-striatal and mesocorticolimbic pathways. Actually, NT behaves either as a ►psychostimulant or as a neuroleptic depending on what part of the mesocorticolimbic DA circuitry is targeted by the peptide. In vitro and in vivo application of NT to DA neurons of the ventral tegmental area (VTA) stimulates DA neuronal activity. In contrast, administration of NT in the nucleus accumbens, a projection area of the VTA, inhibits DA transmission. The stimulatory, psychostimulant-like effects are mediated through NTS1 receptors that are abundantly expressed by VTA DA neuronal cell bodies and dendrites. The inhibitory, neuroleptic-like effects are also mediated via NTS1 receptors located postsynaptically to DA nerve terminals in the VTA. In addition, both ►antipsychotic drugs and psychoactive drugs modify NT expression and transmission in

these circuits, suggesting that the peptide mediates the effects of both types of drugs. Recent studies with either NTS1 antagonist SR 48692 or with NT and NTS1 knockout mice further support the notion that NT participates, via NTS1, in the response to psychostimulants as well as to that of both typical and atypical neuroleptic drugs.

Nociception

Centrally administered NT in rodent elicits a potent, opioid-independent ►analgesic response. Recent studies show that the peptide exerts a biphasic modulation of ►nociception when injected in the rostral ventromedial medulla (RVM), low and high doses of peptide eliciting facilitatory and inhibitory effects, respectively. The recent demonstration that NT knockout mice display defects in stress-induced analgesia may suggest that the transition from pain facilitation to analgesia involves stress-induced increases in NT signaling in pain modulatory regions. Injection of SR 48692 in the RVM blocks the inhibitory but not the facilitatory effect of NT on nociception. This is in contrast with the report that SR 48692 failed to antagonize the analgesic response to NT in the rat and mouse following ip injection. These apparently discrepant data suggest that complex interactions occur between central NTergic systems and nociceptive circuits and that several NT receptor subtypes might be involved in mediating pain modulation by the peptide. Actually, recent evidence indicates that both NTS1 and NTS2 participate in the antinociceptive action of NT. Thus, NTS1 deletion in mice abrogates the analgesic effect of NT. On the other hand, partial reduction of central NTS2 expression in mice by means of icv administration of antisense oligonucleotides significantly decreases the antinociceptive effect of NT.

Feeding Behavior

A number of orexigenic and anorexigenic hypothalamic neuropeptides are known to coordinately regulate body weight through a complex, partially elucidated mechanism orchestrated in part by ►leptin, an adipose tissue-released hormone that acts centrally in the hypothalamus to control food intake and energy expenditure. The anorexigenic effect of centrally administered NT has been known for 20 years. Further support for a role of NT in food intake came from the observation that hypothalamic expression levels of NT are decreased in genetic models of obese rats and mice including the Zucker fa/fa rat and the ob/ob mouse that are deficient in leptin receptor and leptin, respectively. A number of recent reports point to NT as a possible mediator of leptin-induced reduction in food intake. Thus, leptin receptors are present on and activate NT-expressing neurons in the arcuate nucleus and the dorsomedial area of the rat

hypothalamus. Furthermore, central administration of leptin for 3 days increases NT gene expression whereas chronic intraperitoneal administration for 7 days decreases NT levels in the lateral hypothalamus. Leptin and NT reciprocally potentiate each other's inhibitory effect on food intake. Immunoneutralization of central NT with a neurotensin antiserum or administration of the NT antagonist SR 48692 completely block the inhibitory effect of leptin on food intake in food-deprived rats. Finally, in contrast to NT knockout mice that do not differ in their body weight from their wild type littermates, NTS1 knockout mice exhibit increased food consumption, body weight and white adipose tissue mass as compared to wild type littermates.

Drugs

In this part we shall examine the potential of NT receptors-targeting agents as therapeutic drugs.

Cancer

As mentioned above, NT exerts trophic effects on normal tissues. It is also well documented that the peptide stimulates the growth of cancer tissues. This is the case in colon, pancreas, lung, breast and prostate cancers. In general, NTS1 is ectopically expressed in these cancers and NT, through NTS1, activates mitogenic pathways that involve activation of MAP kinase and other nonreceptor tyrosine kinases. NT effects on cancer cell growth are generally inhibited by SR 48692. This compound could therefore have therapeutic value for the treatment of cancers.

NT agonists could also be useful for the treatment of cancer. We have seen that NTS1-agonist complexes are internalized in target cells. This has led to the development of suitably radiolabeled NTS1-targeting agonists with potential diagnostic and radiotherapeutic value. The primary concern in designing these compounds is to make them resistant to peptidases so as to maximize tumor/blood ratios. One such compound, which is in fact a technetium-radiolabeled NN analog, is shown in Table 1.

Schizophrenia and Drug Addiction

Clinical and postmortem data indicate that central NT systems are altered in schizophrenic patients. However, we have seen that NT could exert neuroleptic-like or psychostimulant effects depending on the site of administration in the rat. It has therefore been debated for many years whether a NTS1 agonist or antagonist could be used in the treatment of ▶schizophrenia. Recent evidence points to NT agonists as offering promising leads for developing an active ▶neuroleptic-like drugs. Thus, SR 48692 failed in clinical trials to reveal antipsychotic properties whereas NT agonist

mimetics that cross the blood–brain barrier, such as NT69L (Table 1), proved to exert neuroleptic-like effects in the rat following peripheral administration. On the other hand, there are reasons to believe that a NT antagonist might find useful application in treating drug addicts since ▶amphetamine and cocaine ▶cocaine- and amphetamine-regulated transcript sensitization are attenuated by SR 48692 and SR 142948A in the rat.

Pain Suppression

Data reviewed above support the involvement of NTS2 in mediating NT-induced analgesia. Interestingly, the analgesic potencies of icv injected metabolically stable NT analogs correlates positively with their affinities at NTS2 but not at NTS1. One of these analogs, JMV 431 (Table 1), is highly selective (100-fold higher affinity) for NTS2 versus NTS1 and exhibits high analgesic potency following icv administration. NT69L (Table 1) also induces analgesia following ip injection but its selectivity at NTS2 is not known. Further research to design NTS2-selective novel analogs that cross the blood–brain barrier may offer new avenues for the treatment of pain without the side effects associated with the use of opioids and devoid of NTS1-mediated effects.

Obesity

Evidence presented above strongly suggests that NT is a major link in the complex neuropeptide network that controls body weight and that the peptide effects on feeding are exerted through NTS1 receptor. NT agonists could therefore be useful in the treatment of obesity. In this context, it is of interest that NT69L (Table 1) was found to reduce food intake and body weight following ip administration in normal and genetically obese Zucker *fa/fa* rats.

Neurotransmitter Transporters

CHRISTIAN NANOFF¹, CHRISTIAN PIFL²

¹Institut für Pharmakologie, Medizinische, Universität Wien, Wien, Austria

²Zentrum für Hirnforschung Medizinische, Universität Wien, Wien, Austria

Synonyms

Neurotransmitter transporters; Members of the family of solute carriers; Products of the (solute carrier) SLC1, SLC6, SLC17, SLC18, and SLC22 gene families

Definition

Neurotransmitter transporters create neurotransmitter gradients across membranes, which results in the uptake of the neurotransmitter. By working in reverse they can also release neurotransmitter into the extracellular space (efflux by nonexocytotic release).

Basic Characteristics

Common Features of Neurotransmitter Transport

Neurotransmitter transport is in principle coupled to charge transfer: a gradient of charged effective solutes (e.g., sodium ions) typically is the driving force. As building this gradient consumes energy, neurotransmitter transporters are classified as secondary-active carriers. Alternatively, transporters may mediate the electroneutral exchange of two substrates (antiport).

Substrate specificity is determined by high affinity for the cognate neurotransmitter substrate. However, low affinity uptake does also have a part in the clearance of transmitters from the interstitial space (e.g., in uptake mediated by the extraneuronal monoamine transporter, EMT) and in the intestinal absorption of glycine and glutamate. It is obvious that there is an evolutionary relation of neurotransmitter transporters and amino acid and cation transporters in epithelia.

Neurotransmitter transporters fulfill three fundamental functions.

1. Transport supplies nerve cells with neurotransmitter, which is used to replenish secretory vesicles, thus uptake occurs on the cell surface and on the secretory vesicle.

2. Neurotransmitter transporters determine the neurotransmitter concentration in the interstitium. High-affinity transporters can efficiently remove neurotransmitter from the extracellular space because cellular uptake is typically coupled to the translocation of sodium ions.
3. Neurotransmitter transporters terminate the time interval of synaptic neurotransmission; localization of transporters in the vicinity of exocytotic sites is crucial for their clearance of neurotransmitter molecules following their exocytotic release into the synaptic cleft.

While these functions can be carried out by a single transporter isoform (e.g., the serotonin transporter, SERT) they may be split into separate processes carried out by distinct transporter subtypes, or in the case of acetylcholine, by a degrading enzyme. Termination of cholinergic neurotransmission is due to ►**acetylcholinesterase** which hydrolyses the ester bond to release choline and acetic acid. Reuptake of choline into the nerve cell is afforded by a high affinity transporter (CHT of the SLC5 gene family).

Loss or gain of transport function causes disorders: low levels of monoamine neurotransmitters are associated with depression, uptake inhibition can result in the spill-over of glutamate to neighboring synapses and ►**excitotoxicity**. Glutamate can even be released (by efflux) in large amounts if ion gradients can no longer be maintained due to impaired energy metabolism (as in the case of brain ischemia). In keeping with the potentially noxious effects of glutamate, animal experiments have suggested that enhanced removal of glutamate increases resistance to neurodegeneration in ►**amyotrophic lateral sclerosis**.

Structure

The molecular structure of the glutamate SLC1 (**Table 1**) and the monoamine SLC6 transporters (**Table 2** and **3**) differ remarkably. The glutamate transporters are assembled of three integral membrane proteins to form a bowl embedded in the membrane; each protomer has a specialized hairpin peptide domain to bind and carry the substrate (glutamate and ions). The monoamine transporter protomer is anchored in the membrane with 12 transmembrane spans (relative to eight in the glutamate transporter) but the structure does not disclose how the substrate is translocated. Monoamine transporters also assemble as homo-oligomers; while their quaternary structure likely has evolved to ensure surface targeting of the transporters, the oligomeric state also may be a prerequisite for amphetamine induced efflux.

Turnover of Neurotransmitter at the Synapse

Neurotransmitter turnover differs for the individual neurotransmitters. Glutamate and glycine require

Neurotransmitter Transporters. Table 1 SLC1 family transporters for L-glutamate (and D/L-aspartate)

Transporter (gene)	Distribution	Km ($\mu\text{mol/l}$)	Major Function
EAAC1/EAAT3 (SLC1A1)	Neurons in many brain regions	25–50	Limits glutamatergic signaling
	Kidney epithelium		Resorption of dicarboxylic amino acids
GLT1/EAAT2 (SLC1A2)	Astrocytes in cerebral cortex, hippocampus	5–100	Clearance of interstitial glutamate
GLAST/EAAT1 (SLC1A3)	Glial cells in cerebellum, retina, inner ear	5–70	

Neurotransmitter Transporters. Table 2 SLC6 family transporters for GABA (γ -amino butyric acid) and glycine

Transporter (gene)	Distribution	Km ($\mu\text{mol/l}$)	Major function	Selective inhibitor
GABA transporter GAT1 (SLC6A1)	GABAergic neurons in CNS	≤ 10	Clearance of interstitial neurotransmitter, reuptake into neurons	Tiagabine, an antiepileptic drug
Glycine transporter GlyT1 (SLC6A9)	CNS-glia	~ 20	Clearance of interstitial neurotransmitter	Sarcosine
GlyT2 (SLC6A5)	CNS-neurons		Reuptake into neurons	None

Neurotransmitter Transporters. Table 3 SLC6 family transporters for monoamines

Transporter (gene)	Substrate	Km ($\mu\text{mol/l}$)	Distribution	Function
NET (SLC6A2)	Noradrenaline, dopamine	~ 1	CNS noradrenergic neurons (emanate from locus coeruleus and lateral tegmental area), sympathetic nervous system	Clearance of interstitial neuro-transmitter, reuptake into neurons
DAT (SLC6A3)	Dopamine	~ 5	CNS dopaminergic neurons (emanate from substantia nigra, other midbrain nuclei, hypothalamus)	
SERT, 5HTT (SLC6A4)	5HT = serotonin	~ 1	CNS serotonergic neurons (emanate from raphe nuclei) platelets, smooth muscle, intestine	

nonneuronal cells equipped with distinct transporters for control of their interstitial concentration, whereas dopamine, noradrenaline, and serotonin do not.

Figure 1 depicts a glutamatergic synapse. At a presynaptic terminal l-glutamate is stored in secretory vesicles equipped with vesicular glutamate transporters (VGluT1/2). Upon release glutamate activates ionotropic receptors (\blacktriangleright AMPA receptors and \blacktriangleright NMDA receptors). The figure shows the glial glutamate transporter GLT1 and the neuronal glutamate transporter EAAC1 present on the postsynaptic neuron. Because there is no glutamate transporter on the presynaptic cell its supply with glutamate therefore must be indirect. Much of the glutamate accumulated in glial cells (GLT1 or GLAST) is metabolized to glutamine. Transport of glutamine that has no effect on neurotransmitter receptors occurs through a distinct carrier system (SLC38). Synthesis of glutamate in the nerve cell is then catalyzed by glutaminase, an

enzyme that also occurs in the kidney where it catalyzes the reverse reaction to deliver glutamate and ammonia into the urine.

In the brain glutamate is present at high levels and is mostly intracellular. The level is about thousand-fold higher than that of the monoamine neurotransmitters. It is reasonable to assume that the glial cells, which outnumber the nerve cells, have evolved to detoxify the brain's glutamate load and control excitotoxicity; because they do not store but metabolize glutamate, glial cells expressing glutamate transporters contain less glutamate than glutamatergic neurons.

Figure 2 shows that handling of glycine follows a similar principle. Glycine is a major inhibitory neurotransmitter but in addition it is essential for glutamatergic neurotransmission by serving as co-agonist at the NMDA-receptor. Removal of glycine from the synaptic space is due to uptake by GlyT1 on neuroglia (astrocytes), which is

Neurotransmitter Transporters. Figure 1 Glutamate transporters at a glutamatergic synapse. Upon exocytotic release of glutamate neurotransmission occurs by binding to and activation of ionotropic receptors. AMPA-receptors mediate fast excitatory postsynaptic potentials (EPSP), NMDA-receptors mediate slower calcium influx. Transmission is terminated by desensitization of the receptors and by glutamate diffusion out of the synaptic cleft; glutamate spillover is limited by uptake into the postsynaptic neuron (EAAC1) and into astrocytes (GLT1). (From; Kanai Y, Hediger MA. *Pflügers Arch* (2004) 447:469–479)

Neurotransmitter Transporters. Figure 2 Differential role of the glycine transporter isoforms, according to experiments where GlyT1 and GlyT2 were inactivated. The neuronal and glial location of GlyT1 and GlyT2 are indicated. In the absence of GlyT1 (GlyT1-KO) glycinergic neurotransmission is potentiated. With GlyT2 being inactivated (GlyT2-KO) neurotransmission decreases. (From Gomeza J, Arnsen W, Betz H, Eulenburg V: (2006) Neurotransmitter Transporters, *Handbook of Experimental Pharmacology* (175):457–483. Lessons from the knocked-out glycine transporters.)

responsible for limiting the intensity and duration of glycinergic neurotransmission while GlyT2 replenishes the presynaptic nerve cell (see also Table 2). GlyT2 therefore is a marker of glycinergic nerve terminals which are abundant in the spinal cord, brainstem and the cerebellum. Inactivation of GlyT2 results in muscular spasticity and is lethal; tetanus toxin which specifically blocks neurotransmitter exocytosis from glycinergic interneurons in the spinal cord has a similar effect. The distribution of GlyT1 mostly overlaps with that of GlyT2 but GlyT1 is also present in higher brain regions.

The transporters for 5HT, noradrenaline and dopamine, biogenic monoamines, are genetically related, exist as single isoforms and are expressed on the surface of nerve cells, which use monoamines as (or convert them into) their cognate neurotransmitter. The single-isoform monoamine transporters fulfil all three fundamental functions (reuptake, limiting synaptic transmission, and control of the extracellular neurotransmitter concentration). Inactivation of DAT, NET, or SERT results in an increased extracellular lifetime and level of monoamine neurotransmitter, but decreased intracellular storage and evoked release (Fig. 3).

DAT is predominantly expressed by dopaminergic brain neurons, NET by noradrenergic neurons in the central and peripheral nervous system, and SERT is restricted to the axons of serotonergic neurons, which originate in the ▶**raphe nuclei** and innervate numerous higher brain regions; therefore SERT is widely distributed in the brain. Outside the brain, 5HT transport can be measured on non-neuronal cells (e.g. platelets, lymphoblastoid cells and smooth muscle cells); most of the 5HT appearing in the circulation is taken up by platelets.

In the nervous system, DAT, NET, and SERT are distributed along axons, soma and dendrites. On the subcellular level they are localized at the

peri-synaptic plasma membrane – as opposed to a synaptic localization – indicating that the neurotransmitter diffuses out of the synaptic cleft to be transported back into the nerve cell (Fig. 3); alternatively, the monoamine transmitter may travel longer distances to be taken up far from the release site, possibly by a different nerve cell; the associated form of long-range neurotransmission is called volume transmission.

Ion Coupling Requirements

Most of the neurotransmitter transporters transform gradients of charged solutes (ions) into energy needed to pump neurotransmitters across the membrane. For instance, the glutamate carrier moves three Na^+ ions and one H^+ ion to the inside and 1 K^+ ion to the outside, whereas monoamine transporters carry along one to two Na^+ and one Cl^- ion. By contrast, vesicular transporters accumulate monoamine substrate at the expense of proton antiport (as the interior of the secretory vesicles is acidic); vesicular glutamate uptake additionally requires an electrical gradient. Extraneuronal monoamine transport is different as it is independent from the sodium gradient but only needs a positively charged substrate molecule.

Neurotransmitter transport can be electrogenic if it results in the net translocation of electrical charge (e.g. if more cations than anions are transferred into the cell interior). Moreover, some transporters may directionally conduct ions in a manner akin to ligand-gated ion channels; this ion flux is not coupled to substrate transport and requires a separate permeation pathway associated with the transporter molecule. In the case of the monoamine transporters (DAT, NET, SERT) the sodium current triggered by amphetamine, a monoamine and psychostimulant (see Fig. 4) is considered responsible for a high internal sodium concentration

Neurotransmitter Transporters. Figure 3 Dopamine turnover at a presynaptic nerve terminal. (a) Dopamine is produced by tyrosine hydroxylase (TH). When secretory vesicles are filled, they join the releasable pool of vesicles at the presynaptic membrane. Upon exocytosis, the diffusion of released dopamine is limited by reuptake via DAT. (b) If DAT is inactive, dopamine spreads in the cerebrospinal fluid but cannot accumulate in secretory vesicles. This results in a compensatory increase of dopamine hydroxylase activity and a higher extracellular dopamine level: mice with inactive DAT are hyperactive.

Neurotransmitter Transporters. Figure 4 The structures of DAT/NET substrates share an amino group linked to a phenyl ring by a chain of carbon atoms. MPP⁺ the metabolite of the neurotoxin MPTP (Methyl -phenyl-tetrahydropyridine) is also a substrate for the extraneuronal monoamine transporter.

that allows for neurotransmitter efflux. Amphetamine, in addition, sets free the vesicle content into the cytosol thus providing substrate for efflux; amphetamine molecules are transported by vesicular transporters and because they are weak bases dissipate the pH gradient, which is necessary to maintain high intravesicular substrate concentrations. Hence their effect is diminished by reserpine, an inhibitor of the vesicular monoamine transporter. The use of reserpine depletes the central nervous system of monoamine neurotransmitter, which causes akinesia and depression and in addition lowers sympathetic outflow leading to reduced blood pressure.

Regulation of Transporter Surface Expression

The localization of transporter molecules on the cell surface is dynamic rather than constitutive, such that transport capacity may be adapted to neuronal activity. Obviously, the mechanisms regulating uptake are of principal importance in pharmacology just as pharmacological transport inhibitors can regulate the density of transporters.

There are examples that cells have an intracellular reserve of functional transporter moieties: EAAC1, GAT1, CHT are predominantly – while NET only in some nerve cells – localized in the cell interior where transporters are stored membrane-bound in vesicles. Regulation occurs by transporter redistribution. Increased surface density leads to increased transport capacity while transporter internalization suppresses uptake.

The most prominent way a cell regulates transporter redistribution is via phosphorylation events although it is not clear if phosphorylation of the transporter protein itself is critically involved. High-affinity monoamine transport as well as transport by GAT1 and GlyT2 (SLC6A family members) is diminished upon activation of protein kinase C. PKC elicits internalization of transporter molecules and this is also true for the glutamate transporter (GLT1). By contrast, the

neuronal glutamate transporter EAAC1 increases upon PKC activation due to transporter redistribution from the cell interior to the surface. Since the plasma membrane residency of an EAAC1 transporter molecule is short (in the range of minutes) fast recycling of transporters must occur in a constitutive fashion; the action of PKC appears to slow internalization.

The ▶PKC family of protein kinases comprises an important family of cellular signal transducing molecules; its members may be stimulated by a rise in free intracellular calcium and by esters of fatty acids (such as diacylglycerol), which are products of ▶phospholipase C. Thus, PKC is stimulated indirectly by many receptors (G-protein coupled receptors and receptor tyrosine kinases) or directly by signals that cause calcium influx. In addition, transportable substrates of DAT (dopamine, amphetamines) can also trigger internalization by a mechanism that relies on PKC activation. This is not a general phenomenon among SLC6 family members but may represent a specific neuroprotective mechanism that limits the intracellular accumulation of toxic dopamine metabolites.

A second mechanism that impinges on the localization of transporters is through the association with proteins, the most prominent example being syntaxin. Syntaxin is a t-SNARE protein necessary for the fusion of vesicles with the plasma membrane (see the chapter on exocytosis). On the cell surface syntaxin consistently stabilizes the localization of GABA, noradrenaline, glycine, and 5HT transporters; the PKC α isoform can sever the interaction with syntaxin suggesting a general mechanism for transporter internalization.

Drugs

Glutamate Transporters

Since glutamate is quintessential in most if not all brain functions drugs inhibiting glutamate transport would likely cause detrimental effects. Conversely, increasing glutamate transporter density can have neuroprotective effects in degenerative disorders such as amyotrophic lateral sclerosis (ALS) provided that the disorder is not caused by impaired energy metabolism; the latter might result in transport reversal and glutamate efflux. Increased expression of GLT1 was found to be induced by β -lactam antibiotics and a neuroprotective effect of these drugs has been demonstrated in models of glutamate neurotoxicity.

Monoamine Transporters

The original monoamine hypothesis of depression states that “depressions are associated with a deficiency of catecholamines, particularly norepinephrine, at functionally important adrenergic receptor sites in the brain. Elation conversely may be associated with an excess of such amines.” The hypothesis was articulated in 1966 only after the mechanism of action of the tricyclic antidepressant desipramine and of the psychostimulants

cocaine and amphetamine had been clarified. In principle, the SERT, NET, and DAT are targets for drugs with antidepressant effects; dopamine uptake inhibition, however, has invariably been associated with addiction and none of the available antidepressants is a potent inhibitor of DAT (see Table 4).

Cocaine and desipramine inhibit the reuptake of monoamine neurotransmitters whereas amphetamine, which is a phenylalkylamine – similar in structure to the catecholamines, see Fig. 4 – competes for uptake and more importantly, evokes efflux of the monoamine neurotransmitters. All of them exert antidepressant effects. Cocaine and amphetamine are addictive whereas tricyclic antidepressants and their modern successors are not. The corollary of the addictive properties is interference with DAT activity. Blockade of DAT by cocaine or efflux elicited by amphetamine produces a psychostimulant effect; despite the different mechanisms even the experienced individual can hardly discern their actions. Because of the risk associated with inhibiting DAT mediated dopamine clearance the antidepressant effects of psychostimulants has not been exploited.

There is no definitive answer to whether inhibition of noradrenaline or serotonin is the most important in conferring antidepressant efficacy. The fact that all drugs require a period of several weeks before they become fully effective suggest that they modify gene expression in the brain and that the resulting altered biochemical state takes a long time to become stabilized. Although the selective serotonin reuptake inhibitors (SSRI) are no more efficacious than the first-generation tricyclic antidepressants, and do not act any faster, they are considerably safer in overdose. The toxicity of tricyclic antidepressants is due to their binding to cellular structures other than NET/SERT (such as ion channels and receptors).

Treatment of **attention deficit hyperactivity disorder** (ADHD) in children with psychostimulants

(amphetamine, methylphenidate) has often been labeled paradoxical, since these drugs are known to increase motor activity in healthy animals. Yet, these drugs effectively decrease motor excess in children with ADHD, improve symptoms and do so by increasing extracellular dopamine. The molecular targets are the dopamine carriers DAT and NET; abuse liability can be reduced with oral slow-release formulations of the psychostimulants or with the use of NET inhibitors (atomoxetine).

Undesired Effects of Drugs that Interfere with Transporter Function

The party drug MDMA (3,4-methylene-dioxymethamphetamine) as well as amphetamine causes efflux of all monoamine neurotransmitters. The effects of MDMA are described as psychostimulant and hallucinogenic and are judged differently from those of amphetamine. This difference is due to the stronger inhibition of SERT by MDMA as compared with amphetamine, which is a more potent dopamine releaser and more addictive than MDMA.

MDMA overdose as well as the concomitant consumption of selective serotonin reuptake inhibitors (SSRI) with other drugs that exert serotonergic effects (such as inhibitors of monoamine oxidase) can rapidly lead to the serotonin syndrome. Its symptoms, which are reversible upon cessation, of the drug include confusion, muscle rigidity in the lower limbs, and hyperthermia suggesting an acute reaction to serotonin overflow in the CNS. Blocking the function of SERT outside the brain causes side effects (e.g., nausea), which may be due to elevated 5HT; however, impairment of transporter function is not equivalent to direct activation of 5HT receptors in causing adverse effects such as fibrosis and pulmonary hypertension.

Due to its expression in the sympathetic nervous system NET activity is important in limiting the effects of

Neurotransmitter Transporters. Table 4 Clinically useful inhibitors of monoamine neurotransmitter transporters

Transporter	Moderately selective inhibitors in clinical use	Highly selective inhibitors (≥50-fold)	Nonselective inhibitors
NET	<i>Desipramine</i>	<i>Maprotiline, mianserin</i>	<i>Amoxapin, doxepine, nortriptyline, duloxetine</i>
	Reboxetine		
	Atomoxetine		
SERT	<i>Amitriptyline</i>	<i>Clomipramine</i>	
	<i>Imipramine</i>	Citalopram	
		Fluoxetine	
		Paroxetine	
		Venlafaxin	
DAT	Bupropion	–	–

Older tricyclic antidepressants are set in italics. The specificity of action of *tricyclic antidepressants* (in particular of *amitriptyline, imipramine, doxepine, nortriptyline, maprotiline*) is limited because at therapeutic levels these drugs also block receptors (H₁-histamine, α₁-adrenergic, muscarinic).

Neurotransmitter Transporters. Figure 5 PET images showing the brain distribution of DAT in an adult subject. Transaxial projections are at the level of the basal ganglia and at the upper midbrain. (b) Volume-rendered PET images. Clearly visible is the binding to the caudate (*Caud*) and putamen (*Lent*) structure. The midbrain structure (*arrow*) is the structure behind and below caudate-putamen. Insert: schematic drawing of striatum and thalamus (*Th s* and *Th d*, left and right side, respectively). (From: Jucaite A et al., *Eur J Nucl Med Mol Imaging* (2006); 33(6):657–668)

noradrenaline in the circulation. Thus amphetamines and cocaine can lead to vasoconstriction, high blood pressure, tachycardia, and myocardial ischemia resulting in chest pain. Conversely, NET malfunction due to a genetic effect is a cause of orthostatic intolerance without hypotension. If the metabolic decay of noradrenaline is blocked the susceptibility to transport reversal increases. Under this condition the natural food ingredient tyramine (present in wine and cheese) exerts a peripheral amphetamine-like action and may lead to a hypertensive crisis (“cheese syndrome”).

Age-related neurodegeneration primarily affects dopaminergic neurons projecting from the substantia nigra to the corpus striatum. DAT activity accounts for the vulnerability of dopaminergic neurons, as dopamine metabolites in the nerve cell create oxidative stress, which reduces viability. (i) DAT is necessary for high concentrations of intracellular dopamine; (ii) MPP⁺ the active neurotoxic principle of MPTP (1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridin) is an excellent substrate of DAT (see Fig. 3). MPTP ingestion causes a Parkinson’s disease-related movement disorder of rapid onset. (iii) DAT is also a prerequisite for the brain damage caused by methamphetamine.

Although the corpus striatum is the area with the highest density of DAT in the brain, other brain regions can also succumb to the dopamine-related neurodegeneration (cognitive defects but not movement disorders are consequences of chronic methamphetamine abuse). In order to assess the severity of Parkinson’s disease cocaine analogues labeled with short-lived radioactive isotopes may be employed to quantify the density of dopaminergic nerve cells in vivo using positron emission tomography (PET) scanners. A decrease in imaging of the caudate nucleus/putamen (corpus

striatum) correlates in particular with bradykinesia and rigidity symptoms (an image from a healthy brain is shown in Fig. 5). From Fig. 5 it also becomes clear that the sensitivity of a PET scan is too limited to examine regions expressing DAT at low density.

Older tricyclic antidepressants are set in italics. The specificity of action of *tricyclic antidepressants* (in particular of *amitriptyline*, *imipramine*, *doxepine*, *nortriptyline*, *duloxetine*, *maprotiline*) is limited because at therapeutic levels these drugs also block receptors (H₁-histamine, α₁-adrenergic, muscarinic).

Neurotransmitters

Neurotransmitters are molecules that convey a signal from one nerve cell to the other. Neurotransmitters can be biogenic amines (e.g. norepinephrine, serotonin),

amino acids (e.g. γ -aminobutyric acid, glutamate) or neuropeptides (e.g. corticotropin releasing hormone, substance P).

Synonyms

Neurotrophins

Definition

Neurotrophic factors are operationally defined as molecules that support neuron survival during development and subsequent to lesions. During development a significant portion of neurons undergoes apoptosis, the extent of which is widely believed to be controlled by limiting amounts of trophic factors provided by target tissues. Neurotrophic factors considered here include members of the nerve growth factor (NGF) family, the glial cell line-derived neurotrophic factor (GDNF) family, the ciliary neurotrophic factor (CNTF) family, as well as some members of the fibroblast growth factor (FGF) and transforming growth factor- β (TGF- β) families.

Mechanism of Action NGF Family (Neurotrophins)

Neurotrophins (NGF; brain-derived neurotrophic factor, BDNF; neurotrophin-3, NT-3; NT-4; NT-6) are important regulators of neural survival, development, function, and plasticity of the vertebrate nervous system [1]. Neurotrophins generally function as noncovalently associated homodimers. They activate two different classes of receptors, through which signaling pathways can be activated, including those mediated by Ras and members of the *cdc42/rac/rho* G protein families, MAP kinase, PI-3 kinase, and Jun kinase cascades.

NGF binds to the transmembrane receptor tyrosine kinase (trk, or p140^{trk}), now referred to as TrkA. BDNF binds to TrkB, whereas NT-3 can bind to all three Trk (A,B,C) receptors, with a preference to TrkC, and NT-4/5 can bind both TrkA and TrkB. Furthermore, all neurotrophins also bind with equal affinity to a 75 kD transmembrane glycoprotein, p75^{NTR} (also referred to

as low affinity receptor). Pro-NGF can activate p75^{NTR} and induces cell death in the presence of the coreceptor sortilin (Fig. 1).

Neurotrophin binding leads to autophosphorylation of the cytoplasmic tyrosine kinase domain of trk, containing 10 conserved tyrosine residues. Three of them (Y670, Y674, Y675) are present in the autophosphorylatory loop that controls kinase activity, whereas the others create docking sites for adaptor proteins containing phosphotyrosine-binding (PTB) or src-homology-2 (SH-2) motifs. These adaptor proteins couple Trk receptors to intracellular signaling cascades, which include the Ras/ERK protein kinase pathway, the phosphatidylinositol-3-kinase (PI-3-kinase)/Akt kinase pathway, and phospholipase C (PLC)- γ 1. Neurotrophins induce rapid ruffling and cytoskeletal rearrangements involving small G proteins of the Cdc-42/Rac/Rho family, which regulate the polymerization and turnover of F-actin. The ability of Trk receptors to activate specific signaling pathways is regulated by membrane trafficking. Transmission of the signals from the nerve terminal to neuronal cell bodies requires retrograde transport of, e.g., NGF together with the activated Trk receptors in endocytotic vesicles, whereby membrane sorting is thought to determine which pathways are activated by Trk receptors. Tyrosine kinase-mediated signaling by endogenous Trk receptors has been shown to promote survival and differentiation of all respective neuron populations.

Several signaling pathways are also activated via the p75^{NTR} receptor. Intracellularly, p75^{NTR} interacts with proteins including TRAF6, RhoA, NRAGE, and NRIF, and regulates gene expression, cell cycle, apoptosis, mitogenic responses and growth cone motility. An important pathway promoting cell survival of many cell populations involves activation of NF κ B. All neurotrophins have been shown to promote association of p75^{NTR} with the adaptor protein TRAF-6, whereas only NGF seems to be able to induce nuclear translocation

Neurotrophic Factors. Figure 1 Neurotrophins.

of NF κ B. Binding of neurotrophins to p75^{NTR} has also been shown to activate the Jun kinase pathway.

GDNF Family

GDNF is described as a survival promoting and neuroprotective activity for mesencephalic dopaminergic neurons in vitro and in vivo, as well as for spinal motoneurons [2]. Gene targeting has revealed that GDNF signaling is also required for the development of the enteric nervous system and kidney morphogenesis. GDNF utilizes a receptor system comprised of a signaling component encoded by the c-ret protooncogene and a glycosylphosphatidylinositol (GPI)-anchored coreceptor, GDNF family receptor α 1 (GFR α 1), which is required for ligand binding. The GDNF family comprises four members, all of which utilize Ret as signaling receptor with the aid of different members of the GPI-linked coreceptor: neurturin-GFR α 2, artemin - GFR α 3, and persephin - GFR α 4, although promiscuity between the different receptors is also possible.

The current model of GDNF signaling proposes a rather stringent division in the functions of Ret and the GFR α receptor, whereby Ret is regarded as the signaling receptor and GFR α as the ligand-binding receptor. Signaling is initiated upon formation of the heterodimeric RET/GFR α receptor complex. In this context, GDNF-induced signaling leads to autophosphorylation of the intracellular tyrosine kinase of RET, the involvement of Grb2 adaptor and Shc docking proteins resulting in activation of the Ras/ERK, PI-3 kinase/Akt pathways as well as PLC- γ .

Recent studies have shown that GFR α receptors are localized in lipid rafts of the plasma membrane. The binding of GDNF to GFR α 1 also recruits Ret to the lipid rafts and triggers an association with src, which is required for effective downstream signaling. In absence of RET neural cell adhesion molecule NCAM can serve as a signaling receptor for GDNF in combination with GFR α 1, resulting in activation of Fyn and FAK protein tyrosine kinases. Furthermore, GDNF, ARTN and NRTN but not PSP have been shown to bind to heparin sulfate proteoglycan syndecan 3 serving as a coreceptor by presenting the ligand to the GFL/RET complex (Fig. 2).

CNTF Family

CNTF is expressed in glial cells within the central and peripheral nervous system. CNTF lacks a signal sequence and is not secreted by the classical secretory pathway, but is thought to convey its cytoprotective effects after release from adult glial cells by some mechanism induced by injury [3,5].

CNTF supports survival and differentiation of selected neuron populations including sensory, sympathetic, and motoneurons. Also, nonneuronal cells, such as

Neurotrophic Factors. Figure 2 GDNF family.

oligodendrocytes, microglial cells, liver cells, and skeletal muscle cells, respond to exogenous CNTF. Mice lacking CNTF develop normally and only in adulthood do they exhibit a mild loss in motoneurons, suggesting that CNTF acts on the maintenance of these cells [5].

The CNTF receptor complex is most closely related to, and shares subunits with, the receptor complex for interleukin-6 (IL-6) and leukemia inhibitory factor (LIF). The specificity conferring α subunit of the CNTF receptor complex (CNTFR α) is a GPI-anchored membrane protein lacking a conventional transmembrane domain. Mice lacking CNTFR α die perinatally, suggesting a developmentally important CNTF-like ligand. CNTF binding to CNTFR α results in the formation of a heteromeric tripartite receptor complex upon recruitment of gp130 and LIFR β . IL-6 requires IL6R α and a homodimer of gp130 for activity, and LIF requires gp130 and LIFR β . Signal transduction is mediated via tyrosine phosphorylation through constitutively associated Janus kinases (JAK) and signal transducers and activators of transcription (STAT). Activated STATs dimerize, translocate to the nucleus to bind specific DNA sequences and resulting in enhanced transcription of responsive genes.

FGF Family

FGFs have been demonstrated to influence the growth and function of cells of the vascular, muscular, epithelial and nervous systems. They are now thought to be involved in processes ranging from morphogenesis, tissue maintenance, and repair to oncogenesis. To date, 20 distinct FGFs have been discovered, numbered consecutively from 1 to 20. Particularly FGF2, FGF5, FGF9, and FGF20 have been discussed in the context of regulating neuron survival of, e.g., motoneurons, mesencephalic dopaminergic neurons, cholinergic neurons. FGFs are small polypeptide growth factors, many of which contain signal peptides for secretion. FGFs have a strong affinity for heparin and heparan-like glycosaminoglycans (HLGAG) of the extracellular

matrix. There are four FGF receptors, FGFR-1 to FGFR-4, known, containing two intracellular tyrosine kinase domains. FGFR diversity is additionally increased by alternative splicing of the individual FGFR genes. FGF signaling is propagated via PLC γ , src, Crk-mediated, and SNT-1/FRS2 signaling pathways.

TGF- β Family

TGF- β s are a growing superfamily of cytokines with widespread distribution and diverse biological functions [4]. TGF- β has been described to control neuronal performances including the regulation of proliferation of neuronal precursors, induction/specification of distinct neuronal phenotypes, survival/death decisions and neuronal differentiation. TGF- β s fall into several subfamilies including the TGF- β s 1, 2, and 3, the bone morphogenetic proteins (BMPs), the growth/differentiation factors (GDFs), activins, and inhibins. TGF- β signal through heteromeric complexes of type II and type I serine-threonine kinase receptors ([▶receptor serine/threonine kinases](#)), which activate the downstream Smad signal transduction pathway. Three classes of Smads have been defined: receptor-regulated Smads (R-Smads), common-mediator Smads (co-Smads) and inhibitory Smads (I-Smads). TGF- β binding results in the phosphorylation of Smad2 (R-Smad), its dissociation from the receptor and assembly of heteromeric complexes with Smad4 (co-Smad), which finally translocates to the nucleus where it modulates gene expression. Additionally, there are also SMAD-independent signaling pathways available, involving TAK1/JNK and p38, Ras-Erk, RhoA-p160ROCK or PP2A-S6K pathways.

New Factors

Conserved dopamine neurotrophic factor (CDNF) is a newly discovered growth factor with a high specificity and activity to promote survival of dopaminergic neurons in vitro and in vivo. CDNF is homologous to an astrocyte-derived growth factor, MANF-1.

Clinical Use (Including Side Effects)

Over the past 15 years, neurotrophic factors have generated considerable excitement because of their therapeutic potential for a wide variety of currently incurable degenerative neurological disorders. Attempts to replicate the success of animal studies in demonstrating the therapeutic efficacy in clinical trials has been less successful. CNTF, BDNFs and IGF-I have been tested in clinical trials for the treatment of [▶amyotrophic lateral sclerosis](#), NGF in clinical trials for [▶peripheral neuropathies](#) and GDNF in trials for [▶Parkinson's disease](#) [2,4,5]. However, many issues with regard to technical and pharmacological parameters, such as drug delivery to the site of action, and mode of application, remain to be solved before a final judgement on the use of neurotrophic factor therapy can be drawn.

NFAT Family of Transcription Factors

NOEMI SOTO-NIEVES, IRENE PUGA,
FERNANDO MACIAN
Albert Einstein college of Medicine, Bronx, NY, USA

Synonyms

Nuclear factor of activated T cells cytosolic NFATc

Definition

Originally described in the immune system, NFAT proteins comprise a family of transcriptional factors that play key roles in many cellular processes that control not only immune responses but also the development, regulation, and differentiation of many other tissues. Activation of NFAT proteins results in the expression of specific sets of genes that regulate multiple cell functions [1, 2].

Structure and Members

The NFAT family encompasses five different proteins that form part of the extended ►Rel/NF- κ B family. The five NFAT members are: NFAT1 (also known as NFATc2 or NFATp), NFAT2 (NFATc1 or NFATc), NFAT3 (NFATc4), NFAT4 (NFATc3 or NFATx), and NFAT5 (TonEBP or OREBP). NFAT5 is the only NFAT member that is not regulated by calcium. This protein also lacks the conserved regulatory domain present in the other NFATs and its activation occurs in response to osmotic stress. This chapter will focus exclusively on the four calcium-regulated NFAT family members.

NFAT proteins contain three distinct domains: the NFAT homology region (NHR), the Rel-homology region (RHR), and the C-terminal domain (Fig. 1). The NHR is conserved in all NFATs and contains a strong transactivation domain (TAD) and the regulatory domain, which is essential for the calcium-mediated regulation of NFAT. The regulatory domain contains several phosphorylated serines, the docking sites for ►calcineurin (Cn) and the NFAT kinases, and the sequences that control the shuttling of NFAT between the nucleus and the cytoplasm. The RHR is highly conserved within all NFAT proteins and shares structural homology with the Rel domain of the NF- κ B family of transcription factors. It contains the DNA-binding domain, which is also involved in protein-protein interactions. In the C-terminal resides a TAD, although its function has not been fully characterized yet [2].

Basic Mechanisms

Regulation of NFAT Activation

The activation of NFAT is regulated by calcium. In resting cells, NFAT proteins localize in the cytoplasm

NFAT Family of Transcription Factors. Figure 1 Schematic structure of NFAT proteins. The three main domains of NFAT are shown: the NFAT homology region (NHR), the Rel-homology region (RHR), and the C-terminal domain. The NHR contains the Calcineurin docking site (PxIxIT), the serine-rich regions (SRR), and SPXX-repeat motifs (SPs), which contain the phosphoserine residues that are removed by Calcineurin, the nuclear localization signal (NLS), and the transactivation domain (TAD). The RHR has two different domains, the N-terminal (RHR-N) and the C-terminal (RHR-C), which have specific functions in ensuring DNA contacts and protein–protein interactions. The C-terminal domain also contains an activation domain.

and are highly phosphorylated. Engagement of calcium signaling-coupled receptors causes an increase of intracellular calcium that activates Calcineurin, a ►calmodulin (CaM)-dependent phosphatase. Activated Calcineurin dephosphorylates NFAT inducing its translocation into the nucleus. In the absence of sustained calcium signaling, NFAT is rephosphorylated by nuclear kinases and exported back into the cytoplasm (Fig. 2). Phosphorylation of NFAT proteins occurs in the serine-rich motifs localized in the NHR (see Fig. 1) and controls both cytoplasmic retention and nuclear export. Several cytosolic and nuclear kinases are required to control activation of all calcium-regulated NFAT proteins, including casein kinase 1 and the glycogen synthase kinase 3. Other kinases have been shown to be specific for a particular NFAT family member, like the mitogen-activated protein kinases (MAPKs) p38 and JNK, which specifically phosphorylate NFAT1 and NFAT2, respectively [1, 2].

The NHR contains also the conserved Calcineurin docking site, PxIxIT, required for the physical interaction of NFAT and Calcineurin. Dephosphorylation of at least 13 serines residues in the NHR induces a conformational change that exposes the ►nuclear localization sequences (NLS), allowing the nuclear translocation of NFAT. Rephosphorylation of these residues unmasks the nuclear export sequences that direct transport back to the cytoplasm. Engagement of receptors such as the antigen receptors in T and B cells is coupled to phospholipase C activation and subsequent production of inositol triphosphate. Increased levels of inositol triphosphate lead to the initial release of intracellular stores of calcium. This early increase of calcium induces opening of the plasma membrane calcium-released-activated-calcium ►(CRAC) channels,

which allow entry of extracellular calcium guaranteeing sustained levels of calcium in the cytosol. This sustained calcium mobilization is required to maintain Calcineurin enzymatic activity. The calcium binding protein CaM is activated and binds Calcineurin, displacing its autoinhibitory domain. Activated Calcineurin is then capable of dephosphorylating and activating NFAT. Although the regulation of NFAT proteins is mostly dependent on the intracellular calcium concentrations and on the enzymatic activity of Calcineurin and NFAT kinases, other mechanisms of regulation can also play important roles. For example, the specific NFAT2/ α A isoform promoter contains a NFAT binding site that allows a positive transcriptional autoregulation of this isoform. Similarly, signaling pathways that control the activation of transcription factors cooperating with NFAT also play crucial roles in the overall modulation of NFAT activity.

Mechanisms of Action

Activated NFAT proteins bind DNA and interact with other transcription factors to positively or negatively regulate the transcription of many genes. The RHR contains the DNA binding domain, which is responsible for the interaction of NFAT proteins with specific DNA sequences. It is also mainly through this domain that NFAT can interact with other transcriptional factors to form higher-order transcriptional complexes. The RHR can adopt different structural conformations on DNA binding sites, which allows NFAT to interact with specific transcriptional partners on each NFAT-regulated gene promoters or enhancers. Cooperative interactions with members of the ►activator protein-1 (AP-1) family of transcription factors regulate most NFAT-dependent gene transcription induced in activated immune cells. Several other transcriptional partners have been identified for

NFAT Family of Transcription Factors. Figure 2 Regulation of NFAT activation. Extracellular stimuli activate receptors such as the antigen receptor in T cells that lead to the release of calcium from the intracellular stores in the endoplasmic reticulum (ER) and subsequent opening of the calcium-released-activated-calcium (CRAC) channels. Calcium binds and activates calmodulin (CaM), which in turn binds and activates Calcineurin (Cn). Calcineurin dephosphorylates NFAT inducing its nuclear translocation. Cooperation of NFAT and other transcription factors (e.g., AP-1 proteins) in the nucleus promotes gene transcription. NFAT kinases rephosphorylate NFAT, which induces export back to the cytoplasm and the termination of NFAT activation. NFAT activity may be pharmacologically inhibited by blocking Calcineurin enzymatic activity with cyclosporine A or FK506, or interrupting the interaction of Calcineurin and NFAT with inhibitor peptides [3].

NFAT proteins, for which functional synergy and/or physical protein/protein interaction with an NFAT protein have been described. Positive synergy has been shown between NFAT and Maf, GATA-proteins, MEF2, IRF4, C/EBP, Oct, Egr transcription factors, and PPAR γ ; while interactions with ICR and p21^{snft} negatively regulate NFAT activity. The nature of these complexes is responsible for the activation or suppression of specific sets of genes in multiple tissues in response to different stimuli [4, 5].

NFAT Functions

NFAT was first described in cells of the immune system, but these transcription factors are widely expressed and their function is crucial in the regulation, development, and differentiation of many nonimmune tissues.

Immune System

NFAT was initially identified in activated T cells as a DNA binding activity required for IL-2 expression, a cytokine that plays a key role in T cell activation and survival. Subsequent studies revealed the involvement

of NFAT in the expression of many other cytokines including, among others, IL-3, IL-4, IL-5, IL-10, IL-13, GM-CSF, TNF, and INF γ , as well as several cell surface receptors, such as CD40L, FasL, and IL2-R α , required for proper regulation of immune responses. Activation of T cells by engagement of the **T cell receptor (TCR)** and costimulatory molecules (i.e., CD28) results in the increase of free cytosolic calcium and in the activation of the RAS-MAPK and PKC signaling pathways. Engagement of these signaling pathways induces the activation of members of the NFAT and AP-1 families of transcription factors. In the nucleus, NFAT and AP-1 proteins form cooperative complexes to induce the expression of many activation-induced genes. As described above, other transcriptional partners also play important roles modulating NFAT-mediated gene expression in T cells [4].

In the absence of costimulation, T cells that receive signaling through the TCR become **anergic** and unresponsive to new antigen stimulation. The anergic state in T cells results from activation of NFAT in the absence of AP-1. In this scenario, a specific set of genes is

upregulated. The proteins encoded by these genes are responsible for blocking TCR signaling in anergic T cells.

Besides being a key regulator of mature T cell function, NFAT is also required in T cell development and T-helper cell differentiation. Studies performed on NFAT or Calcineurin-deficient mice have confirmed that NFAT signaling is involved in thymocyte development. NFAT proteins regulate thymocyte proliferation and survival as well as the development of immature CD4⁺ CD8⁻ thymocytes into mature CD4⁺ or CD8⁺ T cells. Cooperation between NFAT proteins and STAT factors is involved in the establishment of the epigenetic changes that determine activation of distinct cytokine genes in specific T helper cell subpopulations. Cooperation with lineage-specific transcription factors, like GATA-3 in T helper 2 cells, is also required to activate the expression of those genes.

The role of NFAT in the immune system is not restricted to T cells. NFAT proteins are also expressed in other cells of the immune system, such as B cells, NK cells, and mast cells, where they have been shown to regulate the expression of cytokines, cell surface receptors, and immunoglobulins [4, 5].

Musculoskeletal System

NFAT proteins are expressed in skeletal, cardiac, and smooth muscle and play important roles in the regulation of the development and differentiation of these tissues. In skeletal muscle, NFAT isoforms are expressed at different stages of development and regulate progression from early muscle cell precursors to mature myocytes. NFAT proteins have also been shown to control the expression of the myosin heavy chain and positively regulate muscle growth [1, 2].

Analysis of animals deficient in NFAT1 has shown that NFAT negatively regulates cartilage growth. Bone remodeling is also regulated by calcium/NFAT signaling. NFAT controls osteoclast and osteoblast differentiation, coupling bone formation and resorption during skeletal development and repair. In osteoclasts, increased intracellular calcium promoted by RANKL signaling activates NFAT2, which promotes the expression of several osteoclast-specific genes [2].

Cardiovascular System

NFAT2 plays a key role in the development of the embryo's heart. In the precursor cells, there is a temporal and spatial specific expression of NFAT2, which directs the formation of the valves and the septum in the heart. In the adult heart, NFAT proteins also cooperate with transcription factors of the GATA and MEF2 families to regulate cardiac muscle hypertrophic responses.

Calcineurin signaling and NFAT also play an important role in the regulation of vascular development, balancing activation and inhibition of angiogenesis. NFAT3 and

NFAT4 are expressed in perivascular mesenchymal cells, which are implicated in the assembly of blood vessels during embryogenesis. The lack of NFAT signaling results in a disorganized and inappropriate growth of developing vessels. In endothelial cells, Vascular Endothelial Growth Factor activates NFAT-dependent transcription of endothelial genes like Cyclooxygenase-2 and promotes endothelial cell migration.

Other Systems

NFAT proteins have also been shown to modulate many other cellular functions. For instance, they regulate neuronal axon growth and are also involved in insulin homeostasis, by controlling beta cell growth and regulating insulin-signaling pathways and adipogenesis. Given that one or more NFAT family members are expressed in almost any tissue, and that recent data have implicated NFAT proteins in the control of essential processes in new cell types, it is becoming increasingly evident that the calcium/Calcineurin/NFAT axis constitutes a crucial signaling pathway for the regulation of the development and function of many different tissues.

Pharmacological Relevance

The development of drugs that block Calcineurin phosphatase activity has allowed successful prevention of graft rejection. Due to the key role that NFAT has in T-cell activation, these inhibitors behave as potent immunosuppressors. Nevertheless, the important roles that NFAT proteins have in other tissues suggest that exploring the use of similar drugs in other pathological contexts may be clinically and therapeutically relevant.

Classical Calcineurin Inhibitors

Cyclosporin A and FK506 are the most commonly used immunosuppressant drugs and their clinical use has transformed the field of organ transplantation. Both drugs have different structures but share a similar mechanism of action: inhibiting Calcineurin enzymatic activity. For successful inhibition, Cyclosporin A and FK506 must form a complex with their intracellular receptors, cyclophilin A and the FK506 binding protein FKBP12, respectively. These complexes bind then to sites located in the region of the Calcineurin A subunit that interacts with Calcineurin B, and inhibit the phosphatase activity required for NFAT activation. The crucial role that Calcineurin and NFAT signaling play in the activation of T and B cells and in the control of many of the genes that regulate immune responses (i.e., cytokines, cytokine receptors, and costimulatory molecules) underlies the effectiveness and potency of these drugs. So far Cyclosporine A and FK506 are the most potent immunosuppressive drugs in clinical use, despite their severe side effects, specially their nephrotoxicity. To

diminish the toxicity of these immunosuppressants, synthetic inhibitors are being designed with similar inhibitory activity on Calcineurin but with reduced renal toxicity [3].

Other Inhibitors

The search for new inhibitors of NFAT with higher specificity and lower toxicity has led to the design of specific peptides that are able to block the NFAT/Calcineurin interaction. The docking site of Calcineurin in NFAT has been used to design small peptides that specifically prevent the binding of Calcineurin to NFAT proteins. Analysis of a combinatorial library of P_xI_xIT-based peptides has produced a high affinity peptide that, in experimental *in vitro* and animal models, blocks NFAT binding to Calcineurin, inhibits NFAT-dependent transcription and prolongs allograft acceptance in mice. Therapeutic use of peptide inhibitors may be hindered by problems associated with delivery and product stability. Small organic molecules, with almost limitless structural possibilities, also offer an exciting possibility to design new inhibitors with improved specificity, stability, delivery, and tissue distribution. Being able to selectively inhibit NFAT makes the future development of these drugs an attractive alternative to the classical inhibitors of Calcineurin activity, as they can offer similar or even better therapeutic effectiveness with fewer secondary effects [2].

Niacin

E. BACK¹, H. K. BIESALSKI²

¹Novartis Pharma GmbH, Nuremberg, Germany

²University of Hohenheim, Institute of Biological Chemistry and Nutrition, Stuttgart, Germany

Definition

Niacin (Fig. 1) is a collective name for all vitamers having the biological activity associated with nicotinamide (= pyridine-3-carboxamide), including nicotinic acid (= pyridine-3-carboxylic acid) and a variety of pyridine nucleotide structures.

Nicotinamide and nicotinic acid are both white crystalline substances. Their aqueous solution has a maximal UV absorbance at 263 nm. Both vitamers have the same biological activity as they can be converted into each other. Figure 2 shows the structure of the coenzyme forms NAD⁺ and NADP⁺.

Most foods of animal origin contain nicotinamide in the coenzyme form (high bioavailability). Liver and meat are particularly rich in highly bioavailable niacin. Most of the niacin in plants, however, occurs as nicotinic acid in overall lower concentrations and with a lower bioavailability. The major portion of niacin in cereals is found in the outer layer and its bioavailability is as low as 30% because it is bound to protein (niacytin). If the diet contains a surplus of L-tryptophan (Trp), e.g., more than is necessary for protein synthesis, the liver can synthesize NAD from Trp. Niacin requirements are therefore declared as niacin equivalents (1 NE = 1 mg niacin = 60 mg Trp).

Mechanism of Action

NAD⁺ and NADP⁺ are coenzymes of dehydrogenases. NADH and NADPH are intermediate carriers of both hydrogen and electrons. Most NAD-dependent enzymes are located in the mitochondria and deliver H₂ to the respiratory chain whereas NADP-dependent enzymes take part in cytosolic syntheses (reductive biosyntheses).

NAD⁺ possesses some non-redox functions as well. The glycosidic linkage between nicotinamide and ribose is a high-energy bond. The energy provided by

Niacin. Figure 1 Structure of nicotinic acid and nicotinamide.

Niacin. Figure 2 Structure of the coenzymes NAD⁺ (nicotinamide-adenine dinucleotid) and NADP⁺ (nicotinamide-adenine dinucleotid phosphate).

breaking this bond allows the addition of ADP-ribose to a variety of nucleophilic acceptors.

Researchers found that NAD serves as a substrate in poly(ADP-ribose) synthesis, a reaction important for DNA repair processes. In addition, it takes part in mono (ADP-ribosyl)ation reactions that are involved in endogenous regulation of many aspects of signal transduction and membrane trafficking in eukaryotic cells.

NADP can be converted to nicotinic acid adenine dinucleotide phosphate (NAADP), which has distinct functions in the regulation of intracellular calcium stores. The studies of these new roles of NAD(P) in metabolism are in their early stages, but they might soon help to better understand and explain the symptoms of niacin deficiency (▶[pellagra](#)) [1].

Clinical Use (Including Side Effects)

Nicotinic acid is used in the treatment of hyperlipidemia. It causes various changes in lipid and lipoprotein metabolism when administered in high doses (up to 5 g/d):

The maximum changes achieved in a study were –20% total serum cholesterol, –40% serum triglycerides and +15% HDL-cholesterol [2]. However, there are considerable short- and long-term side-effects. The treatment should therefore be monitored by a doctor.

Nicotinamide potentiates the cytotoxic effects of chemotherapy and radiation treatment against tumor cells. This effect is probably attributable to increased

blood flow and oxygenation of the tumor tissue. Furthermore, insulin-dependent ▶[diabetes mellitus](#) might be prevented by the administration of high doses of nicotinamide (about 3 g/d) according to recent studies. The mechanisms have yet so far not been fully elucidated and potential side-effects not completely explored [2].

Nicotinic acetylcholine receptor

Definition

The nicotinic receptor (nAChR) comprises a family of receptor subtypes that respond to the neurotransmitter acetylcholine (ACh) and the tobacco alkaloid nicotine.

nAChRs are found in:

1. Skeletal muscle (muscle nAChR, comprised of $\alpha 1, \beta 1, \gamma$ or ϵ , and δ subunits, also present in electric tissues of *Torpedo* and *Electrophorus*)
2. Sympathetic, parasympathetic and sensory neurones, chromaffin, neuroblastoma and PC12 cells (ganglionic nAChR, typically comprised of $\alpha 3, \alpha 5, \beta 2, \beta 4$ or $\alpha 7$ subunits)
3. CNS neurones (in mammals: heteromeric nAChR comprised of α/β combinations from $\alpha 2, \alpha 3, \alpha 4, \alpha 5, \alpha 6, \beta 2, \beta 3, \beta 4$ subunits, or homomeric nAChR comprised of $\alpha 7$ subunits only)
4. Non-neuronal cells (including astrocytes, mechanosensory hair cells, macrophages, keratinocytes, endothelial cells of the vascular system, muscle cells, lymphocytes, intestinal epithelial cells and various cell-types of the lungs)

5. Invertebrate nervous systems (invertebrate nAChR)

The subtypes of nAChR that are not found in skeletal muscle are collectively referred to as 'neuronal nAChRs'.

The muscle nAChR is the prototype of the cys-loop family of ligand-gated ion channels (LGIC) that also include GABA_A, GABA_C, glycine, 5HT₃ receptors, and invertebrate glutamate-, histamine-, ACh-, and 5HT-gated chloride channels.

Basic Characteristics

The nAChR is comprised of five subunits, each of which spans the lipid bilayer to create a water-filled pore or channel (Fig. 1a). Each subunit consists of four transmembrane segments, the second transmembrane segment (M2) lines the ion channel (Fig. 1b). The extracellular N-terminal domain of every subunit

Nicotinic Receptors. Figure 1 (a) Schematic representation of a nAChR. Five subunits span the lipid bilayer to create a water-filled central channel that is permeable to cations when opened in response to agonist binding. Binding of two agonist molecules (represented by red spheres) is required for channel opening. (b) Structure of a single subunit. Each subunit has a large extracellular domain containing the 'cys loop' and traverses the membrane 4 times; the second transmembrane domain lines the ion channel. There is a variable intracellular loop between transmembrane spans 3 and 4 that contains putative phosphorylation sites; this region is likely to be important for regulation, trafficking and interaction with cytoskeletal and scaffolding proteins. (c) The agonist-binding site. Agonist (red sphere) binds to a site at the interface between two subunits. The primary (α) subunit contributes amino acids in three loops (A,B,C) to bind the agonist, supported by additional residues in three loops (D,E,F) from the complimentary face of the adjacent subunit (γ, ϵ or δ in muscle nAChR, α or β in neuronal nAChR). The amino acids indicated by their single letter codes are numbered according to the nAChR from *Torpedo* electric tissue. This source has provided large quantities of muscle-like nAChR for analysis.

contains a 'cys loop' that is the signature sequence of the LGIC family: two cysteine residues, separated by 13 amino acids form a disulphide bond to create a loop. The binding site for agonists, including ACh and nicotine, occurs at the interface between adjacent subunits, in the extracellular part of the receptor created by the N-terminal domains of its subunits. The primary binding site is found on α subunits that possess a pair of adjacent (vicinal) cysteine residues and a number of key hydrophobic residues organised in three loop structures (A,B,C) that coordinate the agonist (Fig. 1c). The complimentary subunit (γ or ϵ and δ in muscle nAChR; α or β in neuronal nAChR) also contribute three loops (D,E,F) containing hydrophobic residues. In muscle and $\alpha\beta$ heteromeric neuronal nAChR there are two binding sites and both must be occupied by agonist in order to open the ion channel.

In the resting (closed) state, the ion channel is occluded by a 'hydrophobic girdle' that constitutes a barrier to ion permeation. Agonist binding in the extracellular domain promotes a conformational change that results in a rotational movement of the M2 helices lining the pore, widening the pore by ~ 3 Å. This results in an influx of Na^+ and Ca^{2+} (the relative permeability of these two cations depends on nAChR subtype), and an efflux of K^+ under normal physiological conditions. Despite the presence of agonist, the nAChR channel closes within seconds to minutes, to enter a ►desensitised state. In this condition, the nAChR is refractory to activation. Multiple desensitised states have been proposed to exist.

At the muscle endplate, nAChR activation produces ►depolarisation that triggers muscle contraction. In sympathetic ganglia, postsynaptic nAChRs also mediate synaptic transmission, resulting in the depolarisation of postganglionic neurones and the increased likelihood of generating an action potential. In the vertebrate CNS this postsynaptic function is less common. nAChR are more often found at presynaptic and extrasynaptic locations on brain neurones and exert a modulatory influence on brain function. This is achieved by alteration in excitability or increases in intracellular Ca^{2+} . Thus presynaptic nAChR stimulate the release of various neurotransmitters in different brain regions; somatodendritic nAChR can promote long-term changes by altering gene expression.

The $\alpha 7$ homomeric nAChR has attracted interest because of its high relative permeability to Ca^{2+} (comparable to that of the NMDA receptor). Its association with glutamate terminals supports a contribution to ►long-term potentiation (LTP) through presynaptic facilitation of glutamate release. Postsynaptically, $\alpha 7$ nAChR can activate several cell signalling pathways, leading to activation of ERK, CREB and ►immediate early genes such as cFos.

Drugs

Nature has created a diverse array of plant and animal toxins that act at mammalian muscle and ganglionic nAChRs or invertebrate nAChRs because the critical physiological functions of these receptors make them prime targets for defensive or predatory strategies. More recently, the perceived validity of neuronal nAChR as therapeutic targets has prompted the generation of new synthetic ligands. Examples are listed in Table 1.

Agonists activate nAChR by binding to the agonist-binding site (Fig. 1). They can remain bound (often with higher affinity) when the nAChR enters the desensitised state.

Competitive Antagonists interact reversibly with the nAChR at, or close to, the agonist-binding site, stabilising the receptor in a conformation with the channel closed and preventing agonists from accessing their binding site. Inhibition by reversible competitive antagonists is surmountable with increasing agonist concentration, shifting the concentration response relationship to the right.

Non-competitive antagonists do not compete for binding to the agonist-binding sites, but interact with distinct sites that modify nAChR function. Their inhibition is not surmountable with increasing agonist concentration. Some non-competitive antagonists are 'channel blockers' that act either by blocking the entrance to the nAChR channel or entering the lumen of the channel. The action of such drugs can be 'state-dependent', requiring prior activation of the nAChR to allow access to the channel. Many compounds that have other primary targets can also act as non-competitive antagonists of nAChR. Examples include antagonists of voltage operated Ca^{2+} channels, NMDA channel blockers, antidepressants, steroids, β amyloid peptide.

Positive allosteric modulators potentiate responses to nicotinic agonists by acting at a site distinct from the agonist-binding site. Such effects are well established for other receptor classes (e.g. benzodiazepines acting at GABA_A receptors), but have only relatively recently been characterised for neuronal nAChR. The acetylcholinesterase inhibitors galanthamine and physostigmine, the neurotransmitter 5HT and the opiate codeine can enhance responses to agonists, without discriminating between nAChR subtypes. The 5HT metabolite 5-hydroxyindole and a novel synthetic molecule PNU-120596 are selective modulators of $\alpha 7$ nAChR.

Therapeutic or Agrochemical Applications

Historically ganglionic nAChR have been targets for treating hypertension. The discovery of a large family of nAChR subtypes in the CNS, coupled with observations that nicotine has anti-nociceptive, neuroprotective and cognitive effects, has led to the recognition that neuronal nAChR are potential targets

Nicotinic Receptors. Table 1 Some drugs that act at nAChRs

	Drug	Source	Specificity
Agonists	ACh	Endogenous agonist	–
	(±)-Anatoxin-a	<i>Anabaena flos aquae</i> (Blue green algae)	–

	Mecamylamine	Synthetic	–

for treating a wide range of disorders. These include Alzheimer's and Parkinson's diseases, schizophrenia, attention-deficit hyperactivity disorder (ADHD), pain. nAChRs in peripheral cells are of interest in treating inflammation in different scenarios including ulcerative colitis and wound healing. Nicotine, cytisine (Tabex) and varenicline (Chantix, Champix) are in use for smoking cessation.

Imidacloprid is a widely used neonicotinoid insecticide that kills pests by targeting their central nAChRs. Levamisol is used to kill nematodes by acting on nAChRs in the worm's muscles.

Nigrostriatal Tract/Pathway

The nigrostriatal tract is one of the four main dopaminergic pathways in the central nervous system. About 75% of the dopamine in the brain occurs in the nigrostriatal pathway with its cell bodies in the substantia nigra, whose axons project in the corpus striatum. Degeneration of the dopaminergic neurons in the nigrostriatal system results in Parkinsons disease.

► Dopamine System

Nitrates

A family of clinically used compounds that release NO and relax most smooth muscles.

► Smooth Muscle Tone Regulation
► Guanylyl Cyclases

Nitroergic Nerve

The nerve whose transmitter function depends on the release of NO. Nonadrenergic, noncholinergic inhibitory responses of smooth muscle are associated mainly with activation of nitroergic nerves.

► Nitric Oxide

Nitroergic Transmission

Nitroergic transmission is synaptic transmission by nitric oxide. In contrast to other transmitters, NO is not preformed and stored in synaptic vesicles. When an

action potential arrives at a nitroergic terminal, the Ca^{2+} entered through the presynaptic Ca^{2+} channels activates neuronal NO synthase and NO is then produced ad hoc from arginine. It is released not by exocytosis but by diffusion through the plasma membrane. In further contrast to other transmitters, the postsynaptic receptor is not a membrane protein but the cytosolic enzyme soluble guanylyl cyclase, which catalyzes formation of the second messenger cyclic GMP. Finally, NO is not inactivated by enzymatic degradation or cellular uptake but by spontaneous oxidation. NO is a transmitter in the enteric nervous system and in some blood vessels where it causes vasodilation.

Definition

In contemporary societies replete with various industries and automobiles, NO_x (NO, NO_2 , and NO_3) has been recognized to be one of the important factors responsible for air pollution. Only two decades ago, NO was found to be an essential molecule that regulates cellular/molecular functions in mammals. NO is also enzymatically synthesized in nonmammals, invertebrates, and yeasts. Therefore, the origin of NO may date back to the birth of life arising from single cell organisms living around 3-billion years ago.

Furchgott and Zawadzki [1] first discovered that endothelial cells release a substance(s) responsible for the relaxation of vascular smooth muscle by acetylcholine; this substance was named “► endothelium-derived relaxing factor (EDRF).” This epoch-making discovery answers the question raised for nearly one hundred years by pharmacologists about why vascular smooth muscle is relaxed by acetylcholine, which however elicits contraction of the other smooth muscles. Because of its instability, the true chemical nature of EDRF was not easily identified. Several years later, several research groups independently found that the biological activities and biochemical properties of EDRF were identical

to those of NO. In the early 1990s, NO synthesizing enzymes and processes were elucidated, enabling researches to develop specific inhibitors for the enzymes involved. This was the dawn of investigations on gas physiology/pharmacology. Discovery of EDRF or endothelial NO highlighted the importance of endothelial cells that were reevaluated for additional physiological significance. Functional importance of NO initially found as an EDRF in blood vessels rapidly expanded as novel findings were obtained about its diverse functions in the whole body [2], including the central and peripheral nervous systems, autonomically innervated organs and tissues, endocrine/exocrine systems, cell differentiation and development, fertility, and immunological responses. Because of their outstanding discoveries of NO and its important physiological roles and pathophysiological implications, Drs. R. F. Furchgott, L. J. Ignarro, and F. Murad, all superb pharmacologists, were honored with the Nobel Prize (Physiology section) in 1998.

Basic Mechanisms

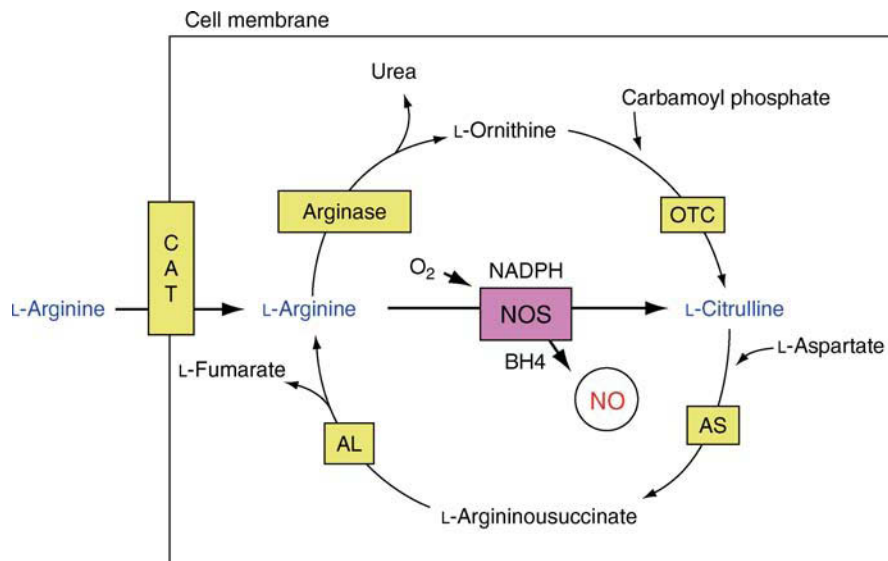

Synthesis and Degradation of NO

Three isoforms of NO synthesizing enzymes (▶nitric oxide synthase (NOS)) were isolated, purified, and cloned: neuronal NO synthase (▶neuronal nitric oxide synthase (nNOS) or isoform (I), immunological or inducible NOS (▶inducible (immunological) nitric oxide synthase (iNOS) or isoform (II), and endothelial NOS (▶endothelial nitric oxide synthase (eNOS) or isoform

(III)). The nNOS and eNOS are constitutively expressed in the central and peripheral nerves and vascular endothelial cells, respectively, and require Ca^{2+} and calmodulin in the presence of tetrahydrobiopterin (BH_4), heme, NADPH, FAD, and FMN for activation. iNOS is not constitutively expressed but is induced in macrophages by bacterial lipopolysaccharides and cytokines; Ca^{2+} is not required for activation. NO is produced when ▶L-arginine is transformed to L-citrulline by catalysis of NOS in the presence of oxygen and cofactors (Fig. 1). The synthesis of NO is inhibited by L-arginine analogs, such as N^G -monomethyl-L-arginine, N^G -nitro-L-arginine, and asymmetric dimethylarginine. NO generated by enzymatic and nonenzymatic processes is rapidly inactivated by oxidation to NO_2/NO_3 . NO is scavenged by superoxide-generating compounds. Binding of NO to superoxide anions forms the bioactive compound ▶peroxynitrite (Fig. 2).

Physiological and Pathophysiological Effects of NO Formed by eNOS

eNOS is present mainly in the particulate fraction of endothelial cells and binds to caveolin-1 in the caveolae, which are microdomains of the plasma membrane. Caveolin-1 inhibits eNOS activity, and this interaction is regulated by Ca^{2+} /calmodulin. The eNOS migrates intracellularly in response to increased cytosolic Ca^{2+} in the presence of calmodulin (Fig. 2) and is activated for NO production. The transmembrane influx of Ca^{2+} and the mobilization from its intracellular

Nitric Oxide. Figure 1 Scheme of the synthesis of NO from L-arginine and its regulatory factors. AS, argininosuccinate synthase; AL, argininosuccinate lyase; OTC, ornithine transcarbamylase; CAT, cationic amino acid transporter. K_m values for arginases I and II approximate 1,000 times higher than those for NOS isoforms. However, once arginases are induced by cytokines, arginases and NOS compete for the utilization of substrate L-arginine.

Nitric Oxide. Figure 2 Scheme of the regulation of vascular smooth muscle function by NO released from the nitrergic nerve and endothelial cell. CaM, calmodulin; L-Arg., L-arginine; L-Citru., L-citrulline; GTN, glyceryltrinitrate (nitroglycerin); sGC, soluble guanylyl cyclase; cGMP, cyclic GMP; PDE5, phosphodiesterase-5; O_2^- , superoxide anion; $ONOO^-$, peroxynitrite; SOD, superoxide dismutase; eNOS*, activated eNOS by Ca^{2+} and calmodulin; eNOS-P, phosphorylated eNOS; Pool, Ca^{2+} stored site; PI_3K , phosphatidylinositol 3 kinase; CV, caveolin; R, receptor. In endothelial cells, eNOS is activated by two separate pathways, Ca^{2+} dependent and Ca^{2+} -independent. Dotted lines, inhibition. Similar mechanisms underlying nitrergic nerve-mediated smooth muscle relaxation are seen in the gastrointestinal tract, urinary tract, and corpus cavernosum penis. In the gastrointestinal tract, NO-mediated relaxations are mediated not only by cyclic GMP but also by hyperpolarization (inhibitory junction potential) associated with cyclic GMP-independent Ca^{2+} -activated K^+ channel opening.

stored sites are caused by stimulation of drug receptors in the endothelial cell membrane or by mechanical stresses applied to endothelial cells. Recently, novel mechanisms responsible for activation of eNOS without increased influx of Ca^{2+} have been revealed. Shear stress, insulin, or bradykinin induces the phosphorylation of Ser^{1177/1179} of eNOS through phosphatidylinositol-3 (PI_3) kinase and the downstream serine/threonine protein kinase Akt (protein kinase B) (Fig. 2), resulting in enhanced NO synthesis.

The release of NO from the endothelium is induced by various chemical substances, including acetylcholine; polypeptides such as substance P, bradykinin, and arginine vasopressin; histamine; ATP/ADP; α_2 -adrenoceptor agonists; thrombin; and Ca^{2+} ionophores. NO formed in response to mechanical stimuli like shear stress or transmural pressure plays an important role in maintaining basal blood flow. Endothelial NO causes vasodilatation, decreased

vascular resistance, lowered blood pressure, inhibitions of platelet aggregation and adhesion, inhibitions of leukocyte adhesion and transmigration, and reduced smooth muscle proliferation; and it acts to prevent atherosclerosis. These effects are mediated by cyclic GMP (►cyclic guanosine monophosphate (GMP)) synthesized in target cells by soluble guanylyl cyclase that is activated by NO (Fig. 2). Endothelial dysfunction participates in serious cardiovascular and metabolic diseases such as hypertension, angina pectoris, myocardial infarction, stroke, renal failure, glaucoma, and diabetes mellitus.

NO Formed by nNOS from ►Nitrergic Nerve

Nonadrenergic noncholinergic inhibitory responses to autonomic nerve stimulation are mainly mediated through NO synthesized by nNOS; NO plays a crucial role as a neurotransmitter from the peripheral efferent nerves, thus being called “nitrergic.” This provides a

new idea that NO, a gaseous and labile compound with a molecular weight of 30, is liberated immediately upon synthesis due to nNOS activated by Ca^{2+} intracellularly introduced into nerve terminals [3], whereas classical neurotransmitters, stable organic molecules, are synthesized and stored in synaptic vesicles and liberated by way of exocytosis when intracellular Ca^{2+} is increased. The receptive site for neurally released NO is intracellular guanylyl cyclase in target organs, which is also in contrast to drug receptors for classical transmitters that are located in cell membranes.

Nitroergic nerves (postganglionic parasympathetic) innervating the vascular wall participate in maintaining vasodilatation in cerebral arteries [3] that have scarce adrenergic vasoconstrictor innervation, and they also contribute to functionally counteract the action of adrenergic vasoconstrictor nerves in peripheral blood vessels to maintain blood flow homeostasis. Cholinergic nerves are not involved in the vasomotor response. This suggests that the peripheral vascular tone is regulated by reciprocal innervation, an adrenergic vasoconstrictor and a nitroergic vasodilator. In the digestive and urinary tracts, cholinergic excitatory and nitroergic/adrenergic inhibitory nerves modulate smooth muscle tone and motility and secretory responses. Intense nitroergic innervations in the pylorus/ileocolonic junction, sphincter of Oddi, and trigonal/urethral muscles contribute to smooth muscle relaxation, allowing the passage of digested contents, bile, and urine, respectively, through the sphincters. Nitroergic nerve activation evokes penile corpus cavernosum smooth muscle relaxation and increases intracavernous pressure. The NO-cyclic GMP pathway plays a crucial role in initiating and maintaining penile erection [4].

On the other hand, afferent nitroergic nerves control some sensory information processing, such as pain and reflex.

Physiologically muscle-derived NO regulates skeletal muscle contractility and exercise-induced glucose uptake. nNOS is located at the plasma membrane of skeletal muscle and facilitates diffusion of NO to the vasculature to regulate muscle perfusion.

NO Formed by nNOS in the Brain

In the brain, NO functions mainly as a neuromodulator. NO signaling appears to be essential for two forms of neural plasticity: long-term potentiation (LTP) in the hippocampus and long-term depression in the cerebellum. These forms of neural plasticity underlie aspects of both learning and information storage in the brain. Glutamate participates mainly in synaptic interactions, but with the help of NO, the strength of excitatory input might be nonsynaptically signaled to the surrounding monoaminergic neurons in the brain. NO formed by *N*-methyl-D-aspartate (NMDA) receptor activation diffuses to adjacent nerve terminals to

modulate neurotransmitter release. NO can also regulate secretion of hormones and neuropeptides. The NO/cyclic GMP pathway may also be involved in sleep and the circadian clock.

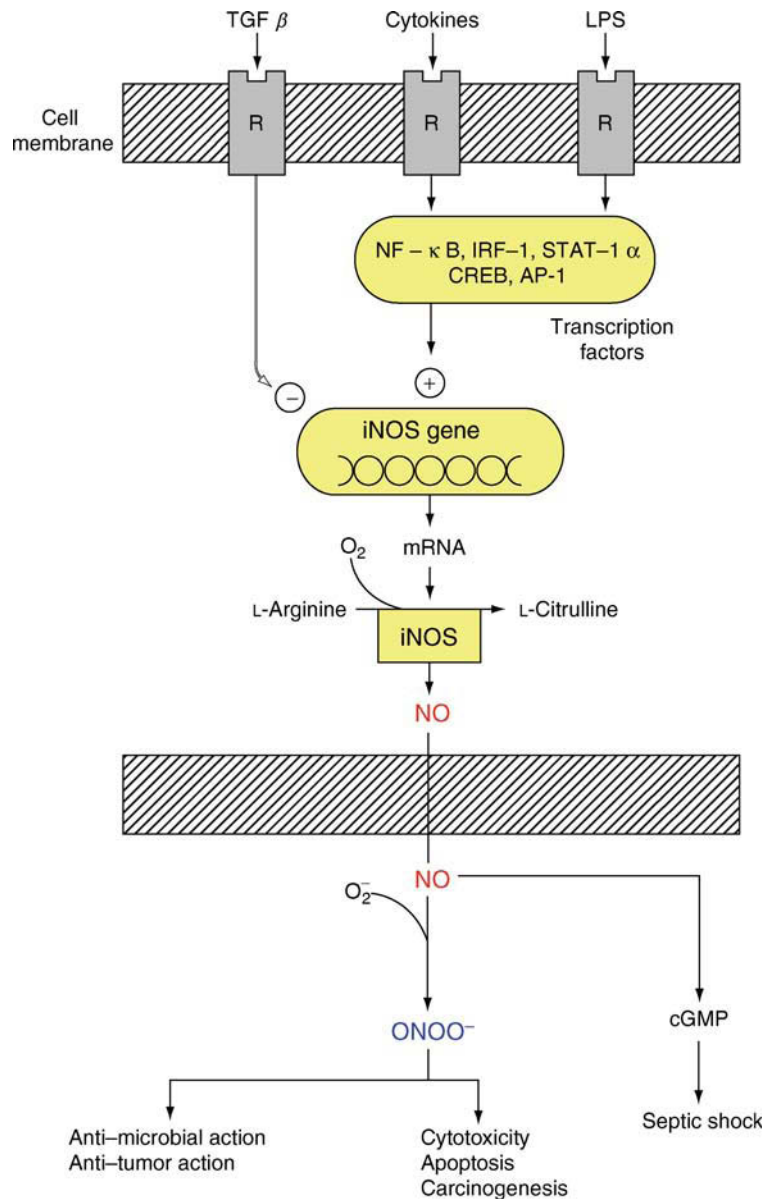

Unlike the NO pathways that regulate hippocampal LTP, cyclic GMP is not involved in NO toxicity. Excess stimulation of nNOS at the synapse has the potential to mediate neurotoxicity in the brain. Many causes of neural injury, including those associated with stroke and certain neurotoxins, are due to excess release of glutamate, which acts at synaptic NMDA receptors to cause neurotoxicity. As a free radical, NO is inherently reactive and mediates cellular toxicity by damaging critical metabolic enzymes and by reacting with superoxide anions to form an even more potent oxidant, peroxynitrite that participates in DNA damage, lipid peroxidation, protein nitration, and cellular energy depletion. Through these mechanisms, NO appears to play a major role in the pathophysiology of stroke, Parkinson's disease, Alzheimer's disease, and Huntington's disease.

NO Formed by iNOS

Under pathological conditions (e.g., during inflammation), high levels of NO are produced after induction of the expression of iNOS mainly in macrophages. NO possesses the protective/destructive duality inherent in every other major component of the immune response. On the one hand, it exerts beneficial effects by acting as an anti-bacterial, anti-parasitic, and anti-viral agent or as a tumoricidal agent; on the other hand, high levels of NO, if uncontrolled, elicits detrimental effects that are produced because NO reacts with concomitantly produced superoxide anions, thereby generating highly toxic compounds such as peroxynitrite (Fig. 3) and hydroxyl radicals. Suppression of mitochondrial respiration is one of the mechanisms underlying NO-induced cytotoxicity. Inducers of iNOS expression include bacterial polysaccharides and immune cytokines such as interferon- γ , tumor necrosis factor α , and interleukin (IL) 1 β . Suppressors of iNOS expression include dexamethasone, corticosteroids, nonsteroidal anti-inflammatory agents, estrogens, transforming growth factor β , IL-4, IL-8, IL-10, IL-11, and IL-13 [5]. Transcription factors and the sequential pathway involved in iNOS expression are shown in Fig. 3.

iNOS is not normally present in the brain and retina, but is detected mainly in glial cells of the brain and retina after inflammatory, infectious, or ischemic damage as well as in the aging brain. Excessive NO production by iNOS seems to contribute to the pathophysiology of many diseases that involve the central nervous system and eye.

Unphysiologically high levels of NO formed by iNOS expressed in tissues (e.g., liver, stomach, and lung) with chronic inflammation following infections of

viruses (e.g., hepatitis and Epstein-Barr), parasites, or bacteria (*Helicobacter pylori*) may play a key role in carcinogenesis. Reactive nitrogen species, such as peroxynitrite, can damage DNA, RNA, lipids, and proteins, leading to increased mutations and altered functions of enzymes and proteins, and thus contributing to the multistage carcinogenesis process.

Excessive NO levels in plasma if being persistently associated with expression of iNOS in macrophages

and vascular smooth muscle cells result in fatal circulatory shock because of the remarkable fall of vascular resistance and venodilatation that involve profound hypotension and acute cardiac failure.

Pharmacological Relevance

Currently, one of the most well-known, promising therapeutic drugs in relation to endogenous NO is sildenafil. The main phosphodiesterase in the human

corpus cavernosum is type 5 cyclic GMP phosphodiesterase (►**phosphodiesterase-5 (PDE-5)**). Selective PDE-5 inhibitors, sildenafil, vardenafil, and tadalafil, enhance the erectile response to sexual stimulation in patients with erectile dysfunction [4]. This effect is associated with interference with the degradation by PDE-5 (Fig. 2) of cyclic GMP produced in cavernous smooth muscles through guanylyl cyclase that is activated by NO released from nitrergic nerves. Of course, care has to be taken to determine whether PDE-5 has been used before nitrates are administered to patients. There is some concern that patients may be adversely affected by an excessive drop of blood pressure in cases of their combined use.

Although the effect of L-arginine is too short to be clinically useful, the possibility for a novel therapeutic strategy with oral L-arginine has been raised. Dietary L-arginine improves endothelial function, inhibits platelet aggregation, reduces monocytes/endothelial cell adhesion in patients with coronary artery disease or heart failure, and lowers systemic blood pressure in patients with essential hypertension and women with preeclampsia. NO mainly synthesized by eNOS appears to participate in the beneficial effects of L-arginine that is evidenced from studies on experimental animals. L-Arginine contributes to improvement of the erectile function in some patients with erectile dysfunction. Treatment with L-arginine would be particularly efficient in patients with elevated plasma levels of the endogenous NOS inhibitor, asymmetric dimethyl-arginine.

►**Nitroglycerin** has long been used for the treatment of acute attack of angina pectoris, and its stable analogs are available to prevent the anginal attack. Nitrovasodilators such as sodium nitroprusside liberate NO from their molecules in the tissue (thus, called NO donors) and elicit actions via cyclic GMP like those seen with endogenously synthesized NO.

Inhaled NO has been used for treatment of persistent pulmonary hypertension of newborn infants, critical respiratory failure of preterm infants, and acute hypertension of adult cardiac surgery patients. PDE-5 inhibitors such as sildenafil are also effective for treatment of pulmonary hypertension. The combination of PDE-5 and NO inhalation yields additive beneficial effects on pulmonary hemodynamics. On the other hand, measurement of exhaled NO is a noninvasive and reproducible test that is a surrogate measure of airway inflammation in patients with bronchial asthma.

Findings obtained from experimental studies suggest that induction of iNOS mediates inflammatory or ischemic brain damage and that excessively activated nNOS under excitotoxic or ischemic conditions produces NO that is toxic to surrounding neurons. Selective inhibition of iNOS or nNOS may be neuroprotective. This is also the case in glaucoma and diabetic

retinopathy. Free radical scavengers may be effective in clinically preventing and treating neurological and psychological symptoms in patients after cerebral ischemic insult. In addition to scavenging free radicals generated by ischemia, these compounds preserve endothelial functions for the beneficial actions of NO in the brain and circulatory system.

Nitric oxide synthase

Definition

NO synthases (NOS, L-arginine, NADPH:oxygen oxidoreductases, nitric oxide forming; EC 1.14.13.39) represent a family of enzymes that catalyze the formation of nitric oxide (NO) from the amino acid L-arginine. In mammals, three isoforms of NOS have been identified. They are termed neuronal NOS (nNOS, NOS I, NOS1), inducible NOS (iNOS, NOS II, NOS2), and endothelial

NOS (eNOS, NOS III, NOS3). Classically, nNOS and eNOS were considered “constitutive” enzymes, whereas iNOS is cytokine-induced. Recent evidence suggests that nNOS and eNOS are also subject to important regulation of expression [1]. Within the human species, amino acid sequences of the three NOS isoforms share 52–58% identity. Each isoform is well conserved across mammalian species (>90% amino acid identity for nNOS and eNOS, >80% for iNOS). NOS enzymes exist in organisms as low as nematodes, protozoa, and even in plants (Fig. 1).

Basic Characteristics

All NOS isoforms utilize L-arginine as the substrate, and molecular oxygen and reduced nicotinamide adenine dinucleotide phosphate (NADPH) as cosubstrates. Flavin adenine dinucleotide (FMN), flavin mononucleotide (FAD), and (6R)-5,6,7,8-tetrahydro-L-biopterin (BH₄) are cofactors of the enzyme. All NOS isoforms contain heme and bind calmodulin. In nNOS and eNOS,

NO Synthases. Figure 1 Schematic diagram displaying the spatial relationships between the three cloned isoforms of NOS. Alignment of the deduced amino acid sequences of the three NOS isoforms revealed 50–60% sequence identity between the enzymes. All NOS isoforms consist of a reductase domain and an oxygenase domain. The reductase domain of the enzymes shows about 35% sequence identity with cytochrome P₄₅₀ reductase, and this enzyme shares the cofactor binding regions of the NOS for reduced nicotinamide adenine dinucleotide phosphate (NADPH), flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN). Consensus sequences for the binding of the cosubstrate NADPH (adenine and ribose), FAD (isoalloxazine and pyrophosphate), FMN, calmodulin (CaM) and heme are indicated. The proximal part of the N-terminal oxygenase domain (black box) shows 65–71% sequence identity between the three NOS isoforms and contains the closely linked binding sites for L-arginine (L-Arg) and (6R)-5,6,7,8-tetrahydro-L-biopterin (BH₄). The C-terminal portion of the isozymes (reductase domain) is responsible for the NADPH diaphorase activity that is common to all three isozymes. nNOS contains an N-terminal tail that includes a GLGF (glycine, leucine, glycine, phenylalanine)-motif or PDZ (postsynaptic density protein 95/discs large/ZO-1 homology)-domain. This motif targets nNOS to other cytoskeletal proteins in brain and skeletal muscle. eNOS contains N-terminal myristoylation (myr) and palmitoylation (palm) sites. These lipid anchors contribute to the membrane localization of this isozyme.

calmodulin binding is brought about by an increase in intracellular Ca^{2+} (half-maximal activity between 200 and 400 nM). This leads to an enhanced binding of CaM to the enzyme, which in turn displaces an autoinhibitory loop and facilitates the flow of electrons from NADPH in the reductase domain to the heme in the oxygenase domain. In iNOS, calmodulin already binds at low intracellular Ca^{2+} concentrations (below 40 nM) due to a different amino acid structure of the calmodulin-binding site. In NOS, a zinc ion is coordinated tetrahedrally to pairs of cysteine motifs (CXXXXC), one motif being contributed by each NOS monomer. The C-terminal portion of all three NOS isozymes conveys ►**NADPH-diaphorase** activity. The NO formed by NOS can act on a number of target enzymes and proteins. The most important signaling pathway stimulated by NO is the activation of soluble guanylyl cyclase and the generation of cyclic GMP (Fig. 2).

Neuronal NO Synthase

Neuronal NO synthase (nNOS) is constitutively expressed in neurons of the brain. Its activity is regulated by Ca^{2+} and calmodulin. Half-saturating L-arginine concentrations are around 2 μM . cDNAs encoding nNOS have been cloned from rat and human brain. The open reading frame of human nNOS consists of 4299 bp, corresponding to 1433 aa. This predicts a protein of 160 kDa, which is in accordance with the molecular mass of the purified protein.

nNOS is not only found in brain. Immunochemical studies identified the enzyme in the spinal cord, in sympathetic ganglia and adrenal glands, in peripheral nitrergic nerves, in epithelial cells of lung, uterus, and stomach, in kidney macula densa cells, in pancreatic islet cells, and in vascular smooth muscle. In terms of tissue mass, the largest source of nNOS in mammals is skeletal muscle.

The gene for human nNOS is located in the 12q24.2–24.31 region of chromosome 12. The nNOS gene is by far the largest of the three NOS genes, spanning over 150 kb of genomic DNA. The mRNA is encoded by 29 exons with translation start and stop sites in exons 2 and 29, respectively. More than ten different exons 1 have been identified, which are mostly spliced to a common exon 2. Moreover, skeletal muscle and some other tissues express an elongated protein (nNOS μ), containing a 102-bp cassette exon insertion between exons 16 and 17 of the human nNOS gene. There is no evidence for a difference in function between “brain-type” nNOS and “muscle type” nNOS μ .

Functions of nNOS include long-term regulation of synaptic transmission in the CNS (long-term potentiation, long-term depression), whereas there is no evidence for an involvement of nNOS-derived NO in acute neurotransmission. Retrograde communication across synaptic junctions is presumed to be involved in memory

formation, and there is evidence that inhibitors of NOS impair learning and can produce amnesia in animal models. Evidence is also accumulating that NO formed in the CNS by nNOS is involved in the central regulation of blood pressure. In the periphery, many smooth muscle tissues are innervated by nitrergic nerves, i.e. nerves that contain nNOS and generate and release NO. NO produced by nNOS in nitrergic nerves can be viewed as an unorthodox neurotransmitter that decreases the tone of various types of smooth muscle. By mediating the relaxation of corpus cavernosum smooth muscle, nNOS is responsible for penile erection. In addition, in the corpus cavernosum, NO-induced smooth muscle relaxation is mediated by cyclic GMP. Cyclic GMP is degraded by ►**phosphodiesterases**, in corpus cavernosum particularly the isoform 5. Thus, nNOS activity represents the basis of the effect of the clinically used ►**phosphodiesterase 5 inhibitors** sildenafil (Viagra[®]), vardenafil (Levitra[®]), and tadalafil (Cialis[®]).

On the pathophysiological side, hyperactive nNOS has been implicated in *N*-methyl-D-aspartate (NMDA)-receptor-mediated neuronal death in cerebrovascular stroke. Some disturbances of smooth muscle tone within the gastrointestinal tract (e.g., gastroesophageal reflux disease) may also be related to an overproduction of NO by nNOS in peripheral nitrergic nerves.

Inducible NO Synthase

Inducible NO synthase (iNOS) is usually not constitutively expressed, but can be induced in macrophages by bacterial lipopolysaccharide (LPS), cytokines and other agents. Although primarily identified in macrophages, expression of the enzyme can be stimulated in virtually any cell or tissue, provided the appropriate inducing agents have been identified (for review see [1] and [3]).

Once expressed, iNOS is active and not regulated by intracellular Ca^{2+} concentration. Half-saturating L-arginine concentrations for iNOS have been reported between 3 and 30 μM . cDNAs encoding iNOS have been cloned from murine, rat, and human cells and tissues. The open reading frame of human iNOS is 3459 bp, corresponding to 1153 aa and predicting a protein of 131 kDa, which is in agreement with data obtained for purified iNOS. The human gene for iNOS has been localized to the 17p11–17q11 region of chromosome 17. The gene contains 26 exons and spans 37 kb of DNA.

When induced in macrophages, iNOS produces large amounts of NO which represents a major cytotoxic principle of those cells. Due to its affinity to protein-bound iron, NO can inhibit a number of key enzymes that contain iron in their catalytic centers. These include ribonucleotide reductase (rate-limiting in DNA replication), iron–sulfur cluster-dependent enzymes (complex I and II) involved in mitochondrial electron transport and cis-aconitase in the citric acid cycle. In addition, higher concentrations of NO,

NO Synthases. Figure 2 (Continued)

NO Synthases. Figure 2 Schematic diagrams showing NOS catalysis under normal conditions and in pathophysiology. (a) NOS monomers and even isolated reductase domains are capable of transferring electrons from reduced nicotinamide-adenine-dinucleotide phosphate (NADPH), to flavin-adenine-dinucleotide (FAD) and flavin mononucleotide (FMN) and have a limited capacity to reduce molecular oxygen to superoxide ($O_2^{\cdot-}$). Monomers and isolated reductase domains can bind calmodulin (CaM), which stimulates electron transfer within the reductase domain. NOS monomers are unable to bind the cofactor (6*R*)-5,6,7,8-tetrahydrobiopterin (BH_4) or the substrate L-arginine and cannot catalyze NO production. (b) The presence of heme allows for NOS dimerization; heme is the only cofactor required for the formation of active NOS dimers. Heme is also essential for the interaction between reductase and oxygenase domains and for the calmodulin-dependent interdomain electron transfer from the flavins to the heme of the opposite monomer. Due to differences in the CaM-binding domain, elevated Ca^{2+} is required for CaM binding (and thus catalytic activity) in nNOS and eNOS, whereas CaM binds to iNOS with high affinity even in the absence of Ca^{2+} . When sufficient substrate L-arginine (L-Arg) and cofactor BH_4 are present, intact NOS dimers couple their heme- and O_2 reduction to the synthesis of NO (fully functional NOS). L-citrulline is formed as the byproduct. NOS enzymes perform two separate oxidation steps, one to form ω -hydroxy-L-arginine and a second to convert this intermediate to NO. All NOS isoforms contain a zinc ion (Zn) coordinated in a tetrahedral conformation with pairs of CXXXXC-motifs at the dimer interface. This site is also of major importance for the binding of BH_4 and L-arginine. (c) Electron transfer from the reductase domain (1) enables NOS ferric (Fe^{3+}) heme to bind O_2 and form a ferrous (Fe^{2+})-dioxy species. This species may receive a second electron preferentially from BH_4 or from the reductase domain (2). The nature of the resulting oxidized BH_4 has been identified by electron paramagnetic resonance as the trihydrobiopterin radical (BH_3^{\cdot}) or the trihydropterin radical cation protonated at N5 ($BH_3^{\cdot}H^+$). The BH_3^{\cdot} radical (or radical cation) can be recycled to BH_4 by the NOS itself (using an electron supplied by the flavins). Alternatively, there is evidence that reducing agents such as ascorbic acid (AscH, which is present in cells in millimolar concentrations) can reduce the BH_3^{\cdot} radical back to BH_4 (Asc = ascorbate radical). (d) Under pathophysiological conditions, all NOS enzymes can uncouple their oxygen reduction from NO synthesis. An established condition under which this occurs is oxidative stress. In this situation superoxide ($O_2^{\cdot-}$) generated by other oxidases can combine with NO generated by a still functional NOS. This leads to an increased formation of peroxynitrite ($ONOO^-$), which – in turn – can oxidize BH_4 to biologically inactive products such as the BH_3^{\cdot} radical or 6,7-[8H]- H_2 -biopterin (BH_2). In the absence of functional BH_4 , also the affinity of the substrate L-arginine (L-Arg) to the NOS is reduced, and NOS catalyzes the uncoupled reduction of O_2 , leading to the production of $O_2^{\cdot-}$ (and possibly also H_2O_2).

as produced by induced macrophages, can directly interfere with the DNA of target cells and cause strand breaks and fragmentation. A combination of these effects is likely to form the basis of the cytostatic and cytotoxic effects of NO on parasitic microorganisms and tumor cells.

However, the high levels of NO produced by activated macrophages (and probably neutrophils and

other cells) may not only be toxic to undesired microbes, parasites, or tumor cells, but, when released at the wrong site, may also harm healthy cells. In vivo, cell and tissue damage can be related to the NO radical (NO) itself or an interaction of NO with superoxide leading to the formation of peroxynitrite ($ONOO^-$). The large majority of inflammatory- and autoimmune lesions are characterized by an abundance of activated

macrophages and neutrophils. High levels of NO can be secreted by those cells, leading to damage of the surrounding tissue. Interestingly, nonimmune cells can also be induced with cytokines to release amounts of NO large enough to affect neighboring cells. Cytokine-activated endothelial cells have been shown to lyse tumor cells, pancreatic islet endothelial cells can be induced to destroy adjacent β -cells, and induced hepatocytes can use NO to kill malaria sporozoites. iNOS activity is likely to be responsible for all of these effects. Additionally, tissue damage produced in animal models of immune complex alveolitis and dermal vasculitis is likely to depend on the presence of excess NO. iNOS-derived NO seems to be involved also in nonspecific allograft rejection. Finally, iNOS is likely to play an important role in septic shock. This disease is characterized by massive arteriolar vasodilatation, hypotension and microvascular damage. Bacterial endotoxins initiate the symptoms. A number of mediators such as platelet-activating factor, thromboxane A_2 , prostanooids, and cytokines such as interleukin-1, tumor necrosis factor- α , and interferon- γ are elevated in septic shock and have been implicated in its pathophysiology. However, the fall in blood pressure is largely due to excess NO production by iNOS induced in the vascular wall, as demonstrated in experiments with NOS inhibitors. Similarly, interleukin-2 therapy is complicated by hypotension, and iNOS induction in response to cytokines may also take place in the vascular system of these patients.

Endothelial NO Synthase

Endothelial NO Synthase (eNOS) expression is relatively specific for endothelial cells. However, the isozyme has also been detected in certain neurons of the brain, in syncytiotrophoblasts of human placenta and in LLC-PK₁ kidney tubular epithelial cells.

The cDNAs encoding eNOS have been cloned from bovine and human endothelial cells. The open reading frame of human eNOS encompasses 3609 bp, corresponding to 1203 aa and predicting a protein of 133 kDa, which is in good agreement with the molecular mass determined for the purified protein. Its activity is regulated by Ca^{2+} and calmodulin. Half-saturating concentrations for L-arginine are around 3 μ M. The human endothelial NOS gene has been localized to the 7q35–7q36 region of chromosome 7. The gene contains 26 exons spanning about 22 kb of genomic DNA.

Similar to nNOS, Ca^{2+} -activated calmodulin is important for the regulation of eNOS activity. However, several other proteins interact with eNOS and regulate its activity. Heat shock protein 90 (hsp90) is found associated with eNOS and probably acts as an allosteric modulator that activates the enzyme. Caveolin-1 binds eNOS and directs it to caveolae. Caveolin-1 is viewed as an inhibitor of eNOS activity, which is being replaced by CaM upon activation of endothelial cells [2].

In addition, eNOS is subject to protein phosphorylation. It can be phosphorylated on several serine (Ser), threonine (Thr), and tyrosine (Tyr) residues; however, major changes in enzyme function have been reported for the phosphorylation of amino acid residues Ser1177 and Thr495 (in the human eNOS sequence) (Fig. 3).

Phosphorylation of Ser1177 is induced when endothelial cells are exposed to fluid shear stress, estrogens, vascular endothelial growth factor (VEGF), insulin, or bradykinin. Shear stress elicits phosphorylation by activating protein kinase A, estrogen, and VEGF phosphorylate eNOS mainly via the serine/threonine kinase Akt, insulin probably activates both Akt and the AMP-activated protein kinase, and the bradykinin-induced phosphorylation of Ser1177 is mediated by Ca^{2+} /CaM-dependent protein kinase II. Phosphorylation of Ser1177 stimulates the flux of electrons within the reductase domain, increases the Ca^{2+} sensitivity of the enzyme, and represents an additional and independent mechanism of eNOS activation (for review see [2] and [4]). Phosphorylation of Thr495, on the other hand, decreases enzymatic activity. This site tends to be phosphorylated under nonstimulated conditions (most probably by protein kinase C). Phosphorylation of Thr495 is likely to interfere with the binding of CaM to the CaM-binding domain. The phosphatase that dephosphorylates Thr495 appears to be protein phosphatase 1. Dephosphorylation of Thr495 has been seen when endothelial cells were stimulated with agents such as histamine or bradykinin (that also elevate intracellular Ca^{2+} concentrations). Substantially more CaM binds to eNOS when Thr495 is dephosphorylated (for review see [2] and [4]). However, dephosphorylation of Thr495 has also been shown to favor uncoupling of oxygen reduction from NO synthesis in eNOS (see above). Other phosphorylation sites of human eNOS exist, but are not known to have major consequences for enzyme activity.

In addition to its vasodilator properties, eNOS-derived NO can convey vasoprotection in several ways. NO released toward the vascular lumen is a potent inhibitor of platelet aggregation and adhesion to the vascular wall. Besides protection from thrombosis, this also prevents the release of platelet-derived growth factors that stimulate smooth muscle proliferation and its production of matrix molecules. Endothelial NO also controls the expression of genes involved in atherogenesis. NO decreases the expression of chemoattractant protein MCP-1 and of a number of surface adhesion molecules thereby preventing leukocyte adhesion to vascular endothelium and leukocyte migration into the vascular wall. This offers protection against an early phase of atherogenesis. Additionally, the decreased endothelial permeability, the reduced influx of lipoproteins into the vascular wall, and the inhibition of low density lipoprotein (LDL) oxidation may contribute to the

NO Synthases. Figure 3 Schematic diagram showing phosphorylation of eNOS by various kinases. Functionally important phosphorylation sites in human eNOS are Ser1177 (pink hexagon) and Thr495 (yellow hexagon). Phosphorylation of Ser1177 enhances electron flux in the reductase domain (pink arrows) and increases eNOS activity. It is brought about by protein kinase A (PKA), protein kinase Akt, AMP-activated protein kinase (AMPK), and Ca^{2+} /CaM-dependent protein kinase II (CaMKII) (pink hexagons). Thr495 tends to be phosphorylated under nonstimulated conditions (most probably by protein kinase C, PKC, yellow hexagon). Phosphorylation of Thr495 reduces eNOS activity (black block arrow). The phosphatase that dephosphorylates Thr495 appears to be protein phosphatase1 (PP1, black flag with black block arrow).

antiatherogenic properties of eNOS-derived NO. Furthermore, NO has been shown to inhibit DNA synthesis, mitogenesis, and proliferation of vascular smooth muscle cells as well as smooth muscle cell migration, thereby protecting against a later phase of atherosclerosis. Based on the combination of those effects, NO produced in endothelial cells can be considered an antiatherosclerotic principle (for review see [4] and [5]).

Impaired NO-mediated vasodilatation has been seen in hypercholesterolemia and atherosclerosis. Arteries, especially human coronary arteries, may thereby be predisposed to vasoconstriction and vasospasm. Indeed, the paradoxical vasoconstriction in response to the endothelium-dependent vasodilator acetylcholine can be used as a diagnostic indicator of beginning coronary atherosclerosis during coronary catheterization. Reduced eNOS-mediated vasodilatation has also been found in arteries from hypertensive and diabetic animals, and impaired responses to endothelium-dependent vasodilators has been demonstrated in the forearm of hypertensive patients. In isolated blood vessels from animals with pathophysiological conditions such as hypertension, diabetes, or nitroglycerin tolerance, evidence has been obtained for eNOS uncoupling. Under these conditions, superoxide is generated from the oxygenase domain instead of NO. Simultaneous addition of L-arginine and BH_4 restores NO production and abolishes superoxide generation by eNOS in vitro. Administration of BH_4 also restored endothelial function in animal models of

experimental diabetes and insulin resistance, as well as in patients with hypercholesterolemia and in smokers. Oxidative stress occurs in pathological conditions such as hypercholesterolemia, diabetes, aging and smoking, and oxidation of BH_4 may be the common cause of eNOS dysfunction in these situations (for review see [4] and [5]).

Nociceptive Transducers

Nociceptive transducers are ion-channel complexes, which generate depolarising currents in nociceptors in response to specific noxious stimuli. Transducer proteins for irritant and chemical stimuli include the vanilloid receptors VR1 and VRL1 (cation-channels gated by protons, capsaicin and noxious heat, i.e. 46°C), the purinergic receptor P2X3 (ATP-gated ion channel) and acid-sensing ion channels such as ASIC- α , ASIC- β and DRASIC (proton-gated ion-channels). The molecular identity of the transducers for noxious mechanical stimuli is as yet unknown. Expression of nociceptive transducers is altered following tissue injury or disease, which contributes to long-term sensitization of nociceptors.

► Nociception

Nociceptors

Nociceptors are a specific subset of peripheral sensory organs, which respond to noxious stimuli. A δ mechanoreceptors and C-polymodal nociceptors are the two main classes of cutaneous nociceptors. The sensory quality of pain evoked by activation of A δ -fibres is

Nodes of Ranvier

The nodes of Ranvier are the gaps formed between myelin sheath cells along the axons. The sodium channels are densely localized at the nodes of Ranvier.

Non-adrenergic Non-cholinergic (NANC) Transmission/Mediators

Non-adrenergic non-cholinergic (NANC) transmission/mediators describes a part of the autonomic nervous system which does not use acetylcholine or noradrenaline as transmitters. NANC-transmitters often function as co-transmitters, which are released together with acetylcholine or noradrenaline. Substances believed to function as NANC transmitters include ATP, which is found e.g. in postganglionic sympathetic neurons of blood vessels and may contribute to the fast contraction of smooth muscle cells, γ -aminobutyric acid (GABA) and serotonin which are found in enteric neurons and are involved in peristaltic reflexes, dopamine, found in some sympathetic neurons (e.g. kidney) and involved in vasodilatation and NO which is released from pelvic or gastric nerves and plays a role in penile erection or gastric emptying. A variety of peptides have also been described to function as NANC transmitters, e.g. neuropeptide Y (postganglionic sympathetic neurons), vasoactive intestinal peptide (parasympathetic nerves to salivary glands), substance P (sympathetic ganglia, enteric neurons) or calcitonin gene-related peptide (CGRP) (non-myelinated sensory neurons).

► Synaptic Transmission

Non-competitive Antagonism

If an antagonist binds to the receptor and precludes agonist activation of that receptor by its occupancy, then

no amount of agonist present in the receptor compartment can overcome this antagonism and it is termed noncompetitive. This can occur either by binding to the same binding domain of the agonist or another (allosteric) domain. Therefore, this definition is operational in that it does not necessarily imply a molecular mechanism, only a cause and effect relationship. The characteristic of noncompetitive antagonism is eventual depression of the maximal response, however, parallel displacement of agonist dose–response curves, with no diminution of maximal response, can occur in systems with receptor reserve for the agonist.

► Drug–Receptor Interaction

Non-competitive Inhibition

Reversible metabolic inhibition caused by an inhibitor binding to an enzyme site different from the substrate. The degree of inhibition is independent of the substrate concentration.

► Drug Interaction

Nonionic Contrast Media

Nonionic contrast media are neutral water-soluble triiodobenzene derivatives; the solubility is provided by hydrophilic groups in the side chains, preferentially hydroxy groups.

► Radiocontrast Agents

Non-neuronal Monoamine Transporters

Non-neuronal monoamine transporters is the collective designation for OCT1, OCT2, and EMT; the term indicates that these three carriers share some substrates with the neuronal monoamine transporters (such as DAT, NET, SERT) and the vesicular monoamine

transporters (VMAT), but they are expressed (at least predominantly) in non-neuronal cells (e.g. in glia cells, hepatocytes or in the proximal tubule).

- Organic Cation Transporters
- Vesicular Transporters

Non-opioid Analgesics

Non-opioid analgesics can be divided into two groups. The first group contains substances having anti-inflammatory effects in addition to their analgesic and antipyretic activity and is called non-steroidal anti-inflammatory drugs (NSAIDs). The second group of non-opioid analgesics, which are not classified as NSAIDs, consists of substances that lack anti-inflammatory properties, such as phenazones, metamizole (dipyrone) and paracetamol.

- Cyclooxygenases
- Analgesics
- Non-steroidal Anti-inflammatory Drugs
- Prostaglandins
- Prostanoids

Non-rapid Eye Movement (NREM) Sleep

As the name suggests, NREM sleep describes collectively all sleep activity that does not class as REM sleep. In humans, it is subdivided into *sleep stages* 1–4; stage 1, representing the lightest stage of sleep (often experienced as drowsiness), and stage 4 the deepest sleep, from which it is most difficult to wake the sleeper. On the EEG, NREM sleep is characterised by the presence of slow waves (i.e. low frequency, high amplitude activity), the relative proportion of which increases as sleep deepens. In contrast to REM sleep, no specific movement of the eyeballs is detectable, and no muscle atonia is present. It is though that dreaming occurs primarily during REM sleep, based on reports of subjects woken at various points during the sleep–wake cycle, although some dreaming activity was found to occur during NREM sleep.

Non-selective Cation Channels

VEIT FLOCKERZI

Institut für Pharmakologie und Toxikologie, Universität des Saarlandes, Homburg, Germany

Definition

Non-selective cation channels are macromolecular pores in the cell membrane that form an aqueous pathway. These enable cations such as Na^+ , K^+ or Ca^{++} to flow rapidly, as determined by their ►electrochemical driving force, at roughly equal rates ($>10^7$ cations per channel pore and per second).

Basic Characteristics

In general, ion channels are multi protein complexes residing in cellular membranes and allowing ions, mainly Na^+ , K^+ , Ca^{++} and Cl^- , to flow rapidly as determined by their electrochemical driving force in a thermodynamically downhill direction. The channel proteins are dynamic structures; they form channels that can exist in at least two conformational states, open and closed. In the closed state the channel can be inactive and/or is reluctant to be activated. Fast shifts in the submillisecond range between these states can be regulated by the membrane potential (►voltage gated ion channels), by ligands (►ligand gated ion channels) or agonist. In many cases these shifts can be modulated on a longer time scale (milliseconds to minutes) by hormones, neurotransmitters, drugs and toxins.

The open channel has in most cases a selective permeability, allowing a restricted class of ions to flow, for example Na^+ , K^+ , Ca^{++} or Cl^- and, accordingly, these channels are called Na^+ -channels, K^+ -channels, Ca^{++} -channels and Cl^- -channels. In contrast, cation-permeable channels with little selectivity reject all anions but discriminate little among small cations. Little is known about the structures and functions of these non-selective cation channels [1], and so far only one of them, the ►nicotinic acetylcholine receptor (nAChR, see Nicotinic Receptors), has been characterized in depth [2, 3]. The nAChR is a ligand-gated channel (see below) that does not select well among cations; the channel is even permeable to choline, glycine ethylester and tris buffer cations. A number of other plasma

membrane cation channels including certain ►ionotropic glutamate receptors, the ►capsaicin receptor and ►cyclic nucleotide-gated channels are also sometimes called non-selective; they favour the flow of Ca^{++} over Na^+ with relative permeabilities of <4 (►glutamate receptors of the NMDA-type), <10 (capsaicin receptor) and <90 (CNG channels). Others, like ►hyperpolarization-activated and cyclic nucleotide-gated channels conduct both K^+ and Na^+ , but are impermeable to divalent cations. Yet another group of channels, which belong to the superfamily of ►TRP channels [4], have been implicated to represent non-selective cation channels. However, their mode of gating and, most importantly, their pore regions have not been determined and characterized as yet. There are two exceptions: The capsaicin receptor, which is mentioned above as slightly Ca^{++} selective channel and the ►epithelial Ca^{++} channel 1 or ECaC1 (synonym TRPV5). The latter channel is highly selective for Ca^{++} compared to Na^+ with a relative permeability above 100. Finally, a subset of channels activated by stretch have been implicated to be non-selective cation channels [1]. These channels appear to be ubiquitous, but their structures are unknown.

Acetylcholine-activated channels are found in the membrane of vertebrate skeletal muscle at the synapse between nerve and muscle, also called the neuromuscular junction (muscle type nAChR). Their function is to depolarize the postsynaptic muscle membrane when the presynaptic nerve terminal releases its chemical neurotransmitter, acetylcholine. The channel is composed of four protein subunits that are assembled in a predetermined arrangement and stoichiometry ($\alpha 2\beta\gamma\delta$) around a central, cation-selective pathway. Transmembrane segments of the AChR subunits like those of other channels are mainly formed by 19–21 amino acid residues that are folded into a α helix. The α helix is a rod-like structure, the tightly coiled polypeptide main chain of which forms the inner part of the rod, and the side chains extend outward in a helical array [5]. Each residue is related to the next one by a rise of 0.15 nm along the helix axis and a rotation of 100° , which gives 3.6 amino acid residues per turn of helix. Accordingly, one turn of the helix is 0.54 nm, which is equal to 0.15 times the number of residues per turn. The hydrocarbon core of cellular membranes is typically 3 nm wide, which accordingly, can be traversed by a α helix consisting of 19–21 residues.

The nAChR is cylindrical with a mean diameter of about 6.5 nm (Fig. 1). All five rod-shaped subunits span the membrane. The receptor protrudes by <6 nm on the synaptic side of the membrane and by <2 nm on the cytosolic side [2]. The pore of the channel is along its symmetry axis and includes an extracellular entrance domain, a transmembrane domain and a cytosolic entrance domain. The diameter of the extracellular entrance domain is <2.5 nm and it becomes narrower at the transmembrane domain. The

Non-selective Cation Channels. **Figure 1** The nicotinic acetylcholine receptor (nAChR) is localized within the cell membrane; above the cell membrane is the synaptic cleft, below the cytoplasm. Drawing of the closed (left) and open (right) nAChR showing acetylcholine (ACh) binding and cation movement. Dimensions of the receptor were taken from references [2, 3].

pore is lined by five α -helices, one from each subunit, and adjacent extended loop regions [3]. If two ACh molecules bind to the receptor sites at the extracellular surface of the receptor, far from each other and from the pore, this pathway opens, allowing permeation of Na^+ (crystal radius 0.095 nm) K^+ (crystal radius 0.133 nm) and Ca^{++} (crystal radius 0.099 nm), and initiates depolarization.

Monovalent or divalent cations, but not anions, readily flow through the open form of the AChR channel. What makes the channel cation selective? The amino acid sequences of the pore-forming helices and the adjacent loop components contain three rings of negatively charged residues. One of them is located within the transmembrane region of the pore, and the other two flank the cytosolic entrance to the pore. Apparently, the upper part of the channel, namely the α -helical components act as a water pore, whereas the lower loop components contribute to the selectivity filter of the channel [3]. Anions, such as Cl^- cannot enter the pore because they are repelled by the negatively charged rings. Studies on the permeability of a series of organic cations differing in size, such as alkylammonium ions, triaminoguanidinium, histidine and choline, indicate that the narrowest part of the pore has the dimension of <0.65 nm by 0.65 nm.

At the level of a [single channel](#), addition of ACh is followed by transient openings of the channel. The current i flowing through an open channel is 4 pA at a membrane potential V of -100 mV. Since one ampere (A) represents the flow of 6.24×10^{18} charges per second, 2.5×10^7 Na^+ ions per second flow through an open channel. The conductance g of a plasma membrane channel is the measure of the ease of flow of current between the extracellular space and the cytosol or vice

versa and is equal to $i/(V-E_r)$, where E_r is the reversal potential at which there is no ionic net flux; g is expressed in units of siemens (the reciprocal of an ohm), i in amperes, and V in volts. E_r equals 0 mV for non-selective cation channels, thus, a current of 4 pA at a potential of 100 mV corresponds to a conductance of 40 ps.

Non-selective Monoamine Reuptake Inhibitor

Non-selective monoamine reuptake inhibitors (NSMRI) are a group of antidepressants, which function by inhibiting the reuptake of noradrenaline

and serotonin from the synaptic cleft by blockade of the neurotransmitter transporters specific for noradrenaline and serotonin. Most tricyclic antidepressants are non-selective monoamine reuptake inhibitors (e.g. imipramine, amitriptyline, desipramine).

NSAIDs; Non-steroidal anti-rheumatic drugs; NSAR
(aspirin-like drugs, Inflammation)

Definition

▶ **Non-opioid analgesic** agents can be divided into two groups. The first group contains substances having anti-inflammatory effects in addition to their analgesic and anti-pyretic activity and are called non-steroidal anti-inflammatory drugs (NSAIDs). The members of this group, with the exception of almost all selective inhibitors of cyclooxygenase 2 (▶ **COX-2**), are acids. Acidic NSAIDs, which include salicylates, derivatives of acetic acid and propionic acid and oxicams among others, comprise molecules containing a lipophilic and a hydrophilic region and are more than 99% bound to plasma proteins.

The second group of non-opioid analgesics, which are not classified as NSAIDs, consists of substances that lack anti-inflammatory properties, such as phenazones, metamizole (dipyrone) and paracetamol. Their molecules are neutral or weakly basic, have no hydrophilic

polarity, and are much less strongly bound to plasma proteins than NSAIDs.

Mechanism of Action

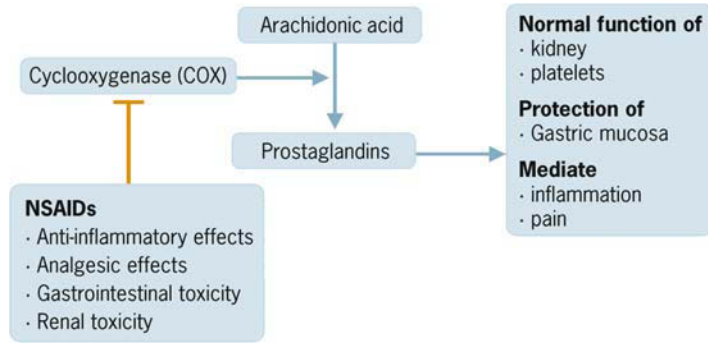

In the 1970s, NSAIDs were shown to interfere with the biosynthesis of ▶ **prostaglandins** [1]. NSAIDs block cyclooxygenases (COX) that catalyze the formation of cyclic endoperoxides from arachidonic acid (Fig. 1). Cyclic endoperoxides are precursors of the prostaglandins, thromboxane-A₂ and prostacyclin. Prostaglandins have a major role in the pathogenesis of pain, fever and inflammation. Inhibition of their biosynthesis would therefore be expected to result in analgesic, anti-pyretic and anti-inflammatory activity. However, since prostaglandins are synthesised in most tissues and have a variety of physiological functions, inhibition of their biosynthesis also causes unwanted effects. The clinically most important of these are gastrointestinal erosion and ulceration with bleeding and perforation and kidney disorders with retention of sodium ions and water.

Moreover, there are COX-independent effects of NSAIDs potentially contributing to the activity of NSAIDs [2].

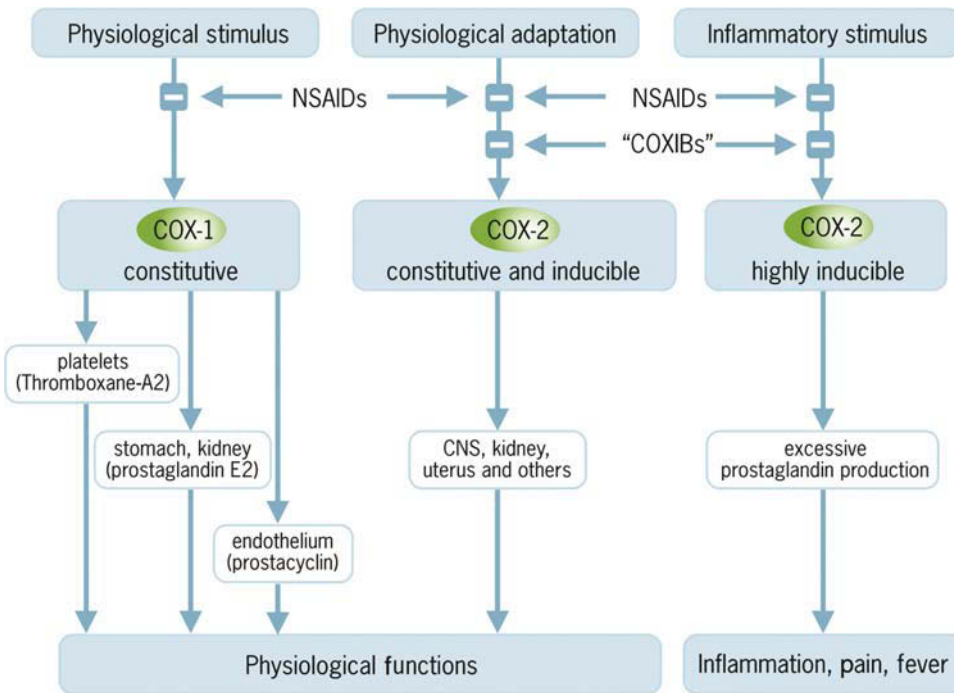

The identification of two distinct types of COX in 1990 [3] encouraged the search for NSAIDs devoid of the side effects associated with ▶ **COX-1** inhibition. The COX isoform COX-1 is physiologically expressed in the stomach, platelets and the kidney and is therefore responsible for the synthesis of prostaglandins needed for normal organ function (Fig. 2). Its inhibition by conventional NSAIDs causes side effects, e.g. inhibition of prostaglandin synthesis in the gastrointestinal tract results in a loss of protection in the gastrointestinal mucosa and ulcerations. The COX isoform, COX-2 is rapidly induced by various factors including cytokines, and its expression is triggered by inflammation, pain or tissue damage. It is clear from this division of COX into COX-1 and an inducible COX-2 that the anti-inflammatory, analgesic and anti-pyretic effects of the NSAIDs are mainly attributable to inhibition of COX-2 whereas inhibition of COX-1 is associated with some of the unwanted effects of the NSAIDs (Fig. 2).

It follows that drugs that selectively inhibit COX-2 should cause fewer side effects than those that inhibit both COX-1 and COX-2. At therapeutic doses, all currently available NSAIDs, with the exception of celecoxib, etoricoxib, lumiracoxib and parecoxib (the prodrug of valdecoxib), are non-selective and inhibit both COX isoforms.

Newer research has shown that the assignment of physiological activity exclusively to COX-1 and pathological activity exclusively to COX-2 is not strictly valid since COX-2 is expressed constitutively in organs such as spinal cord, kidney or uterus (Fig. 2). Furthermore, COX-2 is formed during various

Non-steroidal Anti-inflammatory Drugs. Figure 1 Non-steroidal anti-inflammatory drugs (NSAIDs) block cyclooxygenase (COX), an enzyme catalysing the production of prostaglandins. When fewer prostaglandins are produced, their physiological and pathophysiological effects are decreased, resulting in therapeutic as well as the unwanted effects of the NSAIDs.

Non-steroidal Anti-inflammatory Drugs. Figure 2 Physiological and pathophysiological functions of the COX isoenzymes COX-1 and COX-2, and the consequences of their inhibition by either unselective conventional NSAIDs or COX-2-selective “COXIBs”.

physiological adaptation processes such as the healing of wounds and ulcers.

Clinical Use (Including Side Effects)

NSAIDs are indicated in the treatment of:

- Various pain states (e.g. headache, toothache and migraine), primarily pathophysiological inflammatory pain, e.g. rheumatic pain and pain caused by bone metastases

- Defects of the Ductus arteriosus Botalli (short circuit connection between arteria pulmonalis and aorta; non-closure after birth)
- Fever

Unwanted reactions of NSAIDs include:

- Gastrointestinal disorders (e.g. dyspepsia), gastrointestinal erosion with bleeding, ulceration and perforation

- Kidney malfunctions with retention of sodium and water
- Inhibition of platelet aggregation
- Central nervous symptoms such as dizziness and headache
- Disturbance of uterine motility
- Skin reactions
- Triggering of asthma attacks in asthmatics. This side effect is a pseudo-allergic reaction where COX-inhibition increases the availability of substrates for lipoxygenase, which are converted to bronchoconstrictive leukotriens
- Thromboembolic events (myocardial infarction and stroke, see below)

Non-selective inhibitors of prostaglandin synthesis are contraindicated:

- In gastric and duodenal ulcer
- In asthma
- In bleeding disorders
- During the last few weeks of pregnancy because of the danger in the early seal of the Ductus Botalli

Glucocorticoids increase the risk of gastrointestinal complications caused by NSAIDs. Considerable caution is necessary when using NSAIDs in patients with severe liver and kidney damage and they should not be combined with coumarines. Owing to the limited experience obtained, these precautions and contraindications also apply to COX-2-selective inhibitors.

The following drug interactions are the most important that can occur when conventional NSAIDs are co-administered with other agents:

- The uricosuric effect of probenecid is reduced
- The diuretic effect of saluretics is weakened
- The blood glucose-lowering effect of oral antidiabetics is increased
- The elimination of methotrexate is delayed and its toxicity is increased
- The elimination of lithium ions is delayed
- The anti-coagulation effect of coumarin derivatives is enhanced
- The antihypertensive effect of ACE inhibitors is reduced

Due to the short period of clinical use, the interaction profile of COX-2-selective inhibitors cannot be entirely described at the present time.

Derivatives of Salicylic Acid

Salicylic acid for systemic use has been replaced by acetylsalicylic acid, amides of salicylic acid (salicylamide, ethenzamide, salacetamide), salsalate and diflunisal.

Acetylsalicylic Acid (Aspirin)

The esterification of the phenolic hydroxyl group in salicylic acid with acetic acid results not only in an

agent with improved local tolerability but also greater anti-pyretic and anti-inflammatory activity and, in particular, more marked inhibitory effects on platelet aggregation (inhibition of thromboxane-A₂ synthesis). Because of these qualities, acetylsalicylic acid is one of the most frequently used non-opioid analgesics, and the most important inhibitor of platelet aggregation.

Acetylsalicylic acid irreversibly inhibits both COX-1 and COX-2 by acetylating the enzymes. Since mature platelets lack a nucleus, they are unable to synthesise new enzyme. The anti-platelet effects of acetylsalicylic acid persist therefore throughout the lifetime of the platelet and the half-life of this effect is thus being much longer than the elimination half-life of acetylsalicylic acid (15 min). Since new platelets are continuously launched into the circulation, the clinically relevant anti-platelet effect of aspirin lasts for up to five days. This is the reason why low doses of acetylsalicylic acid (ca. 100 mg per day) are sufficient in the prophylaxis of heart attacks.

After oral administration, acetylsalicylic acid is rapidly and almost completely absorbed but in the intestinal mucosa it is partly deacetylated to salicylic acid, which also exhibits analgesic activity. The plasma half-life of acetylsalicylic acid is ~15 min whereas that of salicylic acid, at low dosages of acetylsalicylic acid, is 2–3 h. Salicylic acid is eliminated more slowly when acetylsalicylic acid is administered at high dose rates because of saturation of the liver enzymes. The metabolites are mainly excreted via the kidney.

The dosage of acetylsalicylic acid in the treatment of pain and fever is 1.5–3 g daily and in the prophylaxis of heart attacks 30–100 mg daily.

Side effects of acetylsalicylic acid administration include buzzing in the ears, loss of hearing, dizziness, nausea, vomiting, and most importantly gastrointestinal bleeding, gastrointestinal ulcerations including gastric perforation. The administration of acetylsalicylic acid in children with viral infections can, in rare cases, produce ►**Reye's syndrome** involving liver damage, encephalopathy and a mortality rate exceeding 50%. Acute salicylate poisoning results in hyperventilation, marked sweating and irritability followed by respiratory paralysis, unconsciousness, hyperthermia and dehydration.

Derivatives of Acetic Acid

Indomethacin

Indomethacin is a strong inhibitor of both COX isoforms with a slight stronger effect in the case of COX-1. It is rapidly and almost completely absorbed from the gastrointestinal tract and has high plasma protein binding (>95%). The plasma half-life of indomethacin varies from 3 to 11 h due to intense enterohepatic cycling. Only about 15% of the substance is eliminated unchanged in the urine, the remainder being eliminated in urine and bile as inactive metabolites (O-demethylation, glucuronidation, N-deacetylation).

The daily oral dose of indomethacin is 50–150 mg (up to 200 mg).

Indomethacin treatment is associated with a high incidence (30%) of side effects typical for those seen with other NSAIDs (see above). Gastrointestinal side effects, in particular, are more frequently observed after indomethacin than after administration of other NSAIDs. The market share of indomethacin (~5%) is therefore low compared to that for other non-steroidal anti-rheumatic agents.

Diclofenac

Diclofenac is an exceedingly potent COX inhibitor slightly more efficacious against COX-2 than COX-1. Its absorption from the gastrointestinal tract varies according to the type of pharmaceutical formulation used. The oral bioavailability is only 30–80% due to a first-pass effect. Diclofenac is rapidly metabolised (hydroxylation and conjugation) and has a plasma half-life of 1.5 h. The metabolites are excreted renally and via the bile.

Epidemiological studies have demonstrated that diclofenac causes less serious gastrointestinal complications than indomethacin. However, a rise in plasma liver enzymes occurs more frequently with diclofenac than with other NSAIDs.

The daily oral dose of diclofenac is 50–150 mg. Diclofenac is also available as eye-drops for the treatment of non-specific inflammation of the eye and for the local therapy of eye pain.

Derivatives of Arylpropionic Acids

2-Arylpropionic acid derivatives possess an asymmetrical carbon atom giving rise to S- and R-enantiomers. The S-enantiomer inhibits COX 2–3 times more strongly than the corresponding R-enantiomer. This finding has led to the marketing of pure S-enantiomers (e.g. S-ibuprofen and S-ketoprofen) in some countries in addition to the racemates where the R-enantiomer is considered as “ballast”. However, it is not yet proven whether 2-arylpropionic acids are better tolerated when given as S-enantiomer than as the racemate. Naproxen, for example, which is clinically available only as the S-enantiomer, does not cause less serious gastrointestinal side effects than, e.g. ibuprofen racemate.

Ibuprofen is the most thoroughly researched 2-arylpropionic acid. It is a relatively weak, non-selective inhibitor of COX. In epidemiological studies, ibuprofen compared to all other conventional NSAIDs, has the lowest relative risk of causing severe gastrointestinal side effects. Because of this, ibuprofen is the most frequently used OTC (“over the counter”, sale available without prescription) analgesic. Ibuprofen is highly bound to plasma proteins and has a relatively short elimination half-life (~2 h). It is mainly glucuronidated to inactive metabolites that are eliminated via the kidney.

The typical single oral dose of ibuprofen as an OTC analgesic is 200–400 mg and 400–800 mg when used in

anti-rheumatic therapy. The corresponding maximum daily doses are 1200 or 2400 mg, respectively but the dose in anti-rheumatic therapy in some countries can be as high as 3200 mg daily.

Other arylpropionic acids include naproxen, ketoprofen and flurbiprofen. They share most of the properties of ibuprofen. The daily oral dose of ketoprofen is 50–150 mg, 150–200 mg for flurbiprofen and 250–1000 mg for naproxen. Whereas the plasma elimination half-life of ketoprofen and flurbiprofen are similar to that of ibuprofen (1.5–2.5 h and 2.4–4 h, respectively), naproxen is eliminated much more slowly with a half-life of 13–15 h.

Oxicams

Oxicams, e.g. piroxicam, tenoxicam, meloxicam and lornoxicam are non-specific inhibitors of COX. Like diclofenac, meloxicam inhibits COX-2 ten times more potently than COX-1. This property can be exploited clinically with doses up to 7.5 mg per day, but at higher doses COX-1-inhibition becomes clinically relevant. Since the dose of meloxicam commonly used is 15 mg daily, this agent cannot be regarded as a COX-2-selective NSAID and considerable caution needs to be exercised when making comparisons between the actions of meloxicam and those of other conventional NSAIDs. The average daily dose in anti-rheumatic therapy is 20 mg for piroxicam and tenoxicam, 7.5–15 mg for meloxicam and 12–16 mg for lornoxicam. Oxicams have long elimination half-lives (lornoxicam 3–5 h, meloxicam ~20 h, piroxicam ~40 h and tenoxicam ~70 h).

COX-2-Selective NSAIDs (COXIBs)

The development of the COXIBs has been based on the hypothesis COX-1 is the physiological COX and COX-2, the pathophysiological isoenzyme. Inhibition of the pathophysiological COX-2 only is assumed to result in fewer side effects as compared to non-selective inhibition of both COX isoenzymes (Fig. 2). Celecoxib, etoricoxib and lumiracoxib (in some countries also parecoxib) are the only COXIBs currently approved.

The indications for these agents are in principle identical to those of the non-selective NSAIDs although the substances have not yet received approval for the whole spectrum of indications of the conventional NSAIDs. Because they lack COX-1-inhibiting properties, COX-2-selective inhibitors show fewer side effects than conventional NSAIDs. However, they are not free of side effects because COX-2 has physiological functions that are blocked by the COX-2 inhibitors. The most frequently observed side effects are infections of the upper respiratory tract, diarrhoea, dyspepsia, abdominal discomfort and headache. Peripheral oedema is as frequent as with conventional NSAIDs. The frequency of gastrointestinal complications is approximately half that observed with conventional NSAIDs.

The precise side effect profile of the selective COX-2 inhibitors however, will only be known after several years of clinical use.

Cardiovascular Effects of COXIBs and Non-Selective NSAIDs

Randomised clinical trials and observational studies have clearly shown an increased risk of thromboembolic events during treatment with COXIBs [4]. The incidence of these events tends to increase with the administered COXIB dose and with duration of treatment (for review see [5]). Confusion exists about the underlying mechanisms. Surely the imbalance between the antithrombotic prostacyclin, which is inhibited by COXIBs and the prothrombotic thromboxane-A₂, which is not inhibited by COXIBs due to the COX-2-selectivity of these drugs, plays an important role. However, recent observational studies with non-selective NSAIDs have also shown an increased risk for cardiovascular events with this group of drugs. Non-selective NSAIDs normally do not cause an imbalance between prostacyclin and thromboxane-A₂ since prostaglandins are inhibited unselectively. Thus other mechanisms, both COX-2-dependent and independent ones may play a role for the cardiovascular risk of selective and non-selective NSAIDs (for review see [5]). Unfortunately long-term placebo and active-comparator-controlled trials are nearly lacking for the non-selective NSAIDs. The actual discussion, which is still not finalised, suggests that both COXIBs and non-selective NSAIDs have a similar increased risk for thromboembolic events. The labelling of all drugs has been changed accordingly although the wording differs from country to country. Irrespective from the actual wording, case caution is always necessary when COX-2-selective or non-selective NSAIDs are used.

Non-viral Peptidases

NEIL D. RAWLINGS

Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridgeshire, UK

Synonyms

Proteases; Proteinases; Proteolytic enzymes

Definition

Peptidases are enzymes that catalyse the hydrolysis of peptide bonds – the bonds between amino acids that are found in peptides and proteins. The terms “protease”, “proteinase” and “proteolytic enzyme” are synonymous, but strictly speaking can only be applied to peptidases that hydrolyse bonds in proteins. Because there are many peptidases that act only on peptides, the term “peptidase” is recommended. Peptidases are included in subclass 3.4 of enzyme nomenclature [1,5].

Basic Characteristics

Active Site Residues

Peptidases are found in all forms of life. There are about 612 peptidases in humans, plus an additional 385 proteins that are homologous to peptidases but either have no or different catalytic activity. In general, 2% of all genes in a genome encode peptidases.

Cleavage of a peptide bond is an example of a nucleophilic attack. The nucleophile in the reaction is either an activated water molecule or part of the side-chain of an amino acid, and peptidases are described as having either a ▶water nucleophile or a ▶protein nucleophile. Peptidases with a water nucleophile either utilize one or two metal ions as ligands for the water molecule, in which case the peptidase generally acts

at neutral pH, or the water is bound by two aspartic acid residues, in which case the peptidase usually has an acidic pH optimum. For peptidases with a protein nucleophile, the nucleophile is either the hydroxyl group from a serine or threonine residue or the thiol group from cysteine. Thus there are five major catalytic types: aspartic, metallo, serine, threonine and cysteine peptidases. A sixth type, glutamic peptidases, is known, but the only known example is from fungi. There are still several peptidases for which the catalytic type is as yet undetermined.

A metallopeptidase binds a divalent metal ion tetrahedrally, with three ligands being amino acid residues and the fourth the water molecule that becomes the nucleophile in the reaction. The amino acid ligand residues are conserved. Most commonly, a zinc ion is bound, but peptidases that bind cobalt, manganese, nickel and copper also exist. Metal ligands are most often histidine residues, but can also be aspartic and glutamic acids, and more unusually asparagine, glutamine or lysine. When a peptidase binds two metal ions five residues are involved, one of which ligates both ions. The metal ion is described as **▶co-catalytic**. Besides metal ligands other residues are often essential for catalytic activity. The peptidases that are involved in the turnover of extracellular matrices, known as **▶matrixins** or **▶matrix-metallopeptidases (MMPs)** are examples of metallopeptidases containing the motif HEXXH. In this motif the two histidines are metal ligands while the glutamic acid is an **▶active site** residue. Glutamate carboxypeptidase binds two zinc ions via two histidines, an aspartic acid and two glutamic acids and in addition has two active site residues, an aspartic and a glutamic acid.

Aspartic peptidases bind and activate water via two aspartic acid residues.

Peptidases with a protein nucleophile often have an active site containing two or three residues. A second residue, most often a histidine (though lysine and arginine can substitute), is required to interact with the nucleophile and become a **▶protor acceptor** or **▶general base** in the catalytic reaction. If a **▶catalytic triad** exists, which is often the case when a histidine residue is the general base, then an aspartic or glutamic acid, asparagine or glutamine is thought to orientate the imidazolium ring of the histidine side chain. In the cysteine peptidase cathepsin B, the order of the catalytic residues is Cys, His, Asn. In the serine peptidase chymotrypsin, the order is His, Asp, Ser.

For many serine and cysteine peptidases catalysis first involves formation of a complex known as an **▶acyl intermediate**. An essential residue is required to stabilize this intermediate by helping to form the **▶oxyanion hole**. In cathepsin B a glutamine performs this role and sometimes a catalytic tetrad (Gln, Cys, His, Asn) is referred to. In chymotrypsin, a glycine is essential for stabilizing the oxyanion hole.

Threonine peptidases (and some cysteine and serine peptidases) have only one active site residue, which is the N-terminus of the mature protein. Such a peptidase is known as an **▶N-terminal nucleophile hydrolase** or **▶Ntn-hydrolase**. The amino group of the N-terminal residue performs the role of the general base. The catalytic subunits of the proteasome are examples of Ntn-hydrolases.

The order and nature of the active site residues and metal ligands is conserved between homologous peptidases. All the members of a family will have the same catalytic type.

Classification and Nomenclature

Peptidases have been classified by the *MEROPS* system since 1993 [2], which has been available via the *MEROPS* database since 1996 [3]. The classification is based on sequence and structural similarities. Because peptidases are often multidomain proteins, only the domain directly involved in catalysis, and which bears the active site residues, is used in comparisons. This domain is known as the **▶peptidase unit**. Peptidases with statistically significant peptidase unit sequence similarities are included in the same **▶family**. To date 186 families of peptidase have been detected. Examples from 86 of these families are known in humans. A family is named from a letter representing the catalytic type (“A” for aspartic, “G” for glutamic, “M” for metallo, “C” for cysteine, “S” for serine and “T” for threonine) plus a number. Examples of family names are shown in Table 1. There are 53 families of metallopeptidases (24 in human), 14 of aspartic peptidases (three of which are found in human), 62 of cysteine peptidases (19 in human), 42 of serine peptidases (17 in human), four of threonine peptidases (three in human), one of glutamic peptidases and nine families for which the catalytic type is unknown (one in human). It should be noted that within a family not all of the members will be peptidases. Usually **▶non-peptidase homologues** are a minority and can be easily detected because not all of the active site residues are conserved.

All peptidases within a family will have a similar tertiary structure, and it is not uncommon for peptidases in one family to have a similar structure to peptidases in another family, even though there is no significant sequence similarity. Families of peptidases with similar structures and the same order of active site residues are included in the same **▶clan**. A clan name consists of two letters, the first representing the catalytic type as before, but with the extra letter “P”, and the second assigned sequentially. Unlike families, a clan may contain peptidases of more than one catalytic type. So far this has only been seen for peptidases with protein nucleophiles, and these clans are named with an initial “P”. Only three such clans are known. Clan PA includes peptidases with a chymotrypsin-like fold, which besides serine peptidases such as chymotrypsin

Links are provided to the relevant summary pages in the *MEROPS* database.

also includes some cysteine peptidases from viruses. Clan PB contains the Ntn-hydrolases, which can be threonine, cysteine or serine in type. Clan PC includes the cysteine peptidase gamma-glutamyl hydrolase and the serine peptidase alpha-aspartyl dipeptidase. There are 45 clans of peptidases, or in other words there are 45 independent origins of peptidases.

Peptidases that are thought to be species variants of the same protein and have similar properties are included in the same ►*MEROPS* identifier. The identifier consists of the three-character family name (padded with zeroes if necessary), a dot, and a unique three digit number. Examples of *MEROPS* identifiers are shown in Table 1. Two special kinds of identifier are used for non-peptidase homologues in the *MEROPS* database for proteins and pseudogenes. For proteins the three digit number begins with a nine, and for pseudogenes the first digit is replaced by a “P”.

With the onset of genomic biology, there are now many sequences derived from genome sequencing projects that are too divergent to be considered species variants of known peptidases. Of the 54,124 sequences in the *MEROPS* database only 18,741 (34.6%) have been assigned to an identifier.

It is recommended that a well-characterized peptidase should have a trivial name. Although not rigidly adhered to, there is a different suffix for each catalytic type, metallopeptidases names end with “lysin”, aspartic peptidases with “pepsin”, cysteine peptidase with “ain” and serine peptidases with “in”.

Compound and Complex Peptidases

Most peptidases have only one peptidase unit; however, there are some exceptions. A ►**compound peptidase** has more than one peptidase unit within a single protein molecule. An example is the somatic form of the angiotensin-converting enzyme, which has two peptidase units. The testicular form of this enzyme contains only the second peptidase unit and is transcribed from the same gene but at an alternative initiating methionine. Each peptidase unit has a *MEROPS* identifier, but additionally there is a special identifier for each compound peptidase, which is XM02-001 in the case of angiotensin-converting enzyme.

A ►**complex peptidase** consists of several proteins in a complex. The 20S proteasome is a complex of 28 subunits, arranged in four stacked rings each containing 7 different subunits. The first and fourth rings contain the same seven (alpha) subunits, as do the second and third (beta subunits). Each subunit is the product of an individual gene, and the subunits are homologous to each other. Only three of the beta subunits are catalytically active, each conferring a different specificity (trypsin-like, chymotrypsin-like or peptidylglutamyl peptide hydrolyzing, now often known as caspase-like). The proteins form a cylinder with the six active sites on the inside and the substrate protein is threaded through one end and degraded to peptides that exit at the opposite end. The 28S proteasome contains additional subunits which form a cap and attach to one end of the 20S proteasome. These

extra subunits are important for unfolding the substrate protein. Again, there is not only a *MEROPS* identifier for each alpha and beta subunit, but also identifiers for the complexes. The 20S proteasome is XT01-001 and the 28S proteasome is XT01-002.

Precursors and Zymogens

Most peptidases are not synthesized as active enzyme but as precursors or ►**zymogens**. The zymogen is transported to the site where it is needed and then activated, usually by the removal of an N-terminal ►**propeptide** by proteolysis. For some members of family S1, especially members of the blood coagulation pathway, a propeptide is not released but cleavage is still required for activity. The propeptide remains attached to the peptidase by a disulfide bridge, becoming the heavy chain in a two-chain complex. Cleavage generates a new hydrophobic N-terminal residue, and a molecular rearrangement then activates the peptidase. For some members of peptidase family M10, the propeptide acts by providing a fourth ligand for the catalytic zinc ion, and only on release of the propeptide does the zinc interact with water and the peptidase become active. Because this fourth ligand is a cysteine, this method of activation is known as a ►**cysteine switch**.

Specificity and Substrate-Binding

The ►**specificity** of a peptidase describes where in a peptide or protein sequence cleavage will occur. Some peptidases will only cleave near the amino- and carboxy-termini of the substrate and these are termed ►**exopeptidases**. A peptidase that does not require free termini and can cleave at any acceptable site within a peptide is termed an ►**endopeptidase**. Most endopeptidases are able to cleave proteins, but there are a few that can only cleave short peptides, and these are known as ►**oligopeptidases**. Neprilysin is an oligopeptidase that degrades peptide hormones such as substance P, thereby switching off the physiological signal. Some endopeptidases are ►**isopeptidases**, cleaving non-standard peptide bonds. An example is isopeptidase T, which releases ubiquitin from ubiquitinated proteins by cleaving the isopeptide bond between the C-terminal Gly of ubiquitin and the amino group of a non-terminal lysine on the protein targeted for degradation.

There are several different types of exopeptidases: ►**aminopeptidases**, ►**carboxypeptidases**, ►**dipeptidyl-peptidases**, ►**tripeptidyl-peptidases**, ►**peptidyl-dipeptidases**, ►**dipeptidases** and ►**omega peptidases**.

Generally, a family of peptidases contains either exopeptidases or endopeptidases, but there are exceptions. Family C1 contains not only endopeptidases such as cathepsin L, but also the aminopeptidase bleomycin hydrolase. Some members of this family can act as exopeptidases as well as endopeptidases. For example, cathepsin B also acts as a peptidyl-dipeptidase, and

cathepsin H also acts as an aminopeptidase. Family S9 includes prolyl oligopeptidase, dipeptidyl-peptidase IV and the omega peptidase acylaminoacyl-peptidase.

The specificity of an endopeptidase is more difficult to describe than that of an exopeptidase. A peptidase with ►**limited specificity** will only cleave after one type of amino acid. Examples are trypsin, which cleaves proteins at lysyl or arginyl bonds, and chymotrypsin, which cleaves after hydrophobic residues. Granzyme B and caspase-3, which are involved in ►**apoptosis** or programmed cell death, cleave only after aspartyl bonds. However, even this can be simplistic; recent evidence has shown that granzyme B from mouse does not cleave Bid, whereas in human cleavage of this protein initiates the apoptotic pathway. The lysosomal endopeptidase legumain cleaves asparaginyl bonds, but under acidic conditions can cleave aspartyl bonds; experiments with processing of the tetanus toxin have shown that only a few asparaginyl bonds are cleaved. Whether this is because only a few bonds are available to the peptidase because of the structure of the substrate or because the specificity of the peptidase is more complicated is unclear. Peptidases that cleave a variety of peptide bonds are described as having ►**broad specificity**.

Cleavage occurs at the ►**scissile bond**. Residues in the substrate towards the N-terminus are numbered P1, P2, P3, etc, whereas residues towards the C-terminus are numbered P1', P2', P3' etc. Cleavage occurs between P1 and P1'. For a peptidase with limited specificity, only the residue in P1 or P1' is important for specificity. A peptidase with an ►**extended substrate binding site** will have a preference for residues in other positions. For example cathepsin L prefers substrates with phenylalanine in P2 and arginine in P1. However, this is a preference only, and cathepsin L cleaves substrates after other amino acids. Caspase-3 has a preference for Asp in both P4 and P1, but it is unusual for substrate specificity to extend much further from the scissile bond. The peptidase with the most extended substrate specificity may be mitochondrial intermediate peptidase that removes an octopeptide targeting signal from the N-terminus of cytoplasmically synthesized proteins that are destined for import into the mitochondrial lumen.

A peptidase has a series of ►**substrate-binding pockets** to accommodate residues of the substrate. The S1 binding pocket accommodates residue P1, the S1' binding pocket accommodates residue P1' and so on. A binding pocket may contain several residues that interact with the substrate, and a single residue may take part in more than one binding pocket. Some peptidases bind the substrate at more than one binding site. A binding site away from the active site is described as an ►**exosite**. The presence of one or more exosites makes the peptidase very specific for a substrate, and it is not unusual for a

peptidase with an exosite to cleave just one protein. Peptidases with such limited specificity include the blood coagulation enzymes. In some peptidases, additional substrate-binding sites are located on domains other than the peptidase unit. For example the matrixins (family M10) interact with proteins of the extracellular matrix through the haemopexin-like domain that is C-terminal to the peptidase unit.

A ► **proteolytic cascade** occurs when one peptidase activates the next in a proteolytic pathway, and this in turn activates the next and so on. This is a mechanism to amplify the initial signal, because one peptidase molecule can activate many zymogen molecules. Examples of proteolytic cascades include blood coagulation, activation of digestive peptidases in the intestine, and apoptosis.

Drugs

The action of a peptidase can be neutralized by an inhibitor. Some inhibitors are very broad in their action and are capable of inhibiting many different peptidases, including peptidases of different catalytic types. Some inhibitors are assumed to be specific for a particular catalytic type, but can inhibit peptidases of different types. Leupeptin, for example, is widely used as an inhibitor of serine peptidases from family S1, but it is also known to inhibit cysteine peptidases from family C1. Cysteine peptidase inhibitors such as iodoacetic acid interact with the thiol of the catalytic cysteine. However, this reduction can occur on any thiol group and can affect other, predominantly intracellular, peptidases with a thiol dependency. One example is thimet oligopeptidase. Metal chelators such as EDTA can inhibit metallopeptidases, but can also affect peptidases that have a requirement for metal ions that is independent of their catalytic activity, such as the calcium-dependent cysteine endopeptidase calpain 1.

Inhibitors which interact only with peptidases of one catalytic type include pepstatin (aspartic peptidases); E64 (cysteine peptidases from clan CA); diisopropyl fluorophosphates (DFP) and phenylmethane sulfonyl-fluoride (PMSF) (serine peptidases). Bestatin is a useful inhibitor of aminopeptidases.

Table 1 lists peptidases that are known or potential drug targets. In nearly all cases the drug will be a synthetic peptidase inhibitor [4].

Noradrenaline Transporter

Noradrenaline transporters (NAT) are localized in the presynaptic plasma membrane of adrenergic nerve terminals. They belong to a family of proteins with 12 putative transmembrane proteins which are responsible for recycling of released neurotransmitters (noradrenaline/adrenaline, dopamine, serotonin, amino acid transmitters) back into the presynaptic nerve ending. Noradrenaline transporters can be blocked by a number of different antidepressant drugs, including tricyclic antidepressants (e.g. desipramine) and selective noradrenaline reuptake inhibitors (e.g. reboxetine).

- Antidepressants
- Synaptic Transmission

Norepinephrine/Noradrenalin

Neurotransmitter and biogenic amine synthesized by neurons in the locus coeruleus from tyrosine which controls behavioral state, postural tone, selective attention, mood and memory extinction, and is part of sympathoadrenal stress management system.

NSF

NSF, the acronym for NEM-sensitive fusion protein, was originally discovered as an essential factor in intracellular membrane transport steps. NSF is now known to catalyze the disassembly of all SNARE complexes. NSF requires the binding of SNAPs to exert its action. NSF is an evolutionarily conserved protein that forms hexameric double-ring structures. During its catalytic cycle, ATP is cleaved and the N-terminal region undergoes massive conformational changes. Recently, NSF has been shown to interact with other proteins such as glutamate receptors, but the significance of these interactions is still controversial.

- ▶ Exocytosis

NSMRI

- ▶ Non-selective Monoamine Reuptake Inhibitors

Ntn-Hydrolase

An enzyme in which the single catalytic residue is at the N-terminus of the protein. Many Ntn-hydrolases are synthesized as precursors and autoactivate; the precursors are therefore peptidases, even if the mature enzyme has no further proteolytic activity. Three of the beta subunits of the proteasome are Ntn-hydrolases.

Nuclear Factor Kappa B

MIREILLE DELHASE
Department of Pharmacology, University of California,
San Diego, CA, USA

Synonyms

Rel proteins

Definition

Nuclear factor kappa B (NF- κ B) is the generic term for a family of dimeric eukaryotic transcription factors, composed of members of the Rel family of DNA-binding proteins including the mammalian proteins RelA (or p65), cRel, RelB, p50 and p52, and the *Drosophila* proteins Dorsal, Dif and Relish. These proteins bind with different affinities to a consensus DNA sequence motif (called the κ B site) consisting of the sequence 5'-GGGRNYYCC-3' in which R is a purine, Y is a pyrimidine, and N is any base.

Basic Characteristics

NF- κ B Structure

NF- κ B is a dimeric, ubiquitously expressed, and evolutionary conserved transcription factor that plays a critical role in immune and inflammatory responses [1]. In mammals, the NF- κ B family consists of five members: NF- κ B1 (p105/p50), NF- κ B2 (p100/p52), RelA (p65), cRel, and RelB. Structurally, NF- κ B proteins share a highly conserved 300 amino acid

►Rel homology domain (RHD) that encompasses a sequence-specific DNA-binding domain, a dimerization domain and a nuclear translocation signal (NLS) (Fig. 1a). RelA, cRel, and RelB contain a transcription activation domain (TAD). NF- κ B1 and NF- κ B2 are synthesized as large precursors, p105 and p100, that are posttranslationally processed to generate the mature forms, p50 and p52, which lack a TAD.

NF- κ B proteins are principally regulated by subcellular localization whereby the inactive cytoplasmic forms become transcriptionally active proteins upon translocation to the nucleus. In most resting cells, NF- κ B is maintained in the cytoplasm by binding to members of the inhibitor of κ B (I κ B) family (Fig. 1b). The I κ Bs (such as I κ B α , I κ B β , and I κ B ϵ) contain 6–7 ►ankyrin repeats that mediate their binding to the RHD and thereby interfere with the function of the NLS. Ankyrin repeats are also found in the precursors NF- κ B1 (p105) and NF- κ B2 (p100), enabling them to function as I κ Bs and retain Rel proteins in the cytoplasm of unstimulated cells.

Nuclear Factor Kappa B. Figure 1 Mammalian NF- κ B proteins and their regulators, the I κ B proteins. (a) NF- κ B proteins share a highly conserved 300 amino acids Rel homology domain (RHD) located at their amino-terminal region, which includes a DNA-binding domain, a dimerization domain, and a nuclear localization signal (NLS). RelA (p65), cRel, and RelB contain in their carboxy-terminal part, a nonhomologous transcriptional activation domain (TAD). RelB has an additional amino-terminal leucine zipper (LZ) motif. NF- κ B1/p50 (or p105/p50) and NF- κ B2/p52 (or p100/p52) contain a glycine-rich region (GRR) and carboxy-terminal ankyrin repeats that are also present in I κ B proteins. Proteolytic processing of NF- κ B1/p50 and NF- κ B2/p52 (sites indicated by arrows) generates the respective mature NF- κ B proteins, p50, and p52. (b) The inhibitor of NF- κ B (I κ B) family members including I κ B α , I κ B β , I κ B γ , I κ B ϵ , and Bcl-3, are characterized by the presence of multiple ankyrin repeats that are essential for binding of I κ Bs to the RHD of NF- κ B proteins. All three I κ B subunits, I κ B α , I κ B β , and I κ B ϵ present in their amino-terminal region two critical serine residues (depicted SS) required for their inducible phosphorylation-mediated degradation.

Nuclear Factor Kappa B. Figure 2 Classical and alternative NF-κB activation pathways. The classical or canonical NF-κB pathway is activated by a variety of stimuli including the proinflammatory cytokines, TNFα and IL-1, and diverse pathogen-associated molecular patterns (PAMPs). Each signal is transmitted to the classical IKK complex (composed of IKKα, IKKβ, and IKKγ) through activation of specific transmembrane receptors. IKK phosphorylates the IκB proteins leading to their polyubiquitination and degradation. This leads to liberation and nuclear translocation of NF-κB dimers (mainly p65–p50) and coordinated activation of multiple inflammatory and innate immune genes. The alternative or noncanonical NF-κB pathway results in the nuclear translocation of p52-RelB dimers after phosphorylation-dependent processing of p100 (NF-κB2). It is strictly dependent on IKKα dimers that are activated by certain cytokines including lymphotoxin-β (LTβ), CD40 ligand (CD40L), and the B-cell-activating factor BAFF/Blys. Activation of the alternative pathway turns on a gene expression program involved in the development and maintenance of secondary lymphoid organs and adaptive immunity.

NF-κB Activation

There are two major signaling pathways leading to nuclear translocation and thereby activation of NF-κB proteins. The most frequent, observed in all cell types, is the classical or canonical NF-κB activation pathway (Fig. 2). This pathway is activated by proinflammatory cytokines such as tumor necrosis factor-α (TNFα) (▶**tumor necrosis factor**) and interleukin-1 (IL-1), as well as pathogen-associated molecular patterns (▶**PAMPs**). These effector molecules act through different receptors belonging to the tumor necrosis factor receptor (TNF-R) and Toll-like receptor (TLR)-interleukin-1 receptor (IL-1R) superfamilies (▶**Toll-like receptors**) and activate a large multiprotein complex, the IκB kinase (▶**IKK**) complex. The most common form of this complex consists of two catalytically active protein kinases, IKKα (or IKK1) and IKKβ (or IKK2), forming heterodimers, which are associated with at least two molecules of the IKKγ regulatory subunit (also called NEMO for “NF-κB essential modulator”). The function of the activated IKK complex is to catalyze the rapid ▶**phosphorylation** of the IκBs at two serine residues located in their amino-terminal regulatory domain (Fig. 1b) triggering their ubiquitination-mediated degradation by the 26S proteasome. NF-κB dimers (predominantly RelA-p50 dimers) are released, translocated to the nucleus where they bind to DNA and activate gene transcription.

A second NF-κB activation pathway, called the alternative or noncanonical pathway is activated in response to certain cytokines that belong to the TNF cytokine family including lymphotoxin-β (LTβ), CD40 ligand (CD40L), and the B-cell-activating factor BAFF (Fig. 2). This pathway strictly depends on the activation of IKKα homodimers, which phosphorylate NF-κB2 at two serine residues located at the carboxy-terminal end of the protein. Phosphorylation of these sites induces the ubiquitin-dependent processing of NF-κB2 to generate the mature p52 protein (amino-terminal portion of NF-κB2) while the carboxy-terminal part is degraded by the 26S proteasome. As NF-κB2 is mainly associated with RelB, its processing leads to the release and nuclear translocation of p52-RelB heterodimers.

NF-κB and Immunity

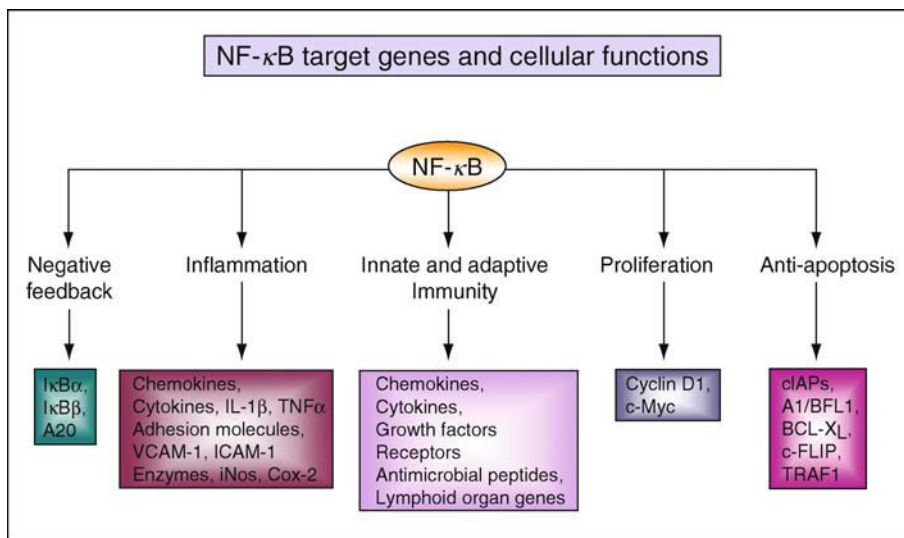

NF-κB regulates both innate and adaptive immune responses (▶**immune defense**) [2]. Understanding the function of NF-κB in the development, maintenance, and activation of cells from the immune system (including hematopoietic cells, macrophages, dendritic cells, B and T lymphocytes) has greatly benefited from the analysis of knockout mice in which individual NF-κB family members were defective.

The innate immune response is initiated once the host detects the presence of foreign pathogens. This recognition step is performed by specialized cells of

the innate immune system, the macrophages, and the dendritic cells. These cells express at their surface or intracellularly, a number of pattern recognition receptors (►PRRs), each of which has the ability to recognize specific pathogen-derived substances called (►PAMPs) characteristics of various classes of microbes including bacteria, viruses, and parasites. Activation of the classical NF- κ B signaling pathway is essential to this acute phase of antimicrobial defense. Defective NF- κ B activity in mice and humans is often associated with susceptibility to microbial infections. Indeed, activation of NF- κ B dimers (mainly RelA-p50) induces transcription of genes encoding cytokines (►cytokines), chemokines, adhesion molecules, and antimicrobial peptides (►defensins), all of which are essential to build the innate immune response, clear the pathogen, and initiate the adaptive immune response (Figs 2 and 3).

NF- κ B is also crucial for the proper functioning of the adaptive immune system not only by acting on the immune cells themselves but also by participating in the development and organization of the secondary lymphoid organs (lymph nodes, spleen, and Peyer's patches), in which both B and T lymphocytes undergo maturation and activation. NF- κ B proteins have an important role in lymphocyte development and

homeostasis, primarily through regulation of the balance between cell proliferation and cell death (Fig. 3). The antiapoptotic function of NF- κ B is required during early development and expansion of B-cells, which occurs in the bone marrow and T-cells, which takes place in the thymus. Different genetic approaches have uncovered the involvement of NF- κ B proteins in T-cell activation and function. For instance, NF- κ B is involved in the production of interleukin-18 (IL-18) and interferon- γ (INF- γ), two cytokines required to develop the cellular or T helper 1 (T_H1) immune response. Activation of both the canonical and non-canonical NF- κ B pathways controls B-cell maturation and function such as immunoglobulin class switching and cytokine production. Recently, efforts have concentrated on understanding the contribution that individual NF- κ B family members make to the development of secondary lymphoid organs and on the identification of specific NF- κ B target genes activated in the different cell types (stromal, dendritic, and lymphoid) implicated in this developmental program. Organogenic stimuli such as LT β activate both the canonical and the non-canonical pathways although with different kinetics. This leads to sequential activation of different subsets of NF- κ B target genes. Expression of proinflammatory

Nuclear Factor Kappa B. Figure 3 NF- κ B cellular functions and target genes. NF- κ B contributes to the induction of multiple target genes that can be divided into five major functional classes, which specify diverse cellular functions. NF- κ B controls its own activity by inducing the expression of its regulators, the I κ B proteins and establishing a negative feedback regulatory loop. NF- κ B induced multiple genes whose products are mediators of inflammation such as proinflammatory cytokines (TNF α and IL-1), adhesion molecules (VCAM-1, ICAM-1, E-selectin), and the inflammatory enzymes, cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS). NF- κ B has critical immunoregulatory functions both in the innate immune defense against pathogens and in the development, maintenance, and activation of the adaptive immunity. The antiapoptotic function of NF- κ B requires the activation of genes whose products are implicated in the inhibition of caspase activity such as the cellular inhibitors of apoptosis (cIAPs) and the cellular FLICE-inhibitory protein (cFLIP) or are negative regulators of the mitochondrial cell death program such as the Bcl-2 family protein members, Bfl-1/A1 and Bcl-X_L. NF- κ B plays a role in cell proliferation and differentiation in particular by regulation the expression of the genes encoding the cell-cycle regulator, cyclin D1, and the oncogene cMyc.

chemokines such as eotaxin, Rantes, and the monocyte chemotactic protein-1 (MCP-1) is under the control of the classical pathway while induction of organogenic chemokines such as SLC (secondary lymphoid tissue chemokine) or SDF-1 (stromal cell-derived factor-1) requires p52-RelB dimers activated in the noncanonical pathway.

NF- κ B, Inflammation and Inflammatory Diseases

NF- κ B is one of the most important regulators of inflammation [2]. Proinflammatory stimuli such as those elicited by the cytokines TNF α and IL-1, are the most potent activators of NF- κ B and trigger a proinflammatory gene expression program consisting of transcription of genes encoding proinflammatory cytokines (TNF α , IL-1, and IL-6), chemokines, adhesion molecules, inflammatory enzymes (cyclooxygenase-2, COX-2; inducible nitric oxide synthase, iNOS), and **matrix metalloproteinases (MMPs)** (**matrix metalloproteases**) (Figs 2 and 3). Massive production of proinflammatory mediators (TNF α and IL-1) amplifies the inflammatory response despite the activation of at least two negative feedback mechanisms mediated by induced expression of the NF- κ B inhibitors (I κ Bs) and of the ubiquitination enzyme A20. Recruitment of inflammatory cells to the site of inflammation and tissue destruction also occurs quite rapidly after NF- κ B activation. High NF- κ B activity is observed at the center of inflammation in several diseases affecting different tissues or organs including rheumatoid arthritis (**inflammation and rheumatoid arthritis**), inflammatory bowel disease, asthma, and psoriasis. Specific inhibition of NF- κ B activity has been shown to substantially reduce the inflammatory response in different animal models of inflammatory diseases. Most antiinflammatory drugs used to treat inflammatory diseases have direct or indirect effects on NF- κ B activity.

NF- κ B and Programmed Cell Death

Programmed cell death, which includes [3] apoptosis and necrosis is largely controlled by NF- κ B (**apoptosis**). The classical pathway is responsible for inhibition of programmed cell death (PCD) triggered by activation of several receptors including type I and type II TNF-receptors (TNF-RI and TNF-RII), TLR4 and T- and B-cell receptors, which are able to generate both survival and death signals once activated. NF- κ B favors survival by inducing the expression of several antiapoptotic genes whose products act at different steps along the receptor-mediated or the mitochondrial proapoptotic cascades. These antiapoptotic proteins include the cellular FLICE-inhibitory protein (c-FLIP), the cellular inhibitor of apoptosis (c-IAP1 and c-IAP2), the X-chromosome-linked IAP (XIAP), the TNF receptor-associated factor-1 and -2 (TRAF1 and TRAF2) and several members of

the Bcl-2 family such as the Bcl-2 homologs Bfl-1/A1 and Bcl-X_L. The first clear evidence that NF- κ B is an effective inhibitor of apoptosis came from the analysis of RelA-deficient mice that die during embryonic development from massive liver apoptosis. Defective NF- κ B activation is unable to protect the hepatocytes from the toxic effects caused by the massive release of TNF α that occurs in the liver of a developing embryo. A similar phenotype is observed in mice defective in IKK β and IKK γ , the two components of the IKK complex that are crucial for activation of the antiapoptotic program mediated through the classical NF- κ B pathway. The alternative pathway also supports an antiapoptotic program important for survival of premature B-cells and development of secondary lymphoid organs as described above. This protective effect of NF- κ B against apoptosis has a dramatic side effect in cancer cells as it antagonizes the killing potential of most anticancer drugs that also activate NF- κ B. In addition, constitutive NF- κ B activity is observed in various solid and hematologic tumors. NF- κ B also influences the tumor microenvironment by producing proinflammatory cytokines that promote tumor cell growth and therefore appears as a major factor in the development of inflammation-associated cancers (**cancer**). The development of specific NF- κ B inhibitors represents an attractive therapeutic approach in cancer therapy.

Drugs

There are several hundred reported NF- κ B inhibitors (see www.nf-kb.org for a complete and updated list). These inhibitors include natural products, chemicals, metabolites, and synthetic compounds. A large majority of these products, in particular commonly used anti-inflammatory drugs such as corticosteroids and the nonsteroidal antiinflammatory drugs (NSAIDs) aspirin, sulindac, ibuprofen and sulphasalazine, have the ability to partially inhibit NF- κ B activity in cell culture. However, the precise mechanism of action and the specific molecular targets of most of these inhibitors remain unclear.

Several strategies targeting different steps of the signaling cascade can be used to inhibit NF- κ B activation and function [4,5]. One general approach is to interfere with NF- κ B nuclear activity by altering dimerization, nuclear translocation, binding to DNA, or interaction with the transcriptional machinery. This includes the use of decoy oligonucleotides that have κ B sites and compete NF- κ B dimers out of their target promoters or cell-permeable peptides able to block specifically the nuclear translocation of NF- κ B.

A second strategy that is more likely to succeed is to interfere with the process of activation of NF- κ B by blocking the activation of the IKK complex or the degradation of I κ Bs. Pharmaceutical companies are investing considerable effort in the development of

proteasome inhibitors, many of which inhibit I κ B degradation and thereby NF- κ B nuclear translocation. However, as the proteasome is involved in the degradation of many different polyubiquitinated proteins, finding an inhibitor specific to NF- κ B activation is extremely difficult. One proteasome inhibitor, bortezomib has entered clinical trial for the treatment of solid and hematologic tumors. It is still unclear whether its therapeutic effect in cancer treatment is entirely or partially due to inhibition of NF- κ B.

A more promising approach to selectively inhibit NF- κ B activation seems to rely on the development of small-molecule inhibitors targeting the activity of signaling kinases in particular IKK α and IKK β . The pharmaceutical industry is actively screening for selective inhibitors of the catalytic activity of IKK α and IKK β . The development of IKK α -specific inhibitors has been hampered in part by an incomplete understanding of its specific function in NF- κ B activation and the lack of specific cell-based assays to test the potential inhibitors. By contrast, the development of specific IKK β inhibitors (see www.nf-kb.org) is progressing rapidly and numerous compounds are in the preclinical phase and their effects and toxicity are being evaluated in various in vitro assays and animal models of inflammatory diseases and cancer.

Nuclear Factor of Activated T Cells Cytosolic NFATc

- ▶ NFAT Family of Transcription Factors

Nuclear Localization Signal

Sequence of amino acids that determine the transport of proteins into the nucleus. Although there is no clear consensus, nuclear localization signals tend to be rich in positively charged residues, which allow interaction with proteins from the nuclear import machinery (i.e., importins).

Nuclear Pore Complex

The nuclear pore complex, located in the nuclear envelope, contains more than 50 proteins. It allows diffusion of small proteins between cytoplasm and nucleoplasm. Larger molecules (>50 kD) are selectively transported by an energy-dependent mechanism.

Definition

Cytochrome P450 (CYP) induction is the process whereby cellular or tissue levels of one or more ▶ **cytochrome P450** enzymes are increased via de novo protein synthesis in response to treatment with certain drugs (e.g., phenobarbital) and environmental chemicals, which are designated P450 inducers. This leads to an increase in the capacity for P450-catalyzed oxidative metabolism of both xenochemicals (i.e., drugs and other foreign chemicals) and endogenous lipophilic substrates. Other drug-metabolizing enzymes, such as drug conjugation enzymes, e.g., glutathione S-transferases and UDP-glucuronyltransferases, are also subject to induction by classic P450 inducers.

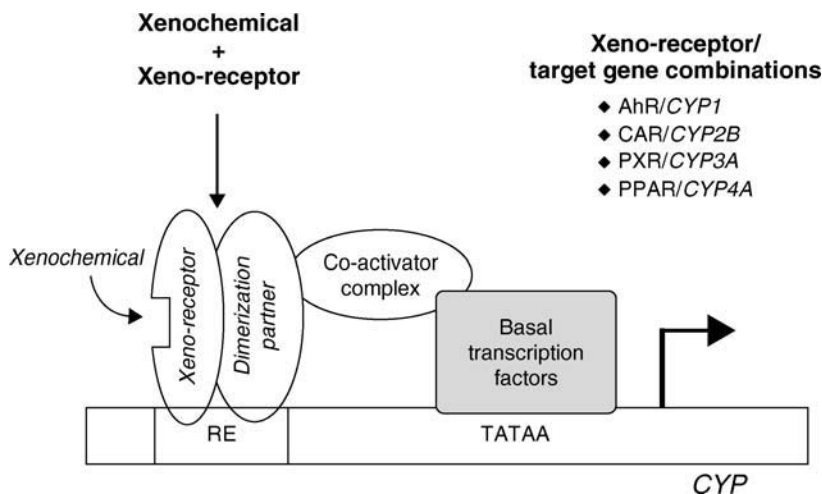

Basic Characteristics

P450 induction can occur in many cell types and tissues, but is most prominent in liver, a major organ for metabolism of steroids, drugs, and environmental chemicals. Many of the inducible P450s are active catalysts of drug metabolism, and P450 induction typically enhances the capacity for foreign chemical biotransformation, resulting in a shorter half-life and more rapid clearance of the compound from the body. Consequently, P450 induction can have a major impact on many processes, including P450-dependent drug metabolism, pharmacokinetics, - and drug-drug interactions; the toxicity and carcinogenicity of foreign chemicals; and the activity and disposition of endogenous steroids and certain other hormones. Although some P450 substrates also serve as P450 inducers, there is no general relationship between the ability of a chemical to induce a particular P450 enzyme and its ability to serve as a substrate of the same P450.

Of the 57 known human P450s, at least ten are subject to induction by xenochemicals. In most cases, the induction of P450 protein and enzyme activity occurs by a mechanism that involves increased transcription of the corresponding P450 gene. Members of four cytochrome P450 gene families, *CYP* families 1, 2, 3 and 4, are induced by receptor-dependent transcriptional mechanisms (Fig. 1). P450 genes belonging to the *CYP1* gene family and the *CYP2S1* gene are induced by the aryl hydrocarbon (Ah) receptor (also known as dioxin receptor), which is a transcription factor and a member of the basic Helix-Loop-Helix/Per-Arnt-Sim (bHLH/PAS) family [1]. In contrast, the induction of

select members of the *CYP2*, *CYP3*, and *CYP4* gene families is mediated by nuclear receptor superfamily members known as constitutive androstane receptor (CAR; induction of select *CYP2* genes) [2, 3], pregnane X receptor (PXR; induction of *CYP3A* genes) [3], and peroxisome proliferator-activated receptor α (PPAR α ; induction of *CYP4A* genes) [4].

CAR is an **orphan nuclear receptor** that mediates the widely studied induction of *CYP2B* genes by phenobarbital and many other “phenobarbital-like” lipophilic drugs and other chemicals [5]. PXR activates *CYP3A* genes in response to diverse chemicals, including certain drugs, natural products, and natural and synthetic steroids [5]. PPAR α mediates the induction of fatty acid hydroxylases of the *CYP4A* family by many acidic chemicals classified as nongenotoxic carcinogens and peroxisome proliferators (4). These three xenochemical receptors are most abundant in liver, where they may be activated by endogenous ligands. CAR and PXR are also expressed in the intestine, where they mediate P450 induction as well. The discovery of endogenous ligands for CAR (androstanes, which decrease basal receptor activity and serve as inverse agonists), PXR (certain pregnenolone derivatives, bile acids, and other steroids), and PPAR α (specific prostaglandins and other fatty acid metabolites) suggests that these three nuclear receptors play an important role in modulating liver gene expression in response to endogenous metabolic or hormonal stimuli, in addition to their more obvious role in modulating liver drug and xenochemical metabolism by induction of cytochromes P450 and other enzymes of foreign compound metabolism.

Nuclear Receptor Regulation of Hepatic Cytochrome P450 Enzymes. Figure 1 General mechanism for transcriptional activation of *CYP* genes by xenochemicals that activate their cognate xeno-receptor proteins. In the case of Ah receptor, the receptor’s heterodimerization partner is Arnt, whereas in the case of the nuclear receptors CAR, PXR, and PPAR α , the heterodimerization partner is RXR. The coactivator and basal transcription factor complexes shown are each comprised of a large number of protein components.

CYP1 Induction via Ah Receptor

The Ah receptor is localized in the cytosol in the basal state, where it exists in a complex containing heat shock protein 90 (Hsp90), a chaperone protein, and co-chaperone proteins (e.g., the hepatitis B virus X-associated protein [XAP2] and p23). Ah receptor is activated upon binding a ligand in the cytosol. The ligand-activated receptor then translocates to the nucleus, where it dissociates from the chaperone and co-chaperone proteins and heterodimerizes with a nuclear protein, Ah receptor nuclear translocator (ARNT). The Ah receptor-ARNT heterodimer binds to DNA enhancer sequences (“dioxin-response elements” or DREs) found upstream of *CYP1* and other Ah receptor-inducible genes involved in biotransformation, cell proliferation, and differentiation, and stimulates target gene transcription. The overall pathway for receptor activation is conserved in many cell types and across species and accounts for the induction of *CYP1* genes by a large number of aromatic hydrocarbons, including important environmental carcinogens found in auto emissions and cigarette smoke. Halogenated and polycyclic aromatic hydrocarbons are prototypic Ah receptor ligands, but certain planar compounds, including dietary plant constituents, can also bind to the Ah receptor, although with varying affinities. The details of the molecular mechanisms of Ah receptor signaling are not fully understood, but they appear to involve multiple events, including (i) interaction of the Ah receptor with various coactivators and corepressors, NF- κ B, and the retinoblastoma protein; (ii) activation of various protein kinases; and (iii) phosphorylation of the Ah receptor.

Role of CAR in CYP2B Induction and other Phenobarbital Responses

The orphan nuclear receptor CAR is the key-regulated transcription factor that mediates the effects of phenobarbital and phenobarbital-like inducers on liver *CYP2B* and other genes [2, 3]. CAR is localized in the cytosol in the basal state (i.e., in the absence of a ligand or an activator), where it is phosphorylated on serine 202 and is in a complex with Hsp90 and a co-chaperone protein known as cytoplasmic CAR retention protein (CCRP). CAR is translocated from the cytosol to the nucleus in response to stimulation of cells by phenobarbital and other CAR activators. This process involves the recruitment of protein phosphatase 2A (PP2A), perhaps in response to activation of AMP-activating protein kinase by phenobarbital. The dephosphorylation of CAR by PP2A allows CAR to dissociate from the CAR–Hsp90–CCRP complex and translocate into the nucleus by a process that is not well understood. CAR binds to specific DNA response elements (PBREs), found upstream of *CYP2B* and other phenobarbital-inducible genes, as a heterodimer with the nuclear receptor **▶retinoid X receptor (RXR)**, which serves as a common

heterodimerization partner for many orphan nuclear receptors, including PXR and PPAR α . The CAR–RXR complex then recruits coactivator complexes (Fig. 1), leading to an increase in the rate of transcription of CAR target genes.

CAR nuclear translocation and (CAR–RXR)-PBRE binding are strongly enhanced in liver *in vivo* following administration of phenobarbital. However, unlike classical nuclear receptor agonists, phenobarbital does not bind to CAR’s COOH-terminal ligand-binding domain (LBD). Mouse *CAR* gene knockout studies demonstrate that CAR is essential, not only for induction of the highly inducible *CYP2B* genes, but also for the multiple pleiotropic responses associated with exposure to phenobarbital and phenobarbital-like inducing agents. These include the induction of many genes involved in xenobiotic transport and biotransformation and repression of the expression of certain genes involved in energy metabolism. CAR is also required for various pathophysiologic effects of phenobarbital in the liver (e.g., hepatomegaly, enhanced hepatocyte proliferation) and for toxicologic or carcinogenic responses that are characteristic of phenobarbital-treated liver (e.g., acetaminophen- and cocaine-induced hepatotoxicity and liver tumor promotion).

CYP3A Induction by PXR

PXR is the major transcription factor that mediates the induction of CYP3A enzymes, most notably CYP3A4, the most abundant P450 enzyme in human liver. CYP3A4 is highly expressed in liver and intestine, in which it metabolizes structurally diverse drugs, environmental chemicals, endogenous steroid hormones, and lipophilic bile acids. The high level of expression of CYP3A4, coupled with its broad substrate specificity, and widespread inducibility following exposure to diverse steroids, antibiotics, and other pharmacological agents that activate PXR, gives rise to many CYP3A-based drug interactions.

PXR was initially thought to reside exclusively in the nucleus, but subsequent studies identified PXR in the cytosol. In contrast to CAR, PXR has little or no intrinsic basal transcriptional activity in the absence of ligand. Similar to CAR, the cytosolic form of PXR exists in a complex with Hsp90 and CCRP. Induction of CYP3A and other PXR target genes requires nuclear translocation of PXR, but the details of how this occurs remain to be elucidated. Activated PXR, which is in a heterodimeric complex with RXR α and binds various coactivators, binds to specific DNA response elements adjacent to PXR target genes, enabling it to stimulate gene transcription.

Major species differences characterize the induction of CYP3A enzymes by drugs, steroids, and other chemicals. These species differences are a direct result

of the species-dependent activation of PXR by individual PXR ligands (Fig. 2). Human PXR but not mouse PXR is activated by rifampicin and other xenochemicals that preferentially induce *CYP3A* genes in human cells and tissues, whereas mouse PXR but not human PXR is activated by the synthetic steroid pregnenolone 16 α -carbonitrile (PCN). Mouse PXR gene knockout studies establish PXR as the major mediator of *CYP3A* induction by various xenochemicals. Moreover, a human pattern of *CYP3A* inducibility can be achieved when the endogenous mouse PXR gene is replaced by its human PXR counterpart. Mouse and human PXR exhibit an uncharacteristically high (~25%) amino acid divergence within the LBD, suggesting that these rodent and human PXR are unusually divergent orthologs whose evolution reflects their adaptation to the unique dietary constituents and distinct endogenous steroid profiles of each species.

PXR may serve as a broadly based “steroid and xenobiotic sensor” whose intrinsic physiologic function is to stimulate synthesis of *CYP3A* enzymes that catabolize endogenous steroidal substrates. This possibility is supported by the striking responsiveness of PXR to endogenous steroids belonging to several distinct classes (pregnanes, estrogens and corticoids) and by the catalysis by many *CYP3A* enzymes of 6 β -hydroxylation reactions using diverse steroidal substrates, including androgens, corticoids, progestins, and bile acids. PXR plays a key role in bile acid homeostasis, as shown by the decreased production and increased hepatic uptake, and detoxification of cholestatic bile acids, such as lithocholic acid, which is mediated by PXR. The activation of PXR by bile acids

Nuclear Receptor Regulation of Hepatic Cytochrome P450 Enzymes. Figure 2 Species-specificity of PXR's *CYP3A* induction response. Shown are the amino acid sequence identities of the COOH terminal ligand-binding domain (LBD) and the central DNA-binding domain (DBD) of rodent and human PXR. *CYP3A11* and *CYP3A23* are mouse and rat P450 3A genes, respectively, whereas *CYP3A4* is a human P450 3A gene. PCN, pregnenolone 16 α -carbonitrile; RIF, rifampicin.

in liver leads to (i) decreased expression of *CYP7*, cholesterol 7 α -hydroxylase, which catalyzes a key rate-limiting reaction of bile acid biosynthesis; (ii) increased expression of the transporter *Oatp2*, which increases hepatic uptake of bile acids from the sinusoidal blood; and (iii) induction of *CYP3A* enzymes that detoxify lithocholic acid by catalyzing its 6-hydroxylation.

PPAR: Xenochemical Induction of *CYP4A* Enzymes and Role in Rodent Hepatocarcinogenesis

CYP4A enzymes catalyze the oxygenation of biologically important fatty acids, including arachidonic acid and other eicosanoids. *CYP4A* gene transcription can be activated in both liver and kidney by a range of acidic drugs and other xenochemicals, including hypolipidemic fibrate drugs, phthalate ester plasticizers used in the medical and chemical industries, and other environmental chemicals. These *CYP4A* inducers are classified as peroxisome proliferator chemicals because they markedly induce liver peroxisomal enzymes, leading to a dramatic increase in both the size and the number of liver cell peroxisomes.

PPAR α is the nuclear receptor responsible for *CYP4A* induction, peroxisomal enzyme induction, and hepatic peroxisome proliferation [4]. The tissue distribution of PPAR α (liver > kidney > heart > other tissues) mirrors the responsiveness of these tissues to peroxisome proliferator chemicals. *CYP4A* induction in liver and kidney and hepatic peroxisome proliferation are both abolished in PPAR α gene knockout mice, demonstrating the essential role of PPAR α for these responses in vivo. The general mechanism of PPAR α activation is similar to that of other nuclear receptors. PPAR α is found in the nucleus in the basal state as a complex with corepressor proteins. Ligand binding leads to dissociation of PPAR α from its corepressor proteins, heterodimerization with RXR α , recruitment of coactivators, and binding to functional DNA response elements, referred to as peroxisome proliferators response elements (PPREs), in the 5'-flank of *CYP4A* and other target genes, resulting in stimulation of gene transcription. PPAR α -RXR complexes bound to PPREs can be synergistically activated by the combination of a PPAR α ligand with the RXR ligand 9-*cis*-retinoic acid.

Persistent activation of PPAR α can induce the development of hepatocellular carcinoma in susceptible rodent species by a nongenotoxic mechanism, i.e., one that does not involve direct DNA damage by peroxisome proliferator chemicals or their metabolites. This hepatocarcinogenic response is abolished in mice deficient in PPAR α , underscoring the central role of PPAR α , as opposed to that of two other mammalian PPAR forms (PPAR γ and PPAR δ), in peroxisome proliferator chemical-induced hepatocarcinogenesis. Other toxic responses, such as kidney and testicular toxicities caused by exposure to certain phthalate

di-ester plasticizers, are not abolished in PPAR α -deficient mice, raising the possibility that the latter toxicities may be mediated by PPAR γ or PPAR δ .

Pharmacological Relevance Nuclear Receptors in Drug Metabolism and Drug Development

The identification of specific nuclear receptors as molecular targets of P450 inducers impacts drug metabolism and drug development in several important ways:

1. Drug interactions, often associated with interindividual differences in drug metabolism, are a major contributor to idiosyncratic drug responses, which can sometimes be fatal. P450 induction, especially the induction of CYP3A enzymes via PXR, can contribute significantly to interpatient differences in drug metabolism. High throughput screens for P450 inducers that activate Ah receptor, CAR, PXR, and PPAR α have been developed and can readily be applied to characterize the P450 induction potential of drugs currently used in the clinic, as well as investigational drugs and lead compounds under development. These efforts may help to predict, and thereby avoid, drug interactions associated with P450 induction.
2. Interindividual differences in the function and expression of nuclear receptors and their accessory proteins, reflecting either genetic or epigenetic factors, may represent another set of determinants of interindividual differences in pharmacokinetics and possibly pharmacodynamics. Further elucidation of the factors that regulate cellular nuclear receptor levels (e.g., glucocorticoids, which increase expression of PXR in human hepatocytes) and the identification of genetic polymorphisms that impact receptor expression, ligand-binding specificity or transcriptional activity are also likely to be important.
3. Receptor proteins involved in the induction of cytochromes P450 and other enzymes of drug metabolism may serve as novel drug targets. Examples of established nuclear receptor drug targets include PPAR α , which is a target of hypolipidemic fibrate drugs, and PPAR γ , which is targeted by anti-type II diabetes drugs of the thiazolidinedione class. CAR and PXR are also therapeutic targets, based on the role of CAR activators in the treatment of jaundice and PXR activators in the relief of cholestasis, associated with hepatotoxic bile acids. PXR antagonists might be used to block CYP3A autoinduction responses, which can substantially shorten the plasma half-life of a drug that simultaneously serves as a CYP3A inducer and a CYP3A substrate, which is a characteristic of several AIDS protease inhibitors and the anticancer drug ifosfamide. The finding that genes encoding liver and intestinal drug transporters are also

targets of CAR and PXR presents not only additional opportunities, but also additional challenges.

Transcription factors

Definition

Nuclear receptors (NRs) are members of a large superfamily of evolutionarily related DNA-binding transcription factors that regulate programs involved in a broad spectrum of physiological phenomena.

The sequencing of the human genome has led to the identification of 48 NRs. Sequence alignment and phylogenetic tree construction resulted in a classification of the human NR family by sequence, but not necessarily by pharmacology, into six evolutionary groups of unequal size. Trivial names have been proposed for some time. A proposition for a systematic numbering system and receptor code, supporting the trivial names,

was made in conjunction with NC-IUPHAR, and has been accepted (Table 1).

Among these NRs, ligands have been identified for only 24 family members. These receptors are ligand-dependent transcriptional factors that respond directly to a large variety of hormonal and metabolic substances that are hydrophobic, lipid soluble, and of small size. Some of these ►ligands, as retinoic acid or estradiol, exert their pleiotropic effects through different receptor ►subtypes that originate from different genes. Moreover, for each subtype several ►isoforms can exist. The other class of NRs is the so-called orphan receptors, for which regulatory ligands are still unknown or may not exist (true orphans), or for which candidates have only recently been identified (adopted orphans).

Basic Mechanisms

Despite a highly evolutionarily conserved structural organization, the function and the mode of action of NRs are very diverse and each receptor has crucial and nonredundant roles, notably in the regulation of many biologically important processes in growth, development, and homeostasis. NRs modulate transcription through several distinct mechanisms, which include both activation and repression activities. These activities, making NR signaling remarkably complex, can be genomic or nongenomic, be ligand dependent or independent, and mediate gene repression, the release of gene repression, gene activation, or gene transrepression by recruiting transcriptional machineries and epigenetic enzymes that modulate the chromatin at target sites (Fig. 1). NRs can also be target of other signaling pathways that modify the receptor post-translationally and affect its function. While some NRs are translocated to the nucleus after synthesis, regardless of the presence of ligand, others such as androgen receptor (AR, NR3C4), mineralocorticoid receptor (MR, NR3C2), progesterone receptor (PR, NR3C3), or glucocorticoid receptor (GR, NR3C1) are located predominantly in the cytoplasm in the absence of ligand. Binding of an ►agonist or some ►antagonists to these cytosolic receptors induces a nuclear translocation.

Modular Organization

All NR proteins exhibit a characteristic modular structure that consists of five to six domains of homology (designated A–F, from the N-terminal to the C-terminal) based on regions of conserved sequence and function (Fig. 2).

The N-terminal A/B region whose structure has not yet been defined contains a transcriptional activation function, referred to as activation function 1 (AF-1), which can operate autonomously. The length and sequence of the A/B region in the different NRs are highly variable, revealing a very weak evolutionary

conservation. This domain is the target of posttranslational modifications and can interact with cofactors such as coactivators or other transcription factors.

The central C region of the NRs harbors the DNA-binding domain (DBD) and corresponds to the most conserved domain. Through this domain, NRs bind to specific DNA sequences called hormone response elements (HREs) (except for DAX1 (NR0B1) and SHP (NR0B2), which do not harbor a DBD). The DBD consists of a highly conserved 66-residue core made up of two typical cysteine-rich zinc-finger motifs, two α -helices, and a COOH extension. It includes several sequence elements, referred to as P-, D-, T- and A-boxes, that define or contribute to the response element specificity. This specificity is generated by dimerization interfaces within the DBDs and direct contacts with the DNA including residues flanking the DNA core recognition sequence. The D region, which is a poorly conserved domain, is considered to serve as a hinge between the DBD and the ligand-binding domain (LBD), allowing flexibility of the DBD–LBD linkage. Therefore, it might permit the DBDs and the LBDs to adopt different conformations without creating steric hindrance problems. This domain also harbors a nuclear localization signal (NLS), or at least some elements of a functional NLS.

The E region, the LBD, which is less conserved than the DBD, is functionally complex, as it mediates ligand binding, dimerization, and contains a ligand-dependent ►transactivation function. The LBD contains four structurally distinct but functionally linked surfaces: (i) a dimerization surface, which mediates interaction with partner LBDs, (ii) the ligand-binding pocket (LBP), which interacts with diverse lipophilic small molecules in the case of liganded NRs, (iii) a ►coregulator-binding surface that binds to regulatory protein complexes, which modulate positively or negatively transcriptional activity, and (iv) an activation function helix, termed AF-2, which mediates ligand-dependent transactivation. Within the AF-2, the integrity of a conserved amphipathic α -helix called AF-2 activation domain (AD) has been shown to be required for ligand-dependent transactivation and ►coactivator recruitment. Moreover, some NRs can also interact with transcriptional ►corepressors through their LBD. Some members of the NR superfamily, the steroid receptors, interact also with heat-shock proteins through their LBD. The LBD crystal structures of all classic liganded receptors and adopted orphan receptors have been determined. These crystal structures revealed a common fold comprising 12 α -helices (H) and a short β -turn (s1–s2), arranged in three layers to form an antiparallel “ α -helical sandwich.” The lower part of the LBD harbors a variable region, which contains the LBP which is an important structural feature of NRs, at least for the liganded receptors, since the first step of receptor activation is initiated by ligand binding. LBP is lined with mostly hydrophobic amino acids and few polar residues

Nuclear Receptors. Table 1 Human nuclear receptors

Names	Nomenclature	Ligand
TR α	NR1A1	Thyroid hormones
TR β	NR1A2	Thyroid hormones
RAR α	NR1B1	Retinoic acid
RAR β	NR1B2	Retinoic acid
RAR γ	NR1B3	Retinoic acid
PPAR α	NR1C1	Fatty acids, leukotriene B ₄ , fibrates
PPAR β	NR1C2	Fatty acids
PPAR γ	NR1C3	Fatty acids, prostaglandin J ₂ , thiazolidinediones
Rev-erba	NR1D1	Orphan
Rev-erb β	NR1D2	Orphan
ROR α	NR1F1	Cholesterol, cholesteryl sulfate
ROR β	NR1F2	Retinoic acid
ROR γ	NR1F3	Orphan
LXR α	NR1H3	Oxysterols, T0901317, GW3965
LXR β	NR1H2	Oxysterols, T0901317, GW3965
FXR α	NR1H4	Bile acids, fexaramine
FXR β	NR1H5	Lanosterol
VDR	NR1I1	Vitamin D 1,25 dihydroxyvitamin D ₃
PXR	NR1I2	Xenobiotics, PCN (16 α -cyanopregnenolone)
CAR	NR1I3	Xenobiotics, phenobarbital
HNF4 α	NR2A1	Orphan
HNF4 γ	NR2A2	Orphan
RXR α	NR2B1	Retinoic acid
RXR β	NR2B2	Retinoic acid
RXR γ	NR2B3	Retinoic acid
TR2	NR2C1	Orphan
TR4	NR2C2	Orphan
TLL	NR2E2	Orphan
PNR	NR2E3	Orphan
COUP-TFI	NR2F1	Orphan
COUP-TFII	NR2F2	Orphan
EAR2	NR2F6	Orphan
ER α	NR3A1	Estradiol-17 β , tamoxifen, raloxifene
ER β	NR3A2	Estradiol-17 β , various synthetic compounds.
ERR α	NR3B1	Orphan
ERR β	NR3B2	DES, 4-OH tamoxifen
ERR γ	NR3B3	DES, 4-OH tamoxifen
GR	NR3C1	Cortisol, dexamethasone, RU486
MR	NR3C2	Aldosterone, spiro lactone
PR	NR3C3	Progesterone, medroxyprogesterone acetate, RU486
AR	NR3C4	Testosterone, flutamide
NGFIB	NR4A1	Orphan
NURR1	NR4A2	Orphan
NOR1	NR4A3	Orphan
SF1	NR5A1	Orphan
LRH1	NR5A2	Orphan
GCNF	NR6A1	Orphan
DAX1	NR0B1	Orphan
SHP	NR0B2	Orphan

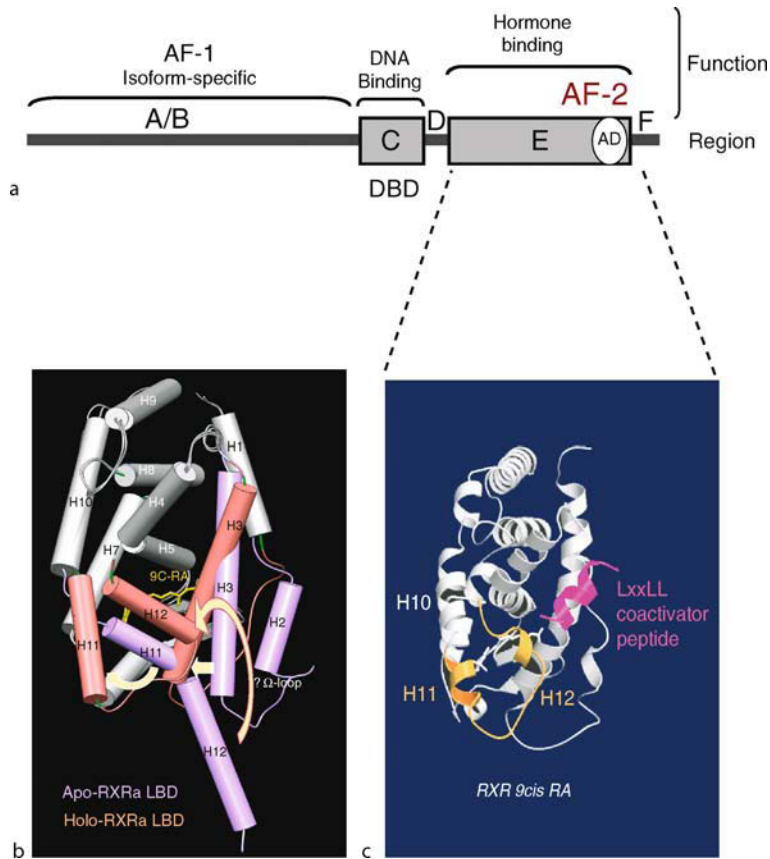

Nuclear Receptors. Figure 1 Mode of action of nuclear receptors. After diffusion through the cytoplasmic membrane, the ligand can interact with its cognate receptor where it can exert a “nongenomic effect” by interacting directly, for example, with kinases (1). The ratio between cytoplasmic and nuclear locations may vary between different receptors and is affected by the nature of a ligand. Ligand binding modulates the interaction of the receptor with a plethora of factors. In the absence of a ligand, several nuclear receptors are believed to be bound to the regulatory regions of target genes as corepressors or HDAC (histone deacetylase) complexes (2). Histone deacetylation is responsible for the chromatin condensation which accounts for the gene silencing effect of unliganded receptors. Ligand binding releases the HDAC complex (3) and results in the recruitment of histone acetyltransferase (HAT) and chromatin-remodeling (CRM) complexes (4). The temporal order and requirement of these complexes may occur in a receptor, target gene in a cell-specific fashion. As the last step (5), the polymerase II holoenzyme, comprising the TAF and MEDIATOR complexes in addition to the enzyme, is recruited and it increases the frequency of transcription initiation.

at the deep end of the pocket near the β -turn act as anchoring points for the cognate ligand or play an essential role in the correct positioning and enforce the selectivity of the pocket. The specificity of ligand binding is also determined by the shape of the LBP, which can vary greatly from receptor subtype to subtype.

The C-terminal F region, that is contiguous with the E domain, is not present in all receptors, and its function is poorly understood.

DNA Recognition

An essential step of NR action is the interaction of these receptors with the specific DNA sequence HREs. Indeed, HREs position the receptors, and the transcriptional complexes recruited by them, close to the target genes. HREs are bipartite elements that are composed of two hexameric core half-site motifs. These consensus nucleotide sequences form direct, indirect, or inverted repeats, which consist of two half-sites separated

Nuclear Receptors. Figure 2 Schematic illustration of the structural and functional organization of nuclear receptors. (a) The evolutionarily conserved regions C and E are indicated as boxes (green), a black bar represents the divergent regions A/B, D, and F. Domain functions are depicted above the scheme. AF-1 Activation Function-1, which is located in the N-term A/B region, AF-2 Activation Function-2. (b) Schematic drawing of the superposition of the canonical unliganded and liganded 3D structures of nuclear receptor ligand-binding domains (LBDs). Upon ligand binding, a series of intramolecular interactions cause the repositioning of H11 in the continuity of H10, and the concomitant swinging of H12. (c) The proper repositioning of structural elements (H3, H4, L3–4, and H12) upon ligand binding allows interaction through the highly conserved α -helical LxxLL motif (in which L corresponds to Leucine and x to any amino acid) with the NR box of nuclear receptor coactivators, such as TIF2/GRIP1, SRC1, or RAC3/AIB1/ACTR.

by a short spacer. In the genome, they are arranged as a multiplicity of response elements characterized by (i) the actual nucleotide sequence of the two core motif half-sites, (ii) the number of base pairs separating them, and (iii) the relative orientation of the motifs.

The NR superfamily can be divided into subgroups on the basis of their pattern of dimerization. One group consists of the steroid receptors, all of which appear to function as homodimers that bind to a degenerate set of response elements containing inverted repeats of a hexameric half-site separated by three base pairs of spacing (IR3). Nearly all known nonsteroid receptors recognize one or two copies of the consensus DNA sequence 5'-AGGTCA-3'. Among these receptors, a major group consists of receptors that form heterodimers with the retinoid X receptors (RXRs). The various RXR heterodimers can bind to direct repeats

(DRs) with one to five base pairs of spacing, referred to as DR1–DR5. Some NRs can also bind DNA efficiently as monomers such as NGFI-B (NR4A1), Rev-erb, RORs, and SF-1 (NR5A1).

The Liganded Receptors

In the case of liganded NRs, ligand binding is the first and crucial molecular event that switches the function of these transcription factors from inactive to active state by inducing a conformational change in the LBD of the receptor (Fig. 1). This specific conformation allows the second step of NR activation that corresponds to the recruitment of coregulatory complexes, which contain chromatin-modifying enzymes required for transcription. The transcriptional coactivators are very diverse and have expanded to more than hundred in number. These include the p160 family of proteins,

CREB-binding protein (CBP) and p300, coactivator-associated arginine methyltransferase-1 (CARM1), and histone acetyl transferases (HATs). The ultimate action of liganded NRs on target genes is to enhance the recruitment and/or function of the general transcription machinery (RNA polymerase II and general transcription factors). From a structural point of view, agonists are ligands that lock the receptor in the active conformation. In contrast, antagonists should be viewed as molecules that prevent NRs to adopt this conformation. Helix 12 is a crucial component of the NR LBDs, because its ligand-induced repositioning in the agonist-bound NR contributes in a critical manner to the surfaces recognized by coactivators and thereby generates a transcriptional active AF-2 domain. Hence, the interactions between AF-2 helix 12 or residues in its proximity and the ligand is critical for the control of agonist–antagonist properties of NRs.

Some NRs exhibit a dual functionality, being able to act as silencers of transcription in the absence of ligands, due to their ability to recruit corepressor complexes at the promoters of target genes, in addition to activating transcription in the presence of agonists. This silencing function has been well established for unliganded retinoic acid and thyroid hormone receptors. Hence, nuclear receptor corepressor 1 (NCoR1) or silencing mediator for retinoid and thyroid hormone receptor (SMRT) are able to bind to these receptors and to recruit transcriptional complexes that contain specific histone deacetylases (HDACs). The ligand-induced conformational change causes dissociation of the corepressors, allowing the receptor to interact with coactivators.

The transcriptional activity of NRs is also modulated by various posttranslational modifications of the receptors themselves or of their coregulatory proteins. Phosphorylation, as well as several other types of modification, such as acetylation, SUMOylation, ubiquitinylation, and methylation, has been reported to modulate the functions of NRs, potentially constituting an important cellular integration mechanism. In addition to the modifications of the receptors themselves, such modifications have been reported for their coactivators and corepressors. Therefore, these different modes of regulation reveal an unexpected complexity of the dynamics of NR-mediated transcription.

Evidence has accumulated over the past few years that NR action is not restricted to the positive or negative regulation of the expression of cognate target genes. Indeed, these receptors together with their mediators are targets of other major signaling cascades, and reciprocally, they can affect the activity of these pathways. Hence, in response to ligands, some NRs, such as GR, regulate gene programs not only by directly binding to HREs but also through signal transduction

crossstalk, for example, by interfering with AP-1 and NF κ B activities that are the prototypes of a negative regulation. Despite the proposal of several distinct mechanisms, the molecular basis of these interferences has remained elusive and requires an unknown state of the receptor.

Another type of NR crossstalk, which has only recently been recognized, is the so-called “nongenomic” actions of several receptors that induce very rapid cellular effects. Effectively, evidence has accumulated over several decades that steroid receptors may have a role that does not require their transcriptional activation, such as modifying the activity of enzymes and ion channels. While the effects of steroids that are mediated by the modulation of gene expression do occur with a time lag of hours, steroids can induce an increase in several second messengers such as inositol triphosphate, cAMP, Ca²⁺, and the activation of MAPK and PI3 kinase within seconds or minutes. Many mechanistic details of these nongenomic phenomena remain poorly understood. Notably, controversy still exists as to the identity of the receptors that initiate the non-genomic steroid actions. However, it now appears that at least some of the reported effects can be attributed to the same steroid receptors that are known as NRs.

The Orphan Receptors

A significant number of the 48 human NRs are still considered as orphan receptors, as no physiologically relevant ligand has been found and the issue of cognate ligands for these proteins remains very controversial and unclear. Whereas a clear structural paradigm has developed to explain the activation of ligand-regulated receptors, no uniform mechanism has been proposed to account for the modulation of orphan NR activity. Nevertheless, the existence of these proteins, that raise questions about the role of ligand-binding, suggests that additional unexplored NR-mediated signaling pathways remain to be characterized.

Several recent structural studies indicate that “true” orphan receptors, that is, NRs that are not recognized by cognate endogenous ligands and in which the AF-2 helix is predisposed in the active conformation, might indeed exist. For instance, the elucidation of the 3D crystal structure of the NURR1 LBD revealed that although this LBD is folded much the same way as the other NRs, it lacks a cavity for ligand binding. Indeed, the LBP that is normally occupied by ligands in other classic NRs is entirely filled by hydrophobic amino acid side chains in NURR1 (NR4A2). Nevertheless, NURR1 can act as a transcription factor since target genes of this receptor have been identified. Therefore, NURR1, as well as NGFI-B, is not regulated by cognate ligands and might be regulated by alternative mechanisms.

Pharmaceutical Relevance

Because of the essential role played by NRs in virtually all aspects of mammalian development, metabolism and physiology, dysfunction of signaling controlled by these receptors is associated with reproductive, proliferative, and metabolic diseases. The ability of some NRs for binding ligands makes them potential pharmaceutical targets. Accordingly, certain liganded NRs have one or more cognate natural or synthetic ligands which are used in therapy. Their successes as drug targets are highlighted by the commonly used of retinoic acid for RAR α (NR1B1) (target for acute promyelocytic leukemia therapy), the synthetic antagonist tamoxifen for ER α (NR3A1) (target for breast cancer therapy), dexamethasone for GR (target for inflammatory disease treatment), or thiazolidinediones for PPAR γ (NR1C3) (target for treatment of type II diabetes).

NR pharmacology, compared with other receptor systems, has to a certain extent led the way in the appreciation that ligands may exert very diverse pharmacology, based on their individual chemical structure and the allosteric changes induced in the receptor/accessory protein complex. This can lead to very selective pharmacological effects, which may not necessarily be predicted from the experience with other agonists/▶**partial agonists**/antagonists. Moreover, one of the most important mechanistic aspects that we have learnt over recent years is that the response of a given tissue is dictated by the set of coregulators with which NRs interact following ligand-induced allosteric alterations that generate, expose, or remove interaction surfaces. Therefore, chemistry can generate not only receptor-selective and various types of full, partial, and ▶**inverse agonists**, but also molecules that activate only a subset of the functions induced by the cognate ligand or compounds that act in a cell-type selective manner, as the selective nuclear receptor modulators (▶**SNuRMs**), leading to NR-based drug development.

Thus, and because therapeutic effects should be maximized and side effects minimized, the characterization of nuclear receptors and their associated proteins and the ligands which interact with them will remain a challenge to pharmacologists.

Nucleic Acid Vaccination

▶ Genetic Vaccination

Nucleophilic

A nucleophilic compound or a group is attracted by a nuclei and has the tendency to share or donate electrons.

Nucleosome

The nucleosome represents the first level of DNA condensation and is the basic building block of all chromatin structures. It was discovered in 1973 and consists of a central histone octamer with about 150 base pairs of DNA wrapped around.

▶ Histone Acetylation

Nucleus Accumbens

The nucleus accumbens is part of the limbic system. It receives dopaminergic input through the mesolimbic system that originates from cell bodies in the ventral segmental area (A10 cell group). This mesolimbic dopaminergic pathway is part of the reward pathways. Drugs of abuse (cocaine, amphetamine, opiates or nicotine) have been shown to increase the level of dopamine release in these neurons.

▶ Drug Addiction/Dependence

Obesity

A disorder defined by an excess amount of white adipose tissue such that health is compromised. It is generally defined on the basis of body mass index (BMI) which is calculated as weight in kg/height in m². Normal weight is regarded as a BMI between 18.5 and 24.9, overweight as 25 and 29.9 and obesity as ≥ 30 . These figures are based on Europeans and North Americans, but in some other populations, such as in East Asia, the BMI threshold for obesity is increasingly considered to be lower.

Oedema

Oedema refers to an accumulation of interstitial fluid to a point where it is palpable or visible. In general this point is reached with a fluid volume of 2–3 liters. Oedema formation is the result of a shift of fluid into the interstitial space due to primary disturbances in the hydraulic forces governing transcapillary fluid transport and of subsequent excessive fluid reabsorption by the kidneys. Deranged capillary hydraulic pressures initiate oedema formation in congestive heart failure, and liver cirrhosis whereas a deranged plasma oncotic pressure

leads to oedema in nephrotic syndrome and malnutrition. Increased capillary permeability is responsible for oedema in inflammation and burns.

Oestrogens

- ▶ Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor

Off-resin Analysis

Off-resin analysis is analysis of a compound cleaved off a polymeric carrier material, usually in solution.

- ▶ Combinatorial Chemistry

Olfactory Epithelium

The epithelium covering the nasal cavity. This epithelium contains numerous cell types including the specialized olfactory sensory neurons which detect the chemical stimuli derived from smells by a specific family of G protein-coupled receptors known as olfactory receptors.

- ▶ Trace Amines

Olfactory Receptors

Sensory receptors that structurally and functionally belong to the G protein coupled receptor superfamily. Olfactory receptors are a large GPCR family with >300 members in human that are expressed in neurons of the nasal olfactory epithelium where they sense mostly volatile olfactory molecule. The overall number of olfactory receptors differs widely between species and an expansion of different receptors is in particular obvious in species that depend on their olfactory sense for survival.

▶ Orphan Receptors

Oligonucleotide

A short (typically up to 80 nucleotides) single-strand DNA molecule.

▶ Microarray Technology

Oligopeptidase

An endopeptidase that is incapable of cleaving proteins but can cleave small peptides. An example is thimet oligopeptidase (*MEROPS* M03.001).

▶ Non-viral Peptidases

Omega Peptidase

An exopeptidase that does not cleave standard peptide bonds. An example is pyroglutamyl-peptidase I (*MEROPS* C15.010), which releases an N-terminal pyroglutamyl from hormones such as thyrotropin-releasing hormone and luteinizing hormone. Omega peptidases are included in Enzyme Nomenclature subclass 3.4.19.

▶ Non-viral Peptidases

On-resin Analysis

On-resin analysis is analysis of compound attached to a polymeric carrier material.

▶ Combinatorial Chemistry

Oncogenes

Oncogenes are genes, which confer malignancy on a cell. Proto-oncogenes are genes that normally control cell division and differentiation; however, they can be converted to oncogenes. Oncogenes often affect one or more signal transduction mechanisms, which impact on the cell division machinery.

Opiates

In the strict sense, opiates are drugs which are derived from opium and include the natural products morphine, codeine, thebaine and many semi-synthetic congeners derived from them. In the wider sense, opiates are morphine-like drugs with non-peptidic structures. The old term opiates is now more and more replaced by the term opioids which applies to any substance, whether endogenous or synthetic, peptidic or non-peptidic, that produces morphine-like effects through an action on opioid receptors.

- ▶ Opioid System

Opioid Receptors

- ▶ Opioid Systems

σ -Opioid Receptors

σ -Opioid receptors are postulated receptors, which mediate the “dysphoric” effects (anxiety, hallucinations, bad dreams etc.), which are produced by some opioids. They are not true opioid receptors, as many other drugs also interact with them. Of the opioids, only benzomorphans, such as pentazocine, interact with sigma-receptors. The molecular identity of sigma-receptors is not known.

Opioid Systems

Otto-von-Guericke-Universität Magdeburg,
Magdeburg, Germany

Synonyms

Opioid receptors; Endogenous opioid peptides; Nociceptin/orphanin FQ; ORL-1

Definition

Opioid systems comprise opiate alkaloids and the families of ▶ **endogenous opioid peptides** (β -endorphin, enkephalins, and dynorphins) interacting with the three opioid receptor subtypes (μ , δ , κ). Pharmacological conventions define “opioid” when the action is produced by a prototypic opiate drug such as morphine and is antagonized by the antagonist naloxone. The classification of the three opioid receptors was confirmed by cloning of the three opioid receptor genes based on the fact that they share a homology of more than 60%. Interestingly, ▶ **ORL-1** an orphan receptor exhibits the same high degree of similarity to the opioid receptors. However, classical opioids do not bind to this receptor, and the endogenous ligand discovered for ORL-1 the peptide nociceptin or orphanin FQ (N/OFQ) causes actions which are different from that of the classical opioid peptides and which are not antagonized by naloxone. Nevertheless, based on the high degree of structural similarity nociceptin/OFQ and the corresponding ORL-1 receptor are regarded to belong to the opioid systems.

Basic Characteristics

During the last 25 years it became clear that there are three types of pharmacologically well-defined opioid receptors (μ , δ , κ) that belong to the heptahelical group of G-protein coupled receptors. The genes of these receptors show a more than 60% homology to each other. A further “orphan” receptor sharing a similarly high degree of homology to the classical opioid receptors was recently identified and named ORL-1 (“opioid receptor like”) (1; [Table 1](#)). The NC-IUPHAR Subcommittee on Opioid Receptors suggested the terms MOP for μ opioid, DOP for δ opioid, KOP for κ opioid (KOP), and NOP for ORL-1 receptors [1].

The opioid receptors are targets of a large variety of exogenous (drugs) and endogenous ligands. Beginning with the discovery of the enkephalins in 1975, several endogenous opioid peptides have been isolated that derive from three precursor genes pro-opiomelanocortin (POMC), pro-enkephalin, and prodynorphin ([Table 2](#)). β -endorphin derives from POMC. Besides

Opioid Systems. Table 1 Opioid receptors and ligands

Opioid Systems. Table 2 Endogenous opioid peptides

Proopiomelanocortin	Proenkephalin	Prodynorphin	Pronociceptin/ OFQ	(Proendomorphin)
β -endorphin	Metenkephalin, leu-enkephalin, MERF, MERGL	Dynorphin A, dynorphin A(1–8), dynorphin B, α -neoendorphin, β -neoendorphin	Nociceptin/ OFQ	Endomorphin-1, endomorphin-2

the pentapeptides met-enkephalin (ME) and leu-enkephalins (LE), proenkephalin is processed in the heptapeptide met-enkephalin-arg⁶-phe⁷ (MERF) and the octapeptide met-enkephalin-arg⁶-gly⁷-leu⁸ (MERGL). Prodynorphin is processed into dynorphin A, dynorphin A (1–8), dynorphin B, α -, β -neoendorphin [2]. In addition, two endogenous pentapeptides have been isolated that exhibit a high selectivity for μ -opioid receptors (MOPs) and have been called endomorphin-1 and endomorphin-2. Attempts to clone the genes for the corresponding precursor molecules have not been successful.

The MOP is the classical target for morphine and mediates the analgesic and addictive effects of the drug [2]. Therefore, in MOP-deficient mice morphine does not exhibit analgesic and positive reinforcing properties [3]. The human MOP gene encodes a heptahelical protein of about 400 amino acids and is localized on chromosome 6q24–25. Of the endogenous peptides, β -endorphin and to a lesser extent also the enkephalins and dynorphins have affinities for MOP. Endomorphin-1 and 2 are two pentapeptides that show the highest selectivity for this receptor. Another selective agonist is the synthetic peptide DAMGO (D-Ala², nMe-Phe⁴, Gly⁵-ol) enkephalin). The action of MOP agonists are competitively blocked by the antagonist naloxone, which is not absolutely specific for MOPs. The somatostatin analogue CTAP (D-Phe-Cys-Thr-D-Trp-Arg-Thr-Pen-Thr-NH₂) has been found to be a more selective MOP antagonist. β -FNA (β -funtalrexamine) and naloxonazine are irreversible antagonists.

Several splice variants of MOP (formerly MOR-1) have been cloned (MOP-1A to MOR-1X). The B, C, and D variants differ in their amino acid sequence at the C-terminal end [4]. These receptor variants differ in their distribution in the central nervous system and in the rate of internalization and desensitization upon

agonist exposure but have similar binding and coupling properties.

The existence of further alternative transcripts of MOP was postulated by the observation that in knockout mice with disrupted exon 1, heroin but not morphine was still analgesically active. Based on earlier observations that the antagonist naloxazone blocked morphine-induced antinociception but not morphine-induced respiratory depression, a subdivision of the MOP in μ_1 and μ_2 was proposed. However, no discrete mRNA for each of these MOP subtypes has been found. It is, however, possible that subtypes of MOPs result from heterodimerization with other opioid receptors or by interaction with other proteins.

Moreover, there exist polymorphic MOP variants. An Asn40Asp polymorphism has been found with a high abundance in the Caucasian and Asian population. This receptor variant is less expressed in the brain and carrier of this polymorphism appears to need more opioids for analgesic treatment. There are many additional MOP polymorphisms with unknown functional significance. In spite of many studies there appears to exist no significant association of polymorphisms in the *MOP* gene and drug addiction [5].

Highest concentrations of MOPs are found in the thalamus, caudate, neocortex in the brain, but the receptors are also present in gastrointestinal tract, immune cells, and other peripheral tissues.

The δ opioid receptor (DOP) is the primary target for met- and leu-enkephalin which also exhibits affinities for μ and κ receptors [2]. DPDPE (D-Pen², D-Pen⁵) enkephalin is a selective agonist, and naltrindole a selective antagonist on DOP. Only one DOP gene has been cloned to date. The human DOP is comprised of 372 amino acids and is localized on chromosome 1p34.3–36.1. Pharmacological experiments in rodents indicate the subdivision into δ_1 and δ_2 receptors.

However, currently no genes encoding these δ receptor isoforms have been cloned. In addition, there is no evidence for the existence of splice variants of this receptor. A DOP that lacks the third intracellular loop was generated by atypical mRNA processing in human melanoma tissues. This atypically processed receptor did not couple to G-proteins. There are several single nucleotide polymorphisms in the *DOP* gene. Associations studies did not reveal a significant relation between the polymorphisms in the *DOP* gene and drug addiction.

A high concentration of DOPs is found in the olfactory bulb, the neocortex, caudate putamen, and in the spinal cord, but they are also present in the gastrointestinal tract and other peripheral tissues. The functional roles of DOP are less clearly established than for MOP; they may have a role in analgesia, gastrointestinal motility, mood and behaviour as well as in cardiovascular regulation [2].

The KOP receptor is the natural target for prodynorphin-derived peptides, such as dynorphin A, dynorphin B, α -neoendorphin etc. The prototypical ligand is ethylketocyclazocine (EKC). Enadoline and U-50488 are selective agonists and norbinaltorphimine is an irreversible selective antagonist [2]. The human KOP gene encodes a protein of 380 amino acids which is localized on chromosome 8q11.12. From the binding characteristics of the prototypical ligand EKC, evidence for the subdivisions in κ_1 , κ_2 and κ_3 has been provided. However, there are no functional pharmacological data supporting these subdivisions. Moreover, no mRNAs coding for these receptor isoforms have been identified. Furthermore, in mice deficient in μ , δ and KOP receptors ("triple knockouts") no evidence for κ_2 binding sites could be found. A KOP with an alternative start site and with no known functional significance has been identified. There exist several polymorphisms in the *KOP* gene. Interestingly, recent studies show a significant association of single nucleotide polymorphisms of KOP (and also for PDYN) with opioid and alcohol addiction.

High concentrations of KOP have been found in the cerebral cortex and hypothalamus; KOP is also present in the gastrointestinal tract, in immune cells as well as in other peripheral tissues. KOPs have been implicated in the regulation of nociception, diuresis, feeding, neuroendocrine and immune system functions [2].

The ORL-1 receptor was identified by its high homology to the other opioid receptor subtypes and termed "opioid receptor like". However, none of the endogenous opioid peptides or the opiate drugs shows a high affinity for this receptor. An endogenous ligand that binds to ORL-1 with high affinity has been identified and termed N/OFQ. Recently, J-113397, a drug with potent and selective antagonist activity at ORL-1 receptors, has been characterized.

According to the NC-IUPHAR Subcommittee on Opioid Receptors it was proposed to term ORL-1 receptor as NOP receptor [1]. The human NOP receptor gene encodes a protein of 370 amino acids. Splice variants have been found in the human and mouse NOP receptor with no known functional significance. NOP receptors are widely distributed throughout the brain and in the spinal cord. They are also present in immune cells. A functional role for N/OFQ has been proposed in nociception, locomotoric activity, reward, stress, and immunomodulation.

The OP group of receptors share common effector mechanisms. All receptors couple via pertussis toxin-sensitive Go and Gi proteins leading to: (i) inhibition of adenylate cyclase; (ii) reduction of Ca^{2+} currents via diverse Ca^{2+} channels; (iii) activation of inward rectifying K^+ channels. In addition, the majority of these receptors cause the activation of phospholipase A_2 (PLA_2), phospholipase $\text{C}\beta$ ($\text{PLC}\beta$), phospholipase D_2 and of MAP (mitogen-activated protein) kinase (Table 3).

Tolerance develops in response to continuous opioid agonist treatment. At the cellular level, receptor desensitization is caused by phosphorylation of receptor kinases leading to uncoupling of the receptor from the G-proteins. Binding of β -arrestin to the phosphorylated receptor initiates receptor endocytosis, which is followed by receptor dephosphorylation and recycling to the membrane. A part of the receptors is degraded in lysosomes. Opioids differ in their ability to internalize opioid receptors. For instance, morphine and buprenorphine are unable to internalize receptors, whereas methadone and fentanyl induce a substantial receptor endocytosis. Since internalization followed by recycling causes a resensitization of the receptors, methadone and fentanyl show a lower development of tolerance. An additional explanation for the differential development of tolerance by opioids is based on the theory of spare receptors. Opioids with a lower intrinsic activity, such as morphine or the partial agonist buprenorphine have to occupy a larger fraction of opioid receptors to produce the same effect. These opioids show therefore a faster tolerance development than opioids with a higher number of spare receptors (i.e., fentanyl or methadone). Moreover, adaptive mechanisms which antagonize opioid action can influence the development of tolerance. Thus, chronic administration of μ opioids has been shown to cause a

Opioid Systems. Table 3 Cellular responses to opioids

Inhibition of adenylate cyclase	Activation of PLA_2

	Activation of PLD_2
Activation of inwardly rectifying potassium channels	Activation of MAP kinase

super activation of certain subtypes of adenylate cyclase. In this case higher doses of opioids are required to inhibit the super activated adenylate cyclase. Long-term changes in adenylate cyclase activity result in activation of cAMP response element binding protein (CREB). This may result in changes in the expression of genes involved in opioid addiction.

In addition to the MOP, DOP, KOP, and NOP receptors the existence of several other opioid receptors has been proposed. The σ receptor, originally classified as an opioid receptor, is no longer regarded as such, since naloxone does not act as an antagonist at this receptor. The σ receptor rather appears to be the target of phencyclidine and related drugs. A σ receptor that does not have the heptahelical structure of G-protein coupled receptor has been recently cloned. A receptor with selective avidity for β -endorphin has been proposed and termed ϵ receptor. In addition, a so-called λ receptor was postulated on the basis of binding experiments. Recently, a ζ opioid receptor was cloned that binds Met-enkephalin in a naloxone displaceable manner and is proposed to regulate cell growth. The relationship of the ζ receptor, which shares no sequence homology to the OP receptors, awaits elucidation.

There has been an extensive search for additional opioid receptor genes with homology to μ , δ , and κ receptors which was, however, unsuccessful. It is likely, therefore, that the functional properties of the subdivision of μ , δ , and κ receptors as well as that of the ϵ and λ receptors results from alternate mRNA processing, posttranslational modification of the receptor, and/or from the formation of homo- and heterodimeric receptor complexes.

Drugs

Of the μ agonists (Table 3) morphine is the classical opioid alkaloid clinically used for treatment of pain. Codeine is a further naturally occurring derivative of morphine with a methylated phenolic hydroxyl group. Its potency is about 10% that of morphine. It is converted to morphine by the CYP2D6 enzyme system. In individuals with gene mutation in the CYP2D6 enzyme system (about 10% of the Caucasian population) codeine shows a marked reduced analgesic potency. Undesirable effects of morphine such as respiratory depression, development of tolerance/dependence led to search for analogues. A first semisynthetic morphine derivative was diacetyl morphine (heroin) which, however, was soon shown to exhibit a higher addictive liability than morphine. Modification of the morphine structure resulted in the development of other semisynthetic morphine derivatives, such as hydromorphone and oxycodone. A simplification of the morphine structure led to the development of fully synthetic drugs such as pethidine, methadone, fentanyl,

sufentanil, alfentanil, and remifentanil. These opiates differ in their potencies and/or pharmacokinetics, but exhibit similar side effects as morphine. Pethidine has a lower potency than morphine (about 20%). It is metabolized to norpethidine which can accumulate and induce convulsions. Therefore, pethidine should be used only to treat acute pain. In view of its spasmolytic effect it is indicated to treat pain caused by kidney stones. The long-acting methadone is a substitute for heroin in addicted patients. Fentanyl and its short-acting and potent derivatives are generally used during anaesthesia. In addition, fentanyl is increasingly used as a plaster preparation (transdermal therapeutic system) for treatment of patients with chronic pain. This allows the maintenance of therapeutic fentanyl level over a period of 3 days with less obstipatory side effects. In general, for the treatment of chronic pain long-acting preparations of opioid drugs (see Table 4) are preferentially used to minimize the development of opioid addiction. Other structural modifications led to the development of the oripavine derivatives (e.g. etorphine and buprenorphine).

Etorphine is much more potent than morphine and its catatonic action is used for sedating large animals. Buprenorphine is a long-acting partial agonist at μ opioid receptors which shows a ceiling effect for inducing analgesia in animals. In humans it is an effective analgesic and is also applied as a plaster to treat chronic pain. Moreover, buprenorphine is also used as a substitute for heroin in addicts. The μ opioid antagonists (naloxone and naltrexone) are clinically given for treatment of heroin overdose. In addition, the longer-acting naltrexone is used for preventing relapse in former heroin addicts. The short-acting antagonist naloxone is also used in combination with tilidine (Valoron®). After oral consumption tilidine is metabolized in the liver to the opioid active nortilidine, whereas the antagonist naloxone is rapidly degraded. The addition of naloxone prevents the intravenous abuse of the preparation by heroin addicts. Recently, naloxone has also been used as a long-acting oral preparation

Opioid Systems. Table 4 Opioid Drugs

Agonists	Partial agonists	Antagonists
Alfentanil, codein, dihydromorphine, etorphine, fentanyl, heroin, hydromorphone, levomethadone, morphine, oxycodone, pethidine, piritramide, remifentanil, sufentanil, tilidine, tramadol	Buprenorphine, pentazocine	Naloxone, naltrexone

together with oxycodone (Tarwin®). The continuous absorption of naloxone by the gut decreases the obstipatory side effect of the opioid agonist oxycodone. Tramadol is a weak opioid agonist. It is a racemic mixture. The (+) enantiomer which has a very low affinity for the opioid receptor is metabolized to the more active opioid *O*-desmethyltramadol. The (–) enantiomer inhibits the reuptake of serotonin and noradrenalin. These monoamines mediate the descending inhibition of pain transmission in the spinal cord. Codeine, tramadol, and tilidine/naloxone are weak opioids, which are applied in stage 2 of the pain scale of the WHO. For treatment of severe pain (stage 3) strong opioids such as morphine, buprenorphine, hydromorphone, or oxycodone are used.

κ receptor agonists produce a powerful antinociceptive effect and do not substitute for morphine in dependent animals. In addition, κ receptor agonists have neuroprotective effects in animal models of cerebral ischemia and traumatic head injury. However, clinical trials using κ agonists unmasked the dysphoric and psychotropic side effects of these drugs in humans. Pentazocin is a synthetic benzomorphan derivative: It is a mixed agonist/antagonist with κ receptor agonistic and partial agonistic properties on the μ receptor. Its interaction with κ receptors has been attributed to its hallucinogenic and dysphoric effects. Clinical trials are presently being carried out to explore whether κ agonists that do not readily penetrate the blood–brain barrier are useful in producing a peripheral analgesic effect in inflammatory pain.

Although preclinical studies suggest that δ agonists are potent analgesics with fewer side effects than μ agonists, none of the nonpeptide agonists or antagonists has been introduced into clinical investigations. Similarly, the clinical perspectives of the use of agonists and antagonists on the ORL-1 (NOP) receptor have to wait for the outcome of clinical trials.

Definition

Orexin-A (OX-A) and Orexin-B (OX-B) are ► **bioactive peptides** derived from a common precursor gene. Both peptides bind with differential affinity to two ► **Gq/11-protein coupled receptors** (OX1R, OX2R) in numerous targets throughout and even outside the nervous system of many species. In mammals, orexins are almost exclusively expressed in a small subset of ► **hypothalamic** neurons integrating a variety of intero- and exteroceptive, ► **nutritional-metabolic** and ► **circadian-photoc** influences. Orexins exert direct neuroexcitatory effects on ► **noradrenergic**, ► **histaminergic**, ► **dopaminergic**, ► **serotonergic**, ► **cholinergic**, and ► **GABAergic** cell populations. Thereby the orexin system drives glutamate transmission and whole brain activity to maintain systemic ► **bistability** and synchronize basic body functions. Loss of orexin neurons causes ► **narcolepsy-cataplexy**. Hyperactivity may predispose to ► **addiction**, as orexins link ► **appetite**, ► **arousal**, and neuroendocrine control with memory functions.

Basic Characteristics

Orexins were discovered in 1998, independently by two scientific groups using reverse genetics [1] and pharmacology [2]. The name orexin (from Greek: orexis = appetite) points to a systemic function first attributed to orexins: Control of ► **food intake** and ► **energy metabolism** (expenditure) [2, 3]. Conserved homologies with members of the *incretin*-peptide family and their

almost exclusive hypothalamic origin in mammals prompted for the synonym hypocretins (=“hypothalamic secretins”, Hcrt1, and Hcrt2, respectively) [1]. Association with narcolepsy-cataplexy [4, 5] indicates their major function: Control of ► **behavioral state** and systemic ► **bistability**. This includes consolidated states of sleep and wakefulness, mood, cognition, and movement, all of which are associated with aminergic transmission and compromised in narcolepsy-cataplexy. Orexins antagonize sleep and muscle atonia promoting arousal and postural stability, particularly in the context of consummatory behaviors. In the meantime, a plethora of additional orexinergic functions have been delineated [1–5]: ► **sympathoadrenal** and ► **neuroendocrine outflow**, ► **feeding rhythm**, ► **thermoregulation**, and ► **learning and memory**, all of which ultimately subserve behavioral state stability, ► **energy homeostasis** and survival. The pleiotropy of orexins is likely relevant for many disorders of ► **sleep**, ► **eating**, ► **mood**, ► **movement**, and ► **memory**.

Molecular Prerequisites of the Orexin System

The orexin system constitutes three phylogenetically conserved genes (Fig. 1). One encodes for the precursor peptide preproorexin (ENSG00000161610), a member of the incretin (PACAP-VIP-glucagon-GLP-1-secretin) family of peptides that is highly conserved across species. Two separate other genes encode for the Gq/11-protein coupled orexin receptors OX1R and OX2R.

The biologically active peptides OX-A (*EPLPDC-CRQKTCSCRLYELLHGAGNHAAGILTL-amide, 33 amino acids, 3,562 kDa) and OX-B (RPGPPGLQGR-LQRLQANGNHAAGILTM-amide, 28 amino acids; 2,937 kDa, 46% homology to OX-A) are C-terminally ► **RF-amide peptides** with approximately 50% sequence identity and slight bombesin-like sequence homology. They are derived from alternate splicing (convertase) and posttranslational modifications (cleavage). OX-A contains two sets of disulfide bonds playing a key role in receptor activation and prolonged half-life, compared to OX-B. The promoter region of the precursor gene contains ► **interferon** (INF α) response elements. Both mRNA and peptide expression in rodents arise by embryonic day E18 and start to diminish after 1 year of age.

Orexin receptors (OX1R and OX2R) are highly conserved (95%) across species. OX2Rs shares 64% identity with OX1Rs, but exhibit considerable differences with respect to agonist affinities, signal transduction and distribution throughout and even outside the nervous system. OX1Rs exhibit about 10–100-fold higher affinity to OX-A than OX-B, while OX2Rs bind both peptides with equal affinity. Binding of orexins to both receptors may be accomplished with [¹²⁵I]-orexin A and is rather specific, although binding of OX-B to ► **orphan G protein-coupled receptors** sensitive to other RF-amide peptides (neuropeptide FF) has been reported.

Orexins. Figure 1 Molecular basis of the orexin system (scheme). OX1R, OX2R: orexin receptor 1 and 2, CB1R: cannabinoid receptor 1, PLC: phospholipase C, IP3: inositol-3-phosphate, cAMP: cyclic-adenosine-monophosphate, VDCC: voltage-dependent calcium channel, TRPC: transient receptor potential channel, NCX: sodium calcium exchanger, GIRK: G protein-coupled inwardly rectifying potassium channel.

Studies in heterologous expression systems indicate that both OX1R and OX2R belong to the Gq/11-subclass of heteromeric G-proteins, commonly promoting Ca²⁺-entry and [Ca²⁺]_i-mobilization through coupling to IP3- and DAG/PKC-dependent signal transduction pathways. OX2Rs may also couple to Gi/o. Studies in native tissues indicate a higher degree of complexity in the signal transduction of OXRs. This includes activation of ▶voltage-dependent Ca²⁺ channels (VDCC), non-selective cationic and ▶transient receptor potential channels (TRPC), electrogenic ▶Na⁺/Ca²⁺ exchangers (NCX), and inhibition of previously activated G protein-coupled inwardly rectifying potassium channels

▶(GIRKs), thapsigargin- and cAMP-sensitive ▶PKA, and DAG-dependent ▶PKC activation, activation of ▶MAPK (p38, p42/44), ▶mTOR, protein synthesis, and proapoptotic pathways (cytochrome *c* release, caspase-3/7/9 activation). OX1Rs hypersensitize due to hetero-oligomerization with ▶endocannabinoid CB1 receptors, providing functional convergence of orexin and endocannabinoid signaling.

Functional Anatomy of the Orexin System

In the mammalian brain orexins are almost exclusively expressed in a small group of neurons located in the lateral ▶hypothalamus (LH) and perifornical area (PFA)

from where they project widely throughout the entire neuraxis (Fig. 2). The human brain contains about 50000–80000 orexin neurons. A similar restricted expression and widespread distribution of orexinergic projections and OXRs have been detected in monkey, hamster, cat, sheep, pig, chicken, various amphibians, and zebrafish.

Major efferent projections of the hypothalamic orexin system comprise descending and ascending, dorsal and ventral pathways that terminate preferentially in aminergic, endocrine, and autonomic control centers in the hypothalamus, ►midbrain, ►brainstem, and ►spinal cord, as well as in ►limbic cortical and subcortical structures, including ►septum, ►amygdala, ►thalamus,

nucleus accumbens, and ►hippocampus. Although a large proportion of orexin neurons contribute projections to multiple destinations, subgroups of cells with differential sensitivity to psychoactive drugs in the LH and PFA make contact with particular targets, suggesting functional dichotomy with respect to appetite and arousal control. The distribution of orexins and their receptors matches with the central representations of the autonomic nervous system, which form the major output for homeostatic and circadian control of peripheral organs. Indeed, 50% of the putative command neurons integrating somatomotor and cardiovascular functions have been identified as orexinergic. The most

Orexins. Figure 2 Functional anatomy of the orexin system with its major in- and output pathways. Hypothalamic orexin neurons (LH/PFA, red dot) convey circadian-photic, nutritional-metabolic neuroendocrine input (yellow and green lines/dots, respectively) to wake-active aminergic, cholinergic, and cortical targets (red lines/dots). During sleep and satiety orexin neurons are inhibited by GABAergic inputs from the VLPO and other inhibitory influences (grey lines and dots). PFA: perifornical area, LH: lateral hypothalamus, OX: orexin, VLPO: ventrolateral preoptic area, MCH: melanin-concentrating hormone, NPY: neuropeptide Y, POMC: proopiomelanocortin, ARC: arcuate nucleus, TRH: thyrotropin-releasing hormone, DMH: dorsomedial hypothalamus, AVP: arginine-vasopressin, SCN: supra-chiasmatic nucleus, OXY: oxytocin, SON: supraoptic nucleus, CRF: corticotropin-releasing factor, PVN: paraventricular nucleus, HA: histamine, TMN: tuberomammillary nucleus, NA: noradrenalin, LC: locus coeruleus, 5-HT: 5-hydroxy-tryptophan, DR: dorsal raphe, DA: dopamine, VTA: ventral tegmental area, SN: substantia nigra, Ach: acetylcholine, PPT/LDT: pedunculopontine/laterodorsal tegmentum, MS/DBB: medial septum/dorsal band of broca, GLP-1: glucagon-like-peptide-1, NTS: nucleus tractus solitarii, IML: intermediolateral tract, HPA: hypothalamo-pituitary-adrenal axis, α MN: alpha-motoneuron.

prominent extrahypothalamic connections of orexin neurons exists with aminergic and GABAergic cell groups in the locus coeruleus (LC, ▶noradrenaline), ▶dorsal raphe (DR, ▶serotonin), ventral tegmental area/substantia nigra (VTA/SN, ▶dopamine), and ▶cholinergic neurons in the ▶pedunculopontine/laterodorsal tegmentum (PPT/LDT), ▶medial septum/dorsal band of broca (MS/DBB), ▶parasympathetic (GLP-1 expressing) ▶nucleus tractus solitarii (NTS), ▶sympathetic intermediolateral tract (IML), and ▶ α -motoneurons (α -MN). Several hypothalamic and extrahypothalamic nuclei are reciprocally directly or indirectly interconnected with orexin neurons (Fig 2): (i) Histamine neurons in the ▶tuberomammillary nucleus (TMN) and perifornical area (PFA) are intermingled with orexin neurons together with (ii) GABAergic afferents from the ▶ventrolateral preoptic area (VLPO) coexpressing the neuroprotective peptide galanin. This triangle forms a bistable functional switch that controls maintenance of wakefulness and sleep–wake transitions and is a prominent target for sedative effects of GABAergic ▶general anesthetics (e.g., propofol). Interestingly, both, the effects of orexins on arousal, as well as those of leptin and ghrelin on feeding depend on histamine H1R-function, suggesting that the histamine system has a key position in behavioral state and neuroendocrine outflow control. (iii) ▶Melanin-concentrating hormone (MCH) neurons are another cell population spatially intermingled with orexin neurons in the lateral hypothalamus (LH) but exhibiting differential topological distribution and largely antagonistic or complementary functions. (iv) Orexigenic ▶neuropeptide Y (NPY) and anorexigenic ▶proopiomelanocortin (POMC) containing neurons in the ▶arcuate nucleus (ARC) are integral part of a brain–gut axis that controls ▶energy balance and ▶food intake. (v) ▶Thyrotropin-releasing hormone (TRH) coexpressing neurons in the ▶paraventricular nucleus (PVN) together with (vi) ▶arginine-vasopressin (AVP) positive neurons in the ▶suprachiasmatic nucleus (SCN) convey neurohumoral nutritional-metabolic (relayed through the ARC) and circadian-photoc influences (relayed through retino-hypothalamic melanopsin-pathways to the SCN) to the ▶dorsomedial hypothalamus (DMH). This DMH is a food-entrainable oscillator (Neural networks integrating circadian-photoc and nutritional-metabolic influences to produce rhythmic food anticipatory behavioural activity (FAA). In mammals, probably controlled by neurons in the dorsomedial in the hypothalamus (DMH).)controlling appetite and feeding-related circadian behaviors. Excitatory interactions of orexins with oxytocin (OXY)- and AVP-expressing neurons in the ▶supraoptic nucleus (SON) affect fluid homeostasis, and possibly social and reproductive competence. Finally, ▶corticotropin-releasing factor (CRF) expressing neurons in the ▶paraventricular nucleus (PVN) mutually interact with orexins along all branches of the hypothalamo–pituitary–adrenal (HPA) axis, supporting energy expenditure in

contexts of increased demand during arousal and defense responses, but also stress-related behaviors (grooming) and stress-induced reinstatement of drugs of addiction, such as cocaine.

The diffuse nature of orexinergic projections is consistent with combined patterns of expression of the two orexin receptors, which is widespread but differential and often complementary within and even outside the CNS. OX2Rs are found primarily in structures attributed to control of sleep–wake functions, whereas OX1Rs are more abundant in ▶limbic structures controlling aspects of feeding, autonomic outflow, ▶energy homeostasis, and to a lesser extent also ▶REM-sleep.

Extrahypothalamic OX-B-like immunoreactivity, reminiscent to that of CRF, has been described in clustered GABAergic neuronal populations, in the lateral division of central nucleus of the ▶amygdala, the ▶bed nucleus of the stria terminalis, and in the ▶hippocampus. Moreover, ectopic expression of preproorexin mRNA in the gut, ependymal cells, neuroblastomas, and of orexin receptors in ▶adrenal gland, cancer and ▶hematopoietic stem cells suggests yet unexplored roles of orexins as paracrine factors controlling blood–brain barrier, and tumor or stem cell function.

Physiology and Function of the Orexin System

The activity of hypothalamic orexin neurons exhibits diurnal rhythms and varies according to behavioral and nutritional state. In vivo, orexin neurons fire spontaneously during active waking in association with movement when muscle tone is high. Activity is lower during quiet waking and absent during sleep when postural tone is low. In REM sleep, with minimal ▶postural tone, orexin neurons are silent in spite of the muscle twitches occurring during this state. In vitro, orexin neurons display a rather low membrane potential (~ -50 mV) and activity is dynamically regulated by their intrinsic properties as well as excitatory feed forward and inhibitory feedback through a variety of transmitters and intero- and exteroceptive neuroendocrine, circadian (SCN, DMH), and gastrointestinal, nutritional-metabolic (DMH, ARC, NTS) state cues. Importantly, orexin neurons are excited by ▶hypoglycemia and directly inhibited by ▶glucose (through TASK, tandem-pore domain potassium channels). Likewise, ▶ghrelin, a short-term hunger signal from the stomach excites orexin neurons and promotes food intake, while the adipostatic and long-term satiety factor ▶leptin has inhibitory effects on orexinergic activity, energy expenditure, and food intake. Moreover, glutamatergic input to orexin neurons varies according to nutritional state in a leptin-sensitive manner, increasing with overnight food deprivation and decreasing by refeeding.

Orexin neurons, likely to be glutamatergic themselves, express the ▶excitatory amino acid transporter EAAT3, ▶vesicular glutamate transporters VGLUT1 and VGLUT2, secretogranin II, ionotropic (NMDAR,

AMPA) and metabotropic (mGluRs) ►glutamate receptors, and the neuronal ►pentraxin Narp, implicated in clustering of AMPA receptors. Other proteins detected in orexin neurons include precursor-protein convertase and ►dynorphin which modulates orexinergic signaling and plays a role in orexin-induced feeding, the transcription factor Stat-3, and receptors for GABA (epsilon subunit), biogenic amines, ►purines (ATP P2X, adenosin), opioids (mu and kappa), leptin, and ►pancreatic polypeptide Y4. Accordingly, intrinsic activity of orexin neurons (in vitro) is increased by glutamate, ATP, ►acetylcholine (M₃), ►ghrelin (GHSR), ►glucagon-like peptide-1 (GLP-1), CRF, AVP and OXY(V_{1a}), ►neurotensin, and ►cholecystokinin (CCK-A) but inhibited via negative feedback through presynaptic metabotropic glutamate autoreceptors (mGluRs), GABA_{A/B}, catecholamine (α₂), serotonin (5HT_{1A}), ►leptin (ob-R), NPY (Y1), MCH, and sleep-promoting, anti-epileptic effects of ►adenosine (A₁).

Pathophysiology and Dysfunction of the Orexin System

Hypofunction of the orexin system is causally related to the sleep disorder narcolepsy-cataplexy, and animal models of that disease. In humans, loss and degeneration of orexin neurons, likely due to an ►autoimmune attack or ►neurotoxicity pathogenesis, is the most frequent (1:2000) cause of narcolepsy-cataplexy, a disease characterized by intrusions of REM sleep like phenomena into wakefulness, increased daytime sleepiness, sleep fragmentation, vivid dreaming, hypnagogic hallucinations, and in some cases cataplexy. Cataplexy is a sudden loss of postural muscle tone generally triggered by emotionally arousing, appetitive or pleasurable stimuli, such as joy and laughter in humans, or food presentation in animals. Interestingly, ►narcolepsy exhibits a high comorbidity with migraine, consistent with a role of orexins in nociception and pain, and possibly neuroinflammation.

Dogs with a sporadic mutation of OX2R trafficking and function, as well as mice with a complete destruction of orexin neurons (by expression of an orexin-ataxin transgene), or deletion of OX1/2-receptors exhibit a phenotype similar to that of narcolepsy-cataplexy in humans, including abnormalities in sleep architecture (decreased sleep onset REM latency, rapid intrusions of REM sleep phenomena into wakefulness), energy balance (increased ►body mass index), and neuroendocrine functions. Orexin-deficient mice eat less, but gain weight, and show disrupted ►food anticipatory behavior (in face of restricted daily feeding), indicating imbalanced energy homeostasis and feeding rhythms, associated with reduced expression of clock genes (*Per1*, *Bmal1*, and *NPAS2*). Likewise, lesions of the suprachiasmatic nucleus or loss of ►clock gene function eliminates diurnal orexin rhythms and is associated with attenuated diurnal feeding rhythms, hyperphagia, ►obesity, and a ►metabolic

syndrome comprising hyperleptinemia, hyperlipidemia, hepatic steatosis, hyperglycemia, and hypoinsulinemia. Overexpression of ►uncoupling protein-2 (UCP-2) selectively in mitochondria of orexin neurons in mice increased ►life span and decreased ►core body temperature through local warming of ambient hypothalamic structures. This emphasizes a central role of orexins in energy balance and ►thermoregulation, independent from peripheral thermogenesis.

Hyperactivity of the orexin system, e.g. triggered by energy depletion, metabolic failure, hypoglycemia or hypoxia, in the context of starvation, sleep deprivation, and stress, may predispose to ►addiction and ►compulsion. Orexin neurons are selectively activated by natural rewards such as food (a common trigger of canine narcolepsy) but also by withdrawal from drugs of abuse, such as ►morphine and ►cocaine. Moreover, orexins through mechanisms promoting synaptic plasticity control reinforcement of hippocampal long-term potentiation and memory consolidation. In contrast, ►narcoleptics rarely develop ►addiction, in spite of the addictive properties of most of their pharmacological treatments. Likewise, orexin-deficient mice are less susceptible to drugs of addiction and show attenuated ►stress responses, behaviorally (defense) and in sympathoadrenal functions (blood pressure and heart rate). Pleiotropy of orexinergic dysfunction may thus be relevant for many disorders of eating, sleep, mood, movement, and memory.

Drugs

Pharmacological targeting of the orexin receptors by selective OXR ►agonists or ►antagonists could provide near causal therapy of narcolepsy-cataplexy, or efficient treatment of ►insomnia, and possibly addiction, respectively. However, orally active, blood-brain barrier permeable, small molecule OXR agonists are not yet available. All drugs currently used to treat symptoms of narcolepsy-cataplexy thus mimic orexinergic effects by interfering with aminergic (amphetamines, antidepressants, modafinil) and GABAergic (gamma-hydroxy butyrate) neurotransmission. Of the available prodrugs antagonizing orexin receptor function only ACT-078573 has been tested in humans, so far (Table 1). ACT-078573 is an orally active, brain penetrating OX1/2R-antagonist and has been introduced as an efficient sleep-promoting and possibly anti-addictive drug in rats, dogs, and humans. It lacks unwanted side effects of GABAergic sedative substances (i.e., REM sleep suppression and addiction) and did not produce cataplexy in humans after acute ingestion. This suggests that other factors produced by orexin neurons (e.g., ►NARP, dynorphin) may contribute to the development of cataplexy, or chronic blockade of OX1/2R-antagonists may be required to produce cataplexy. Long-term studies in humans are

Orexins. Table 1 Pharmacology of orexin receptors

Organic Cations

Organic cations are compounds that meet the two criteria of a single positive charge (no negative charge) and a significant degree of hydrophobicity (alkyl chains or aromatic rings, little capacity to form hydrogen

bonds). Typical examples are tetraethylammonium (TEA), N¹-methylnicotinamide (NMN), and MPP⁺.

►Organic Cation Transporters (OCT)

Organic Nitrates

Organic nitrates are polyol esters of nitric acid. This group of drugs includes glyceryl trinitrate (nitroglycerine), isosorbide mononitrate (ISMN), isosorbide dinitrate (ISDN) and amyl nitrite (AN). Organic nitrates release nitric oxide (NO), a process which involves an enzymatic step. NO release from organic nitrates activates the soluble form of guanylyl cyclase by interacting with a heme group in the enzyme. The formation of cyclic cGMP by guanylyl cyclase leads then to the relaxation of smooth muscle cells. Organic nitrates at clinical concentrations mainly lead to a relaxation of venous capacitance vessels. Organic nitrates are mainly used for the prophylaxis or acute treatment of anginal pain. The antianginal effect of organic nitrates decreases after repeated administration (tolerance). The main adverse effects are hypotension and headache.

►Guanylyl Cyclases

Organophosphates

Organophosphates are a group of pentavalent phosphorus compounds, which contain an organic group (e.g. parathion, malathion, tabun, sarin, soman).

Organophosphates are irreversible acetylcholinesterase inhibitors. They are used as insecticides or “nerve gas”

► Acetylcholinesterase

ORL-1

The ORL-1 receptor was identified by its high homology to the other opioid receptor subtypes and termed “opioid receptor like”, although none of the endogenous peptides or opiate drugs show a high affinity for this receptor. An endogenous peptide which binds to this “orphan” receptor with high affinity was identified and termed noceptin or orphanin FQ.

► Opioid Systems

Orphan G-protein-coupled Receptors

► Orphan Receptors

Orphan Nuclear Receptors

Orphan nuclear receptors are a sub-group of the nuclear receptor (NR) family of transcription factors. The nuclear receptors (NRs) are characterized by: (i) a common modular domain structure and (ii) direct binding to DNA via zinc-finger motifs. In general, the modular domain structure consists of the following: an N-terminal domain containing a ligand-independent activation function (constitutive activity); the DNA-binding domain (DBD) containing two zinc-finger motifs; the hinge domain which links the DBD and the ligand-binding domain (LBD); and the LBD containing the ligand binding site and ligand-dependent activation function (ligand-dependent activity). Orphan receptors share the structural characteristics of NRs, including the presence of a LBD, though ligands for this sub-group of NRs have not been identified to date.

Definition

Orphan receptors are proteins that bind and are activated by hitherto unknown signaling molecules (called ligands, neurotransmitters, or hormones). However, they share structural components with identified receptors whose signaling molecules are already known. The physiological functions of orphan receptors are unidentified. The identification of the natural ligand of an orphan receptor holds the key to our understanding of its physiological role and potential as a drug target.

Basic Mechanism

Members of two structurally very distinct receptor families are termed orphan receptors. One is the family of the ►nuclear receptors which are cytosolic proteins that upon ligand binding change their conformation, translocate to nuclear binding sites, and act as transcription factors to regulate the expression of other genes. The second group of receptor proteins is the ►G protein coupled receptor (GPCR) superfamily representing seven-transmembrane-helix surface receptors that reside in the plasma membrane. When bound to a specific ligand, conformational changes in the receptor molecule lead to activation of heterotrimeric G proteins (short for guanine nucleotide binding proteins) which in turn act as signal transducers to switch on their respective effector proteins such as ►phospholipases, ►adenylyl cyclases, or ion channels. This essay addresses in particular orphan GPCRs, but the basic principles described below for the identification of ligands also applies to nuclear orphan receptors.

Historically, orphan receptors were first identified by homology screening techniques based on low-stringency DNA hybridization followed by PCR-assisted strategies. The success of these methods led to the realization that large numbers of GPCRs exist but gave still just a glimpse of the overall size of this receptor superfamily. With the completion of the human genome sequencing project, ►bioinformatics search tools quickly led to a comprehensive picture of the receptor repertoire in the human genome. Presently the genes of about 800 human GPCRs have been identified from which approximately 50% are represented by ►olfactory and ►taste receptors. The other half consists

of receptors with already known ligands leaving presently about 110 orphan GPCRs. As primary step toward drug discovery, determining a physiological function for these newly identified receptors is of vital importance, and thus identification of a natural or ►**surrogate ligand(s)** is primary aim. Orphan receptor specific ligands can be directly injected into animals and serve as indispensable molecular tools to study the *in vivo* function of the orphan receptor by acutely altering animal behavior and physiology, hence shedding light on the receptor's intrinsic function. In order to identify ligands, there are at least two necessary steps to complete. First the development of a suitable assay system and secondly the screening of synthetic compound libraries, that is, compilations of biological active ligands or biological tissue extracts that contain molecules able to activate a particular orphan receptor. The whole process is generally referred to as ►**reverse pharmacology** and interchangeably used with the term deorphanization.

Assay Systems for Orphan Receptors

Orphan receptors, in particular the orphan GPCRs, rely on an intact cellular environment for proper function that provides the necessary G protein and effector machinery to enable the identification of an activating ligand (Fig. 1). The receptors are initially cloned by recombinant DNA technologies and then introduced into a suitable expression system, most often immortalized mammalian cell lines. These cells are capable of expressing the receptor at the cell surface and in addition provide all the additional protein components to couple the receptor to a signal transduction pathway. In the most direct way, the orphan receptor expressing cells can be directly probed for specific binding of radioactively labeled ligand(s). Such binding strategies proved highly successful when applied to orphans at the beginning of the orphan receptor era, a time many potential neurotransmitters were known but their molecular targets remained elusive. However, the binding approach is limited to already known ligand structures. The much more exciting, but also more difficult approach, is to utilize the orphan receptors functional properties to isolate natural ligands, which means to identify novel cellular transmitters. Since the binding of a ligand to the orphan will lead to conformational changes in the receptor protein, this in turn generates a downstream signaling event that can be readily detected by physicochemical methods. With such a strategy, the orphan receptor itself serves as a sensor for its own unknown ligand(s).

The majority of GPCRs couple to three families of G protein alpha subunits which differ in their ability to activate three distinct primary signaling cascades. The stimulatory G-protein G_{α_s} , positively regulates the activity of adenylyl cyclase causing an increase of intracellular cAMP levels as second messenger. In

contrast, G_{α_i} protein subunits inhibit adenylyl cyclase, hence lowering intracellular cAMP levels. G proteins of the $G_{\alpha_q/11}$ type activate phospholipase C β leading to transient increase of intracellular calcium that in turn activates many cellular processes. By directly measuring either changes in intracellular cAMP or increase of intracellular calcium levels the activity of the majority of orphan GPCRs can be monitored. However, until recently there was no structural analysis method able to predict which second messenger will be modulated by a given orphan receptor, forcing the experimenter to run different assay systems simultaneously. ►**Constitutive receptor activity** can be used to predict the likely signaling mechanism and promiscuous $G_{\alpha_{15/16}}$ subunits or genetically engineered G protein chimeras can be used to force the coupling of an orphan GPCRs to a desired effector system, reducing the number of assays significantly. In addition, a plethora of alternative assay systems for GPCRs are presently available that can be adapted for monitoring orphan receptors. Finally it has to be stressed out that an orphan receptor assay system, due to the lack of an agonist is difficult to validate and therefore some uncertainty about the functionality of the system always remains. Despite the odds, 5–10 receptors are successfully deorphanized each year since 1999.

Ligand Screening for Orphan Receptors

Once an assay system has been established the search for ligands can be initiated. Screening is a rather elaborate task and is preferentially done in ►**high throughput screening** assay formats to handle the enormous number of assay points that are necessary to find novel ligands. Since ligands for GPCRs are extremely diverse in structure and function the right selection of candidate ligand libraries is of paramount importance. Pharmaceutical companies compiled sets of known and putative ligands for screening which contain proven GPCR small molecules, lipids, candidate molecules, and metabolites from the literature, peptides and proteins predicted by ►**bioinformatics**. Screening all libraries on all orphan receptors can be an expensive endeavor. To limit the cost of such a venture, bioinformatics can help to classify orphan GPCRs based on their sequence similarity and to predict candidate ligands. Such an approach pairs candidate ligand libraries to the most likely receptor structure and increases the chance to match the right ligand with its potential receptor. So far, ligand matching proved to be the most successful approach of all, but its limits are obvious. Technically the most challenging but also the one that generates most impact on basic sciences is the identification of novel ligands from biological tissue extracts. In this approach candidate tissues, generally the one where the orphan receptor is highly expressed, are homogenized and extracted. The biological extracts are then fractionated by biochemical methods and screened for biological activity using the same assays methods as described above. Following

Orphan Receptors. Figure 1 Two principal strategies to identify molecules that activate orphan receptor as exemplified by the orphan G protein coupled receptors. (a) A cloned receptor is introduced into a mammalian cell line where it is expressed at the cell surface. The cells are exposed to minute amounts of tissue extracts and then immediately monitored for changes in intracellular second messenger molecules, like cyclic adenosine monophosphate or inositol 1,4,5-trisphosphate. If the extract contains an orphan receptor specific molecule, the relative activity of the cell expressing the orphan receptor will be significantly higher compared to that of a control cell line. Positive tissue extracts are repeatedly fractionated and tested on the orphan receptor cell, till the active compound is sufficiently pure for structure determination. This strategy discovers novel signaling molecules. (b) An alternative approach is to use libraries of single compounds that are already known for their biological activity. These libraries are systematically applied to different orphan receptors expressed in mammalian cells and the relative responses monitored. If a single compound matches a certain orphan receptor, its host cell line will specifically respond but others remain silent. This strategy can only identify already known biologically active molecules. G, G-protein; E, Effector protein (see text).

the detection of a biological activity, it is necessary to purify the active compound by repetitive fractionations and finally elucidate the structure. This approach was so far most successful for the identification of novel

peptides where minute amounts of material can be analyzed due to the existence of highly sensitive analytical technology. Although this approach faces many technical challenges, identification of novel

transmitter belonging to other chemical classes than peptides is expected in the future.

Assays for Orphan Receptors without Ligands

Numerous examples of successful identification of novel ligands for orphan receptors exist, but recently discovered and unexpected GPCR phenomena unfold the possibility that some orphan receptors might act as regulators of other GPCRs, thus having ligand-independent functions. A large body of evidence suggests that some GPCRs are capable of forming both homo- and heterodimers in the cellular membrane that is required for proper receptor trafficking. Formation of heterodimers might also result in a changed pharmacology and even generate new ligand binding sites. The remaining “difficult” orphans are candidates for the discovery of novel GPCR functions and will need the development of new assay systems that are capable of probing beyond classical GPCR signal transduction, for example, protein–protein interaction, receptor trafficking, and novel signaling pathways.

Pharmacological Relevance

GPCRs are important drug targets. About 30% of all clinically marketed drugs are modulators of GPCR function making GPCRs the most successful of any target class relevant to drug discovery. Orphan receptors belonging to the GPCR superfamily are indeed viewed as potential new drug targets and are currently being exploited for their potential in treating diseases, including obesity, sleep-related and mental disorders, inflammation, and cardiovascular disease. Ligand identification for orphan receptors will lead to the discovery of novel response systems and open new therapeutic avenues for a variety of human diseases. Each identified receptor ligand pair in itself provides an assay system that can be directly applied to ► **drug discovery**, i.e. sieving through chemical libraries that contain hundreds of thousands of small molecules with the goal to identify so-called hit compounds acting as agonist or antagonist at the screened receptor system. Hit compounds can be further refined by medicinal chemistry and developed into therapeutic drugs depending on their toxicological, pharmacokinetic, metabolic profiles as well as their patentability. However, drug development programs are costly endeavors and investment into novel receptor–ligand pairs demands their validation as potential drug targets. Presently, the major challenge lies in the identification of the physiological and pathophysiological importance of newly deorphaned receptors in order to motivate drug development.

There are now many examples of novel peptide transmitter systems that have been identified through orphan receptor ligand screening and greatly impacted the basic understanding of human physiology. Prime examples for the discovery of novel transmitter with therapeutic implications are the neuropeptides ► **orphaninFQ/**

nociceptin, ► **orexin/hypocretin**, and ► **ghrelin** for treatment of anxiety, sleep disorders, and obesity, respectively. Other orphan GPCRs turned out to be the pharmaceutical targets of already known therapeutic drugs. For example, the oral available and potent ► **antiplatelet drug** clopidogrel was found to bind an orphan GPCR whose natural ligand was identified as adenosine diphosphate (ADP) and now named P2Y₁₂. The identification of this therapeutically proven orphan receptor made it an immediate candidate for drug development without further validation. Since the entire number of biochemical targets that have led to marketed drugs is fewer than 500 and the GPCRs make up the majority of those, it is anticipated that at least some novel therapeutic drugs will emerge from orphan receptor research.

Orphan Serpentine Receptors

► Orphan Receptors

OrphaninFQ/Nociceptin

A 17 amino acid long peptide sequentially related to opioid peptides in particular dynorphin A. OFQ/N is inactive at the δ , κ , and μ opioid receptors, but binds to its own NOP receptor (formerly ORL-1, for opioid receptor like-1). In contrast to opioid peptides, OFQ/N has no direct analgesic properties. OFQ/N is the first example for the discovery of a novel neurotransmitter from tissue extracts by using an orphan receptor as bait. Centrally administered in rodents, OFQ/N exerts anxiolytic properties. OFQ/N agonists and antagonists

are presently undergoing assessment for their usefulness to treat various mental diseases, including depression and anorexia nervosa.

Osteoarthritis

Osteoarthritis is a disease of the load-bearing joints, characterised by gradual erosion of cartilage and deformation of bone. Pain is the main symptom, initially eased by rest, but later analgesics such as aspirin-like drugs are indicated.

- ▶ Cyclooxygenases
- ▶ Non-steroidal Anti-inflammatory Drugs

Osteoblast

An osteoblast is the cell forming new bone. Osteoblasts are derived from stromal bone marrow stem cells.

- ▶ Bone Metabolism

Osteoclast

One of the cell types involved in bone metabolism. In concert with osteoblasts, their cellular counterpart, these cells maintain bone hemostasis and constant

blood calcium levels by regulating formation (osteoblasts) and resorption (osteoclasts) of mineralized bone matrix. Osteoclasts differentiate from myeloid precursors in the bone marrow.

- ▶ Bone Metabolism

Osteocyte

A cell embedded within the mineralised matrix of bone. Osteocytes are derived from former osteoblasts and are responsible for intra-skeletal sensing and signalling.

- ▶ Bone Metabolism

Osteoporosis

Osteoporosis is a common condition, in which bone density is decreased as a consequence of an imbalance between bone formation (osteoblast) and bone loss (osteoclast). This leads to fragile bones, which are at an increased risk for fractures. The term “porosis” means spongy, which describes the large holes seen in these bones.

Synonyms

Cytochrome P450 (CYP); Cytochrome P450 isozymes; Cytochrome P450 mono-oxygenases; Mixed function oxidases

Definition

Cytochrome P450 (CYP) mono-oxygenases, also called mixed function oxidases, are versatile hemoprotein enzymes that catalyze the cleavage of molecular oxygen to incorporate one oxygen atom into a substrate molecule and one atom into water [1]. The general stoichiometry of the reaction is as follows (S-H, substrate):

The numerous biotransformations catalyzed by cytochrome P450 enzymes include aromatic and aliphatic hydroxylations, epoxidations of olefinic and aromatic structures, oxidations and oxidative dealkylations of heteroatoms and as well as some reductive reactions. Cytochromes P450 of higher animals may be classified into two broad categories depending on whether their substrates are primarily endogenous or xenobiotic substances. Thus, CYP enzymes of families 1–3 catalyze

the ►**phase I metabolism** of most drugs and ►**xenobiotics**, often a prerequisite for a phase II conjugation reaction and subsequent elimination from the body. Although usually involved in detoxification, sometimes the products of CYP-catalyzed reactions can also be pharmacologically active (in this case the substrate is called a ►**prodrug**), or it may be carcinogenic, toxic, or otherwise harmful. In contrast, the CYP enzymes of families CYP4 to CYP51 primarily participate in critical physiological pathways leading to steroid hormones, bile acids, prostaglandins and other important endogenous compounds.

Basic Characteristics

Cytochrome P450 Electron Transport Systems

The P450 mono-oxygenase system functions as an electron transport chain in which electrons are transferred from cellular pyridine nucleotides (NADPH/NADH) to the P450 hemoprotein. In vertebrates, there are two principal types of P450s and electron transfer chains. One is found in the mitochondrial inner membrane and the other in the endoplasmic reticulum (ER). The electron donating protein of the ER system (Fig. 1a) is called NADPH-cytochrome P450 oxidoreductase (CYPOR). It consists of two domains with two different prosthetic flavin groups FAD (flavin adenine dinucleotide) and FMN (flavin mononucleotide), which transfer two electrons acquired from NADPH directly, but only one at a time, to the P450 heme iron. CYPOR is bound to the ER membrane by its N-terminal tail, whereas the bulk of the protein is on the cytosolic side of the ER membrane. In humans, CYPOR is encoded by a single gene (*POR*) on chromosome 7 which encodes a protein of 677 amino acids. The crystal structure of CYPOR has been determined. In certain reactions catalyzed by microsomal P450s, the second electron can also be donated by cytochrome b_5 , a smaller heme containing protein (MW ~ 15 kDa),

which accepts electrons from NADH via the flavoprotein NADH-cytochrome b_5 -reductase.

In mitochondria (Fig. 1b), the electron acceptor protein is also a flavoprotein termed NADPH-adrenodoxin reductase (MW ~ 50 kDa) because it was discovered in the adrenal cortex and because it donates its electrons not directly to the P450 but to the smaller redox protein adrenodoxin (MW ~ 12.5 kDa). The two iron-sulphur clusters of this protein serve as electron shuttle between the flavoprotein and the mitochondrial P450.

Cytochrome P450 Structure

The name cytochrome P450 (P for pigment) derives from the unusual spectrum compared to other hemoproteins. Carbon monoxide strongly binds to the reduced (ferrous) heme iron inducing a strong absorption at 450 nm that was first discovered in 1958 and that can be used to quantitate cytochrome P450 via its reduced CO-difference spectrum. The structural difference between cytochrome P450 and other hemoproteins is the unusual fifth ligand to the heme iron, which is a histidine in other hemoproteins and a conserved cysteine thiolate in all P450s, located close to their C-termini. X-ray crystal structures available not only for bacterial but also for several human microsomal P450s have confirmed the role of the conserved thiolate ligand and provided deep insights into substrate binding and structural peculiarities [2]. The many sequences available and the recent structural data indicate significant structural similarities between all P450s, which have about 500 amino acids and most likely evolved from a single common ancestor gene. Microsomal P450s are bound to the membrane by a single hydrophobic N-terminal transmembrane anchor in such an orientation that the heme moiety is colocalized with the CYPOR flavodomain at the cytoplasmic side of the ER. Mitochondrial P450s are synthesized as slightly larger precursors with an N-terminal signal sequence that is being cleaved

P450 Mono-oxygenase System. Figure 1 (a) Components of the microsomal P450 mono-oxygenase system. (b) Components of the mitochondrial P450 mono-oxygenase system.

off during translocation of the protein to the inner mitochondrial membrane.

Cytochrome P450 Gene Superfamily

Cytochromes P450 are the products of a gene superfamily with currently more than 6,000 known forms (isozymes) from all types of living organisms. Cytochrome P450 proteins are classified into families and subfamilies based on their sequence similarities. Any two forms with more than 40% identity at the amino acid level belong to the same family (indicated by an arabic numeral), whereas they belong to the same subfamily (indicated by a capital letter) if they share more than 55% of identical amino acids. Individual isozymes of the same subfamily are distinguished by an additional arabic number. Based on the results of the human genome project, humans have 57 individual functional *CYP* genes which are organized in 18 families and 43 subfamilies and which are found dispersed over all autosomal chromosomes. A particular aspect of mammalian cytochrome P450 systems is the high number of ►pseudogenes which harbour mutations that prevent the expression of functional proteins. Humans have more than 25 *CYP* pseudogenes that make molecular genetic analysis complex due to their high sequence homology. Other mammals share the same 18 *CYP* families with humans, but the number of individual functional isozymes in each family or subfamily can be very different. Based on their role in metabolism, the 18 *CYP* families can be broadly classified into those catalyzing the metabolism of xenobiotics (families *CYP1*, *CYP2*, and *CYP3*), and those that are responsible for biotransformations of important endogenous substances (families *CYP4* to *CYP51*; Table 1). Whereas mutations in several *CYP* genes of the first category are frequent in the population and lead to polymorphic drug oxidation, mutations in *CYPs* catalyzing physiological reactions are rare and often the cause for inherited metabolic disorders.

Human Drug Metabolizing Cytochromes P450

Typical characteristics of the drug metabolizing P450s are their broad and overlapping substrate specificities and their extremely variable expression and function both in terms of inter- and intraindividual variation which has a tremendous influence on the ►pharmacokinetics of most drugs in clinical use. The in vivo activity of a specific P450 enzyme can principally be estimated by measuring metabolite concentrations of an ingested selective probe drug in urine, blood or breath of patients. Three basic mechanisms are responsible for variability in the activity of drug metabolizing enzymes: (i) genetic polymorphism; (ii) gene regulatory mechanisms that lead to enzyme induction or downregulation; and (iii) direct inhibition of enzyme activity.

Polymorphisms in Drug Metabolizing P450s

A ►genetic polymorphism is a difference in DNA sequence that has a frequency of at least 1% in a population. Many drug-metabolizing enzyme genes are highly polymorphic with consequences for expression and function of the gene product, such that they affect the disposition of drugs and xenobiotics (►pharmacogenetics). The best studied example of a P450 genetic polymorphism is that of *CYP2D6* [4]. It results in two major phenotypes in the population, the extensive metabolizer (EM) phenotype and the ►poor metabolizer (PM) phenotype. The PM phenotype is inherited as an autosomal recessive trait and affects about 5–10% of Caucasians who are unable to metabolize a range of drugs which are substrates for *CYP2D6*. For drugs with narrow therapeutic window, these individuals may be at risk to develop adverse drug reactions when given normal drug doses. Further examples for polymorphisms in *P450* genes are mentioned below. The Internet Home Page of the Human Cytochrome P450 (*CYP*) Allele Nomenclature Committee lists all known human cytochrome P450 alleles at ►<http://www.cypalleles.ki.se>.

Gene Regulatory Mechanisms in Drug Metabolizing P450s

A variety of regulatory mechanisms are acting on different *P450* genes to regulate their constitutive expression and response to environmental stimuli [5]. Members of the *CYP1* family and some other drug metabolizing enzymes including some UDP-glucuronosyltransferases (UGTs) are collectively induced by polycyclic aromatic hydrocarbons (PAH) that serve as ligands to a specialized receptor called the ►aryl hydrocarbon receptor (AhR) which translocates to the nucleus following binding of another protein component called arnt (AhR nuclear translocator). In the nucleus these two proteins bind DNA and activate transcription. Another regulatory mechanism is responsible for the 40–50 fold induction of *CYP2B* enzymes of humans and rats following administration of phenobarbital and other barbiturates. The ►orphan nuclear receptor CAR (constitutively activated receptor) plays a central role in mediating the effect of phenobarbital that leads to induction of *CYP2B6*. PXR, another orphan nuclear receptor, binds a different range of ligands including the antibiotic rifampin, and leads to induction of a different profile of genes, in particular *CYP3A4*. Both CAR and PXR bind to DNA in the form of heterodimers with the retinoic X-receptor, RXR, as binding partner [5]. Other chemicals also induce P450s, e. g. ethanol induces the *CYP2E1* enzyme. The general feature of these regulatory mechanisms is that substrates induce their own metabolism.

Direct Inhibition of P450

Direct inhibition of P450 enzymatic activity is the most common reason for drug–drug interactions.

P450 Mono-oxygenase System. Table 1 Overview of the cytochrome P450 superfamily in humans

Family	Subfamily, genes, pseudogenes (P)							Typical substrates/functions

CYP 39								24-Hydroxycholesterol 7-hydroxylase
CYP 46								Cholesterol 24-hydroxylase
CYP 51		51P1	51P2	51P3				Lanosterol 14-alpha demethylase (cholesterol biosynthesis)

Data mainly from reference [3].

P, pseudogenes; PAHs, polycyclic hydrocarbons; PCBs, polychlorinated biphenyls.

P450 inhibitors can be either of the competitive or of the mechanism-based type. Potent competitive inhibitors are often, but not always, substrates which have a high affinity for the enzyme. Mechanism-based or suicide enzyme inhibition occurs when a substrate is activated to a reactive intermediate that subsequently binds either to the P450 polypeptide or to the heme moiety thereby inactivating it irreversibly. Examples for both types of inhibitors are known for almost every drug-metabolizing P450. Substance interfering with P450 enzyme activity may also originate from food, e.g. grapefruit juice contains CYP3A4 inhibitors that have significant effects on in vivo drug concentrations lasting several days.

Drugs

Human Drug Metabolizing CYPs

CYP1A1: Typical substrates are polycyclic aromatic hydrocarbons (PAHs) like benzo(a)pyrene or methylcholanthrene. The carcinogenicity of these substances depends on their metabolic activation by CYP1A1. Some of the PAHs that induce CYP1 enzymes via the Ah receptor are found in cigarette smoke and charred food. CYP1A1 is expressed at very low levels in the liver of uninduced individuals but is found in extrahepatic tissues including placenta, lung, and lymphocytes. **CYP1A2** has a broader substrate specificity than CYP1A1, including many aromatic and heterocyclic amines and is more abundantly expressed in human liver. Typical substrates are caffeine, phenacetine, clozapine, estrogens and others. Caffeine N3-demethylation can be used as a selective 1A2 marker activity, whereas 7-ethoxyresorufin O-deethylation or phenacetin O-deethylation reflect both CYP1A isozymes. Genetic polymorphisms have been found in all human CYP1 genes and their associations with various forms of cancer were intensely studied. The *CYP1A1/2* genes are located on chromosome 15.

CYP1B1 (chromosome 5) has been linked to primary congenital glaucoma. CYP1B1 is not regularly expressed in liver but is often found in various kinds of tumours. It metabolizes retinoids and many aromatic amines and PAHs to potentially carcinogenic products.

The CYP2 family is the largest CYP family in humans and it comprises about 16 functional genes and 11 pseudogenes.

CYP2A6 is the principal enzyme for nicotine metabolism. A selective probe drug for CYP2A6 is coumarin. Clinically important drug substrates are rare for this enzyme. Several genetic polymorphisms have been found in the *CYP2A6* gene which affect mainly expression levels. It has been suggested that smokers with genetically determined low CYP2A6 expression need to consume less nicotine to achieve the same satisfying blood levels of the drug.

CYP2B6 is the only functional isozyme of the 2B subfamily in humans, as *CYP2B7* is a pseudogene. Both genes are located within a large *CYP2* gene cluster on chromosome 19. CYP2B6 is highly variable owing to its inducibility by barbiturates and other drugs but its expression and function are also affected by frequent genetic polymorphisms. Clinically important substrates are the cytostatic cyclophosphamide, the antidepressant bupropion, and the antiretroviral drugs used in HIV treatment, efavirenz and nevirapine. S-Mephenytoin N-demethylation and bupropion hydroxylation are selective marker activities that can be used both in vitro and in vivo.

The **CYP2C** subfamily comprises the four genes *CYP2C8*, *2C9*, *2C18*, and *2C19*, which are together localized on chromosome 10. The members of this subfamily show surprisingly large variation in substrate specificity and regulation. **CYP2C8** appears to have a narrow substrate specificity with taxol 6- α hydroxylation being the most selective marker activity. **CYP2C9** is very abundantly expressed in human liver and has a broad substrate specificity accepting many weakly acidic substances like the hypoglycemic agent tolbutamide, the anticoagulant warfarin, the anticonvulsant phenytoin and several NSAIDs (nonsteroidal antiinflammatory drugs). **CYP2C19** substrates are (S)-mephenytoin, the 4-hydroxylation of which provides a very specific marker activity, the \blacktriangleright proton pump inhibitor omeprazole, the antimalarial proguanil, and diazepam. All *CYP2C* genes are genetically polymorphic. Clinically relevant are the two major variant alleles of *CYP2C9*, *2C9*2* and *2C9*3* which are associated with decreased enzyme activity, as well as the genetic polymorphism of *CYP2C19*, also known as the S-mephenytoin polymorphism, which affects about 3–5% of Caucasians and up to 20% of Asian populations in the homozygous form. **CYP2C18** was found to be expressed in liver only as mRNA but not as a protein.

CYP2D6 was the first P450 for which a classical pharmacogenetic polymorphism became known. The enzyme and its gene, which is localized together with two pseudogenes on chromosome 22, has been very thoroughly studied [4]. CYP2D6 is responsible for more than 70 different drug oxidations, mostly of substrates containing a basic nitrogen. They include antiarrhythmics (e.g. propafenone), antidepressants (e.g. amitriptyline, venlafaxine), antipsychotics (e.g. thioridazine), beta-Blockers (e.g. metoprolol), opioids (e.g. codeine) and more. Sparteine and debrisoquine, which are no longer in use, lead to the discovery of the genetic *CYP2D6* polymorphism, also known as the sparteine/debrisoquine polymorphism. More than 50 functionally distinct alleles which are associated with either complete lack of function (null-alleles) or with decreased or increased enzyme activity are known

(CYPallele nomenclature homepage at ►<http://www.cypalleles.ki.se>). The individual inherited allele combination (genotype) determines whether an individual will have the ►ultrarapid metabolizer (UM), extensive (EM), intermediate (IM) or ►poor metabolizer (PM) phenotype. About 5–10% of Caucasians carry two null-alleles and are consequently PMs; about 10–15% are IMs carrying alleles with reduced function, and about 10% are UMs some of whom carry an allele with a duplicated functional gene. In other ethnic populations, these percentages can be very different. Thus, in Asians the PM phenotype has a frequency of only 0.5–1%, whereas in certain Arabian and Eastern African populations, the frequency of the UM phenotype can be as high as 30%. The phenotype can be determined either by using one of several available specific probe drugs, e.g. dextrometorphan or metoprolol, or it can be predicted by genetic diagnosis.

CYP2E1 (chromosome 10) metabolizes small molecules including ethanol, halogenated hydrocarbons like halothane, as well as small aromatic and heterocyclic compounds, many of which also act as inducers. For example, it is known that CYP2E1 is induced in alcoholics. Only few drug substrates of CYP2E1 are known, but the enzyme activates many xenobiotic metabolites to toxic intermediates. Chlorzoxazone 6-hydroxylation has been proposed as a marker activity. Several polymorphisms were described in the *CYP2E1* gene, some of which were found to be more frequent in Asians and believed to be associated with increased cancer risk linked to smoking.

CYP2F1 appears to be expressed preferentially in lung where it bioactivates the selective pneumotoxins 3-methylindole and naphthalene.

CYP2J2 is abundant in cardiovascular tissue and active in the metabolism of arachidonic acid to eicosanoids that possess potent anti-inflammatory, vasodilatory, and fibrinolytic properties. Polymorphic alleles with reduced function are known. Some other *CYP2* subfamilies and isozymes listed in Table 1 are still not well characterized, in part because most of them were discovered in the course of the human genome project.

The **CYP3A** subfamily is highly important for human drug metabolism. CYP3A4 plays the major role because it is abundantly expressed not only in liver but also in intestinal enterocytes. CYP3A4 makes significant contributions to the metabolism of more than half of all clinically used drugs including large molecules like the immunosuppressant cyclosporin A, macrolide antibiotics like erythromycin, or anticancer drugs like taxol, and smaller molecules like benzodiazepines, HMGCoA reductase inhibitors, anaesthetics and many more. CYP3A4 expression levels are increased following exposure to a number of drugs that bind to the nuclear receptor PXR (pregnane X-receptor) which

increases the rate of *CYP3A4* gene transcription. Furthermore, there are sex-related differences in CYP3A4 expression with women having significantly higher levels, which translate into higher *in vivo* clearance of several drug substrates. Whereas genetic polymorphism does not appear to play a major role in determining CYP3A4 activity, expression of the two subfamily members, CYP3A5 and CYP3A7, is confined to a smaller fraction of the population who carry particular alleles of these genes. CYP3A7 is more abundantly expressed in fetal liver than in adult liver. CYP3A43 was found to be expressed at very low levels.

CYPs in Physiological Pathways

Most of these enzymes have steroids or fatty acids as their substrates (Table 1). Many P450s in endogenous biotransformation pathways are characterized by usually very narrow substrate and product specificity and by tight regulatory systems, especially those involved in steroid hormone biosynthesis.

The **CYP4** family comprises a larger number of subfamilies and isozymes. The major substrates for CYP4A forms are fatty acids which are hydroxylated at their omega position. The physiological significance of this is largely unknown. Non-fatty acid substrates may be metabolized by specific CYP4A forms. Expression of CYP4 enzymes is regulated by peroxisome proliferators like clofibrate (peroxisomes oxidize fatty acids), drugs that bind to another nuclear receptor termed PPAR (peroxisome proliferator activated receptor).

CYP5 synthesizes thromboxane A₂, a fatty acid in the arachidonic acid cascade that causes platelet aggregation. Aspirin prevents platelet aggregation because it blocks the ►cyclooxygenases COX1 and COX2 which catalyze the initial step of the biotransformation of arachidonic acid to thromboxane and prostaglandins.

CYP7A1 catalyzes the 7 α -hydroxylation of cholesterol, the first and rate limiting step of bile acid synthesis. This is also the principal way to eliminate cholesterol. **CYP7B1** is primarily expressed in brain and catalyzes the synthesis of various neurosteroids and also the 7 α -hydroxylation of oxysterols.

CYP8A1 is the complementary enzyme to CYP5 in that it synthesizes prostacyclin in the arachidonic acid cascade. **CYP8B1** catalyzes the steroid 12-alpha hydroxylation in the cholic acid biosynthesis.

CYP11A1 is known as the mitochondrial side chain cleavage enzyme that converts cholesterol to pregnenolone, the first step in steroid hormone biosynthesis. Steroid hormone levels are under tight endocrine control via the P450 enzymes involved in their biosynthesis, which are transcriptionally regulated by ACTH (adrenocorticotrophic hormone) via intracellular cAMP. Genetic defects in CYP11A1 lead to a lack

of glucocorticoids, feminization and hypertension. **CYP11B1** is the mitochondrial 11-beta hydroxylase that synthesizes cortisol and corticosterone. Genetic defects in this gene lead to congenital adrenal hyperplasia. **CYP11B2**, aldosterone synthase, hydroxylates corticosterone at C-18. Genetic deficiency of CYP11B2 is the cause of congenital hypoaldosteronism.

CYP17 is the 17 alpha-hydroxylase and 17–20 lyase, two different reactions catalyzed by one enzyme and required for production of testosterone and estrogen, respectively. Defects in this enzyme affect development at puberty.

CYP19 is known as ►aromatase that synthesizes estrogen converting ring A of the steroid nucleus into an aromatic ring. Lack of this enzyme causes a lack of estrogen and failure of women to develop at puberty. Because estrogens are involved in breast cancer development, CYP19 is an important target to develop specific anti breast-cancer agents that inhibit the enzyme.

CYP21 catalyzes steroid C21 hydroxylation required for cortisol biosynthesis. Genetic defects in this gene cause congenital adrenal hyperplasia.

CYP24 is a 25-hydroxyvitamin D3 24-hydroxylase that degrades vitamin D metabolites.

CYP26 consists of three enzymes each representing a separate subfamily (Table 1) probably are all involved in retinoic acid hydroxylation. **CYP26A1** is an all trans retinoic acid hydroxylase which degrades retinoic acid, an important signalling molecule for vertebrate development. It acts through retinoic acid receptors. The other CYP26 isozymes are also retinoic acid hydroxylases.

CYP27A1 catalyzes the side chain oxidation (27-hydroxylation) in bile acid biosynthesis. Because bile acid synthesis is the only elimination pathway for cholesterol, mutations in the *CYP27A1* gene lead to abnormal deposition of cholesterol and cholestanol in various tissues. This sterol storage disorder is known as cerebrotendinous xanthomatosis. **CYP27B1** is the 1-alpha hydroxylase of vitamin D3 that converts it to the active vitamin form. The function of **CYP27C1** is not yet known.

CYP46 hydroxylates cholesterol at the 24-position, a reaction that appears to play a role for cholesterol homeostasis in the brain.

CYP51 catalyzes lanosterol 14-alpha demethylation required in the biosynthesis of cholesterol in mammalian liver but it is also expressed in sperm where it synthesizes meiosis-activating sterols. This enzyme is evolutionarily highly conserved in plants, fungi and animals, and bacteria and may be the ancestor of all eukaryotic P450s. CYP51 enzymes are important targets for cholesterol-lowering drugs, antifungal agents like ketoconazole, and herbicides.

Pain and Nociception

ROHINI KUNER

Institute for Pharmacology, University of Heidelberg,
Heidelberg, Germany

Definition

Pain is a combination of sensory (discriminative) and affective (emotional) components. The sensory component of pain is defined as nociception.

Physiological pain constitutes a protective function as it warns the body against potentially damaging stimuli. Under certain circumstances, pain converts into a chronic disease and is manifest clinically as nociceptive hypersensitivity (►hyperalgesia and ►allodynia) or as spontaneous pain. Pathological pain syndromes include ►neuropathic pain, chronic inflammatory pain (e.g. rheumatic pain, Morbus Bechterew), neuralgias, ►causalgias, phantom limb pain, cancer pain and chronic ischemic pain (e.g. of cardiac origin), amongst many others.

Basic Mechanisms

Physiology of Pain and Analgesia

Table 1 illustrates the anatomical components of nociceptive system and their physiological functions. Harmful stimuli applied to the body activate the peripheral endings of primary sensory neurons, called ►nociceptors, whose cell bodies lie in the dorsal root ganglia (DRG) or the trigeminal ganglia. Distinct classes of nociceptors encode discrete intensities and modalities of pain. Receptor molecules that impart these specific properties to nociceptors constitute a novel area of intense investigation in pain research. These include the transient receptor potential channel V1 (TRPV1), which serves as a transducer of noxious thermal and chemical (protons) stimuli and the tetrodotoxin-resistant Sodium channels ($Na_v1.7$ and $Na_v1.8$), which act as potential generators or amplifiers in nociceptors [1].

Nociceptive information is conveyed from peripheral endorgans to the central nervous system by primary afferent fibres. Amongst these, the C-fibres and A δ -fibres, which synapse with and activate numerous second order neurons located in the superficial laminae of the spinal dorsal horn, are of arch significance in context of the physiology as well as the pathophysiology of pain. The amino acid neurotransmitter, glutamate, serves as the primary nociceptive neurotransmitter at these synapses by activating several types of ►glutamate receptors such as α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, *N*-methyl-D-aspartate (NMDA) receptors and metabotropic glutamate receptors (mGluRs). Neurotransmission

at primary afferent-second order neuron synapses is further modulated and/or mediated by other agents that are released synaptically from primary afferent terminals upon peripheral nociceptive stimulation. These include neurotransmitters, such as ►substance P (Fig. 1), calcitonin gene related peptide, somatostatin and ATP and ►neurotrophins such as brain-derived neurotrophic factor (BDNF). It is believed that AMPA and kainate receptors mediate transmission of basal (physiological) pain whereas mGluRs and substance P-, NMDA-, calcium-permeable AMPA- and BDNF-receptors play a key role in induction and maintenance of pathological pain [2].

Afferent input from cutaneous and visceral nociceptors is known to converge on spinal neurons, which accounts for the referral of pain between visceral and cutaneous structures (e.g. cardiac pain gets referred to the chest and left upper arm in patients suffering from angina pectoris). Projection neurons in the spinal dorsal horn project to cell nuclei in supraspinal areas such as the thalamus, brainstem and midbrain. Of these, the synaptic junctions in the thalamus play a very important role in the integration and modulation of spinal nociceptive and non-nociceptive inputs. Nociceptive inputs are finally conducted to the cortex where the sensation of pain is perceived (Fig. 1). The mechanisms via which the cortex processes nociceptive inputs are only poorly understood.

Nociceptive activity can be modulated at several peripheral and central relay points in pain pathways. For example activation of myelinated primary fibres that conduct non-nociceptive input reduces the activity of spinal nociceptive projection neurons and thereby reduces the perception of pain. This is potentially one mechanism via which non-pharmacological approaches such as transelectrical nerve stimulation and acupuncture might relieve pain. Local interneurons exert excitatory or inhibitory influences on projection neurons in the spinal cord (Fig. 1) and thalamus. Furthermore, spinal nociceptive output is strongly modulated by descending systems that originate at supraspinal sites, such as the periaqueductal grey, rostroventromedulla and pons. Stimulation of these brain regions, either electrically or chemically, e.g. by morphine and other opiates, produces analgesia in humans. Both facilitatory as well as inhibitory descending influences on pain have been described [3]. Descending inhibitory pathways utilise monoamines such as noradrenaline and serotonin as neurotransmitters and terminate on nociceptive neurons in the spinal cord as well as on spinal inhibitory interneurons that store and release ►opiods (Fig. 1). The latter exert both pre-synaptic and post-synaptic inhibitory actions at primary afferent synapses in the spinal dorsal horn by activating specific opiod receptors. Thus, supraspinal pathways and local spinal circuits co-ordinately modulate incoming nociceptive

Pain and Nociception. Table 1 Physiology and pathophysiology of the nociceptive system

Anatomical component	Nociceptor terminal	Afferent	Spinal cord	Brain
Normal function	Transduction	Conduction	Processing, mono- and polysynaptic-reflexes	Processing, perception, emotional components of pain, polysynaptic reflexes
Pathological change	Sensitisation, desensitisation, changes in activation thresholds	Abnormal conduction, ectopic activity, sprouting	Hypersensitivity, hyposensitivity, changes in activation thresholds, expansion or reduction of receptive fields, deafferentation, spontaneous activity	
Etiology	Trauma, viral infections, ischemia, inflammation, genetic defects	Neuropathy, genetic defects	Peripheral inflammation, peripheral neuropathy, trauma, genetic defects, spinal cord injury, inflammation in the central nervous system	
Clinical manifestation	Primary hyperalgesia, allodynia, spontaneous pain		Secondary hyperalgesia, allodynia, spontaneous pain, aberrantly referred pain	
Pharmacological intervention	NSAIDs, local anesthetics, opioid analgesics, sodium-channel blockers		Opioid analgesics, NSAIDs, calcium-channel blockers	

signals [3]. Furthermore, the ►endocannabinoid system can strongly modulate pain via actions at almost all of the avenues in the somatosensory pain pathway described above.

Processes Underlying Pathological Pain

Common pathological alterations in nociceptive pathways and their underlying etiological factors are listed in Table 1. Damaging stimuli such as trauma, viral infections, noxious temperature or noxious pressure (e.g. by tumour outgrowth) can elicit both short-term and long-term changes in the activity of nociceptors and/or central nociceptive neurons. Peripheral effects include the release of chemoactive substances from damaged cells, blood vessels or from nociceptors themselves (Fig. 1), which either activate or sensitise nociceptors. These peripheral mechanisms are typically short-term in nature and are predominantly manifest as primary hyperalgesia. Chronic nociceptor activity can also produce long-lasting sensitisation of nociceptors by transcriptional regulation of genes encoding important nociceptive molecules in dorsal root or trigeminal ganglia neurons, thereby leading to the up- or down-regulation of receptors, enzymes or other signalling molecules on primary afferent terminals [1, 2]. Such molecular events lead to alterations in transduction as well as conduction properties of primary afferents.

Nociceptive neurons in the spinal cord as well as in higher centres such as the thalamus and cortex can also undergo alterations in activity following chronic peripheral changes and trauma (Table 1). These changes are typically long-term in nature and lead to the clinical syndromes of centrally maintained pain (secondary hyperalgesia, allodynia, spontaneous pain). Alterations

in the synaptic efficacy of primary afferent-first order neuron synapses constitute a prime underlying mechanism [2]. At the molecular level, these are brought about by long-term changes in the expression and signalling mechanisms of receptors for nociceptive neurotransmitters and neuromodulators on pre-synaptic terminals and in post-synaptic cells in the spinal cord [2]. Recent studies suggest that spinal microglia play an important role in mechanisms underlying neuropathic pain by secreting pro-nociceptive neuromodulators such as ATP, BDNF etc.

Pharmacological Intervention

Avenues Targeted by Contemporary Analgesics

Synthesis Pathways for Peripheral Chemoactive Agents

Prime examples for this class of analgesics are non-steroidal anti-inflammatory drugs (►NSAIDs, e.g. aspirin, ibuprofen), which act by blocking cyclooxygenases (COX-1 and/or COX-2), the enzymes responsible for synthesis of prostaglandins, mainly prostaglandin E₂ (PGE₂), in peripheral tissues and thereby preventing or terminating the sensitisation of nociceptors (Fig. 1). A central component to NSAID-produced analgesia has been described, the mechanisms underlying it being complex. NSAIDs are particularly effective against pain in the extremities, headache, migraine and dental pain, and are generally insufficient in treating chronic central pain.

Nociceptive Conduction by Primary Afferents

Anaesthetics such as lidocaine and tetracaine reversibly block the generation and conduction of action potentials in primary afferent fibres without inducing systemic effects when applied locally to dermatotomes. Their

Pain and Nociception. Figure 1 Schematic representation of nociceptive mechanisms and their sensitisation: Noxious stimuli such as protons (H^+), heat etc., which are applied to end organs, activate nociceptors (magnified in inset on the left). Injury leads to the release of prostaglandins such as prostaglandin E_2 (PGE_2), serotonin (5-HT), nerve growth factor (NGF) and ATP from damaged cells, bradykinin (BK) from blood vessels and substance P (subP) from nociceptors. These agents either activate nociceptors directly or sensitise them to subsequent stimuli by parallel activation of intracellular kinases by G-protein-coupled receptors and tyrosine kinase receptors. Primary nociceptive afferents (C-fibres, $A\delta$ -fibres) of dorsal root ganglion (DRG) neurons synapse on second order neurons in the spinal dorsal horn (magnified in upper inset). Here, glutamate (Glu) and subP released from nociceptor terminals activate glutamate receptors (NMDAR, AMPAR, mGluRs) and neurokinin-1 receptors (NK-1), respectively, located post-synaptically on spinal neurons and induce sensitisation by modulating calcium (Ca^{2+}) signalling. These synapses are negatively modulated by spinal inhibitory interneurons, which release endogenous opioids (activate μ OR), endocannabinoids (Endocann.; activate CB1), glycine (Gly; activates GlyR) or γ -amino-butyric acid (GABA; activates $GABA_A$ and $GABA_B$). Spinal projection neurons convey nociceptive information to the brain and brainstem. Activation of descending noradrenergic and/or serotonergic systems, which originate in the brain and brainstem, leads to the activation of spinal inhibitory interneurons thereby resulting in anti-nociception.

main action is to block voltage-dependent sodium channels by physically plugging the transmembrane pore. The degree of blockade is inversely proportional to the extent of myelination on the nerve fibres. Therefore, the nociceptive C-fibres and $A\delta$ -fibres are blocked preferentially in comparison with thickly myelinated non-nociceptive primary afferents.

Opioid Receptors

Similar to endogenous opioids, opiates like morphine and other synthetic opioids activate G-protein-coupled receptors which couple to G-proteins of the $G_{i/o}$ family.

They act as analgesics by inhibiting release of nociceptive neurotransmitters from primary afferent terminals as well as by depressing post-synaptic potentials on second order neurons. Opioid receptors are also present on some nociceptors and their expression and peripheral transport is increased upon peripheral inflammation. Peripheral opioid analgesia has been established in animal models. Although clinical studies have yielded mixed results so far, this field holds great promise. Despite side effects, such as euphoria, dysphoria, sedation, respiratory depression and obstipation and tolerance and dependence phenomena which arise upon

chronic use, opioid analgesics currently constitute prime therapeutics used in the treatment of labour pain and severe chronic pain, particularly that arising from inflammation, cancer or central mechanisms.

Blockers of Sodium and Calcium Channels

Anticonvulsants, which are blockers of ion-channels, have been empirically found to be effective in symptomatic management of neuropathic pain, probably owing to the similarities between the pathophysiological phenomena underlying epilepsy and neuropathic pain [4]. Recent clinical trials support the use of sodium channel blockers, e.g. carbamazepine, lamotrigine and calcium channel blockers, e.g. Gabapentin and Ziconitide in the treatment of neuropathic pain syndromes such as painful diabetic mononeuropathy, post-herpetic neuralgia, trigeminal neuralgia and central pain [4].

Antidepressives

Antidepressive agents which increase synaptic availability of serotonin and noradrenaline have been empirically found to be efficacious against chronic pain, particularly that of neuropathic origin.

Novel and Emerging Drug Targets

Glutamate Receptors

The NMDA subtype of glutamate receptors are key mediators of chronic nociceptive phenomena in the spinal cord and the thalamus. NMDA receptor antagonists like MK-801, d, 1–2-amino-5-phosphonvaleric acid etc. effectively inhibit several kinds of chronic pain, such as neuropathic and inflammatory pain, in corresponding animal models [5]. In clinical trials, NMDA receptor antagonists were found to effectively inhibit chronic pain in humans but also to produce severe side effects on the central nervous system, including psychotomimetic effects, which limit their therapeutic application. Clinically used agents which block NMDA receptors weakly include ketamine and dextromethorphan. Development of novel drugs which selectively block specific-subtypes of NMDA receptors, e.g. NR2B-containing NMDA receptors and calcium-permeable AMPA receptors offer new hope for achieving specific analgesic effects. Furthermore, drugs acting on specific mGluR subtypes involved in nociception are currently being developed as potential analgesics.

GABA, Glycine and Cannabinoid Receptors

GABA is the most prominent inhibitory neurotransmitter in the mammalian nervous system and acts via ►GABA receptors. Activation of GABA_B receptors by GABA released from local spinal interneurons (Fig. 1) negatively modulates nociceptive transmission in the spinal cord. Agonists at GABA_B receptors

(e.g. baclofen) inhibit pain in animal models and in humans, but also produce muscle relaxation. There is scope for finding drugs selectively activating GABA_B receptors, GABA_A receptors and glycine receptors expressed in nociceptive neurons or in the spinal dorsal horn in order to block pain without affecting motor function. Furthermore, Gi-coupled receptors for cannabinoids (CB₁ and CB₂) constitute the most promising current targets for developing novel and effective analgesics.

Nociceptive Transducers

These molecules largely include membrane-bound cation channels which serve as receptors for heat (TRPV1, TRPV2), cold (ANKTM1) and protons (TRPV1, acid-sensing ion channels) etc. Several splice variants of acid-sensing ion channels as well as tetrodotoxin-resistant sodium channels (Na_v1.8, Na_v1.7) are selectively expressed in nociceptors [4]. Pharmacological intervention at these channels therefore holds promise for producing analgesics with fewer side effects on other organs. It is likely, however, that these agents will also block acute, physiological pain.

Neurotrophin Receptors

Neurotrophins such as nerve growth factor (►NGF) and ►BDNF are now emerging as important modulators of nociceptor activity as well as central mechanisms of pain. Receptors and signalling mechanisms involved in neurotrophin-produced modulation of nociception are areas of intensive current research and represent novel avenues for pharmacological intervention in chronic pain states, e.g. via humanised monoclonal antibodies against NGF. Furthermore, because of their trophic effects on injured nerves, targeting neurotrophins may be useful in regeneration of traumatised nerves as well as in arresting and reversing disease processes underlying sprouting of nociceptors in diseased states.

Palmitoylation

Palmitoylation is the post-translational lipid modification of cysteine-residues in a variety of proteins.

► Lipid Modifications

PAMPs

Pathogen-associated molecular patterns (PAMPs) are microbial components derived from pathogens such as bacteria, viruses, fungi, and parasites. PAMPs are specifically recognized by the Toll-like receptors (TLRs), which are expressed by cells of the innate immune defense such as dendritic cells and macrophages. PAMPs comprise for very diverse components including lipopolysaccharide (LPS) from Gram-negative bacteria, lipoproteins and lipopeptides, flagellin, bacterial and viral unmethylated CpG DNA, or double-stranded RNA (dsRNA) produced by most replicating viruses.

- Nuclear Factor Kappa B
- Toll-like Receptors

Pancreatic β -cell

The predominant cell type in the pancreatic islets of Langerhans. The main secretory product of the β -cell is the peptide hormone insulin which has vital actions for the control of nutrient homeostasis and cellular differentiation.

- Diabetes Mellitus
- Oral Antidiabetic Drugs
- Ca^{2+} Channel Blockers

Pancreatic Polypeptide

The hormone pancreatic polypeptide (PP) is a 36 amino acid peptide, which is closely related to *neuropeptide Y* and *peptide YY*. PP is mainly found in pancreatic cells distinct from those storing insulin, glucagon or somatostatin. It acts on receptors that belong to the family of *neuropeptide Y* receptors, particularly on the Y_4 subtype.

► Neuropeptide Y

Pantothenic Acid

E. BACK¹, H. K. BIESALSKI²

¹Novartis Pharma GmbH, Nuremberg, Germany

²University of Hohenheim, Institute of Biological Chemistry and Nutrition, Stuttgart, Germany

Synonyms

(R)-(+)-N-(2,4-dihydroxy-3,3-dimethyl-1-oxobutyl)- β -alanine)

Definition

Pantothenic acid is an unstable, highly hygroscopic viscous water and alcohol-soluble oil of light yellow color. The vitamin is stable to heat and light. In pharmaceutical preparations, Na^+ - or Ca^{2+} -salts of the alcohol panthenol are more commonly used because it has an overall higher stability. Pantothenic acid occurs in most food stuffs. Liver, kidney, and brain contain particularly high concentrations of pantothenic acid, yet numerous small contributions from other dietary sources, e.g., fruits, vegetables, milk and milk products, cereals or pulses, are more important for the coverage of daily requirements [1,2].

Figure 1 shows the structure of pantothenic acid ((R)-(+)-N-(2,4-dihydroxy-3,3-dimethyl-1-oxobutyl)- β -alanine). Only D(+)-pantothenic acid occurs naturally and is biologically active. The alcohol (R)-panthenol (= (D)-panthenol) shows biological activity as well.

Mechanism of Action

Pantothenic acid is an essential component of coenzyme A (CoA) (Fig. 2) and – as pantotheine – of fatty acid synthase. The HS-group of cysteamine is

Pantothenic Acid. Figure 1 Structure of pantothenic acid.

Pantothenic Acid. Figure 2 Structure of co-enzyme A.

in both cases the active site for the binding of acyl- or acetyl-residues. There is also a pantothenate-dependent step in the synthesis of leucine, arginine, and methionine.

The main role of CoA is acyl- and acetyl-group transfer and condensation. CoA plays a vital role in the metabolism of carbohydrates, fatty acids, and nitrogen compounds. In addition to the role in energy generation and molecular syntheses, pantothenic acid participates in regulating numerous proteins by donating acetyl- and fatty acyl-modifying groups, which alter the location and/or activity of the acylated protein [2].

Clinical Use (Including Side Effects)

Panthenol is frequently used in ointments and solutions for the treatment of burns, anal fissures, and inflammation of the conjunctiva. The vitamin has to be substituted in patients on total parenteral nutrition and in those who regularly undergo dialysis. Hypervitaminosis has not been observed for doses up to 5 g/d (22). Furthermore, the administration of pantothenic acid leads to improved surgical wound healing due to its antiinflammatory properties.

Parasympathetic Nervous System

The autonomic nervous system, which regulates functions that occur without conscious control, consists of two major divisions, the sympathetic and the parasympathetic nervous system. In the periphery, it consists of nerves, ganglia, and plexuses that provide innervation to the heart, blood vessels, glands, other visceral organs, and smooth muscle in various tissues. The parasympathetic nervous system is concerned primarily with conservation of energy and maintenance of organ function during periods of minimal activity. Acetylcholine is the neurotransmitter at all preganglionic autonomic fibers and at all postganglionic parasympathetic fibers.

Parathyroid Hormone

A major regulator of bone metabolism and calcium homeostasis, parathyroid hormone (PTH) is stimulated through a decrease in plasma ionised calcium and increases plasma calcium by activating osteoclasts. PTH also increases renal tubular calcium re-absorption as well as intestinal calcium absorption. Synthetic PTH (1–34) has been successfully used for the treatment of osteoporosis, where it leads to substantial increases in bone density and a 60–70% reduction in vertebral fractures.

Paraventricular Nucleus

The paraventricular nucleus in the hypothalamus is located adjacent to the third ventricle and has been identified as a satiety center. Neurons in the paraventricular nucleus produce neuropeptides which inhibit feeding when injected into the brain (thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH), oxytocin).

- ▶ Appetite Control

Parkin

Parkin is a ubiquitin ligase encoded by a gene affected in autosomal recessive juvenile parkinsonism (AR-JP). This gene is located on chromosome 6 and encodes a protein of 465 amino acid residues with moderate similarity to ubiquitin at the amino terminus and a RING-finger motif at the carboxy terminus.

- ▶ Ubiquitin/Proteasome System

Parkinson's Disease

Parkinson's disease (PD) is a progressive disease characterized by akinesia, muscle tremor, and rigidity resulting from the degeneration of melanin-containing cells of the substantia nigra and the resulting reduction in brain dopamine levels. PD initially responds to L-DOPA therapy but the disease eventually enters a refractory phase possibly due to the continued loss of cells. Drugs that destroy dopaminergic neurons, block dopamine synthesis or antagonize D2-like receptors have PD-like effects.

PAS Domain

PAS domains are protein domains, encompassing about 250–300 amino acids, which in higher eukaryotes function as surfaces for both homotypic interactions

with other PAS proteins and heterotypic interactions with cellular chaperones, such as the 90-kD heat shock protein (Hsp90). They are named according to the first letter of each of the three founding members of the family of PAS domain containing proteins, PER, ARNT and SIM. Most of the PAS proteins also contain basic-helix-loop-helix (bHLH) motifs immediately N-terminal to their PAS domain. The HLH domains participate in homotypic dimerization between two bHLH-PAS proteins, and they position the basic region to allow specific contacts with the major groove of target regulatory elements found in DNA. Important members of the PAS superfamily are the aryl hydrocarbon receptor (AHR), which together with ARNT forms the receptor for a class of co-planar polyhalogenated aromatic hydrocarbons like dioxins. Although structurally distinct from the group of nuclear receptors, the Ah receptor functions in similar fashion. In the absence of ligand, the receptor resides in the cytosol as an inactive complex with Hsp90. Binding of dioxins enables the receptor to translocate to the cell nucleus and to bind to specific DNA recognition motifs. Other members of the PAS superfamily include the products of the period and clock genes, which are involved in the regulation of circadian rhythms as well as hypoxia-inducible factor (HIF1), which mediates the effect of hypoxia on the regulation of the expression of a variety of genes, including those encoding erythropoietin or vascular endothelial growth factor.

Passive Diffusion

The passage of a small and/or highly lipophilic molecule through the membrane phospholipid bilayer according to the gradient of its concentrations across the plasma membrane. It is slower than facilitated diffusion, which, however, also follows the gradient of solute concentrations across the membrane.

Patch-Clamp Method

The patch-clamp technique is based on the formation of a high resistance seal (10^9 – $10^{10}\Omega$) between the tip of a glass micropipette and the cell membrane it touches (gigaohm-seal). This technique allows recordings of ionic currents through single ion channels in the intact cell membrane and in isolated membrane patches at a

defined membrane potential (voltage-clamp). Variations of the technique include whole-cell voltage-clamp recording and recordings in inside-out or outside-out membrane configurations.

PDZ Domain

Synonyms

Post synaptic density protein/Drosophila disc large tumor suppressor/zonula occludens-1 protein

Definition

Protein-protein interaction domain that binds to short peptide motifs at the C-terminal of target proteins. Particularly important in spatial organization of receptors and ion channels.

► Adaptor Proteins

PEG

Polyethylene glycol (PEG) is a polymer. PEG refers to an oligomer or polymer of ethylene oxide. PEG is a liquid or low-melting solid, depending on its molecular weight. Derivatives of PEG are in common use, the most common derivative is the methyl ether (methoxypoly(ethylene glycol)), abbreviated mPEG. PEGylation, the process by which polyethylene glycol chains are attached to proteins or peptide drugs, making these more resistant to degradation by proteolytic enzymes. By increasing the molecular mass of proteins/peptides and shielding them from proteolytic enzymes, PEGylation improves pharmacokinetics.

- ▶ Tumor Necrosis Factor (TNF)

Pellagra

The clinically manifest form of niacin deficiency is called pellagra. Early symptoms are unspecific, including sleep disturbance, lack of appetite, weight reduction, diarrhea, and abdominal pain. Typical symptoms of more severe stages relate to skin (symmetrical, pigmented, and itching areas on sun-exposed skin), intestinal tract (glossitis, stomatitis, vomiting), and nervous system (pain and numbness of extremities, peripheral neuritis, psychological changes).

- ▶ Niacin

Pemphigus Blistering Disease

Pemphigus describes a group of rare autoimmune blistering diseases of the skin caused by autoantibodies to desmosomal components. These antibodies lead to a loss of adhesion between keratinocytes, called acantholysis. In pemphigus vulgaris, which is caused by autoantibodies to desmoglein 3, the blisters are located in the suprabasal layer, whereas in pemphigus foliaceus, which is caused by autoantibodies to desmoglein 1, the blisters occur within the upper layers of the epidermis. The major therapeutic strategy in pemphigus is chronic immunosuppressive therapy with glucocorticosteroids in combination with immunosuppressive adjuvants.

Peptide Mass Fingerprint

Peptide mass fingerprinting (PMF) is a mass spectrometry based method for protein identification. The protein is cleaved by an enzyme with high specificity (trypsin, Lys-C, Asp-N, etc.) or chemical (CNBr). The peptide mixture generated is analyzed by matrix-assisted laser desorption/ionization (MALDI) or electrospray ionization (ESI)

mass spectrometry. The determined set of masses (mass fingerprint) is characteristic for the protein present and is used to search peptide masses generated by theoretical fragmentation of protein sequences in databases.

► Proteomics

Peptide YY

The hormone peptide YY (PYY) is a 36 amino acid peptide, which is closely related to *neuropeptide Y* and *pancreatic polypeptide*. PYY is predominantly synthesised and released by intestinal endocrine cells, and can also coexist with glucagon in pancreatic acini and enteroglucagon in endocrine cells of the lower bowel. It acts on the same receptors as *neuropeptide Y*. The endogenous long C-terminal PYY fragment PYY_{3–36} is a biologically active and subtype-selective metabolite.

► Neuropeptide Y

Peptidoglycans

Peptidoglycans are covalently closed net-like polymers forming the rigid matrix of the bacterial cell wall. Glycan chains of alternating *N*-acetylglucosamine and *N*-acetylmuramic acid residues are substituted for by *L*-alanyl- γ -*D*-glutamyl-*L*-diaminoacyl-*D*-alanine stem tetrapeptides, and cross-linked through direct interpeptide linkages or cross bridges. Bacteria that are actively multiplying (i.e. in the exponential phase of growth) manufacture a (4–3) peptidoglycan in a penicillin-susceptible manner. Cross linking involves the carbonyl of the *D*-alanine at position 4 of a stem peptide and the ω -amino group of the diaminoacid residue at position 3 of another stem peptide. Bacteria also manufacture a (3–3) peptidoglycan in a penicillin-resistant manner, conferring intrinsic resistance to β -lactam antibiotics. Cross linking involves the carbonyl of the diaminoacid residue at position 3 of a stem peptide and the ω -amino group of the diaminoacid residue also at position 3 of another stem peptide.

Peptidyl Transferase Center

The peptidyl transferase center is the site of peptide bond formation on the ribosome and the target for a chemically diverse set of antibiotics. It is located in a cavity on the 50S subunit that leads into a peptide exit tunnel that passes through the body of the 50S subunit. The active site is in a deep cleft that is packed with nucleotides from the highly conserved internal loop in domain V of 23S ribosomal RNA (rRNA), termed the peptidyl transferase loop. In general, the single-stranded nucleotides in the loop are the closest to the active site, with the helices around the internal loop radiating away from the catalytic center. The peptidyl transferase loop has previously been implicated as a component of the catalytic site through the localization of chemical footprints and crosslinks from both antibiotics and transfer RNAs (tRNAs) to this region. In addition, for many of the peptidyl transferase antibiotics, mutations at single nucleotides in the peptidyl transferase loop produce antibiotic resistance.

► Ribosomal Protein Synthesis Inhibitors

Peptidyl-Dipeptidase

An exopeptidase that sequentially releases dipeptides from the C-terminus of a protein or peptide. An example is angiotensin-converting enzyme (also known as peptidyl-dipeptidase A; *MEROPS* XM02-001), which plays an important role in the control of blood pressure by converting angiotensin I to angiotensin II. Peptidyl-dipeptidases are included in Enzyme Nomenclature sub-subclass 3.4.15.

► Non-viral Peptidases

PER1

(Period 1) Clock gene and transcriptional repressor and negative limb (complex with CRY, PER2) of molecular circadian oscillators, essential for circadian clock plasticity and entrainment.

► Orexins

Percutaneous Coronary Intervention

Percutaneous coronary intervention (PCI) is one of a host of techniques performed by using a catheter inserted via a major limb artery that aims to relieve narrowing of coronary arteries. For example, percutaneous transluminal coronary angioplasty (PTCA) is the classic PCI that uses a catheter-directed balloon to dilate a stenotic coronary artery, and more recent PCIs include stent implantation, rotational atherectomy, and laser angioplasty.

► Anticoagulant

Periaqueductal Grey

The periaqueductal grey (PAG) is a major part of the descending inhibitory antinociceptive system. The periaqueductal grey area is localized in the midbrain, a small area of grey matter surrounding the central canal. Neurons of the PAG are excited by opioids leading to the stimulation of cells in the nucleus raphe magnus, which, via the dorsolateral funiculus, send projections to the dorsal horn which are mainly serotonergic. These serotonergic and opioidergic neurons lead to the inhibition of nociceptive transmission in the dorsal horn.

► Nociception

Pericytes

Pericytes are mural cells which stabilise capillaries and control functions of capillary endothelial cell properties.

► Angiogenesis and Vascular Morphogenesis

Peripheral Nerve

A peripheral nerve comprises different axons responsible for different modalities. It may contain efferent myelinated motor fibres, efferent unmyelinated autonomic fibres

or afferent myelinated and unmyelinated sensory fibres. Depending on size, myelination and conduction velocity fibres are named A-, B- or C-fibres.

► Local Anaesthetics

Peripheral Neuropathy

Peripheral neuropathy is degeneration of peripheral nerves. Because motor and sensory axons run in the same nerves, usually both motor and sensory functions are affected in this disease. Neuropathies may be either acute (e.g., Charcot-Marie-Tooth disease) or chronic (e.g., Guillain-Barre syndrome) and are categorized as demyelinating or axonal.

► Neurotrophic Factors

Peroxisome Proliferator-Activated Receptors

JANE A. PINAIRE, ANNE REIFEL-MILLER
Lilly Research Laboratories, Eli Lilly and Company,
Indianapolis, IN, USA

Synonyms

PPARs; PPAR α : NR1C1; PPAR δ : NR1C2, PPAR β , NUC1, FAAR (fatty acid-activated receptor); PPAR γ : NR1C3

Definition

The peroxisome proliferator-activated receptors (PPARs), members of the ►nuclear receptor superfamily, are ►transcription factors and their activity is modulated by the binding of ligand. Ligand binding (►drug-receptor interaction) elicits (i) binding of the receptor to specific DNA response elements located in close proximity to the promoter region of target genes and (ii) activation of target gene transcription. Three distinct PPAR isotypes exist: PPAR α , PPAR γ , and PPAR δ . The PPARs play essential roles in mediating lipid and glucose metabolism and homeostasis. In addition, recent evidence suggests that PPARs have important functions in additional diverse physiological processes

including ►inflammation and ►atherosclerosis, reproduction and fertility, ►Cell Cycle Control, skin biology and wound healing, cancer, and normal development of the nervous system.

Basic Characteristics

The Nuclear Receptor Family

The nuclear receptor (NR) family of transcription factors is quite large (65 distinct NR genes identified throughout the animal kingdom from nematodes to man) and may be categorized into three sub-groups: classic hormone receptors such as the glucocorticoid, estrogen, thyroid, retinoic acid, and vitamin D receptors; “sensor” receptors such as the PPARs, the liver X receptor (LXR), the farnesol X receptor (FXR), and the retinoid X receptor (RXR); and ►orphan nuclear receptors such as apolipoprotein A-I regulatory protein-1 (ARP-1) and chicken ovalbumin upstream promoter transcription factor (COUP-TF). In general, these categories describe characteristics of ligand binding. Ligands specific for the orphan receptors, if any exist at all, have not been identified to date. Classic hormone receptors bind specific ligands with high affinity. On the other hand, a broad range of lipophilic molecules bind to the “sensor” receptors, generally with lower affinity as compared to hormones that bind to the classical hormone receptors. The molecules that bind and activate the PPARs are most likely fatty acid-derived key metabolic substrates and intermediates that, by binding and modulating receptor activity and target gene transcription, provide a mechanism for rapid response to changes in metabolic status. The natural (endogenous) and synthetic (exogenous) ligands of the PPAR isotypes will be described in greater detail below. The current opinion is that alterations in the levels of fatty acids or fatty acid-derived molecules, resulting from changes in food availability (fasting/feeding/exercise) or pathophysiological conditions (chronic inflammation, ►insulin resistance, type 2 ►diabetes mellitus, atherosclerosis, or cancer), signal the appropriate PPAR isotypes to mediate lipid catabolism or storage.

The PPAR Isotypes

All members of the NR family are thought to have evolved from a common ancestral orphan receptor. Phylogenetic analysis suggests the ancestral NR appeared early during evolution, and the large number of family members has resulted from two distinct waves of gene duplication. The first wave generated an ancestral PPAR, whereas the vertebrate-specific second wave gave rise to the distinct PPAR isotypes. Once the three isotypes emerged, each is thought to have independently developed the ability to bind various ligands. Each isotype is encoded by a distinct gene. The first PPAR gene identified was mouse PPAR α . Initially

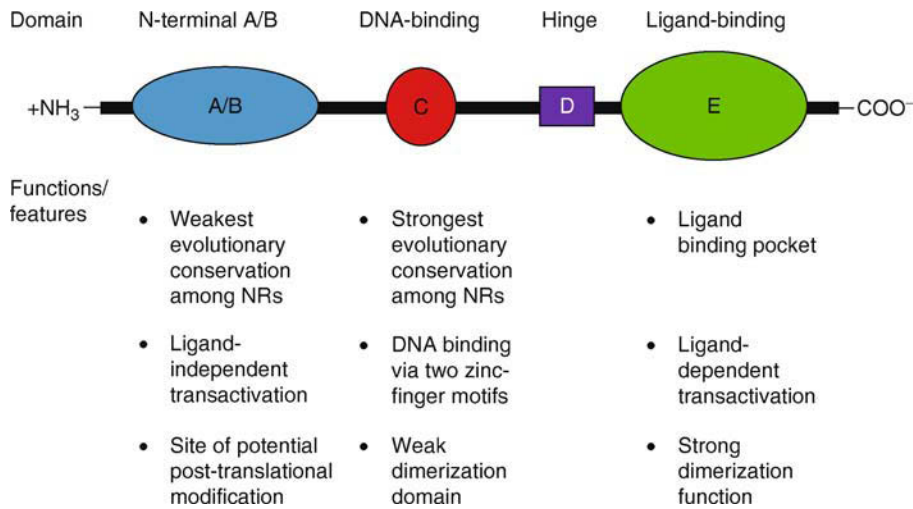

classified as an orphan receptor, the mouse PPAR α was subsequently found to be activated by peroxisome proliferators (PPs), hence the name peroxisome proliferator-activated receptor. Peroxisome proliferators are a structurally diverse group of compounds that induce proliferation of peroxisomes and hepatocarcinogenesis in rodents and include the widely used hypolipidemic fibrate drugs, such as fenofibrate (Tricor[®]) and gemfibrozil (Lopid[®]), as well as phthalate ester plasticizers, some herbicides, and chlorinated hydrocarbons. Peroxisomes are small membrane-bound compartments present in the cells of most eukaryotes and contain the enzymes for β -oxidation of long-chain fatty acids. Treatment of rodents with PPs predominantly affects the liver, with increased liver size due to both cellular hypertrophy and hyperplasia. In addition to increases in the size and number of peroxisomes, transcription of the genes encoding enzymes responsible for peroxisomal β -oxidation is also induced. Peroxisome proliferation and hepatocarcinogenesis are not seen in humans.

Modular Domain Structure of PPARs

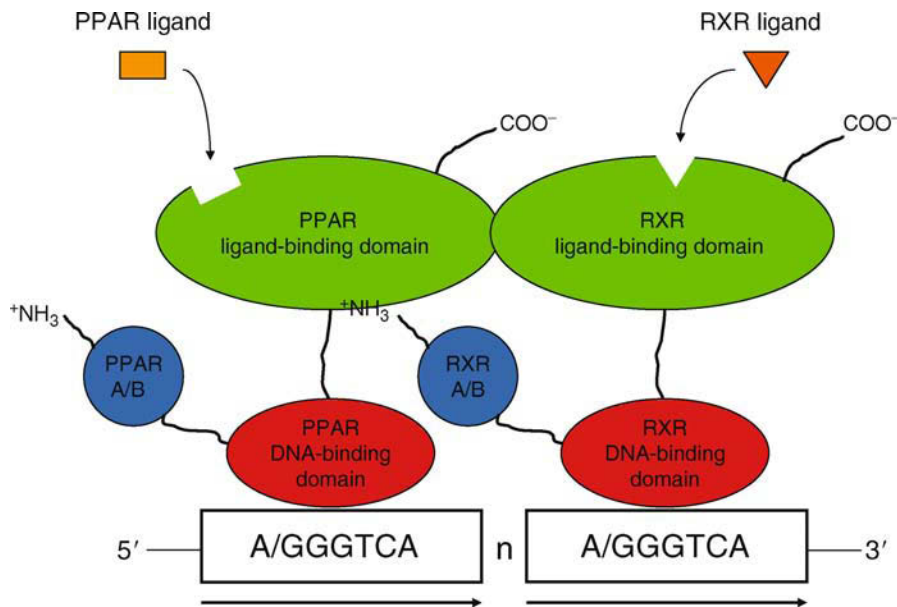

Consistent with other members of the NR family, the PPARs have a modular structure composed of five distinct regions (A–E) as shown in Fig. 1. The N-terminal A/B region is the least conserved among the NRs, and its length differs significantly among the NRs. Furthermore, this region is often a site for post-translational modification of receptor activity. The A/B region contains a weak ligand-independent transcriptional activation function (AF-1). Region C, the most highly conserved region among the NRs, contains the DNA-binding domain with its two zinc-finger motifs, the hallmark characteristic of the NR family. The D region serves as a hinge, allowing the more conserved and structured C and E domains to swivel to accommodate multiple conformations. Region E is also highly conserved and contains several distinct functions: the ligand-binding domain, the ligand-dependent transcriptional activation function (AF-2), and the primary dimerization domain.

DNA Recognition by PPARs

Response elements bound by members of the NR family consist of a consensus DNA hexamer (A/GGGTCA) arranged as either a single half-site or, more often, as two tandem half-sites arranged as direct, inverted (palindrome), or everted repeats. The spacing between the half-sites also plays a role in determining specificity for different NRs. In general, the majority of PPAR responsive elements (PPAR-RE) identified in genes responsive to PPAR ligands have a DR1 (direct repeat separated by 1 spacer nucleotide) structure, though other more complex PPAR-REs have been reported. As shown in Fig. 2, PPARs only bind DNA

Peroxisome Proliferator-Activated Receptors. Figure 1 Common structural and functional features of nuclear receptor transcription factors. Consistent with other members of the nuclear receptor superfamily, the PPARs have a modular domain structure consisting of domains A/B, C, D, and E. Each domain is associated with specific functions.

Peroxisome Proliferator-Activated Receptors. Figure 2 Binding of PPAR:RXR heterodimers to DR1 PPRE-responsive elements. *Abbreviations:* DR1, a direct repeat organization of the A/GGGTCA hexamer half-site separated by a single nucleotide spacer.

as heterodimers with the ►retinoid X receptor (RXR), another “sensor receptor” member of the NR family, and cannot bind DNA target elements as homodimers or monomers. There is a distinct “polarity” of the PPAR:RXR heterodimer, with the PPAR occupying the 5′ position and RXR the 3′ position when bound to the DR1 PPAR-RE.

Mechanism of Transcriptional Activation by PPAR Ligands

Figure 3 provides a very general overview of transcriptional activation in response to a PPAR ligand. Fig. 3a shows the schematic representation of a PPAR target gene in the absence of PPAR ligand. Co-repressor proteins bound to both unliganded PPAR and RXR

Peroxisome Proliferator-Activated Receptors. Figure 3 Transcription of PPAR target genes. A schematic representation of the transcription of PPAR-regulated genes in the absence (a) and presence (b) of PPAR ligand. *Abbreviations:* PPAR-RE, peroxisome proliferator-activated receptor-response element; RNA Pol II, RNA polymerase II; TATA-BP, TATA-binding protein.

possess enzyme activities (deacetylation, demethylation) that condense the chromatin, making it inaccessible to the transcriptional machinery (RNA Polymerase II and associated transcription factors). Fig. 3b shows the changes in the promoter region in response to the presence of ligand. Ligand binding promotes the dissociation of co-repressor proteins from PPAR and RXR and favors association with co-activator proteins. Co-activator proteins possess enzyme activities (acetylation and methylation) that decompact chromatin, making it accessible for binding by the transcriptional machinery. Importantly, the transcriptional activity of a gene is the result of the integration of multiple physiological signals (developmental, nutritional (fasting or fed), hormonal, or cell-specific) converging at the gene promoter.

Physiological Functions of PPARs

The tissue-specific patterns of expression of the PPAR isotypes suggested that these proteins have distinct physiological roles, and this was further supported when each was specifically disrupted in mouse gene knockout models.

PPAR α

Tissue-Specific Expression. In adult rodents, PPAR α is expressed in liver, kidney, intestine, heart, skeletal muscle, retina, adrenal gland, and pancreas. In adult human, PPAR α is expressed in the liver, heart, kidney, large intestine, skeletal muscle (mostly slow-twitch oxidative type I fibers), and in cells of atherosclerotic lesions (endothelial cells, smooth muscle cells, and monocytes/macrophages). Therefore, regardless of

species, PPAR α expression is highest in tissues with high rates of fatty acid catabolism.

Natural PPAR α Ligands. Multiple molecules endogenous to the cellular environment have been shown to bind and activate PPAR α *in vitro*, but it remains unclear whether there is a single predominant PPAR α ligand *in vivo*. Molecules demonstrated to bind PPAR α include mono- and polyunsaturated fatty acids and various fatty acid-derived eicosanoids. Interestingly, mice without a functional gene encoding fatty acid synthase (FAS) exhibit a phenotype very similar to fasted mice lacking a functional PPAR α gene: defects in fatty acid oxidation and severe hypoglycemia. These defects in FAS-deficient mice are corrected with treatment of PPAR α agonist, suggesting that FAS activity may regulate PPAR α activity by providing newly synthesized ligand and that, as ligands and activators of PPAR α , fatty acids derived from adipose depots may not be equivalent to fatty acids synthesized *de novo* via FAS.

Insight from the PPAR α Knockout Mouse. PPAR α -deficient adult mice are viable, fertile, and healthy, indicating that PPAR α is not essential for embryonic development. When adult PPAR α ^{-/-} mice are treated with fibrates, the characteristic response to PP is abolished, with no liver weight increase, no increase in

the size or number of peroxisomes, and no transcriptional induction of genes involved in peroxisomal β -oxidation. Furthermore, lipid droplets deposited in hepatocytes suggest a key role for PPAR α in maintaining normal lipid homeostasis. In the past decade since the PPAR α ^{-/-} mouse model was first reported, a wealth of evidence has confirmed the essential role of PPAR α in fatty acid catabolism via peroxisomal and mitochondrial β -oxidation and in **lipoprotein metabolism**. Table 1 summarizes the role of PPAR α in hepatic lipid metabolism, lipoprotein metabolism, and atherosclerosis.

PPAR γ

Tissue-Specific Expression. In the adult rodent, PPAR γ is expressed in brown and white adipose tissue, and at lower levels in intestine, retina, skeletal muscle, and lymphoid organs. In human, PPAR γ is most abundantly expressed in white adipose tissue and at lower levels in skeletal muscle, the heart, and liver, but not in lymphoid tissues, although PPAR γ has been identified in macrophages in human atheromas.

Natural PPAR γ Ligands. Endogenous ligands demonstrated to bind and activate PPAR γ *in vitro* include unsaturated fatty acids and their derivatives such as prostaglandin J2 (15-deoxy- Δ 12,14-PGJ2). Consistent

Peroxisome Proliferator-Activated Receptors. Table 1 PPAR α target tissues, cellular effects, and physiological effects

Tissue	Cellular effects	Physiological effects
Liver	↑ Fatty acid uptake into hepatocytes	↓ VLDL production
	↑ Peroxisomal and mitochondrial fatty acid β -oxidation	↑ Clearance of TG-rich lipoproteins
	↑ Transcription of lipoprotein lipase (LPL) gene	↓ Circulating TG concentrations
	↓ Synthesis of apoC-III (inhibitor of LPL)	↓ Proportion of small, dense LDL-C particles
	↑ Transcription of apoA-I and apoA-II genes (components of HDL)	↑ Proportion of large LDL-C particles (more efficiently cleared by the LDL-receptor)
		↑ Circulating HDL-C concentrations
↑ Reverse cholesterol transport (delivery of excess cholesterol in the peripheral tissues to the liver via HDL-C for hepatic excretion into the bile)		
	↓ Hepatic markers of inflammation (CRP, fibrinogen, etc.)	
Pancreas	↑ Fatty acid oxidation	Protection of pancreatic β -cells from lipotoxicity
	Potentiation of glucose-stimulated insulin secretion	
Atherosclerotic lesion	↓ Monocyte recruitment	↓ Progression of atherosclerosis
	↓ Expression of adhesion molecules	
	↓ LDL oxidation	
	↑ Cholesterol efflux from foam cells	
	↓ Inflammation and smooth muscle cell proliferation	

Abbreviations: apoC-III, apolipoprotein C-III; apoA-I, apolipoprotein A-I; apoA-II, apolipoprotein A-II; CRP, C-reactive protein; VLDL, very low density lipoprotein; TG, triglycerides; LDL-C, low density lipoprotein cholesterol; HDL-C, high density lipoprotein cholesterol.

with the other PPAR isotypes, it is unclear whether a predominant bioactive ligand exists *in vivo*.

Insight from the PPAR γ Knockout Mouse. Deletion of the PPAR γ gene results in embryonic lethality. At day 9.5 of gestation or earlier PPAR $\gamma^{-/-}$ embryos are viable, but no PPAR $\gamma^{-/-}$ embryos are viable after E9.5. This embryonic lethality is due to defects in the placenta leading to cardiac defects. When the placenta defect was corrected by genetic placental reconstitution, one PPAR $\gamma^{-/-}$ pup survived to term and demonstrated marked abnormalities in lipid deposition (lipodystrophy and fatty liver) and hemorrhages leading to death during the first week of life. Consistent with the tissue expression of PPAR γ , the PPAR γ -null mouse indicated that the receptor has essential roles in maintaining normal adipose tissue development. Subsequent studies have shown that PPAR γ plays a pivotal role in adipocyte differentiation and metabolism, insulin sensitivity, inflammation, and atherosclerosis. More recently PPAR γ has been implicated as both a tumor suppressor and a tumor promoter. The diverse functions of PPAR γ are summarized in Table 2.

PPAR δ

Tissue-Specific Expression. In the adult rat, PPAR δ is expressed in all tissues examined, and often at levels higher than PPAR α and PPAR γ . In human, PPAR δ is ubiquitously expressed, with higher expression in the digestive tract and placenta.

Natural PPAR δ Ligands. Similar to the other PPAR isotypes, endogenous ligands shown to bind and activate PPAR δ *in vitro* include fatty acids and eicosanoids, and it is not clear whether PPAR δ is preferentially bound and activated by specific ligands *in vivo*. However, fatty acids derived from very low density lipoprotein (VLDL) particles have been shown to activate PPAR δ target genes in a receptor-dependent manner, suggesting that fatty acids delivered to tissues via VLDL may possibly bind and activate PPAR δ *in vivo*.

Insight from the PPAR δ Knockout Mouse. For many years the physiological relevance of PPAR δ was unclear, in large part due to its ubiquitous expression which led to the assumption that this isotype served a “general housekeeping” role. However, deletion of the PPAR δ gene results in frequent (>90%) midgestation lethality due to defects of the placenta. All adipose depots are substantially decreased in adult PPAR δ -deficient animals; abdominal fat, interscapular brown fat, mesenteric fat, and adipose stores associated with internal organs are all underdeveloped compared to wild type animals through a decrease in adipocyte number. The subcutaneous fat layer, on the other hand, is approximately twofold thinner in PPAR δ -null animals by a reduction in both adipocyte number and size. The PPAR $\delta^{-/-}$ mouse provided evidence that, similar to the PPAR α and PPAR γ isotypes, PPAR δ has an important role in normal adipose development

Peroxisome Proliferator-Activated Receptors. Table 2 PPAR γ target tissues, cellular effects, and physiological effects

Tissue	Cellular effects	Physiological effects
Adipose	Adipocyte differentiation	↑ Proportion of small, insulin sensitive adipocytes
	Adipose remodeling; increase in subcutaneous adipose depots; decrease in visceral depots	↓ Proportion of hypertrophic, insulin resistant adipocytes
	↑ Transcription of lipoprotein lipase, fatty acid transport protein, and oxidized LDL receptor	Redirects fat for storage from visceral to subcutaneous adipose depots
	↑ Transcription of PPAR γ -coactivator 1 α (PGC-1 α)	↑ Expression of genes promoting storage of fat in subcutaneous adipocytes
	↑ Insulin sensitivity ^a	↑ Mitochondrial biogenesis, increasing fatty acid oxidation in adipocytes
	Altered expression and secretion of adipose tissue-derived factors thought to affect insulin sensitivity: adiponectin, TNF- α , IL-6, etc.	↑ Insulin sensitivity and glucose-lowering
Macrophage/atherosclerosis	↑ Reverse cholesterol transport from foam cells	↓ Progression of atherosclerosis
	↓ Expression of multiple inflammatory proteins	
Multiple cancers (colon, breast, prostate and others)	Tumor suppressor effects	To be determined
	Colon cancers with APC gene mutations: tumor promoter effects	

^aThe exact mechanism by which PPAR γ ligands affect insulin resistance (improved glucose uptake by peripheral tissues, most notably skeletal muscle) remains unclear.

Abbreviations: LDL, low density lipoprotein; TNF- α , tumor necrosis factor- α ; IL-6, interleukin-6; APC, adenomatous polyposis coli tumor suppressor.

Peroxisome Proliferator-Activated Receptors. Table 3 PPAR δ Target tissues, cellular effects, and physiological effects

Tissue	Cellular effects	Physiological effects
Adipose	↑ Fatty acid transport and oxidation	↑ Oxidative disposal of fatty acids
	↑ Oxidative metabolism, mitochondrial respiration and thermogenesis	↓ Storage of excess fat in adipocytes ↓ Weight gain
Skeletal muscle	↑ Fatty acid transport and oxidation	↑ Oxidative disposal of fatty acids
	↑ Oxidative metabolism, mitochondrial respiration and thermogenesis	↓ Storage of excess fat in skeletal muscle
	Muscle fiber remodeling; increased proportion of oxidative slow-twitch fibers (often increased in response to endurance training)	↓ Weight gain ↑ Glucose uptake into muscle
Heart	↑ Fatty acid transport and oxidation	↑ Oxidative disposal of fatty acids
	Maintains fatty acid oxidation as the primary source of energy in the postnatal heart	Protects against situations where fatty acid oxidation decreases and glucose utilization increases e.g., sepsis
Macrophage/ atherosclerotic lesion	Anti-inflammatory effects ^a	
Additional PPAR δ effects	↑ Serum levels of apoA-I and apoA-II (components of HDL-C)	↑↑ Circulating HDL-C concentrations ^b
	↓ Expression of <i>Niemann-Pick C1-like-1 (NPC1L1)</i> gene (a key mediator of intestinal cholesterol absorption)	↓↓ Circulating TG and LDL-C concentrations ^b
		↓ intestinal cholesterol

^aContradictory results from preliminary studies suggest that the role of PPAR δ in atherosclerosis requires further investigation.

^bThe exact mechanism by which PPAR δ ligands potently raise HDL-C levels and lower TG and LDL-C levels remains unclear.

Abbreviations: apoA-I, apolipoprotein A-I; apoA-II, apolipoprotein A-II; HDL-C, high density lipoprotein cholesterol; TG, triglycerides; LDL-C, low density lipoprotein cholesterol.

and in lipid homeostasis. Table 3 summarizes the functions of PPAR δ .

Additional Functions of PPARs

CNS Development

The expression of all three PPAR isotypes peaks in the rat central nervous system between days 13.5–18.5 of gestation, and while expression of both PPAR α and PPAR γ decline post-natally, expression of PPAR δ remains high (except for the retina, where all three isoforms are expressed in the adult rodent). An important role for PPAR δ in CNS development is underscored by the occurrence of defective myelination in the PPAR δ -null mouse.

Epidermal Maturation and Wound Healing. All three PPAR isotypes are expressed during epidermal maturation; each isotype has a specific pattern of expression in regard to development and the various layers of the epidermis. An important role for PPAR δ in the development and/or maintenance of normal skin health is indicated by the presence of defective wound healing in the PPAR δ -null mouse.

Drugs

Table 4 summarizes the physiological functions of the PPAR isotypes and their synthetic ligands.

PPAR α

Fibrates such as fenofibrate (Tricor[®]) and gemfibrozil (Lopid[®]) are FDA-approved for the treatment of dyslipidemia, and their primary effects are to lower triglycerides (TG) and raise high density lipoprotein cholesterol (HDL-C, the “good” cholesterol). Fibrates may also moderately decrease low density lipoprotein cholesterol (LDL-C, the “bad” cholesterol). Several clinical trials have demonstrated that fibrates slow the progression of atherosclerosis and reduce the risk of cardiovascular morbidity and mortality, particularly in patients with features of insulin resistance (overweight or obesity, hyperinsulinemia, hyperglycemia, or atherogenic dyslipidemia).

PPAR γ

Many synthetic ligands have been shown to bind and activate PPAR γ , but two molecules belonging to the thiazolidinedione (TZD) class have been FDA-approved for the treatment of type 2 diabetes: pioglitazone (Actos[®]) and rosiglitazone (Avandia[®]). TZDs are a class of ►oral anti-diabetic drugs, and several clinical trials have demonstrated that both pioglitazone and rosiglitazone reduce insulin resistance and improve glucose control in patients with type 2 diabetes. Although the exact mechanism by which TZDs improve insulin sensitivity remains unclear, one

Peroxisome Proliferator-Activated Receptors. Table 4 Summary of the physiological actions of PPAR isotypes and their synthetic ligands

PPAR isotype	Tissues of highest expression	Primary physiological effects	Endogenous ligands	Synthetic ligands	Associated disease state/indication
PPAR α	Liver, heart, skeletal muscle, atherosclerotic lesions	TG- and LDL-C-lowering and HDL-C-raising; re-directs excess cholesterol from the peripheral tissues to the liver for excretion into the bile via HDL-C; slowed progression of atherosclerosis	Fatty acids, eicosanoids: (fatty acids derived from FAS?)	Fibrates; fenofibrate (Tricor [®]), genfibrozil (Lopid [®])	Dyslipidemia
PPAR γ	White adipose tissue, atherosclerotic lesions	Insulin-sensitizing and glucose-lowering; re-directs TG from non-adipose tissues and visceral adipose depots for storage in subcutaneous adipose tissue; slowed progression of atherosclerosis	Fatty acids, eicosanoids	Thiazolidinediones; pioglitazone (Actos [®]), rosiglitazone (Avandia [®])	Type 2 diabetes, (insulin resistance, metabolic syndrome)
PPAR δ	Ubiquitous	Potent TG- and LDL-C-lowering and potent HDL-C-raising; increased oxidative disposal of fatty acids in adipose and skeletal muscle; thermogenesis; weight loss	Fatty acids, eicosanoids; (fatty acids derived from VLDL particles?)	GW501516 <i>currently in Phase II clinical trials</i>	Dyslipidemia, obesity? atherosclerosis?

Abbreviations: TG, triglycerides; LDL-C, low density lipoprotein cholesterol; HDL-C, high density lipoprotein cholesterol; FAS, fatty acid synthase; VLDL, very low density lipoprotein.
 US product information: Actos[®]: ▶ <http://www.Actos.com>; Avandia[®]: ▶ <http://www.Avandia.com>; Tricor[®]: ▶ <http://www.tricortablets.com>; Lopid[®]: ▶ <http://www.pfizer.com>.

potential mechanism is that TZDs increase plasma levels of adipose-derived factors (▶ **adipokines**) associated with improved insulin sensitivity while decreasing plasma levels of several adipokines associated with insulin resistance.

PPAR δ

Although no PPAR δ -specific ligands are currently FDA-approved, GW501516 is a compound being developed jointly by GlaxoSmithKline and Ligand Pharmaceuticals. This compound is currently in Phase II trials for the treatment of dyslipidemia.

In summary, the PPARs coordinately function to decrease lipid content in non-adipose tissues by a variety of mechanisms, and in doing so improve insulin sensitivity and glucose control and slow the progression of atherosclerosis. Although these functions of PPARs are currently the best understood, additional roles of PPAR isotypes in other diverse physiological processes is being investigated. As additional roles are defined, PPAR isotypes will continue to be important molecular targets for identifying ligands (drugs) with potential applications to reproduction and fertility, myelination and normal development of the nervous system, and cell-cycle control, skin biology, wound-healing and cancer.

Peroxynitrite

A potent oxidant that is formed by NO reacting with superoxide anions.

- ▶ Nitric Oxide

Pertussis Toxin

Pertussis toxin is produced by the bacterium *Bordetella pertussis*. It covalently modifies G-proteins of the G_i/G_o family (transfer of a ADP-ribose moiety of NAD onto G-protein α -subunits). ADP-ribosylated G-proteins are arrested in their inactive state and, as a consequence, functionally ‘uncoupled’ from their respective effectors. Examples for pertussis toxin-sensitive cellular responses include the hormonal inhibition of adenylyl cyclases, stimulation of K^+ channels, inhibition of Ca^{2+} channels and stimulation of the cGMP-phosphodiesterase in retinal rods.

- ▶ Somatostatin
- ▶ Transmembrane Signaling
- ▶ Heterotrimeric GTP-Binding Proteins

PEST Sequences

PEST sequences are protein regions with a high content of the amino acid regions proline (P), glutamate (E), serine (S), and threonine (T). These sequences often serve as destruction signals recognized by the ubiquitin proteasome system (UPS). Phosphorylation of serine or threonine residues in these regions appears to be the trigger for recognition by certain SCF-RING ubiquitin (Ub) ligases.

- ▶ Ubiquitin/Proteasome System

PGI₂

Prostacyclin.

- ▶ Prostanoids

P-Glycoprotein

The permeability-glycoprotein (P-gp) is the first ABC-transporter identified in human. It is also termed ABCB1 or MDRA and eliminates a variety of structurally unrelated compounds from the cell. P-gp is highly expressed in certain cancer cells thereby conferring resistance against many anticancer drugs. P-gp is also expressed in normal tissues like the blood–brain barrier, the intestine, or the blood–placenta barrier, where it protects the brain, the body and the growing foetus against toxic compounds.

- ▶ MDR-ABC Transporters
- ▶ ABC-Transporter

PH Domain

Synonyms

Pleckstrin homology

Definition

Domains consisting of about 120 amino acid residues. Important for localizing target proteins to the plasma membrane.

- ▶ Adaptor Proteins

PH-Sensing Receptors

Group of Rhodopsin – like G protein-coupled receptors comprising GPR4, GPR65 (T cell death-associated gene 8, TDAG8), and GPR68 (ovarian cancer G protein-coupled receptor 1, OGR1). These receptors are activated at neutral to slightly acidic extracellular pH, and likely implicated in pH homeostasis, bone metabolism, angiogenesis, inflammation.

- ▶ Proton-Sensing GPCRs

Phage

- ▶ Bacteriophage

Phagocyte/Phagocytosis

Phagocytes are a group of cells that may engulf and internalise antigens, pathogens or apoptotic cells and destroy them.

Pharmacogenetics

JÜRGEN BROCKMÖLLER
Zentrum Pharmakologie und Toxikologie, Georg-August-Universität Göttingen, Göttingen, Germany

Definition

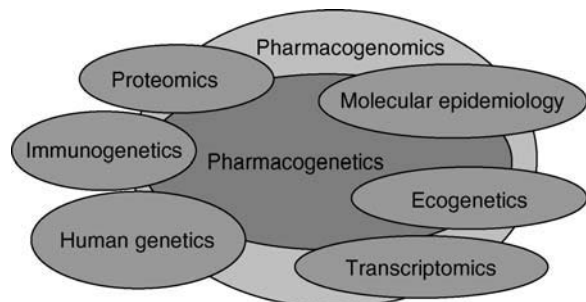

Pharmacogenetics is the study of genetically determined inter-individual variation within one species with respect to the response to drugs. Inherited genetic variations with frequencies above one percent are termed ▶ **polymorphisms**. In the human genome, there are more than three million polymorphisms. Some of these polymorphisms are the cause why some people do not respond to drugs or do respond extremely heavily or suffer from adverse events to drugs. Pharmacogenetics also includes the impact of genetic variability for an organism's response to any external chemical, physical or microbial influence (▶ **ecogenetics**), and some genetic polymorphisms affect internal processes of an organism. Therefore, pharmacogenetics may also provide explanations of individual differences in the ▶ **susceptibility** for a number of diseases. In contrast to inherited disease genes studied in human genetics, pharmacogenetic polymorphisms are not closely related

to disease and typically the effect of genetic polymorphism become only apparent upon exposure to drugs or other conditions (▶ **gene–environment interactions**).

Basic Mechanisms

Pharmacogenetics is a rapidly evolving field of research [1–5]. Fig. 1 illustrates the relationships of pharmacogenetics with other related disciplines. Historically, pharmacogenetic research started with the measurement of the ▶ **phenotype**, which is the apparent variability in structures or functions of one species (phenotyping). For instance, carriers of the deficiency of the drug metabolizing enzyme ▶ **cytochrome P450 2D6** were identified as persons who did not excrete significant amounts of metabolites of drugs like debrisoquine or sparteine (i.e., they showed the deficient or ▶ **poor metabolizer phenotype**). The frequency distribution of this phenotype is illustrated in Fig. 2. For a monogenic determined polymorphism, the phenotype can typically be classified into two groups (▶ **bimodal distribution**) or three groups (▶ **trimodal distribution**). The values separating the two or three groups is termed ▶ **antimode**. For autosomal genes, a bimodal distribution would correspond to a dominant mode of inheritance. Trimodal distributions are more frequent in pharmacogenetics that mostly correspond to a ▶ **codominant** mode of inheritance. Nowadays, genetic polymorphisms are identified by molecular genetic analysis of genomic DNA (genotyping). The analysis of the correlation between a DNA variation and the phenotype (genotype–phenotype correlation) is an essential topic of current ▶ **functional genomics** research.

Essential to the definition of Pharmacogenetics is the term genetic polymorphism. It is extrapolated that there are at least three million genetic polymorphisms in the human genome. Historically, a genetic polymorphism was defined as a genetic variation with a population frequency of 1% and above, but the larger inter-ethnic variation of population frequencies makes a strict definition based on such frequencies impractical. The most common molecular type of polymorphism is the

Pharmacogenetics. Figure 1 Relationship between Pharmacogenetics and other disciplines illustrated using a Venn diagram.

Pharmacogenetics. Figure 2 Cytochrome P450 2D6 (*CYP2D6*) polymorphism as a prototype for a pharmacogenetic polymorphism. The activity was measured using the drug debrisoquine as a test drug and measuring the urinary excretion of the test drug and its 4'-hydroxylated metabolite. The bimodal frequency distribution of *CYP2D6* in a human population ($N = 454$) is shown with the rapid or so-called extensive metabolizers on the left side of the antimode and the deficient or so-called poor metabolizers on the right side. Poor metabolizers are unable to generate significant amounts of the 4'-hydroxylated metabolite as indicated by the fact that their metabolic ratio is at least 12 corresponding to 12-times more parent drug than metabolite.

► **single nucleotide polymorphism (SNP)**. SNPs are classified according to their location in the coding region of exons as either synonymous SNPs (no change of the amino acid sequence) or nonsynonymous SNPs (change of the amino acid sequence). Most SNPs are localized outside the protein coding sequences. Many of these noncoding SNPs may be absolutely silent, but some of these polymorphisms have significant effects on gene transcription or splicing. Other molecular types of genetic variation include insertions or deletions of one or several nucleotides or even entire genes. Some polymorphisms consist of duplications or higher number amplifications of entire functional genes (for instance, the gene duplication of *CYP2D6* results in a phenotype with very extensive expression of the enzyme and ultra-rapid biotransformation of *CYP2D6* substrates). Another distinct type of polymorphisms are the so called variable number of tandem repeat polymorphisms (VNTR) where a segments of repetitive DNA sequence exit with inter-individually variable number of repeats (also termed microsatellites).

Some authors use the term ► **mutation** as a synonym for genetic polymorphism. However, it is recommended to reserve the term mutation for genetic variations acquired within the life span of an organism such as those mutations acquired in tumor tissues during multi-step carcinogenesis.

Within a chromosome, genetic polymorphisms are inherited in a linked fashion and on average, the more closely two polymorphisms are located to each other the more tightly they are linked, but polymorphisms even located one base-pair apart may not be linked. The specific combination of genetic polymorphisms within one chromosome is termed ► **haplotype**. Compilations of genetic polymorphisms such as those for human cytochrome P450 enzymes (► www.imm.ki.se/CYPalleles) or those for ► *N*-acetyltransferases (► <http://www.louisville.edu/medschool/pharmacology/NAT.html>) define the polymorphic alleles as much as possible as haplotypes of linked SNPs or other types of variants. Theoretically, medical studies on the function of polymorphisms should always be based on haplotypes, but complete experimental identification of haplotypes from the diploid cells is almost unfeasible with current technologies.

Genetic polymorphisms may affect the fate of a drug within the body of an organism (► **pharmacokinetics**) and genetic polymorphisms may affect how the drug is acting on the molecular targets of the organism (► **pharmacodynamics**). Polymorphisms relevant for pharmacokinetic variability are in drug transporters relevant for active or facilitated transport through biological barriers and in the enzymes catalyzing drug biotransformation. The effect of polymorphisms in the enzymes of drug biotransformation has been the main

Pharmacogenetics. Figure 3 Illustration of the genotype–phenotype correlation on the example of the cytochrome P450 2C19 polymorphism. The upper part illustrates a molecular analysis of this polymorphism using PCR and restriction fragment analysis resulting in a loss of the restriction site in carriers of the nonfunctional variant *2. The genotype *CYP2C19*2*2* indicates poor metabolizers of substrates of the enzyme CYP2C19 and as shown below, the area under the concentration time curve of them is about 15-fold higher compared to homozygous extensive metabolizers (genotype *CYP2C19*1*1*). The phenotype of the heterozygotes is inbetween corresponding to a codominant mode of inheritance typical for polymorphisms in drug metabolizing enzymes.

focus of pharmacogenetic research in the past. Fig. 3 illustrates on the example of the ►cytochrome P450 2C19 polymorphism the genotype–phenotype correlation. In this example, the exposure of the human body to omeprazole differs about 15-fold depending on the cytochrome P450 polymorphism as expressed as the area under the blood plasma concentration time curve (►AUC) of the drug. In general, the rapid metabolizers may be prone to ineffective action of the drug and the deficient metabolizers (the so-called poor metabolizers) may be prone to adverse effects due to overdosage. The medical impact differs depending on the therapeutic index and other properties of each drug; in the given example of omeprazole, low efficacy in rapid metabolizers was identified as a problem.

There are only very few genes which do not carry any polymorphisms. And there exists even a significant number of polymorphic genes that are not expressed at all in part of the population due to genetic polymorphisms. Table 1 summarizes a few selected polymorphisms with their functional and medical impact.

Pharmacological Relevance Individualization of Drug Treatment

If the genotype–phenotype correlation is sufficiently high, an individual’s phenotype can be predicted by the

genotype. Thus, genotyping can be used to predict in part an individual’s response to specific drugs. A drug therapy optimized according to a number of genetic variants is likely to be more efficacious and will produce fewer or less severe adverse effects compared with current drug therapy. It is anticipated that in future nonresponders to drugs who are explained by ultrarapid drug biotransformation or by their less reactive receptors will receive higher drug doses or alternative drugs. Heavy responders to drug due to genetic receptor variation or due to poor drug biotransformation will receive lower doses or alternative drugs. In particular, subjects prone to idiosyncratic adverse drug reactions that are due to immunogenetic polymorphisms, impaired detoxification of reactive metabolites or other genetic variations will not be treated with the drugs which may be dangerous for this subgroup.

In current daily medical practice, the concept of pharmacogenetic genotyping prior to drug treatment is not routinely used with a few exceptions. At some clinics, phenotyping or genotyping ►thiopurine S-methyltransferase (Table 1) is performed prior to therapy with azathioprine and the doses are adjusted accordingly. Currently routine application of pharmacogenetic testing in medicine is limited in part due to lack of knowledge about application and impact of

Pharmacogenetics. Table 1 Selected genetic polymorphisms and their medical impact

Enzyme	Functional effects of polymorphism and frequency	Examples for the medical impact
Glucose-6-phosphate dehydrogenase	Low or absent enzyme activity in about 10% of African populations.	Hemolysis following intake of a number of drugs which have electrophilic reactive metabolites, but also, carriers of this enzyme deficiency have a partial protection from malaria.
Pseudocholine esterase	Low or absent activity in 0.05% of Caucasian populations.	Prolonged action of succinylcholine and mivacurium.
Paraoxonase (PON1)	Low activity in carriers of the glutamine192 variant with a population frequency of about 50% for the homozygous glutamine genotype in Caucasians.	Carriers of low activity may show higher lipid peroxidation and higher toxicity from organophosphorothioate insecticides.
NADPH:quinone oxidoreductase 1	Pro187Ser variant occurring with about 5% frequency is functionally almost completely deficient.	Impaired activity associated with benzene toxicity and cancer chemotherapy induced leukemia.
Cytochrome P450 2C9	Low activity in about 10% (heterozygotes) and very low activity in about 0.8% (homozygotes) of Caucasian populations.	Prolonged action of several CYP2C9 inactivated drugs like phenytoin, tolbutamide, ibuprofen, or S-warfarin.
Cytochrome P450 2C19	Deficient activity in about 3% of Caucasian populations and in about 20% of Asian populations.	Prolonged action of several CYP2C19 inactivated drugs like omeprazole or diazepam in the poor metabolizers.
Cytochrome P450 2D6	Extremely high activity in about 2% of Caucasian populations and completely deficient activity in about 7%.	Inefficiency in ultrarapid metabolizers and extremely heavy effects in poor metabolizers for more than 50 drugs. A few drugs requiring bioactivation by CYP have low efficacy in poor metabolizers (example: codein is activated to morphine via CYP2D6).
N-acetyltransferase 2	Low activity in about 60% of Caucasian populations.	High incidence of adverse events from the drug isoniazide in slow acetylators.
Glutathione S-transferase M1	Deficient activity in about 50% of Caucasians.	Carriers of the deficiency may have a slightly increased risk for a number of smoking-related cancers.
Thiopurine S-methyltransferase	Low activity in about 10% of Caucasians and deficient activity in about 0.4%.	High incidence of severe adverse events from azathioprine and 6-mercaptopurine in carriers of low activity.
β -Adrenergic receptor 2	Amino acid variants appear to be associated with receptor function and agonist induced downregulation.	Some variants may predispose to some types of asthma and modulate action of β -2-adrenergic drugs.
Factor V Leiden	Factor V Leiden refers to a Arg506Gln replacement which occurs with about 5% frequency in the heterozygous form in Caucasians. The variant is inactivated approximately ten times slower than normal factor V.	About five-fold increased risk for thrombosis in heterozygous carriers of the glutamine variant. Extremely increased risk in homozygous carriers and in heterozygotes taking oral contraceptives. On the other hand, possibly protection from severe blood loss during accidents, surgery or child birth.
5-Lipoxygenase	A VNTR polymorphism in 100 bp upstream from the ATG start codon is associated with transcription efficiency.	Differences in response to 5-lipoxygenase inhibitors and leucotriene receptor antagonists.
β -Adrenergic receptor 2	Amino acid variants moderately associated with receptor function and agonist induced downregulation.	Some variants may predispose to some types of asthma and modulate action of β -2-adrenergic drugs.
Cysteine-cysteine chemokine receptor 5 (CCR5)	A 32-bp deletion with a population frequency of about 0.1 in Caucasians results in truncated nonfunctional receptor.	Carriers of this variant are partially protected from HIV infection, particularly the homozygous carriers.
G protein β -3 subunit	Truncated protein with increased signal transduction in carriers of the 825T allele.	Associated with hypertension and with the response to thiazide diuretics.

pharmacogenetics among physicians and in part due to the limited availability of rapid genotyping methods. In some instances only moderate specificity or sensitivity depending on the relevant gene and the clinical problem may also be a problem. For instance, poor biotransformation of substrates of CYP2C19 or CYP2D6 can be predicted with a 100% specificity and positive predictive value, thus, low doses can be prescribed to poor metabolizers with sufficient certainty. But sensitivity and negative predictive value are less than 100% since other factors like drug–drug–interactions, rare unidentified polymorphisms or unidentified liver disease may also result in poor metabolism.

Pharmacogenetics as a Compound Selection Tool in Drug Development

In drug development the impact of frequent genetic polymorphisms particularly in genes involved in drug biotransformation is routinely studied by *in vitro* methods and by clinical trials in humans. Preference is given to those drugs not significantly affected by genetic polymorphisms, but existing effects of genetic polymorphisms is not necessarily a knockout criterion if the drug has specific properties not available with other analogues of that class. In addition, pharmacogenetic testing during clinical drug trials may help to reduce variability and thus to more specifically identify the effects of a certain drug in smaller numbers of subjects.

Pharmacogenetics as a Discovery Tool for Mechanisms of Diseases and New Therapeutic Principles

The existence of naturally occurring variations in almost all genes in the human population provides a way to identify the genes involved in disease pathogenesis. This may be particularly helpful in those diseases or adverse drug effects where the mechanisms are unknown. By correlating genetic polymorphisms in possibly related genes (candidate gene approach) or in the entire genome (gene mapping approach) one may be able to identify genes and their polymorphisms that are causative for that disease. This may then allow to design new drugs or other therapeutic principles targeted at these genes.

Broader concept of pharmacogenetics

Definition

The conceptual difference between “pharmacogenomics” and “pharmacogenetics” is ambiguously justified, but may be easily compared with the differential concepts of mono/oligogenic and polygenic disease. In contrast to “pharmacogenetics,” which is more or less dedicated to study the impact of a few polymorphic drug-related pharmacokinetic/dynamic targets (drug-metabolizing enzymes, receptors, etc.), the concept of “pharmacogenomics” is applied for the study of an ensemble of drug-related pathways (inflammatory pathways for atherosclerotic disease or the renin–angiotensin system for essential hypertension for example), more complex system biologic pathways (hypothesis-driven) or genome-wide disease- or drug-response susceptibility (nonhypothesis driven).

Principal Goals

The anticipated goal of both disciplines is to help ensuring the “right” drug selection, optimizing choice of drug combinations and dosing, improve drug efficacy and to minimize drug toxicity. This should finally result in the establishment of more personalized treatment concepts for ► **complex disease**.

Basic Mechanisms Prerequisites

The prerequisite of the relatively new disciplines pharmacogenetics/pharmacogenomics is that individuals

effectively differ in their genomic nucleotide sequences (nucleotide diversity represented by differential sequence order of nucleotides G, A, T, and C, throughout the genome), representing a complex interindividually variant genetic make-up. In a usual genetic scan, single-base substitutions (▶[single-nucleotide polymorphisms \[SNPs\]](#)) are the most common form of genetic variation (85%) followed by insertion/deletion variations (8%), repeat polymorphisms (6%), and others (1%). A gene is usually composed of 5'-flanking including a distal, proximal, and core promoter and 5'-untranslated portion, exonic, intronic, 3'-untranslated, and 3'-prime (both 3'-flanking) regions. Already in the late 1990s, from a systematic genetic scan of dozens of ▶[candidate genes](#) (candidate genes are suspected of involvement in the disease process.) for cardiovascular disease (CVD) a considerable genetic diversity in a population of European ancestry has been observed [1]. The average level of nucleotide diversity (π) estimated from the pooled genes was about 3.7×10^{-4} , which means that two randomly chosen sequences from the population are expected to differ approximately every 2,700 bp. The average nucleotide diversity was 4.4×10^{-4} in the 5'- and 3'-flanking gene regions (1 variable site/2,300 bp) and 3.0×10^{-4} in the exonic regions (1 variable site/3,400 bp); these data were confirmed by subsequent studies in Caucasian samples. The lower sequence diversity observed in exonic than in the 5'- and 3'-flanking regions presumably reflected a more stringent selective pressure with respect to coding than to noncoding sequences.

Recent Advances

Celera Genomics and separately the international Human Genome Project consortium each described their first drafts of the genetic blueprint for a human in 2001, even when both teams combined samples from several individuals and created composite genomes that contained only half of a human's DNA. According to a recent study by Venters' group (October 2007), however, haploid genomes underestimate the amount of genetic variation between individuals by a factor of 5. The availability of almost the entire human genome sequence allows for the immediate access to specific target sequences across the human genome. The technologies to explore genetic sequences on a "genome-wide" scale and high-throughput genotyping methods literally exploded since then. ▶[Genome-wide approaches](#) take advantage of the fact that alleles at nearby ▶[loci](#) often show strong ▶[linkage disequilibrium](#) (LD), which is coupled with observations that human recombination is concentrated into short hotspots (1–2 kb) that occur every 100–200 kb; as these recombination hotspots are often coincident with a breakdown of allelic association a few markers within each domain of strong association can be used to tag nearby variation. Choosing SNPs at set intervals across the genome will fail to capture local patterns of allelic association, therefore, the International

HapMap Project was founded in 2002, with the goal of mapping the structure of allelic association across the human genome (The International HapMap Consortium). High-throughput whole-genome genotyping of a few hundred thousand well-chosen SNPs should provide adequate power in most populations to detect single-locus associations for SNPs of moderate frequency and relative risk. For that purpose, an Affymetrix GeneChip Human Mapping 100K SNP set (100K set) has been launched in 2004. This 100K set included 116 204 SNPs, with a median and mean intermarker distance of 8.5 and 23.6 kb, respectively, with 92% of the genome within 100 kb of a SNP. As genome-wide association (GWA) studies are likely to require >100,000 SNPs, 500K sets have been published and genome-wide scans, identifying associations of common variants on chromosome 9p21 with MI in Caucasian populations have proven to being replicated by independent groups. This could also be applied for certain population samples allocated to pharmacological important entities such as "good responder," "non-responder," samples with significant side effects, also. All of these samples might have a common underlying genetic imprint that might only be detected in large-scale genomic applications. Beside the current versions of 500 or even 1000K chips, newly generated chips in that range might cover additional gene regions in a complementary setting to already existing ones. As most of the SNPs included in the 100K (and presumably in the 500K set either) are not coding ones (60% represent SNPs 2 kb outside a gene; 30% of SNPs are intronic ones; <1% are coding variants), once a ▶[candidate gene locus](#) is proposed, extensive resequencing is warranted to actually identify the responsible variant.

The Concept of Pharmacogenomics

Some 50 years ago, it has been observed that the interindividual differences in drug response, besides age, gender, drug interaction, and the like, may also be assigned to inheritable factors. This was then referred to as "pharmacogenetics," which is the subject of another chapter within this encyclopedia. Genes that encode products, which interfere directly or indirectly (downstream or upstream of the drug target of interest) with drug action, may be polymorphic ("pharmacodynamogenetics"). An important example is the polymorphic beta-2-receptor (ADRB2). A glycine at codon 16 (Gly16) has been associated with increased agonist-promoted downregulation of ADRB2 as compared with Arg16. Glu27, on the other hand, has been shown to be resistant to downregulation when compared with Gln27, but only when coexpressed with Arg16. When compared with Gly16 homozygotes, Arg16 homozygotes were 5.3 times and Arg16 heterozygotes were 2.3 times more likely to respond to albuterol, respectively. Other investigators reported that an adenylyl cyclase type 9 (AC9) Ile772Met variant, an effector for airway ADRB2, altered albuterol responsiveness in the context of

concomitant inhaled corticosteroid administration, which renders the pharmacogenetic impact more complex.

Whereas pharmacogenetics deals with more or less well-defined genetic targets including drug metabolizing enzymes (CYP, NAT, TPMT, etc.) or specific pharmacological targets (receptors, counter receptors, ion channels, and the like), the term “pharmacogenomics” is applied for a more comprehensive and complex “genomic” analysis of genetic predisposition to drug response. In that respect, pharmacogenomics is aimed at identifying polymorphic pathways (system biologic) or even (yet unknown) genome-wide susceptibility to interindividual predisposition to drug response, which could also involve the search for susceptibility to complex disease.

► **Genotype–phenotype** (drug response) relationships are complex and the prerequisites to increase the likelihood of getting meaningful knowledge of these complex patterns is: (i) the sequence of all human genes; (ii) large freely accessible database accumulating genetic variants; (iii) new technologies allowing high throughput accurate genotyping at low cost; (iv) new bioinformatic and statistical tools allowing to deal with huge amount of data; (v) mega-studies connected to biobanks providing the necessary material for large-scale genotyping. Accounting for the simultaneous contribution of several genetic and nongenetic factors will be prerequisite for understanding the causal framework underlying complex drug-related traits.

Practical Considerations

In case an individual carries many different trait-“causing” or “-susceptibility” ► **alleles**, which qualifies the patient as “at-high-risk” for developing the disease; drug response to, for example, blood pressure lowering may also differ, depending on disease susceptibility. These individuals might require differential dose regimes and/or other drug combinations as usually prescribed without this additional knowledge of genomic susceptibility.

Another important “socioeconomic” problem is the occurrence of drug side-effects. In Germany, severe side-effects occur in >108,000 patients/year, leading to >>2,250 deaths/year with estimated direct costs of annually 400 million Euro. In its less severe characteristic, side-effects significantly affects adherence to continuous drug therapy (compliance); dry cough, for example occurs in approximately 5–10% of patients taking ACE inhibitors, but it definitely results in drug discontinuation. It has been proposed that there may be race- or ethnicity-related differences in the prevalence of cough attributed to ACE inhibitor therapy as it is significantly more prevalent in Blacks. This suggests that frequency and severity of drug side-effects may also be genetically (background) determined, and this would be again more important for life-threatening side-effects such as angioedema.

As these drug (side) actions may also involve polymorphic pathways, they are also amenable to gene

or genome scans. It is also conceivable that certain positive side-effects (antiinflammatory, anti-aggregatory actions of for example statins) only occur in those patients, which are susceptible to these actions, i.e., carriers of gain-of-function variations in the “inhibitory” pathway, and not in those with loss-of-function variations. With respect to the latter example, statins are known to inhibit isoprenoid generation, resulting in the inhibition of small GTP-binding protein activation such as Rho, Ras, and Rac, which then inhibits the activation of various downstream signaling pathways including mitogen-activated protein kinases (MAPKs), extracellular signal-regulated kinases (ERKs), p38MAPKs, c-jun N-terminal kinases (JNKs), and phosphatidylinositol 3-kinase (PI3K). Statins exert antiinflammatory properties by inhibiting transcription factors such as nuclear factor-kappa B (NF-κB) and activator protein-1 (AP-1), but also as recently been reported via nuclear receptors such as peroxisome proliferator-activated receptor-alpha (PPARα) and PPARγ. These lipid-independent, diverse biological effects produced by the inhibition of isoprenoid synthesis have been collectively referred to as the statins’ pleiotropic effects and are thought to interfere with biological actions such as cell proliferation, oxidative stress, and inflammation and consequently the development of atherogenesis. Patients genetically high or low “functionally” susceptible to these pathways may differentially (and dose-dependently) respond to statin therapy. Other not yet known drug-related pathways within a given tissue or cellular context of interest may be identified by use of gene expression analyses or proteomic approaches. For the treatment of ► **essential hypertension** it has been convincingly shown that the response to diuretic therapy apparently depends on the presence of alpha-adducin genotypes (e.g., Gly460Asp). As the genetic impact on the phenotype was rather straightforward, a pharmacogenomic trial has recently been launched using a new drug target for essential hypertension treatment [2].

Other factors that may complicate dose–response relationships are gene–gene (epistasis; [3]) or gene–environment interactions (ecogenetic context, for example ► **allele-dependent** association with left-ventricular mass depending on salt-ingestion [4] or HDL-C level depending on alcohol consumption [5]). In the latter cases, the anticipated reduction of left ventricular hypertrophy or elevation of HDL-C level upon, for example, with ACE inhibitor or statin therapy, respectively, may not be attained with conventional drug doses (in either direction).

As pharmacogenetics and pharmacogenomics are not mutually exclusive, but even sometimes display overlapping features, both disciplines are aimed at better tailoring medical therapy for a given complex disease such as essential hypertension or other CVD. In the wake of new technologies to identify candidate region for whatever phenotype, more robust and complex bioinformatic analyses are necessary to

compute the observed genomic “effects” on drug response-related phenotypes to establish appropriate guidelines for a more individually tailored drug therapy. The ultimate goal is to (i) prescribe the most appropriate drug(s) for the patient, to (ii) individualize drug dosing, (iii) to optimize the number of prescribed compounds on a daily basis (convenience, adherence to drug therapy), and (iv) to reduce or even avoid side-effects and toxicity. To attain these goals, basic science has to be translated into clinical practice by use of practical clinical trials, outcome-oriented pharmacogenomic trials, and clinical trial regulatory measures.

Pharmacokinetics

FRIEDER KELLER, CHRISTIAN AYMANN,
DAVID CZOCK
Nephrology Division, Department of Internal
Medicine I, University Hospital, Ulm, Germany

Definition

In clinical life, as outlined in this essay, ►**pharmacokinetics (PK)** is used instrumental to improve drug therapy. For this purpose, pharmacokinetics must be presented in general and transmissible terms. The case of kidney failure gives one important example of how disease influences pharmacokinetics and how pharmacokinetics can be used to produce the same pharmacodynamic effect in such patients. The aim and end

will be an individualized drug ►**dose** by means of pharmacokinetic and pharmacodynamic principles.

Basic Mechanisms

Since the dose is given to produce an effect, it is obvious that pharmacokinetics is a required but not yet sufficient tool for drug dose adjustment ►**Pharmacokinetics (PK)** must be combined with ►**pharmacodynamics (PD)** to derive the individualized dose.

Drug => PK + PD => Individualized Dose

Also pharmacogenetics (PG) can be integrated into a common concept, and be figured as pharmacokinetic (PK) and pharmacodynamic parameters (PD) for the individual patient.

PG => PK + PD

One drug level (C_{indiv}) can be used with the means and standard deviation (SD) of population parameters (P_{pop}) as a priori knowledge for an individual parameter estimate using the Bayesian objective function.

$$\text{MIN} = \text{SIGMA}[(C_{\text{indiv}} - C_{\text{pop}})^2 / \text{SDc}^2] \\ + \text{SIGMA}[(P_{\text{pop}} - P_{\text{indiv}})^2 / \text{SDp}^2]$$

Based on therapeutic drug monitoring (►**TDM**) and the individual parameter estimates, every drug can be made applicable to every patient by individual dose adjustment.

Pharmacokinetics

According to the basic natural law, the time-dependent decrease ($-dA/dt$) is proportional to the actual amount of a drug (A) in the body. The proportionality constant is the elimination rate (*Ke*).

$$-dA/dt = Ke * A$$

This differential equation can be integrated and the actual amount (A) is described by an exponential equation.

$$-dA/A = Ke * t$$

$$\ln(A) - \ln(A_0) = -Ke * t$$

$$\exp(\ln(A/A_0)) = \exp(-Ke * t)$$

$$A = A_0 * \exp(-ke * t)$$

The ►**half-life (T_{1/2})** is the time to decrease the amount in the body to one half where (0.693 = ln2).

$$1/2 = \exp(-Ke * T_{1/2})$$

$$\exp(Ke * T_{1/2}) = 2$$

$$Ke * T_{1/2} = \ln(2)$$

$$T_{1/2} = \ln(2)/Ke$$

$$T_{1/2} = 0.693/Ke$$

$$A = A_0 * \exp(-0.693 * t / T_{1/2})$$

$$A = A_0 * 2^{(-t/T_{1/2})}$$

If an immediate effect is needed, a loading dose (D_{load}) must be given to administer the therapeutic amount ($D_{load} = A_0$). To maintain the drug effect, the maintenance dose (D) must be administered repetitively with the administration interval (τ).

$$D = A_0 - A$$

$$D = D_{load} * (1 - \exp(-0.693 * \tau / T_{1/2}))$$

Thus, for drug dosing, one only needs to know the loading dose or the standard dose and the elimination half-life.

Volume, Clearance, and Half-life

What can be measured in the body is the concentration (C) not the amount. The concentration is related to the amount (A) by the distribution ► volume (V_d).

$$C = A / V_d$$

$$C_0 = D / V_d$$

As the amount in the body decreases, the concentration decreases by the same law ($-dC/dt = Ke * C$), i.e., first-order kinetics resulting in an exponential function. The integral is the area under the concentration time curve (AUC).

$$C = C_0 \exp(-Ke * t)$$

$$AUC = C_0 [(1/Ke) * \exp(-Ke * t_{oo}) - (1/Ke) * \exp(-Ke * t_0)]$$

$$AUC = C_0 / Ke$$

The ► clearance (Cl) is the constant parameter relating the change of the amount to the concentration ($-dA/dt = Cl * C$).

$$Cl = (-dA/dt) / C$$

$$Cl = D / AUC$$

From the above functions ($Cl = D / AUC$) and ($D = C_0 * V_d$) the fundamental equation can be derived (Fig. 1).

$$Cl = Ke * V_d$$

$$Cl = 0.693 * V_d / T_{1/2}$$

The half-life can be read off from the time interval ($t_{0.50} = T_{1/2}$) or ($t_{0.10} = 3.3 * T_{1/2}$) or ($t_{0.05} = 4.32 * T_{1/2}$) or the interval ($t_2 - t_1$) between any concentration-fraction (C_2/C_1).

$$T_{1/2} = 0.693 * (t_2 - t_1) / \ln(C_1/C_2)$$

Continuous Infusion, Zero Order, and Michaelis–Menten Kinetics

If the drug is administered by a constant infusion rate (IR), the curve follows an unsteady function with zero-order kinetics ($dC/dt = \text{const.}$) before the infusion is stopped ($t < T_{infus}$) and first-order kinetics after cessation of infusion. Zero-order kinetics frequently can also be observed with drug absorption where ($K_{0abs} = IR$) and ($T_{abs} = T_{infus}$) hold true.

Pharmacokinetics. Figure 1 Main pharmacokinetic processes and parameters: Half-life ($T_{1/2}$), volume (V_d), elimination rate constant (Ke), and clearance (Cl).

$$C = (IR/Cl) * (1 - \exp(-0.693 * t / T_{1/2}))$$

$$C_{ss} = IR / Cl$$

$$C = (IR/Cl) * (1 - \exp(-0.693 * T_{infus} / T_{1/2})) * \exp(-0.693 * (t - T_{infus}) / T_{1/2})$$

Log-concave kinetics can be due to saturable Michaelis–Menten elimination depending on the maximal metabolism capacity (V_{max}) and the Michaelis constant (K_m).

$$-dC/dt = V_{max} * C / (K_m + C)$$

$$T_{1/2} = 0.693 * (K_m + C) / V_{max}$$

With high concentration values ($C \gg K_m$), the metabolism capacity is saturated and zero-order kinetics result ($-dC/dt = V_{max}$).

$$C = -V_{max} * t$$

But with low concentration values ($C \ll K_m$), first-order kinetics result ($-dC/dt = (V_{max}/K_m) * C$).

$$C = C_0 * \exp(-(V_{max}/K_m) * t)$$

With the Michaelis–Menten equation, there is no integrated solution for the concentration, but only for the time

$$t = (C_{max} - C) / V_{max} + (K_m / V_{max}) * \ln(C_{max} / C)$$

However, saturable kinetics can also be described by a 1-exp function. This function indeed has an integrated solution for the concentration.

$$-dC/dt = V_{max} * (1 - \exp(-C/K_m))$$

$$C = K_m * \ln[1 - (1 - \exp(C_{max}/K_m))] * \exp(-V_{max} * t / K_m)$$

Bi-exponential Kinetics

After intravenous drug administration, a log-convex concentration decline points to a multi-exponential function. For the most frequent case, a bi-exponential equation with the inter-compartment rate constants (k_{12}) and (k_{21}) can be fitted.

$$C = Ca * \exp(-\alpha * t) + Cb * \exp(-\beta * t)$$

$$Co = Ca + Cb$$

$$AUC = Ca/\alpha + Cb/\beta$$

$$T1/2\alpha = 0.693/\alpha$$

$$T1/2\beta = 0.693/\beta$$

$$k21 = (Ca * \beta + Cb * \alpha) / (Ca + Cb)$$

$$k10 = \alpha * \beta / k21$$

$$k12 = \alpha + \beta - k21 - k10$$

The concentration (C_{tiss}) in the peripheral volume ($V2$) or tissue compartment follows also a bi-exponential function.

$$C_{tiss} = (Co * k12 / (\alpha - \beta)) * (\exp(-\beta * t) - \exp(-\alpha * t))$$

The concentration of a metabolite (Cm), too, follows such a bi-exponential kinetics depending on the metabolite formation rate constant ($Kmet$).

$$Cm = Cm0 * (\exp(-Kmet * t)) - \exp(-Ke * t)$$

With bi-exponential kinetics it can be difficult to select the appropriate volume term, since several volume parameters can be derived.

$$V_{ss} = V1 + V2$$

$$V1 = D/Co$$

$$V2 = V1 * (k12/k21)$$

$$Vd = V1 * k10/\beta$$

$$Vd = D / (\beta * AUC)$$

$$V_{extrap} = D/Cb$$

It is the advantage of the clearance parameter that only one clearance term is obtained.

$$Cl = k10 * V1$$

$$Cl = \beta * Vd$$

One solution to the volume problem was proposed using moment analysis. The steady-state volume of distribution (V_{ss}) can be derived from the area under the curve (AUC) and the area under the first moment curve (AUMC).

$$V_{ss} = D * AUMC / (AUC^2) = Cl * MRT$$

$$MRT = AUMC / AUC$$

The mean residence time (MRT) gives one parameter for the multi-exponential elimination kinetics with more than one half-life.

$$AUC = \sum_{i=1}^n (Ci-1 + Ci) * (ti-ti-1) / 2 + Cn / \lambda_{daz}$$

$$AUC = \sum_{a=z}^a (Ca / \lambda_{daa})$$

$$AUMC = \sum_{i=1}^n (ti-1 * Ci-1 + ti * Ci) * (t - ti-1) / 2 + tn * Cn / \lambda_{daz} + Cn / \lambda_{daz}^2$$

$$AUMC = \sum_{a=z}^a (Ca / \lambda_{daa}^2)$$

The dominant half-life must represent 90% of the AUC ($0.90 * AUC = 1.44 * Co * T1/2_{dom}$), and it corresponds to the MRT estimate where ($1/\ln 2 = 1.44$).

$$T1/2_{dom} = 0.693 * MRT$$

Oral Dose and Bioavailability

After oral dosing, the bi-exponential Bateman function holds true with the absorption rate constant (Ka).

$$C = Co * (Ka / (Ka - ke)) * (\exp(-Ke * t) - \exp(-Ka * t))$$

$$Co = F * D / Vd$$

$$t_{max} = \ln(Ka/Ke) / (Ka - Ke)$$

$$C_{max} = Co * \exp(-Ke * t_{max})$$

The elimination half-life after oral dosing is longer than after intravenous dosing ($T1/2_{po} > T1/2_{iv}$) when the so-called “flip-flop” condition applies ($Ka < Ke$).

$$T1/2_{iv} = 0.693/Ke$$

$$T1/2_{po} = 0.693/Ka$$

According to the law of corresponding areas (FH Dost), the area derived from the integrated Bateman function ($AUC_{po} = AUC_{iv}$) is the same as the area after intravenous dosing if the **bioavailability** (F) is complete.

$$AUC_{po} = Co * (Ka / (Ka - Ke)) * (1/Ke - 1/Ka)$$

$$AUC_{po} = Co/Ke$$

The systemically available fraction or bioavailability (F) can be defined by the fraction of the area after oral and intravenous dosing, respectively.

$$F = AUC_{po} / AUC_{iv}$$

The apparent clearance (Cl/F) and the apparent volume (Vd/F) estimates are related to the bioavailability after oral dosing.

$$Cl/F = D / AUC_{po}$$

$$Vd/F = D / (\beta * AUC_{po})$$

A special case occurs with the entero-hepatic recycling of a drug that can be described by using the sum of two Bateman-like functions.

$$C = Cal * (\exp(-Kel * t) - \exp(-Kal * t)) + Ca2 * (\exp(-Ke2 * t) - \exp(-Ka2 * t))$$

A special case for reduced bioavailability results from first-pass extraction that sometimes might be subjected to saturable Michaelis–Menten absorption kinetics. The lower the hepatic drug clearance is (Cl_{hep}) in relation to liver blood flow (Ql), or the faster the drug absorption rate constant (Ka), and the higher the dose (D) are, the more bioavailable is the drug (F).

$$F = 1 - Cl_{hep}/Ql$$

$$F = 1 - ((Vmax * Vd) / (Ka * D)) * \ln(1 + (Ka * D) / (Km * Ql))$$

Plasma Binding

The free plasma fraction (f_p) determines the relation between free, bound (►plasma binding PB%), and total concentration.

$$\begin{aligned} PB\% &= 1 - f_p \\ f_c &= C_{\text{free}}/C \\ C &= C_{\text{free}} + C_{\text{bound}} \\ f_p \uparrow &= C_{\text{free}}/(C_{\text{free}} + C_{\text{bound}}) \downarrow \\ f_p \uparrow &= C_{\text{free}}/C \downarrow \\ C_{\text{free}} &= \text{const.} \end{aligned}$$

The total clearance increases in proportion to the free plasma fraction while free plasma clearance remains constant.

$$\begin{aligned} f_p \uparrow * C \downarrow &= C_{\text{free}} = \text{const.} \\ f_p * AUC &= \text{const.} \\ Cl_{\text{free}} &= F * D / AUC_{\text{free}} \\ AUC_{\text{free}} &= \text{const.} \\ CL \uparrow &= f_p \uparrow * Cl_{\text{free}} \\ Cl_{\text{free}} &= \text{const.} \end{aligned}$$

The apparent volume of distribution (V_d) slightly increases depending on plasma volume (V_p), tissue volume (V_t), and free tissue fraction (f_t) whereas the half-life slightly decreases with significantly increasing free plasma fraction.

$$\begin{aligned} V_d \uparrow &= V_p + V_t * f_p \uparrow \uparrow / f_t \\ T1/2 \downarrow &= (0.693 / Cl_{\text{free}}) * (V_d \uparrow / f_p \uparrow \uparrow) \end{aligned}$$

Since the binding capacity (B_{max}) is saturable and depending on the affinity constant (K_{aff}), the free plasma fraction (f_p) increases with increasing total and thus also bound concentrations.

$$\begin{aligned} C_{\text{bound}}/C_{\text{free}} &= B_{\text{max}} - K_{\text{aff}} * C_{\text{bound}} \\ f_p &= 1 / (1 + B_{\text{max}} - K_{\text{aff}} * C_{\text{bound}}) \end{aligned}$$

Fortunately, changes in drug binding are expected to have no clinical relevance except for TDM where a new target concentration (C_{target}) must be explicitly stated – usually lower than with normal ►plasma binding.

$$C_{\text{target}} \downarrow = C_{\text{free}} + C_{\text{bound}} \downarrow .$$

Renal Impairment

The kidney function confers high impact on drug kinetics when a high fraction (f_{ren}) of the drug dose (D) is eliminated in urine (Aurine). The renal fraction (f_{ren}) can be underestimated when bioavailability (F) is neglected. The renal clearance, however, can be derived from the amount eliminated by the renal route (Aurine) independent from bioavailability (F).

$$f_{\text{ren}} * F = \text{Aurine} / D_{\text{oral}}$$

$$Cl_{\text{ren}} = \text{Aurine} / AUC$$

$$f_{\text{ren}} * F = Cl_{\text{ren}} / Cl$$

Total drug clearance is the sum of nonrenal clearance and renal clearance (Cl_{ren}). According to the MDRD-2 formula, the estimated GFR (eGFR) is a function of serum creatinine (SCr in mg/dl) and age (Age in years). It has the unit ml/min per 1.73 m^2 .

$$Cl = Cl_{\text{nonren}} + Cl_{\text{ren}}$$

$$Cl_{\text{ren}} = A * eGFR$$

$$eGFR = 186 * [SCr]^{-1} * [Age]^{-1.154} - 0.203$$

$$Cl = Cl_{\text{nonren}} + A * eGFR$$

The renal clearance can be underestimated in the case of renal drug metabolism. The total drug clearance depends on bioavailability. Therefore, the most reliable estimate for the fraction eliminated by the renal route (f_{ren}) is given by the normal clearance (Cl_{norm}) and drug clearance in case of acute and/ or chronic renal failure (Cl_{fail}), or from half-lives ($T1/2_{\text{norm}}$) and ($T1/2_{\text{fail}}$).

$$f_{\text{ren}} = 1 - Cl_{\text{fail}} / Cl_{\text{norm}}$$

$$f_{\text{ren}} = 1 - T1/2_{\text{norm}} / T1/2_{\text{fail}}$$

The interpolation of individual clearance (Cl), volume (V_d), plasma binding (PB%), and half-life ($T1/2$) for any stage of renal impairment is obtained from the normal clearance (Cl_{norm}), volume ($V_{d_{\text{norm}}}$), plasma binding estimate (PB%_{norm}), or half-life ($T1/2_{\text{norm}}$), and the parameters for kidney failure (X_{fail}). The individual renal function is estimated by the GFR (eGFR = MDRD-2) where (eGFR_{fail} = 0).

$$Cl = Cl_{\text{fail}} + A * eGFR$$

$$V_d = V_{d_{\text{norm}}} + / - B * (eGFR - eGFR_{\text{norm}})$$

$$PB\% = PB\%_{\text{norm}} + / - G * (eGFR - eGFR_{\text{norm}})$$

$$T1/2 = T1/2_{\text{norm}} / (1 - f_{\text{ren}} + f_{\text{ren}} * eGFR / GFR_{\text{norm}})$$

With

$$A = (Cl_{\text{norm}} - Cl_{\text{fail}}) / eGFR_{\text{norm}}$$

$$B = - / + (V_{d_{\text{fail}}} - V_{d_{\text{norm}}}) / eGFR_{\text{norm}}$$

$$G = - / + (PB\%_{\text{fail}} - PB\%_{\text{norm}}) / eGFR_{\text{norm}}$$

With bi-exponential kinetics, it should be sufficient to linearly correlate beta with eGFR.

$$\beta = \beta_{\text{fail}} + (\beta_{\text{norm}} - \beta_{\text{fail}}) *$$

$$eGFR / eGFR_{\text{norm}}$$

The volume will decrease when renal impairment is associated with a decrease in the elimination rate beta ($\beta_{\text{norm}} \Rightarrow \beta_{\text{fail}}$). On the other side, the volume will increase when the free plasma fraction (f_p) increases in renal impairment where $f_p = 1 - PB\%$. The volume decreases, when the free tissue fraction (f_t) increases in renal impairment.

$$Vd = V1 * (1 + k12 / (k21 - \beta))$$

$$Vd = V1 + V2 * fp / ft$$

Hemofiltration and Hemodialysis

The effect of ►hemofiltration on drug elimination can be estimated from serum creatinine (SCr), age, and the MDRD-2 formula to predict the combined effect of filtration rate (eGFR = GFR_{residual} + HFR) on drug clearance and drug half-life during hemofiltration.

$$T1/2 = T1/2_{norm} / (1 - f_{ren} + f_{ren} * eGFR / GFR_{norm})$$

$$Cl = Cl_{fail} + A * eGFR$$

The effect of ►hemodialysis can be derived from the removed fraction (FR) that is the relative amount eliminated from the body during the time (*t*HD) of one dialysis session. This fraction can be derived from the half-life on dialysis (T1/2_{on}) or from the area under the curve (AUC) on and off dialysis.

$$FR = 1 - \exp(-0.693 * t_{HD} / T1/2_{on})$$

$$FR = (AUC_{off} - AUC_{on}) / AUC_{off}$$

The total fraction (FR) eliminated must be distinguished from the specific fraction (FR_{fract}) that is eliminated by the dialysis alone.

$$FR_{fract} = \exp(-0.693 * t_{HD} / T1/2_{off}) - \exp(-0.693 * t_{HD} / T1/2_{on})$$

After dialysis, often a rebound is seen in concentrations since elimination from plasma is faster than drug flux from tissue to plasma ($C_{rebound} = C_{tissue} - C$). The concentration in plasma follows a bi-exponential kinetics during hemodialysis whereas the concentration in tissue follows mono-exponential kinetics.

$$C = C_0 * (\exp(-\alpha_{HD} * t_{HD}) + \exp(-\beta_{HD} * t_{HD}))$$

$$C_{tissue} = C_0 * \exp(-\beta_{HD} * t_{HD})$$

$$C_{rebound} = -C_0 * \exp(-\alpha_{HD} * t_{HD})$$

For a prolonged dialysis duration ($t = 3/\alpha = 4.32 * T1/2_{\alpha}$), there will be no longer a rebound after termination of dialysis.

Accumulation Kinetics and Multiple Dosing

If a drug is given repetitively with a constant dose (D) and a constant administration interval (Tau) accumulation occurs until a steady-state concentration (C_{ss}) is obtained after 4.32 times the elimination half-life ($t_{ss} = 4.32 * T1/2$).

$$C_{ss} = F * D / (Cl * Tau)$$

In the steady state, the peak concentration and the trough concentration can be distinguished.

$$C_{peak} = C_0 / (1 - \exp(-0.693 * Tau / T1/2))$$

$$C_{trough} = C_0 / (\exp(0.693 * Tau / T1/2) - 1)$$

The calculated peak concentration is not always the measured concentration. For bi-exponential kinetics the calculated peak concentration is less, but after oral dosing, the calculated peak concentration is higher than the highest measurable plasma concentration. The peak concentration provides a target for the loading dose to start with (D_{load}).

$$D_{load} = C_{peak} * Vd$$

For bi-exponential accumulation kinetics the contribution of the fast alpha phase ($R_{\alpha} = 1 / (1 - \exp(-\alpha * Tau))$) decreases ($R_{\alpha} * C_a \ll R_{\beta} * C_b$) as compared with the contribution of the slow beta-phase ($R_{\beta} = 1 / (1 - \exp(-\beta * Tau))$).

Pharmacodynamics

The drug dose (D) produces a concentration (C) and the concentration produces an effect (E).

$$D \Rightarrow PK \Rightarrow C \Rightarrow PD \Rightarrow E$$

The most general equation for the correlation between effect (E) and concentration (C) is given by the sigmoid E_{max} model where the concentration (CE₅₀) produces the half-maximum effect and the Hill coefficient (H) specifies the sigmoidicity (Fig. 2).

$$E = E_{max} / (1 + (CE_{50}/C)^H)$$

If the Hill coefficient is less than one ($H < 1$), the maximum effect will never be obtained with increasing concentrations ($E < E_{max}$). If the Hill coefficient is more than ten ($H > 10$), an on-off phenomenon can be described at CE₅₀. The effect can be assumed to be marginal and less than 5% of E_{max} for the threshold concentration (CE₀₅) but almost 95% of E_{max} for the ceiling concentration (CE₉₅).

$$CE_{05} = CE_{50} * 0.053^{(1/H)}$$

$$CE_{95} = CE_{50} * 0.053^{(-1/H)}$$

Established standard dosage produces the target concentration (C_{target}) between normal peak and trough levels.

$$C_{peak} = C_{trough} * \exp(0.693 * Tau / T1/2)$$

$$C_{trough} \approx CE_{05}$$

$$C_{peak} \approx CE_{95}$$

The time of effect duration (TED) is a function of the elimination half-life. Two special cases are most important, the 50% effect bisection time (TED₅₀) and the duration of 90% of the effect (TED₉₀).

$$TED_{50} = T1/2 * (1.44/H) * \ln(2 + (C_{peak}/CE_{50})^H)$$

$$TED_{90} = T1/2 * (1.44/H) * \ln(10 + 9 * (C_{peak}/CE_{50})^H)$$

For single dose monoexponential kinetics and direct effect conditions, the area under the effect time curve (AUEC) can be derived by integration of the Hill equation.

Pharmacokinetics. Figure 2 Sigmoid E_{max} model of pharmacodynamics with Hill coefficient (H), concentration producing half-maximum effect (CE_{50}), threshold concentration (CE_{05}), and ceiling concentration (CE_{95}).

$$AUEC = 1.44 * T_{1/2} * (E_{max}/H) * \ln(1 + (C_0/CE_{50})^H)$$

For irreversible effects no ceiling concentration is assumed; the incremental increase in concentrations and the absolute height of the peak might be more impacting.

Pharmacological Relevance

Luzius Dettli was not only the first who described the linear function for the dependence of drug elimination on glomerular filtration rate. He was also the first who proposed the fundamental dose adjustment recommendation, the proportional dose reduction rule. Two alternatives are given to either reduce the single dose (D) or extend the interval (τ).

$$D/\tau = (D/\tau)_{norm} * C_i/C_{i, norm}$$

$$D/\tau = (D/\tau)_{norm} * T_{1/2, norm}/T_{1/2}$$

If $(\tau)_{norm} = \text{const.}$

$$D = D_{norm} * C_i/C_{i, norm}$$

$$D = D_{norm} * T_{1/2, norm}/T_{1/2}$$

The administration interval could be selected based on standard peak and trough concentrations or from effect duration time (TED_{50} , TED_{90}). If the dose is reduced, a loading dose ($D_{load} = C_{peak} * V_d = D_{norm}$) must be administered to obtain an immediate effect. If $D_{norm} = \text{const.}$

$$\tau = (\tau)_{norm} * C_{i, norm}/C_i$$

$$\tau = (\tau)_{norm} * T_{1/2}/T_{1/2, norm}$$

A second, completely different dose adjustment rule exists. Calvin Kunin proposed to start with the standard dose and to administer one half of the standard dose after one individual half-life. The half-dosage rule of Kunin should only be applied if the individual half-life is longer than the standard administration interval.

$$D_{load} = D_{norm}$$

$$D/\tau = 1/2 * D_{load}/T_{1/2}$$

$$D = 1/2 * D_{load}$$

$$\tau = T_{1/2}$$

$$C_{peak} = \text{const.}$$

$$C_{trough} > (C_{trough})_{norm}$$

The Dettli rule might result in underdosage because of too infrequent peak levels; the Kunin rule might result in overdosage because of toxic trough levels. The third, the target concentration approach was proposed by Nikolas Holford.

$$D/\tau = C_{target} * C_i$$

$$C_{target} = CE_{50} * E/(E_{max} - E)$$

The effect area should remain constant ($AUEC = \text{const.}$). Thus the target concentration (C_{target}) might be derived from the normal peak concentration (C_{peak}).

$$C_{target} = CE_{50} * [(1 + (C_{peak}/CE_{50})^H)^H * (T_{1/2, norm}/T_{1/2}) - 1]^{(1/H)}$$

When the half-life is prolonged, the target concentration will decrease ($C_{target} < C_{peak}$).

Supplementary Dose after Hemodialysis

During the time on dialysis (t_{HD}) a fraction (FR) of the amount in the body is eliminated. The required amount in the body often corresponds to the loading dose (D_{load}) or to $(D_{load} - D_{fail})$. This fraction must be replaced by a supplementary dose (D_{suppl}) to maintain therapeutic drug levels for the time interval between two dialysis sessions.

$$D_{suppl} = FR * (D_{load} - D_{fail})$$

The dose after dialysis (D_{hd}) must replace the maintenance dose adjusted to renal failure (D_{fail}) and the

supplementary dose (D_{suppl}) that both are functions of the loading dose. According to the Kunin rule one obtains for the most general conditions:

$$D_{\text{hd}} = D_{\text{fail}} + D_{\text{suppl}}$$

$$D_{\text{fail}} = \frac{1}{2} * D_{\text{load}}$$

$$D_{\text{suppl}} = FR * D_{\text{load}}$$

$$D_{\text{hd}} = (1/2 + FR) * D_{\text{load}}$$

Pharmacological Barriers

Physiological barriers limiting the passage of pharmacological compounds within the body.

► MDR-ABC Transporters

Pharmacological Chaperone

Pharmacological chaperones are substances that selectively facilitate misfolded proteins to fold and thereby allowing them to gain certain wild-type characteristics, like promoting their cell surface expression and/or rescuing their functional activity. They can be ligands, substrates or inhibitors of unstable receptors, transmembrane channels or enzymes. These substances are promising drugs for a specific therapeutic approach for

Pharmacophore Modelling

Computer-assisted approach which aims at deriving a detailed model of the ligand-binding pocket(s) of a receptor or enzyme from biochemical and pharmacological data obtained in pharmacological experiments such as ligand-binding assays and receptor mutagenesis studies. According to IUPAC a pharmacophore is considered an ensemble of steric and electronic features that is necessary to ensure the optimal supramolecular interactions with a specific biological target and to trigger (or inhibit) its biological response.

Pharmacodynamic Tolerance

Pharmacodynamic tolerance develops in response to continued application of drugs, by mechanisms that include reversible cellular adaptation processes, such as receptor desensitization, internalization and downregulation as well as changes in the activity and levels of other components of the receptor's signal transduction pathways.

► Tolerance and Desensitization

Phase I and Phase II Metabolism

The metabolism of foreign compounds (xenobiotics) often takes place in two consecutive reaction, classically referred to as phases one and two. Phase I is a

functionalization of the lipophilic compound that often is the prerequisite for further conjugation reactions, also termed phase II. The conjugated product is usually sufficiently water soluble to be excretable into the urine. The most important biotransformations of Phase I are aromatic and aliphatic hydroxylations catalyzed by cytochromes P450. Other phase I enzymes are for example epoxide hydrolases or carboxylesterases. Typical phase II enzymes are UDP-glucuronosyltransferases (UGT), sulfotransferases (SULT), N-acetyltransferases (NAT) and methyltransferases (e.g. thiopurin S-methyltransferase or TPMT).

- ▶ Familial Persistent Hyperinsulinemic Hypoglycemia of Infancy

PHLPP

A phosphatase that dephosphorylates a conserved carboxyl-terminal site on PKC and Akt, thus inactivating these kinases and terminating their signaling pathways.

- ▶ Protein Kinase C

Phorbol Esters

Natural products from the Euphorbiaceae family of plants that mimic the effects of diacylglycerol by binding the C1 domain of proteins such as PKC.

- ▶ Protein Kinase C

Phosphatase

A phosphatase is an enzyme that hydrolyzes phospho-monoesters, a reaction yielding free phosphate and alcohol. Substrates for phosphatases include both

phospholipids and proteins. A wide variety of protein phosphatases exist and are generally classified according to their substrate specificities. For example, protein tyrosine phosphatases dephosphorylate phosphotyrosine residues while dual specificity phosphatases dephosphorylate both phosphothreonine and phosphotyrosine residues.

► Protein Phosphatases

Phosphate Transferring Enzyme Inhibitors

► Protein Kinase Inhibitors

Phosphatidic Acid

Phosphatidic acid is glycerol esterified at the sn-1 and sn-2 positions to two fatty acids and at the sn-3 position to phosphoric acid. It is a product of phospholipase D action that is also an intermediate in the biosynthesis of phosphatidylserine and phosphatidylinositol.

► Phospholipases

Phosphatidylinositide Kinases

► Phospholipid Kinases

Phosphatidylinositol

Phosphatidylinositol (abbreviated PtdIns, or PI) is a minor class of phospholipids composed of glycerol, fatty acids and inositol. PIs are found in the cytosolic side of eukaryotic cell membranes. They are substrates for a large number of enzymes which are involved in cell signalling.

► Phospholipid

Phosphatidylinositol 4,5-bisphosphate

Phosphatidylinositol 4,5-bisphosphate is a derivative of phosphatidylinositol in which the inositol ring is phosphorylated at positions 4 and 5.

► Phospholipases

Phosphatidylinositol 3-kinase

Family of enzymes phosphorylating phosphatidylinositol (PtdIns), PtdIns(4)phosphate, and PtdIns(4,5)phosphate in the 3-position. The PtdIns(3)phospholipids are second messengers in processes like cell growth, cytoskeletal rearrangement, and vesicular transport. PI 3-kinases are heterodimers composed of a catalytic and a regulatory subunit. The enzymes are activated by insulin, many growth factors, and by a variety of cytokines. Their activity can be inhibited by wortmannin and LY294002.

Synonyms

Cyclic nucleotide phosphodiesterases; PDEs

Definition

Cyclic nucleotide phosphodiesterases (PDEs) are a class of enzymes that catalyze the hydrolysis of 3',5'-cyclic guanosine monophosphate (cGMP) or 3',5'-cyclic adenosine monophosphate (cAMP) to 5'-guanosine monophosphate (GMP) or 5'-adenosine monophosphate (AMP), respectively.

Basic Characteristics

The cyclic nucleotide PDEs are a superfamily of enzymes that hydrolyze cGMP and cAMP to their respective 5'-monophosphates. Cyclic nucleotide signaling is important in a large number of processes including proliferation, ▶chemotaxis, muscle contraction, and relaxation, energy metabolism, and inflammation. Therefore, together with the cyclases (adenylyl and guanylyl cyclase), the PDE family is crucial for survival and for maintaining quality of life in eukaryotic organisms. Currently, there are 11 known PDE gene families, all of which have unique characteristics in terms of substrate specificity, expression patterns, kinetics, and regulatory properties (Table 1). The current nomenclature for a PDE contains, in order, two letters to indicate species, a number indicating gene family, a letter to represent an individual gene, and a number to signify splice or start site variant. For example, MMPDE9A1 represents the mouse PDE9 gene family, gene A, splice variant 1. In general, all PDEs share the same structural organization. Each protein has an N-terminal motif that is used to regulate

the protein's activity or localization, and a C-terminal catalytic domain, followed by a short tail. The catalytic domains of all Class 1 PDEs share approximately 35% sequence identity, including a conserved signature sequence, H-D-X₂-H-X₄-N.

Substrate Specificity

The substrate specificity of the PDEs range from dual specificity enzymes (PDE1, 2, 10, and 11) to those that preferentially hydrolyze either cGMP (PDE5, 6, and 9) or cAMP (PDE3, 4, 7, and 8). In fact, the relative substrate specificities can vary between members of a gene family. For example, within the PDE1 gene family, PDE1A has a K_m for cGMP that is much lower than that for cAMP, while PDE1C has roughly equal affinity for both nucleotides. In addition, the activity of a PDE toward one cyclic nucleotide can vary depending on the concentration of the other cyclic nucleotide. For instance, PDE2 will hydrolyze cAMP and cGMP with relatively similar K_m values. However, the presence of a small amount of cGMP (through allosteric binding sites) stimulates the activity of PDE2 towards cAMP. There are also PDEs for which one cyclic nucleotide acts as a competitive inhibitor for the other. For example, cAMP is a competitive inhibitor of cGMP hydrolysis by PDE10, and cGMP is a potent inhibitor of cAMP hydrolysis by PDE3s. Thus, with a wide variety of specificities and affinities for the different nucleotides, the PDEs are a group of enzymes that are well adapted to fine tune the cyclic nucleotide pools within the cell.

Regulatory Domains

All of the PDEs possess a significant amount of sequence that is N-terminal to the catalytic domain. In fact, the N-terminus can be larger than the catalytic domain itself. Within the N-terminus there are domains used to regulate the activity of the catalytic site (Fig. 1). The PDE1 family members have two Ca²⁺/calmodulin-binding domains. Binding of Ca²⁺/calmodulin to these domains stimulates the activity of the PDE1s several fold. PDE2, PDE5, PDE6, PDE10, and PDE11, all have allosteric cGMP-binding or cAMP-binding GAF domains (named after cyclic GMP-binding PDE, ▶adenylyl cyclase, FhlA) in their N-termini. Binding of cGMP or cAMP to these domains have various effects on PDEs. For PDE2, binding of cGMP to its GAF domain results in stimulation of its cAMP hydrolyzing activity. Binding of cGMP to PDE5 increases its susceptibility to phosphorylation, and also has a direct effect on activity. PDE10 and PDE11 have unusual GAF domains. The affinity of PDE10 for cGMP is low, with a reported K_d of greater than 10 μM. It has a much higher affinity for cAMP. In the PDE11 family, there are reported splice variants with full length and truncated GAF domains. It is unclear, what role these truncated forms might play, if any, in PDE11 function. The N-terminus of PDE8 has another small molecule

Phosphodiesterases. Table 1 Characteristics of the individual Class 1 cyclic nucleotide PDE families

PDE Family	Genes	Probable splice variants	Regulatory domains/role	Phosphorylation	Substrate (s)	Commonly used inhibitors
PDE1	1A, 1B, 1C	9	CaM/activation	PKA	cGMP, cAMP	KS-505
PDE2	2A	3	GAF/activation	Unknown	cAMP, cGMP	EHNA
PDE3	3A, 3B	1 for 3A; 2 for 3B	Transmembrane domains/membrane targeting	PKB, PKA	cAMP > cGMP	Milrinone
PDE4	4A, 4B, 4C, 4D	>20	UCR1, UCR2/unclear	ERK, PKA	cAMP	Rolipram
PDE5	5A	3	GAF/activation	PKA, PKG	cGMP	Sildenafil, Vardenafil, Tadalafil,
PDE6	6A, 6B, 6C	1 each	GAF/activation	PKC, PKA	cGMP	Sildenafil, Dipyrimadole, Zaprinast
PDE7	7A, 7B	6	Unknown	Unknown	cAMP	None identified
PDE8	8A, 8B	6	PAS/unknown	Unknown	cAMP	None identified
PDE9	9A	4	Unknown	Unknown	cGMP	None identified
PDE10	10A	2	GAF/activation?	Unknown	cAMP, cGMP	None identified
PDE11	11A	4	GAF/unknown	Unknown	cAMP, cGMP	None identified

**Phosphodiesterases. Figure 1** Domain organization of the phosphodiesterase family.

binding domain, the PAS domain. PAS domains are found in a number of eukaryotic systems and are found within proteins that are involved in sensing their environment such as oxygen, energy, or light levels.

They also bind small molecules and can be involved in protein–protein interactions. PAS domains in other proteins commonly function either as protein interaction sites or small molecule binding domains. Occasionally,

they serve both functions. However, it is not known for PDE8 whether the PAS domain has either of these functions. It will be of great interest if a small molecule regulatory ligand that binds to the PAS domain can be identified.

PDEs are also regulated by targeting and phosphorylation. Some of the PDE3 family members have six putative transmembrane domains in their N-terminal regions, which is the likely reason much PDE3 activity is largely membrane associated. Some PDEs, such as PDE2A2 and PDE9A1, have putative N-myristoylation sites which presumably target these proteins to the membrane. While this has not been demonstrated for PDE9, a membrane associated form of PDE2 activity has been shown. PDE6, the PDE involved in retinal ►phototransduction, is prenylated and tightly associated with the disc membranes of the photoreceptor cells. Lipid modification, however, is not the only mechanism for localizing PDEs. Examples of proteins that associate with PDEs and likely target them to cellular compartments are emerging. Recently, RACK1, a ►scaffolding protein that associates with PKC and Src, was also shown to bind PDE4D5. PDE4D also associates with a centrosomal protein, myomegalin, and a PKA anchoring protein, mAKAP. All of these associations with PDE4D are likely to be targeting this PDE to specific cAMP pools in the cell. Interactions of PDE4 family members with XAP2 immunophilins, src like tyrosine kinases, β -arrestins, DISC1, and several A-kinase anchoring proteins (AKAPs) have all been reported. Many of these are known to have functional consequences. Undoubtedly, more examples of this type of targeting will be discovered.

Compartmentalization of PDEs

Compartmentalization of cyclic nucleotide signaling within the cell is a notion that has been around for some 20 years, yet has been difficult to demonstrate for the PDEs. However, some examples of compartmentalization of PDEs in cells have been shown. The best studied example is in the photoreceptor, where PDE6 is concentrated on the membrane disks along with the other players in the phototransduction cascade. There, PDE6 is activated in response to light and hydrolyzes local cGMP, and resident cGMP-gated cation channels close, hyperpolarizing the cell. In kidney mesangial cells, the production of ►superoxide and mitogenesis are both stimulated through the elevation of cAMP. The production of superoxide is rolipram sensitive, indicating a role for PDE4 in this process. Mitogenesis is cilostamide sensitive, implying a role for PDE3. Superoxide generation is not effected by cilostamide and mitogenesis is insensitive to rolipram. Thus, while both of these processes are cAMP-dependent, different cAMP pools and PDEs are involved in each. Another example of compartmentalization of PDE activities in the cell exists in the olfactory epithelium, where

PDE1C2 and PDE4A are expressed. PDE1C2 is found in the cilia of the epithelium, where it colocalizes with adenylyl cyclase. PDE4A is found throughout the epithelial layer, but not in cilia. Therefore, as in the kidney mesangial cells, different PDEs must be working on different cyclic nucleotide pools. More recently, substantial data has been developed for compartmentalization of cAMP and PDEs in cardiac myocytes.

Drugs

Currently, Viagra (Pfizer, Inc.) and its more recent competitors Levitra[®] and Cialis, are the best examples of specific PDE inhibitors put to clinical use. Stimulation of the smooth muscle cells of the corpus callosum by nitric oxide results in the elevation of cGMP. This increase in cGMP levels results in relaxation of the vascular smooth muscle and engorgement of the penis. Viagra, through inhibition of PDE5 in the smooth muscle cells, potentiates this effect. Because it is highly selective for PDE5, Viagra has been used to treat male erectile dysfunction with generally minor side effects. It is now being increasingly used for other indications including pulmonary hypertension.

Beyond Viagra, there are a number of other PDE inhibitors that are used clinically. In fact, the classic drugs papaverine and dipyridamole were used clinically before their effects on PDEs were known. Caffeine and theophylline (a compound found in tea) are also PDE inhibitors. However, all of these drugs most likely have multiple targets, making conclusions regarding the roles of PDEs in processes that are sensitive to these agents difficult to interpret. Certainly, some of their effects are due to their actions on adenosine receptors.

The PDE3 inhibitor, cilostazol, has been used as an antithrombotic agent and is currently being used in patients being treated for intermittent claudication. Cilostazol is also used for the prevention of ►restenosis after treatments such as angioplasty. Another PDE3 selective inhibitor, milrinone, has been used in the treatment of congestive heart failure. Milrinone also has been shown to increase the conductance of the CFTR transporter *in vitro*.

PDE4 inhibitors may also serve as antiinflammatory agents. Older PDE4 inhibitors tended to be limited by their emetic side effects, but newer drugs are now in clinical trials and may have milder side effects. These drugs (Ariflo; GlaxoSmithKline, and Roflumilast; Byk Gulden) are being tested for the treatment of asthma and chronic obstructive pulmonary disease with some success.

Dipyridamole is a PDE5/PDE6 selective inhibitor that is used widely in conjunction with aspirin to reduce clotting and prevent stroke. More recent studies with a fixed combination of these two drugs (Aggrenox) has been shown in the recent European Stroke Prevention Study 2 to be of greatly added benefit over aspirin alone for prevention of recurrent stroke.

Finally, IBMX is a methylxanthine derivative that has long been used in vitro as a general PDE inhibitor. IBMX is effective at inhibiting most PDEs, with IC₅₀s of 2–50 μM. However, the more recently cloned PDEs, PDE8, and PDE9, are IBMX-resistant. It is therefore important to keep this in mind when using IBMX to investigate potential roles for PDEs. A rather comprehensive review of the PDE field has appeared recently[1].

Phosphoinositol Kinases

- ▶ Phospholipid Kinases

Phospholipases

JOHN H. EXTON
Howard Hughes Medical Institute and Department of Molecular Physiology and Biophysics, Vanderbilt University School of Medicine, Vanderbilt University, Nashville, TN, USA

Definition

Enzymes that hydrolyze ▶ phospholipids

Basic Characteristics

Phospholipases are widely distributed in nature and carry out many important cellular functions. They are classified into four types: A₁, A₂, C and D. Phospholipase A₁ and A₂ act on the ester bonds that link fatty acids to the sn-1 and sn-2 positions of the glycerol backbone of phospholipids (Fig. 1). Their action generates free fatty acids and lysophospholipids. Phospholipase C acts on the phosphodiester bond that links the headgroup of the phospholipid to the glycerol backbone. It yields phosphorylated headgroups and ▶ diacylglycerol (DAG). Phospholipase D acts on the other side of the phosphodiester bond to yield free headgroups and ▶ phosphatidic acid (PA). Phospholipases alter cell activities through their effects on membrane phospholipids. Their products also influence cellular functions by acting as intracellular and extracellular messengers. Thus the lipids (fatty acids, DAG, PA) released as a result of phospholipase activity can alter the activity of enzymes and other cellular proteins or they can be metabolized to other lipids, some of which are released and exert diverse effects (eicosanoids, lysophosphatidic acid). Mammalian phospholipase C acts on inositol phospholipids, principally ▶ phosphatidylinositol 4,5-bisphosphate (PIP₂) and the phosphorylated headgroup primarily released by phospholipase C action (inositol 1,4,5-trisphosphate, IP₃) plays a major role in Ca²⁺ mobilization in the cell, with subsequent important physiological consequences. As expected from their important physiological functions, many phospholipases are highly regulated by hormones, neurotransmitters, growth factors and cytokines.

Phospholipase A1

Phospholipase A1 (PLA₁) is widely distributed. It has not been studied extensively and is not known to be

Phospholipases. Figure 1 Generic phospholipid with sites of action of phospholipases shown.

regulated. Its major substrates are PA, phosphatidylcholine (PC) and phosphatidylethanolamine (PE) and it releases mainly saturated or monounsaturated fatty acids, which are predominantly present at position sn-1 of these phospholipids. Through the combined action of PLA₁ and lysophospholipase, arachidonic or other unsaturated fatty acids can be released from the sn-2 position also. A PA-preferring PLA₁ isozyme has been cloned. It has a molecular mass of 98 kDa and is expressed in brain and testis. No other isozymes have been cloned. The function of PLA₁ relates to phospholipid remodeling, i.e. the substitution of one fatty acid by another, which it accomplishes in combination with lysophospholipid acyltransferase.

Phospholipase A₂

Phospholipase A₂ (PLA₂) occurs in several forms as the products of different genes (Tables 1 and 2). Some forms are of low molecular mass (<14 kDa) and are secreted by cells, whereas others are of higher mass (26–114 kDa) and are mainly located in the cytosol [1]. The smaller forms are components of snake and bee venoms, but some are also present in mammalian tissues and are secreted into pancreatic juice and synovial fluid [1]. They have a rigid crystal structure due to their high disulfide bond content (Table 1). Catalysis involves a conserved His that, together with a conserved Asp, polarizes a bound H₂O to attack the substrate carbonyl group. They require millimolar Ca²⁺ for activity. The Ca²⁺ is bound to a conserved glycine-rich loop and interacts with the conserved Asp to stabilize the transition state. Secretory PLA₂s (sPLA₂s) act predominantly on PC and PE and have been classified into several groups (I, II, III, V and X) based on sequence differences (Table 1). For conciseness, only the mammalian groups will be described. Group I sPLA₂ is present in pancreatic acinar cells as a proenzyme form. It is released into pancreatic juice and is converted by trypsin to the active form, which is involved in digestion. Group II sPLA₂ exists in several subgroups and is present in synovial fluid and many tissues. Group III sPLA₂ is present in several human tissues and has a preference for phosphatidylglycerol. Groups V and X are also widely distributed and are active on PC and PE. Serum levels of sPLA₂s are elevated in inflammatory conditions and trauma, and secretion of these isozymes into other body fluids occurs in specific diseases, e.g., pancreatitis, inflammatory bowel disease and arthritis. The secretion and expression of sPLA₂s is increased by pro-inflammatory cytokines, e.g., tumor necrosis factor α and certain interleukins, resulting in the production of arachidonic acid that is subsequently converted to prostaglandins and other eicosanoids.

The cytosolic forms show no sequence homology to the secreted forms and have a different catalytic mechanism [1]. They are widely distributed and occur

Phospholipases. Table 1 Classification of low molecular mass phospholipase A₂ isozymes that use catalytic His

^aGroup IVC does not require Ca²⁺

as either Ca²⁺-dependent and Ca²⁺-independent forms (Table 2). Ca²⁺-dependent PLA₂ (Group IV or cPLA₂) occurs in three isoforms (α , β , γ). cPLA₂ α is regulated by cytokines and growth factors and plays a major role in the regulated production of arachidonic acid. It shows marked specificity for phospholipids containing arachidonic acid in position sn-2 and also exhibits

lyosphospholipase activity. The arachidonic acid produced is subsequently metabolized to a variety of eicosanoids (e.g., prostaglandins, prostacyclin, thromboxanes, leukotrienes) that contributes to inflammation and a large variety of other physiological responses. These include changes in blood flow, platelet function, smooth muscle contractility, renal function, endocrine responses and gastrointestinal secretion. These effects may be positive or negative, depending on the specific eicosanoid and target tissue.

cPLA₂α (85 kDa) has been much studied and contains a Ca²⁺-lipid-dependent binding (CaLB) domain in its N-terminus [1]. The structure of this domain is similar to that of the C-2 Ca²⁺-binding domains found in ►protein kinase C, phospholipase Cδ and synaptotagmin. The catalytic mechanism is different from that of the low molecular mass PLA₂s and involves a Gly-Leu-Ser-Gly-Ser sequence, which resembles that seen in many serine esterases and neutral lipases. The central Ser (Ser²²⁸) serves as the active site nucleophile and catalyzes hydrolysis in association with Asp⁵⁴⁹. Like other serine esterases in which the nucleophilic serine is on a “nucleophilic elbow” (a turn between a β strand and α-helix), cPLA₂ has a central β-sheet with Ser²²⁸ located within this “elbow.” However, other structural features of the catalytic site are quite different from those of other serine esterases. Surprisingly, the catalytic site is buried quite deeply in the catalytic domain core suggesting that the enzyme must become embedded in the lipid bilayer.

An increase in Ca²⁺ in the micromolar range induces translocation of cPLA₂ to the nuclear membrane. The translocation involves the CaLB domain that presents the catalytic domain to the phospholipid substrate, resulting in increased arachidonic acid release. The enzyme is also phosphorylated and activated by mitogen-activated protein kinases (MAPKs). The phosphorylation is catalyzed by both extracellular signal-regulated kinase (ERK) and p38 MAPK, and involves a specific residue (Ser⁵⁰⁵). This Ser residue is located within the catalytic domain in close proximity to the C-2 Ca²⁺ binding domain. It has been proposed that phosphorylation of Ser⁵⁰⁵ improves the positioning of the catalytic site in relation to the lipid bilayer. In addition to its rapid activation by agonists that elevate cytosolic Ca²⁺ and activate MAP kinase, cPLA₂ can be regulated at the transcriptional level by the proinflammatory cytokines interleukin 1 and tumor necrosis factor α, whose action is inhibited by glucocorticoids. Other factors (macrophage colony-stimulating factor, lipopolysaccharide, epidermal growth factor) also activate transcription of cPLA₂.

The Ca²⁺-independent cytosolic PLA₂ (iPLA₂ or Group VI) isozymes are widely distributed and located predominantly in the cytosol [1], although there are some membrane-associated forms (Table 2). Their molecular masses range between 84 and 90 kDa due

to multiple splice variants, and some forms contain ankyrin repeats. They contain the lipase consensus sequence and the active Ser found in cPLA₂s. They are involved in phospholipid fatty acid remodeling and may be involved in arachidonic acid release and prostaglandin formation, although this is limited compared with other PLA₂ isozymes.

Two other groups of PLA₂s (Groups VII and VIII) inactivate platelet-activating factor (PAF) [1]. They are also called PAF-acetylhydrolases and are highly specific for PAF or PAF analogues with short-chain oxidized fatty acids in position sn-2. PAF is a modified form of PC in which the sn-1 chain is linked by an ether linkage, and an acetyl group is present at sn-2. It has many potent effects including vasodilation, platelet activation, chemotactic action and smooth muscle contraction. These types of PLA₂ have the characteristic lipase catalytic sequence of cytosolic PLA₂s, but are of lower molecular mass (26–45 kDa). They exist as either intracellular or secreted forms, and are found in many tissues.

Phospholipase C

In contrast to phospholipases of the A type, which have broad substrate specificity, phospholipase C (PLC) in mammalian cells acts only on inositol-containing phospholipids, in particular PIP₂, which is cleaved to form IP₃ and DAG (►PI response). Mammalian PLC occurs as four different isozymes (β, γ, δ and ε) and there are several subtypes of these (β1–β4, γ1, γ2, δ1–δ4) [2]. The β1, β3, γ1, δ1, δ4 and ε isozymes are widely distributed, whereas the β2 and γ2 forms are found predominantly in hematopoietic cells, and the β4 isozyme is confined to retina and brain. The β and γ isozymes are highly regulated by different agonists, whereas the δ isozymes are not subject to agonist control, but are stimulated by a rise in cytosolic Ca²⁺ [2]. The β isozymes are activated by α- or βγ-subunits released from heterotrimeric proteins of the G_q and G_{i/o} families as the result of activation of certain receptors. The γ isozymes are activated by growth factor receptors that encode tyrosine kinase activity and by cytokines that induce tyrosine phosphorylation of their receptors. The PLCε isozyme contains a Ras guanine nucleotide exchange factor domain (GRF CDC25) and two Ras binding domains. It is directly activated by active Ras, which also causes its membrane translocation.

All PLC isozymes have conserved catalytic domains designated X and Y, and a C2 domain similar to that in cPLA₂ (Fig. 2). In addition, the β, γ and δ isozymes have pleckstrin homology (PH) domains and EF-hand domains located in the N-terminal region. The γ isozymes differ in that they have Src homology domains (SH2 and SH3) and an additional PH domain split by the SH domains. The β and γ isozymes are of 140–155 kDa mass, whereas the δ isozymes are smaller (85 kDa) and the σ isozyme is larger (240 kDa).

The three-dimensional structure of PLC- δ 1 has been defined. The catalytic domain is in the form of an α/β or TIM barrel (discovered first in triosephosphate isomerase). The active site is in the cleft of the barrel and contains a coordinated Ca^{2+} that is required for catalysis. The proposed general mechanism is general base/general acid catalysis. Membrane binding of the enzyme depends on the PH domain, which is proposed to tether the enzyme through PIP_2 binding. The C2 domain is proposed to fix the catalytic domain so that it can penetrate the membrane, allowing PIP_2 hydrolysis to proceed.

The β isozymes are activated by G protein-coupled receptors through two different mechanisms [2]. The first involves activated α -subunits of the G_q family of heterotrimeric G proteins (G_q , G_{11} , G_{14} , $G_{15/16}$). These subunits activate the β 1, β 3 and β 4 PLC isozymes through direct interaction with a sequence in the C terminus. The domain on the $G_q\alpha$ -subunit that interacts with the β isozymes is located on a surface α -helix that is adjacent to the Switch III region, which undergoes a marked conformational change during activation. The second mechanism of G protein activation of PLC β isozymes involves $\beta\gamma$ -subunits released from $G_{i/o}$ G proteins by their pertussis toxin-sensitive activation by certain receptors. The $\beta\gamma$ -subunits activate the β 2 and β 3 PLC isozymes by interacting with a sequence between the conserved X and Y domains.

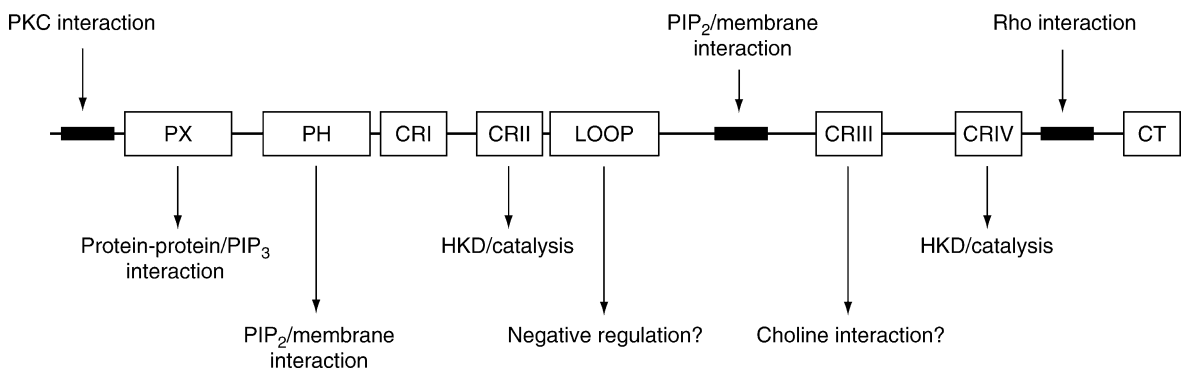

The physiological importance of PLC activation is to cleave PIP_2 into IP_3 and DAG. IP_3 induces the release of Ca^{2+} from Ca^{2+} stores in the endoplasmic reticulum, which results secondarily in increased Ca^{2+} influx into the cell. The resultant increase in cytosolic Ca^{2+} causes a variety of physiological responses including smooth muscle contraction in many organs, secretion of cellular constituents in many cells and glycogen breakdown and other metabolic responses in liver and other organs. The DAG that accumulates in the plasma membrane as a result of PLC activation causes membrane translocation and activation of most isozymes of protein kinase C (PKC). This kinase acts on many membrane proteins (e.g., receptors, ion channels, transporters) to modulate their activities and modify certain physiological responses.

Phospholipase D

Phospholipase D is widely distributed in bacteria, fungi, plants and animals, and is present in almost all mammalian cells [3]. In mammals, it occurs as alternatively spliced products of two genes (PLD1 and PLD2) (Fig. 3). Most mammalian cells express different levels of both isoforms. Both PLD1 and PLD2 have four conserved sequences (I-IV), and sequences I and IV contain the HXKX_4D (HKD) motif that is characteristic of the PLD superfamily, which includes bacterial endonucleases, phospholipid synthases, viral envelope

Phospholipases. Figure 3 Representation of the domain structure of phospholipase D1 (adapted from [4]).

proteins and a murine toxin (Fig. 3) [3]. Both HKD domains are required for catalytic activity and they dimerize to form the catalytic center. Catalysis occurs in a two-step reaction involving the two His residues of the dimer [3]. The first step is a nucleophilic attack by one His on the substrate phosphorus to produce a phosphatidyl-enzyme intermediate. The second step involves the other His that protonates the oxygen of the leaving group. Both PLD isoforms require PIP₂ for activity, but are distributed in different cellular sites and are differentially regulated. PLD1 is activated in vitro by the α and β isozymes of PKC and by members of the Rho and ARF families of low Mr G proteins [3]. Combinations of these proteins produce synergistic activation of the enzyme. In contrast, PLD2 is not regulated by these factors in vitro. The interaction site for PKC α is at the N-terminus of PLD1, while that for RhoA is at the C-terminus. The binding site for ARF is unknown.

PLD is highly regulated in vivo by hormones, neurotransmitters and other G protein-coupled agonists, and also by growth factors and cytokines. The regulation is not direct but involves signaling through PKC and Rho family proteins. The enzyme can be phosphorylated on Tyr and Ser/Thr residues in vivo, but the role of these phosphorylations in its regulation is unclear. The cellular roles of PLD include the regulation of Golgi function, exocytosis, endocytosis, the actin cytoskeleton, superoxide production and growth. It has been proposed that the role of ARF in vesicle trafficking in the Golgi involves not only coatomer formation, but also PLD activation, which stimulates vesicle budding through PA formation. PLD is implicated in catecholamine secretion, endocytosis of membrane receptors and glucose transport. The rearrangement of the actin cytoskeleton resulting in stress fiber formation also depends on PLD activity. The activation of NADPH oxidase that yields superoxide in neutrophils involves PA formation via PLD activity, and PLD has been implicated in ERK activation in some cells.

Drugs

Phospholipase A2

Glucocorticoids inhibit cPLA₂ at the level of transcription and this is part of their anti-inflammatory action. Antimalarial drugs (mepacrine, aminoglycosides and polyamines) inhibit PLA₂ activity, but they are too non-specific to be therapeutically useful. This is also true of covalent-modifying PLA₂ agents such as manoalide and *p*-bromophenacyl bromide, which are selective for sPLA₂ in vitro. Another agent 3-(3-acetamide-1-benzyl-2-ethylindol-5-oxy) propane sulfonic acid (LY311727) inhibits sPLA₂ selectively in cell studies, but there have been no reports of its use in vivo. Arachidonyl trifluoromethyl ketone and methylarachidonyl fluorophosphonate are

potent cPLA₂ inhibitors. However, they are too toxic and insufficiently specific to be useful therapeutically. Bromoenol lactone, which is a potent inhibitor of cPLA₂, has actions on other lipid-metabolizing enzymes and therefore limits its use in vivo.

Phospholipase C

There are no specific inhibitors of PLC, but compounds that interact with PIP₂, e.g., neomycin can reduce its activity. However, such drugs interfere with other signaling processes involving this lipid. The aminosteroid 1-[6-[[17 β -3-methoxyestra-1,3,5(10)-trien-17-yl]amino]hexyl]-1*H*-pyrrole-2,5-dione (U-73122) has been reported to inhibit PLC, but has other effects related to cell Ca²⁺ homeostasis.

Phospholipase D

There are no specific inhibitors of PLD. Xanthogenate tricyclodecan-9-yl (D609) and 1-*O*-octadecyl-2-*O*-methyl-sn-glycero-3-phosphocholine (ET-18-OCH₃) lack specificity since they act by competing with substrate (phosphatidylcholine). Primary alcohols such as ethanol, propanol and butanol inhibit the actions of PLD by reducing the formation of PA through the transphosphatidyl reaction that generates phosphatidylalcohols. Since PA is the primary signaling molecule produced by PLD action, the cellular actions of this lipid are curtailed.

Phospholipids

Phospholipids are a major component of all biological membranes together with glycolipids and cholesterol. Due to their polar nature, i.e. hydrophilic head and hydrophobic tail, phospholipids form in water vesicles or liposomes.

Phosphoinositol kinases; Phosphatidylinositol kinases;
 Phosphatidylinositide kinases

Definition

► **Phospholipid** kinases comprise a family of enzymes that phosphorylate ► **phosphatidylinositol** and phosphatidylinositides at positions 3', 4' or 5' but not at positions 2' and 6' of the inositol ring (Fig. 1). Phosphatidylinositides represent approximately 1% of all membrane lipids such as those of the plasma, nuclear and endomembranes. In unstimulated cells, more than 90% of all phosphoinositides correspond to unphosphorylated phosphatidylinositol (PtdIns), whereas the remaining 10% consist of roughly equal amounts of phosphatidylinositol 4-phosphate (PtdIns(4)P) and phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P₂) [1]. PtdIns and its derivatives are referred as phosphoinositides or PIs. Initially, it was assumed that these phosphoinositides function exclusively as precursors for signalling molecules. For instance, PtdIns(4,5)P₂ serves as a substrate for phospholipase C and phosphoinositide 3-kinases (PI3K). Interestingly, PtdIns(4,5)P₂ also interacts with intracellular proteins in a regulatory manner, thereby affecting their localization and activity. In resting cells, less than 0.25% of the phosphoinositides are 3'-phosphorylated. Stimulation of cells with ligands that activate receptor tyrosine kinases or ► **G protein-coupled receptors** (GPCRs) results in the rapid and transient phosphorylation of PtdIns(4,5)P₂ to phosphatidylinositol 3,4,5-triphosphate PtdIns(3,4,5)P₃. This 3'-phosphorylated phosphoinositide behaves as a typical second messenger. Hence, the responsible phosphoinositide 3-kinases are considered as important regulatory molecules of the cell.

All phosphoinositides are found in the cytosolic half of the lipid bilayer of the plasma or intracellular compartment membranes (left part). The different kinases acting on phosphoinositides in mammalian cells are shown in solid lines and the phosphoinositide 3-kinases, in bold. The phosphoinositides counterpart pathways catalysed by known phosphatases are represented by dashed lines. The best known phosphatases are PTEN (Phosphatase and tensin homolog deleted on chromosome 10) and SHIP (SH₂ domain-containing inositol 5-phosphatase).

Basic Characteristics

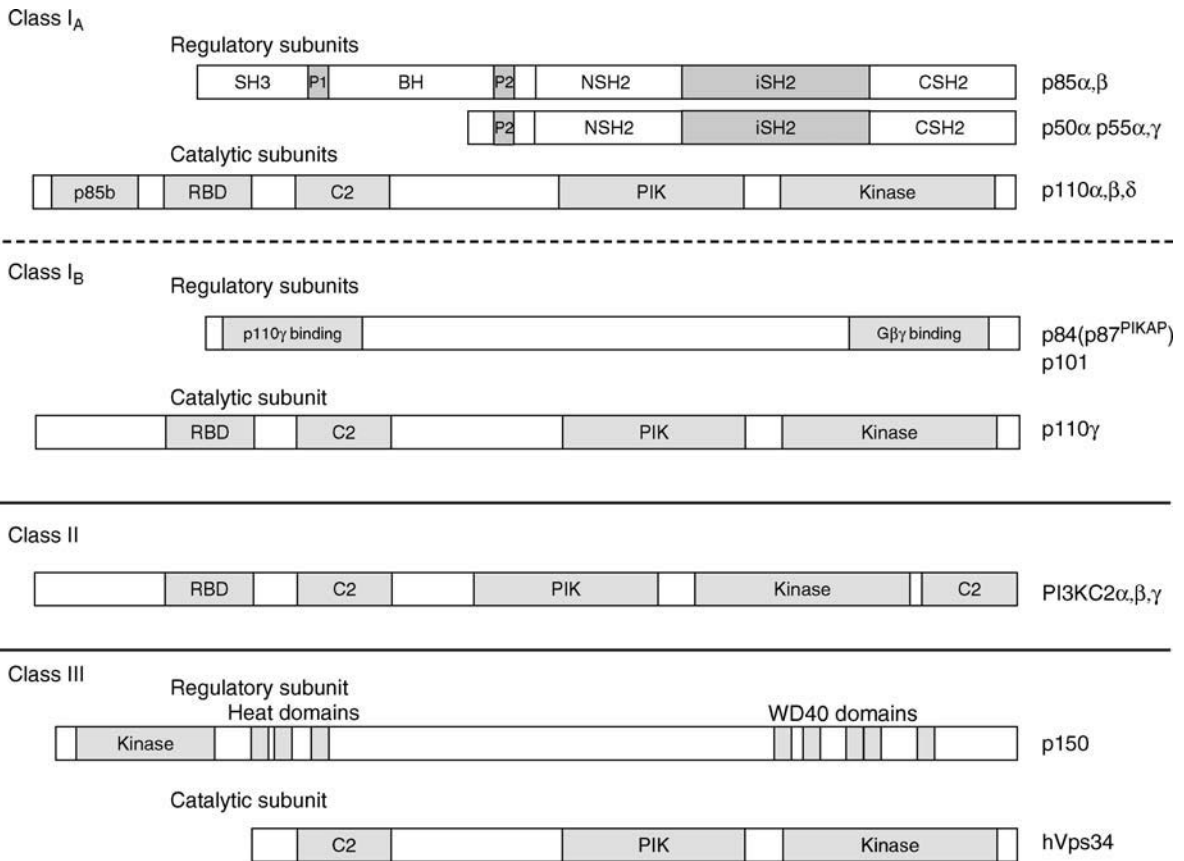

Cellular phosphoinositide concentrations are under tight control by phospholipid kinases and phosphatases. Phospholipid kinases preferentially phosphorylate distinct positions of the inositol ring and hence are subdivided into phosphoinositide 3-kinases (PI3Ks), phosphoinositide 4-kinases (PI4Ks), and phosphoinositide 5-kinases (PI5Ks) that phosphorylate PIs on position 3', 4' and 5', respectively. In a canonical pathway, PtdIns(4,5)P₂ is generated from PtdIns(4)P by the enzymatic activity of phosphatidylinositol 4-phosphate 5-kinase (PIP5K) (Fig. 1). Additional pathways are likely to be discovered.

Among the described phosphoinositides, PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ have been recognized as important intracellular mediators of signalling processes. These molecules act as second messengers generated after stimulation of cells by extracellular stimuli. They are involved in cell survival pathways, the regulation of gene expression, cell metabolism and cytoskeletal rearrangements involved in cell motility [2]. Correspondingly, the enzymes producing PtdIns(3,4,5)P₃ have been implicated in major human diseases such as diabetes, cancer and inflammatory processes. This has generated high interest in establishing specific pharmacological tools to interfere with PtdIns 3-dependent pathways. Based on their substrate specificity, phosphoinositide 3-kinases (PI3K) are subgrouped into three classes (Fig. 2).

Shown are schematic representations of the catalytic and regulatory subunits of PI3Ks. SH2, SH3 (src-homology domain 2 and 3), P1, P2 (proline rich region 1 and 2), RBD (ras binding domain) represent protein-protein interaction domains. The C2 domain is a membrane-binding domain that was first identified as a calcium-binding domain in protein kinase C (PKC). The PIK (phosphoinositide kinase) domain is shared by all the lipid kinases; p85b indicates the binding site for the regulatory subunits.

Classification of PI3Ks

All class I PI3Ks are heterodimeric enzymes composed of a 110 kDa catalytic subunit (with the isoforms p110 α , β , δ or γ) that associates with a regulatory subunit. Although the class I PI3Ks are capable of phosphorylating PtdIns, PtdIns(4)P and PtdIns(4,5)P₂ in vitro, it appears that they only use PtdIns(4,5)P₂ as a substrate in vivo. Receptor-induced formation of PtdIns(3,4,5)P₃ from PtdIns(4,5)P₂ seems restricted to the enzymatic activity of class I kinases. Class I_A PI3K catalytic subunits are relatively unstable and form a complex with either one of five different regulatory subunits (p85 α , p55 α , p50 α , p85 β or p55 γ), which contain ► **two src-homology 2 (SH2-domains)**. These SH2-domains specifically recognize phosphorylated tyrosine residues that are present on activated growth

Phospholipid Kinases. Figure 2 Classification of phosphoinositide 3-kinases.

factor receptors or on growth factor receptor substrates. This interaction results in a translocation of the cytosolic heterodimeric enzyme to the inner leaflet of the plasma membrane, thus bringing the catalytic subunit p110 close to its lipid substrate PtdIns(4,5)P₂. In addition, the interaction with the tyrosine-phosphorylated receptor induces a conformational change of p85, which disinhibits the enzymatic activity of the p110 catalytic subunit. The p85 subunits contain characteristic protein domains which allow multiple protein–protein interactions (Fig. 2). For instance, the inter-SH2-region (iSH2) of p85 mediates the interaction with the catalytic p110 subunit. Interestingly, p85 may possess also a PI3K-activity independent role. Indeed, this regulatory subunit has been implicated, independently of the catalytic subunit p110, in cell migration and cytokinesis. All class I PI3Ks are also assumed to be under control of monomeric **Ras proteins**. There is evidence that the different Ras isoforms activate PI3Ks with different potencies. The impact of this type of regulation is currently not well understood. Very little is known in molecular terms about the apparent preference of a given receptor for a specific catalytic subunit. One may speculate that both the growth factor receptor interacting with p85 and the Ras protein interacting with p110 can

influence the assignment of a specific p110 isoform to a specific signalling pathway. Class I_A PI3Ks are mainly involved in the regulation of cell growth and proliferation [2]. Furthermore, they are essential for mediating insulin functions, and have been linked to diabetes mellitus type 2. An increase of the class I_A PI3K activity has been found in a number of different human cancers.

Class I_B PI3Ks signal downstream of GPCRs. The p110 γ catalytic subunit is associated with one of two regulatory subunits, p101 or p84 (also known as p87^{PIKAP}). p101 and p84 are structurally distinct from class I_A PI3K adaptor proteins. Similar to class I_A PI3Ks, unstimulated class I_B PI3K γ is predominantly localized in the cytosol. Upon GPCR activation, G β γ dimers directly bind PI3K γ and induce a recruitment to the plasma membrane and a subsequent activation of PI3K γ . p84-containing PI3K γ is less sensitive towards G β γ than p101-containing PI3K γ . The physiological significance of this difference is not known. In addition to its predominant expression in the haematopoietic cells, PI3K γ is also found in other organs and tissues including cardiac and vascular tissues.

Two other classes of PI3Ks have been less intensively investigated. Class II PI3Ks are subdivided into PI3K-C2 α , PI3K-C2 β and PI3K-C2 γ . They are large

monomeric enzymes of 170–210 kDa molecular weight that phosphorylate PtdIns to PtdIns(3)P. In contrast to class I PI3K mainly cytosolic, class II PI3Ks are predominantly found in membrane fraction of cells including plasma and intracellular membranes [1]. They respond to a wide array of stimuli, such as chemokines, insulin and growth factors through mechanisms that are not yet well defined. Based on their potential role in cell survival and cell migration, class II PI3Ks are also considered as potential targets for anticancer therapies.

The vacuolar protein-sorting protein (Vps34p) represents the prototypical class III PI3K. Vps34p was initially identified in *Saccharomyces cerevisiae*. In mammalian cells, hVps34 is involved in the regulation of ►autophagy, a conserved lysosomal degradation pathway. A serine/threonine kinase, i.e. p150, is known to form a heterodimer with hVps34, and to be responsible for the membrane association of this PI3K. A Bcl-2-interacting protein named Beclin 1 forms a complex with hVps34/Class III PI3K to generate PtdIns(3)P, which is thought to be important in mediating the localization of other proteins to preautophagosomal membranes. Interestingly, Beclin is found monoallelically deleted in a high number of humans cancers. Currently, investigations are underway to define the role of autophagy in human diseases like cancer, pathogen infection and neurodegeneration. Because of its role in autophagy, type III PI3K may be a potential therapeutic target for the treatment of these diseases [3].

Protein Kinase Activity of PI3K

In all the known catalytic subunits of PI3K, the C-terminal kinase domains show considerable similarity with classical serine/threonine kinases. Indeed, PI3Ks can function as dual-specific enzymes and exhibit a protein kinase activity in addition to their lipid kinase activity. Novel aspects of PI3K regulation were revealed by the discovery that the PI3K lipid kinase activity can be modulated by autophosphorylation of the catalytic subunit p110 and/or by trans-phosphorylation of the associated regulatory p85. Accordingly, it became apparent that both enzymatic qualities, i.e. the lipid as well as the protein kinase activities, are required for certain physiological processes. For instance, the endocytosis of β -adrenergic receptors requires both lipid and protein kinase activities of PI3K γ . To date, however, very few protein substrates for PI3K are known. Recently, a surprising role for PI3K γ as a scaffolding protein has emerged from cardiovascular studies of genetically engineered mice expressing a catalytically inactive point mutant of PI3K γ . These results have led to the proposal that PI3K γ regulates cardiac contractility independent of its kinase activity.

Downstream Effectors of PI3Ks

The importance of PI3Ks arises from the fact that numerous important signalling molecules need to be

localized to the plasma membrane to fulfill their functions. Binding to 3'-phosphorylated phosphoinositides constitutes a major mechanism of membrane translocation for the signalling molecules. The prototypical phosphoinositide binding domain is the ►pleckstrin homology-domain (PH-domain), which binds to the second messengers PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ with different affinities (Fig. 3). A PH-domain protein known to play a pivotal role in PI3K signalling is protein kinase B (PKB), also called *Akt* [4]. Plasma membrane recruited and activated PKB triggers multiple signalling cascades implicated in an array of normal and pathophysiological cell processes, such as inflammation, metabolism and tumorigenesis (Fig. 3).

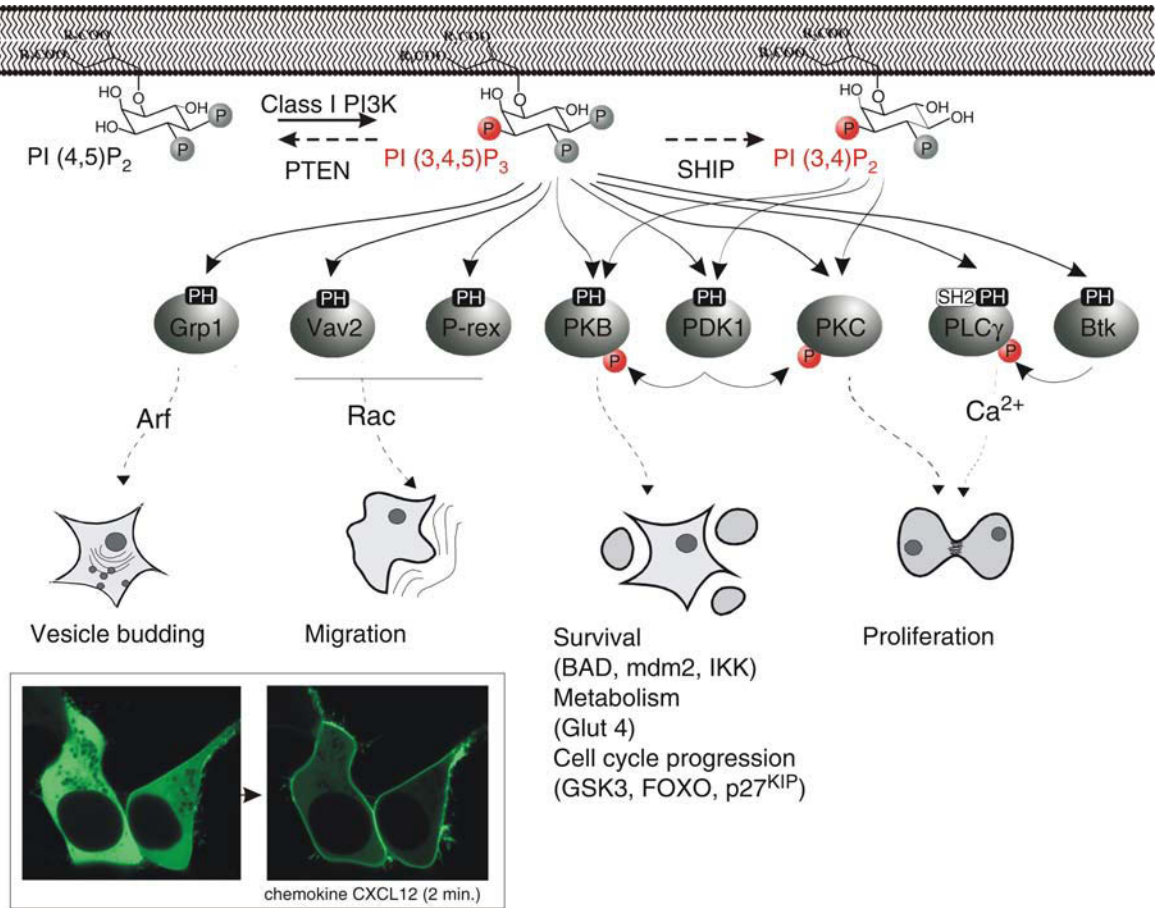

Bottom left panel: Visualization of the translocation of GFP-fused Grp1 PH-domain in living cells. Human embryonic kidney cells (HEK293) were stimulated with the chemokine CXCL12. The GFP-fused Grp1 PH-domain protein translocates from the cytosol to the plasma membrane, reflecting an increased PI3K γ -mediated PtdIns(3,4,5)P₃ production. HEK293 were transfected with the chemotactic GPCR (CXCR4), PI3K γ and GFP-fused Grp1 PH-domain.

Numerous other PH-domain containing proteins are implicated in important physiological processes, such as the guanosine nucleotide exchange factors (GEFs) Vav and P-Rex. GEFs exchange GDP for GTP and lead to an activation of small GTPases. Vav and P-Rex regulate the activity of the small GTPase Rho/Rac and are involved in cytoskeletal remodelling and cell motility. Grp1, a GEF for the small GTPase Arf, is necessary for vesicle budding (Fig. 3).

PtdIns(3)P generated by class II or III PI3Ks interacts with the FYVE Zinc finger domains (acronym of FYVE: *Fab1p*, *YOTB*, *Vac1p* and *EEA1*) as well as PX domains (a domain originally identified as a common motif in the p40phox and p47phox of the neutrophil NADPH oxidase complex). Other phosphoinositides-binding domains have been identified. Among them, are FERM domains (band four-point one, ezrin, radixin, moesin) that link cytoskeleton to the plasma membrane, or ENTH domains (epsin N-terminal homology) that play a role in endocytosis.

Drugs

As described above, PI3Ks are critical for many signalling pathways that control growth and survival of the cells. Not surprisingly, PI3Ks are regarded as attractive drug target for cancer therapy and for the treatment of other human diseases. The development of PI3K deficient mice has contributed to our understanding of specific physiological roles of the various catalytic and regulatory subunits in mammals. The deletion of either p110 α or p110 β genes in mice results in embryonic lethality, thus limiting the analyses of the post-embryonic functions of these catalytic PI3K isoforms. In contrast, mice lacking the genes encoding for PI3K δ and γ are

Phospholipid Kinases. Figure 3 Role of PH-domain containing effectors of class I PI3Ks in various cellular processes.

viable. The studies of characteristics of PI3K γ - and δ -deficient mice have revealed the importance of these two isoforms in certain immune cell functions, such as the development of T and B cells, leukocyte migration, mast cell degranulation and oxidative burst of neutrophils. The classical PI3K inhibitors \blacktriangleright Wortmannin and LY294002 show very little selectivity for the different PI3K isoforms. A recent challenge for pharmaceutical and academic groups alike consists in identification of isoform-selective small-molecule PI3K inhibitors. Such inhibitors could be used for treatment of cancer, neurodegeneration or inflammatory diseases. Recently, very promising studies show that new inhibitors targeting specifically PI3K γ reduce the severity of inflammatory diseases in mice model of rheumatoid arthritis and lupus [5]. These isoform-selective inhibitors could potentially be of great use for the treatment of human inflammatory diseases.

Phospholipid Phosphatases

Phospholipid phosphatases are enzymes such as SHIP (SH2-domain containing inositol-5-phosphatase) or PTEN (phosphatase and tensin homolog deleted on chromosome 10) which dephosphorylate phosphoinositides. Whereas SHIP removes phosphate from the 5'

position, PTEN dephosphorylates the 3' position of the inositol. Therefore, PTEN has opposite effects to phosphatidylinositol (PI) 3-kinases and is considered to be a tumor suppressor.

- ▶ Phosphatases
- ▶ Phospholipid Kinases

Phosphorylation

Phosphorylation is the reversible process of introducing a phosphate group onto a protein. Phosphorylation occurs on the hydroxyamino acids serine and threonine or on tyrosine residues targeted by Ser/Thr kinases and tyrosine kinases respectively. Dephosphorylation is catalyzed by phosphatases. Phosphorylation is a key mechanism for rapid posttranslational modulation of protein function. It is widely exploited in cellular processes to control various aspects of cell signaling, cell proliferation, cell differentiation, cell survival, cell metabolism, cell motility, and gene transcription.

Phosphotyrosine-binding Domains

Synonyms

PTB

Definition

Noncatalytic phosphotyrosine binding (PTB) domains are 100–150 residue modules, which bind Asn-Pro-X-Tyr motifs. PTB-domain binding specificity is determined by residues at the amino-terminal side of the phosphotyrosine. In most cases, the tyrosine residue must be phosphorylated in order to mediate binding. PTB domain containing proteins are often found in signal transduction pathways.

- ▶ Growth Factors

Photoaging

Photoaging and photodamage (dermatoheliosis) are terms used interchangeably to describe chronic changes in the appearance and function of the skin caused by

repeated sun exposure rather than by the passage of time (the latter is called intrinsic or chronologic aging). Epidemiologic and laboratory evidence indicates that sun exposure and other sources of UV radiation (UVR) play the major role in causing the undesirable skin changes of fine and coarse wrinkles, roughness, laxity, mottled pigmentation, actinic lentigines, actinic keratoses, leathery texture/coarseness, scaling/xerosis, sallowness, and telangiectasia. Cigarette smoking is the only other environmental factor that has been related to the development of changes in the skin associated with aging.

Photoaging and photodamage are serious medical problems, not just cosmetic or aesthetic concerns, because prevention of photoaging and photodamage may prevent the progression of changes toward skin cancer.

The use of sunscreens that protect against UVB and UVA should be encouraged. There is no safe way to tan!

²Chair of Cell Biology, University of Nottingham Medical School, School of Biomedical Sciences, Nottingham, NG7 2UH

Definition

► PIAS (protein inhibitors of activated STATs) proteins were first discovered in yeast-two-hybrid screens as interacting molecules with ► STAT transcription factors. The mammalian family consists of the founding member PIAS3, which was described as a repressor of STAT3, and three additional members, PIAS1, PIASy (also known as PIAS4), and PIASx (also known as

PIAS2 with α and β splice variants, termed ARIP3 (androgen receptor-interacting protein 3) and Miz1 (*Msx*-interacting zinc finger), respectively. Despite their name, PIAS proteins do not selectively inhibit STAT-mediated ► cytokine signaling (Fig. 1), but function as transcriptional coregulators in diverse pathways either by activating or repressing gene expression [1–4]. PIAS proteins have been shown to interact with a broad range of transcription factors unrelated to STATs, such as p53, c-Jun, Smad, β -catenin/lymphoid enhancer factor 1, NF- κ B p65, nuclear hormone receptors, and other proteins. Recently, PIAS proteins have been identified as ► SUMO E3 ligases, which catalyze the covalent addition of small ubiquitin-like modifier (SUMO) to different target proteins acting in these pathways.

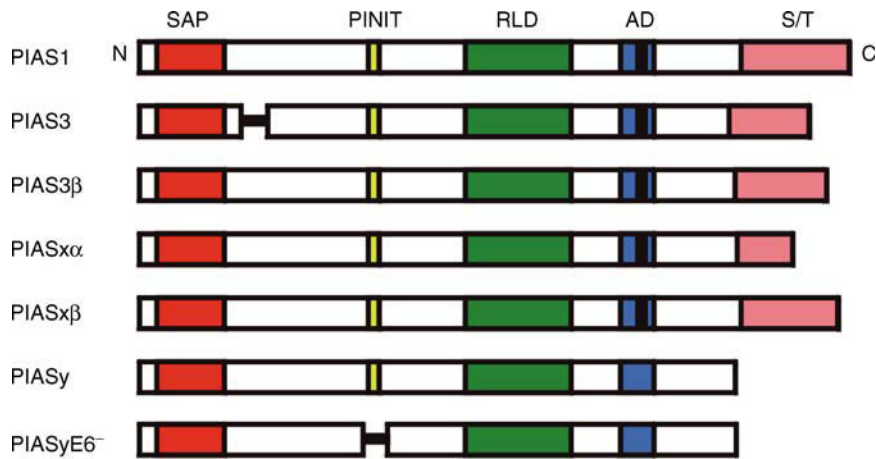

Domain Structure and Function

With the exception of a variable carboxy-terminal region, the mammalian PIAS proteins all share a high degree of sequence homology and a common domain structure (Fig. 2).

The overall sequence identity at the amino acid level is more than 40%. PIAS1 with a length of 651 amino acid residues is the largest member, whereas PIASy lacking the C-terminal serine/threonine-rich domain is the smallest. In the amino-terminus of all PIAS proteins a SAP domain is located which contains an LXXLL amino acid motif (where X denotes any amino acid residue). The acronym refers to three defining members of the class of SAP-containing proteins, namely scaffold-attachment factor (SAF), apoptotic chromatin-condensation inducer in the nucleus (*ACINUS*), and PIAS, and has been suggested to confer binding to chromatin structures. The SAP domain of PIASy and PIAS1 has been shown to bind synthetic nonspecific (A + T)-rich DNA sequences in

PIAS Proteins. Figure 1 Reporter gene assay with an interferon- γ -driven artificial promoter demonstrating the inhibitory transcriptional activity of increasing amounts of PIAS on STAT1 signal transduction.

PIAS Proteins. Figure 2 Domain structure of PIAS proteins. For abbreviation see text.

vitro, suggesting that it targets PIAS proteins to the nuclear matrix. The PINIT motif is present in all PIAS proteins except the splice variant PIASyE6⁻ which lacks exon 6. Mutation in the PINIT motif results in disrupted nuclear localization of PIAS3, suggesting a role in nuclear retention. Another conserved domain is the RING-finger-like domain (RLD), which resembles the zinc-binding RING fingers found in a subclass of ubiquitin E3 ligases, except for a different spacing of the zinc-coordinating residues. And indeed, the RLD domain has been shown to confer E3 ligase activity for SUMO modification. The carboxy-terminus of PIAS proteins contains a highly acidic domain (AD) with a putative SUMO-interaction motif (SIM; except for PIASy, in which the SIM is missing) and a serine/threonine-rich domain (S/T).

Basic Characteristics

PIAS proteins have been described as adapter molecules that function as E3-like ligase in enhancing the interaction between the SUMO-conjugating enzyme Ubc9 and the respective substrates. PIAS proteins facilitate the formation of an isopeptide bond between the C-terminus of SUMO with the ε-amino group of a lysine residue in the target protein. SUMOylation has been suggested to regulate a variety of cellular processes, such as modulation of transcriptional activity, targeting of proteins to subnuclear structures, and protein stability. PIAS might repress or stimulate gene expression, depending on the target gene and the transcriptional cofactors involved. The molecular mechanisms of PIAS-mediate gene regulation include inhibition of DNA-binding of transcription factors as well as recruiting of coregulators, such as histone deacetylases, p300 or, CPB [cyclic-AMP-responsive-element binding (CREB)-protein]. Sequestering transcription factors in subnuclear structures has been proposed as another mechanism for PIAS action. The

role of SUMOylation in these processes is currently unclear and needs further attention. PIAS1-knockout mice show increased protection against pathogenic infection, but are otherwise viable. PIASy-deficient mice display no obvious phenotype, suggesting a redundancy with other members of the family of PIAS proteins.

Drugs

Specific antagonists of PIAS proteins are not available. The engagement of PIAS proteins in different signal pathways suggests that inhibition of PIAS might cause pleiotropic effects. Due to the promiscuous actions of PIAS, the pharmacological reactions resulting from blockade of PIAS functions are currently far from being predictable. Moreover, the response may differ depending on which member of the PIAS family is preferentially targeted.

Pituitary Adenylyl Cyclase-Activating Polypeptide

Pituitary Adenylyl Cyclase-activating Polypeptide (PACAP) is a 38-amino acid peptide (PACAP-38), which is widely expressed in the central nervous system. PACAP is most abundant in the hypothalamus. It is also found in the gastrointestinal tract, the adrenal gland and in testis. Its central nervous system functions are ill-defined. In the periphery, PACAP has been shown to stimulate catecholamine secretion from the adrenal medulla and to regulate secretion from the pancreas. Three G-protein coupled receptors have been shown to respond to PACAP, PAC₁ (PACAP type I) specifically binds PACAP, VPAC₁ and VPAC₂ also bind vasoactive intestinal peptide (VIP). Activation of PACAP receptors results in a G_s-mediated activation of adenylyl cyclase.

PKA

Protein kinase A (PKA) is a cyclic AMP-dependent protein kinase, a member of a family of protein kinases that are activated by binding of cAMP to their two regulatory subunits, which results in the release of two active catalytic subunits. Targets of PKA include L-type calcium channels (the relevant subunit and site of phosphorylation is still uncertain), phospholamban (the regulator of the sarcoplasmic calcium ATPase, SERCA) and key enzymes of glucose and lipid metabolism.

Placebo Effect

FABRIZIO BENEDETTI

Department of Neuroscience, University of Turin Medical School, and National Institute of Neuroscience, Turin, Italy

Synonyms

Placebo response

Definition

The placebo effect is the reduction of a symptom, or a change in a physiological parameter, when an inert treatment (the placebo) is administered to a subject who is told that it is an active drug with specific pharmacological properties. The placebo effect, so far considered a nuisance in clinical research when a new treatment has to be tested, has now become a target of scientific investigation to better understand the physiological and neurobiological mechanisms that link a complex mental activity to different functions of the body. Usually, in clinical research the term placebo effect refers to any improvement in the condition of a group of subjects that has received a placebo treatment, thus it represents a group effect. Conversely, the term placebo response refers to the change in an individual caused by a placebo manipulation. However, these two terms are sometimes used interchangeably. It is important to realize that there is not a single placebo effect but many, which occur through different mechanisms in different conditions, systems and diseases [1, 2, 3].

Basic Mechanisms

Methodological Considerations

The identification of a placebo effect is not easy and its study is full of drawbacks and pitfalls. In fact, the effect which follows the administration of a placebo can be due

to many factors, such as spontaneous remission, i.e. natural history (natural course of a disease or a symptom), regression to the mean (statistical phenomenon which assumes that individuals tend to receive their initial symptom assessment when the symptom is near its greatest intensity, and that their symptom level is likely to be lower when they return for a second assessment), symptom detection ambiguity and biases. All these phenomena need to be ruled out by means of control groups. The possibility of spontaneous remission can be discarded by means of a no-treatment group, which gives us information about the natural course of a symptom. Regression to the mean, can be controlled by using an experimental model in healthy volunteers. Symptom detection ambiguity and biases can be avoided by using objective physiological measurements. It is also important to rule out the possible effects of co-interventions. For example, the mechanical insertion of a needle for the injection of an inert substance may per se induce analgesia, thus leading to erroneous interpretations.

When all these phenomena are ruled out and the correct methodological approach is used, striking placebo effects can be detected which are mediated by psychophysiological mechanisms worthy of scientific inquiry [4, 5]. Therefore, it is this psychological component that represents the real placebo effect.

Psychological Mechanisms

The placebo effect is basically a context effect, whereby the psychosocial context (e.g. the therapist’s words, the sight of complex machines, and other sensory inputs) around the medical intervention plays a crucial role. Today we know that the context may produce a therapeutic effect through at least two mechanisms: conscious anticipatory processes and unconscious conditioning mechanisms. In the first case, expectation (anticipation of an event; according to expectation theories, expecting an outcome affects the outcome itself) and anticipation of clinical benefit has sometimes been shown to induce a real clinical improvement. In the second case, contextual cues (e.g. colour and shape of a pill) may act as a conditioned stimulus that, after repeated associations with an unconditioned stimulus (the active pharmacological agent contained in the pill), are capable alone of inducing a clinical improvement. In the case of pain and Parkinson’s disease, it has been shown that expectations play a crucial role, even though a ►conditioning procedure is performed.

Neurobiology of Placebo Analgesia

The neural mechanisms underlying the placebo effect are only partially understood and most of our knowledge comes from pain, although recently Parkinson’s disease, immune and endocrine responses, and depression have emerged as interesting models (Fig. 1). In each of these

Placebo Effect. Figure 1 Cascade of events that may occur during a placebo procedure in different systems and diseases. In pain, both opioid and non-opioid mediators can be released through the activation of a descending inhibitory network. The respiratory centres may be inhibited by opioid mechanisms as well. The beta-adrenergic sympathetic system is also inhibited during placebo analgesia, although the underlying mechanism is not known (reduction of the pain itself and/or direct action of endogenous opioids). Cholecystikinin (CCK) counteracts the effects of the endogenous opioids, thus antagonizing placebo analgesia, and is also a mediator of the hyperalgesic nocebo effect. Placebos may also affect hormone secretion, like growth hormone (GH), adrenocorticotrope hormone (ACTH) and cortisol, as well as some immune mediators, such as IL-2, gamma-IFN and lymphocytes. In Parkinson's disease, placebos induce dopamine release in the striatum, whereas in depression they affect the same brain regions that are affected by serotonin re-uptake inhibitors, thus suggesting the involvement of serotonin in the placebo effect in depression.

conditions, different mechanisms seem to take place, so that we cannot talk of a single placebo effect but many.

As to pain and analgesia, in the studies so far performed there is a general agreement that the ►endogenous opioid peptide systems play an important role in some circumstances. There are several lines of evidence indicating that placebo analgesia is mediated by a descending pain-modulating circuit which uses endogenous opioids as neuromodulators. This evidence comes from a combination of both imaging and pharmacological studies. In fact, by using ►positron emission tomography (PET), it was found that the very same regions of the brain in the cerebral cortex and in the brainstem are affected by both a placebo and the opioid agonist remifentanyl, thus indicating a related mechanism in placebo-induced and opioid-induced analgesia [5]. In particular, the administration of a placebo induces the activation of the rostral

anterior cingulate cortex (rACC), the orbitofrontal cortex (OrbC) and the brainstem. Moreover, there is a significant covariation in activity between the rACC and the lower pons/medulla at the level of the rostral ventromedial medulla (RVM), and a subsignificant covariation between the rACC and the periaqueductal grey (PAG), thus suggesting that the descending rACC/PAG/RVM pain-modulating circuit is involved in placebo analgesia. In another study with ►functional magnetic resonance imaging (fMRI), it was shown that placebo administration produces a decrease of activity in many regions involved in pain transmission, such as the thalamus and the insula.

The studies with PET and fMRI tell us that placebo analgesia and opioid analgesia share a common neural mechanism and that pain transmission is inhibited by placebos, but they do not allow to conclude that the placebo-activated descending network is an opioid

network. In support of the involvement of endogenous opioids in this descending circuit there are several pharmacological studies which show that placebo analgesia is antagonized by the opioid antagonist naloxone. In addition, it has been shown that the endogenous opioid systems have a somatotopic organization, since local placebo analgesic responses in different parts of the body can be blocked selectively by naloxone. A recent PET study used in vivo receptor binding to show that placebos induce the activation of *mu* opioid receptors in different brain areas, like the dorsolateral prefrontal cortex, nucleus accumbens, insula and rACC.

The placebo-activated endogenous opioids do not act only on pain transmission, but on the respiratory centres as well, since a naloxone-reversible placebo respiratory depressant effect has been described. Likewise, a reduction of ►beta-adrenergic system activity, which is blocked by naloxone, has been found during placebo analgesia. These findings indicate that the placebo-activated opioid systems have a broad range of action, influencing pain, respiration and the autonomic nervous system, though it is not known whether they act only through a descending modulating network. The placebo-activated endogenous opioids have also been shown to interact with endogenous substances that are involved in pain transmission. In fact, on the basis of the anti-opioid action of ►cholecystokinin (CCK), CCK-antagonists have been shown to enhance placebo analgesia, thus suggesting that the placebo-activated opioid systems are counteracted by CCK during a placebo procedure.

It is important to point out that some types of placebo analgesia appear to be insensitive to naloxone, thus suggesting that neuromodulators other than opioids can be involved in some circumstances. For example, if a placebo is given after repeated administrations (pre-conditioning) of the non-opioid painkiller ketorolac, the placebo analgesic response is not blocked by naloxone.

Parkinson's Disease

The release of endogenous substances following a placebo procedure is a phenomenon which is not confined to the field of pain, but it is also present in motor disorders, such as ►Parkinson's disease. As occurs with pain, in this case patients are given an inert substance (placebo) and are told that it is an anti-parkinsonian drug that produces an improvement in their motor performance. A study used PET in order to assess the competition between endogenous dopamine and ¹¹C-raclopride for D₂/D₃ receptors, a method that allows identification of endogenous dopamine release [4]. This study shows that placebo-induced expectation of motor improvement activates endogenous dopamine in the striatum of Parkinsonian patients. As this occurs in both the dorsal and ventral striatum, a region involved in reward, it has been argued that the

expectation-induced release of dopamine in Parkinson's disease is related to reward mechanisms.

Placebo administration in Parkinson patients affects the activity of the neurons in the subthalamic nucleus, a brain region belonging to the basal ganglia circuitry and whose activity is increased in Parkinson's disease. Verbal suggestions of motor improvement during a placebo procedure are capable of reducing the firing rate and abolishing bursting activity of subthalamic nucleus neurons, and these effects are related to clinical improvement [1].

Immune and Endocrine Responses

Placebo responses in both the immune and endocrine system can be evoked by pharmacological pre-conditioning. In fact, after repeated administrations of drugs, if the drug is replaced with a placebo, immune or hormonal responses can be evoked that are similar to those obtained by the previously administered drug. For example, immunosuppressive placebo responses can be induced in humans by repeated administration of cyclosporine A (unconditioned stimulus) associated to a flavoured drink (conditioned stimulus), as assessed by interleukin-2 (IL-2) and interferon- γ (IFN γ) mRNA expression, in vitro release of IL-2 and IFN γ , and lymphocyte proliferation. Likewise, if a placebo is given after repeated administrations of sumatriptan, a serotonin agonist of the 5-HT_{1B/1D} receptors that stimulates ►growth hormone (GH) and inhibits cortisol (►glucocorticoids) secretion, a placebo GH increase and a placebo cortisol decrease can be found. These studies support a conditioning mechanism in both immunosuppressive and hormonal placebo responses.

Depression

Depressed patients who receive a placebo treatment show both electrical and metabolic changes in the brain. In the first case, placebos induce electroencephalographic changes in the prefrontal cortex of patients with major depression, particularly in the right hemisphere. In the second case, changes in brain glucose metabolism were measured by using PET in subjects with unipolar depression. Placebo treatments are associated with metabolic increases in the prefrontal, anterior cingulate, premotor, parietal, posterior insula, and posterior cingulate cortex, and metabolic decreases in the subgenual cingulate cortex, parahippocampus and thalamus. Interestingly, these regions are also affected by the selective serotonin re-uptake inhibitor, fluoxetine, a result that suggests a possible role for serotonin in placebo-induced antidepressant effects.

Nocebo Effect

The nocebo effect, or response, is a placebo effect in the opposite direction. For example, administration of an inert substance along with verbal suggestions of pain

increase may induce a hyperalgesic effect. In this case, anticipatory anxiety may play a fundamental role. Nocebo hyperalgesia has been found to be blocked by proglumide, a non-specific CCK-A/CCK-B receptor antagonist. This suggests that expectation-induced hyperalgesia is mediated, at least in part, by CCK. These effects of proglumide are not antagonized by naloxone, thus endogenous opioids are not involved. Since CCK plays a role in anxiety and negative expectations themselves are anxiogenic, proglumide is likely to act on a CCK-dependent increase of anxiety and pain during the verbally induced negative expectations. Although, mainly due to ethical constraints, the nocebo effect has not been investigated in detail, as has been done for the placebo effect, it shows the powerful effect of the top-down modulation of pain. In other words, cognitive and emotional factors can modulate pain perception in opposite directions.

Pharmacological Relevance Implications for Clinical Trials

According to the classical methodology of clinical trials, any drug must be compared with a placebo in order to assess its effectiveness. If the group that takes the drug shows a larger clinical improvement than the group that takes the placebo, the drug is considered to be effective. However, in light of the recent advances in placebo research, some caution is necessary in the interpretation of some clinical trials. In fact, by considering the complex cascade of biochemical events induced by placebo administration, any drug that is tested in a clinical trial may interfere with these placebo/expectation-activated mechanisms, thus confounding the interpretation of the outcome of a clinical trial. As we have no a priori knowledge of which substances act on placebo-activated endogenous opioids, dopamine, serotonin – and indeed almost all drugs might interfere with these neurotransmitters – one way to eliminate this possible pharmacological interference is to make the placebo-activated biochemical pathways ‘silent’. This can be achieved by the hidden administration of drugs.

Hidden Administration of Drugs

It is possible to eliminate the placebo (psychosocial) component and analyze the pharmacodynamic effects of a treatment, free of any psychological contamination, by administering drugs covertly. In this way, the cascade of biochemical events triggered by a placebo procedure can be eliminated. To eliminate the psychosocial context in which a treatment is given, and thus the placebo component of the treatment, the patient is not made aware that a medical therapy is being carried out. To make this possible, drugs are administered through hidden infusions by machines. A hidden drug infusion can be performed through a computer-controlled infusion pump that is pre-programmed to deliver the drug at the desired time. It is crucial that the patient does

not know that any drug is being injected, so that he or she does not expect anything. The computer-controlled infusion pump can deliver a drug automatically, without a doctor or nurse in the room, and without the patient being aware that a treatment has been started [3].

The analysis of different treatments, either pharmacological or not, in different conditions has shown that an open (expected) therapy, that is carried out in full view of the patient, is more effective than a hidden one (unexpected). Whereas the hidden injection represents the real pharmacodynamic effect of the drug, free of any psychological contamination, the open injection represents the sum of the pharmacodynamic effect plus the psychological component of the treatment. The latter can be considered to represent the placebo component of the therapy, even though it cannot be called placebo effect, as no placebo has been given. It is important to realize that, by using hidden administration of drugs, it is possible to study the placebo effect without the administration of any placebo.

Plasmid

Plasmids are extrachromosomal, mainly circular genetic elements that reproduce autonomously within the bacterial cell. Their sizes vary from 1 to over 1,000 kbp. Plasmids are not essential for growth but carry genes that may confer selective growth advantage in specific environments. Examples are genes controlling the production of toxins, virulence factors or enzymes allowing the catabolism of unusual substrates. R plasmids (resistance plasmids) confer resistance to antibiotics and various other inhibitors of growth, e.g. heavy metals.

► Microbial Resistance to Drugs

α_2 -Plasmin Inhibitor

The α_2 -plasmin inhibitor, a single-chain glycoprotein (70 kDa), forms rapidly an equimolar complex with plasmin, where the enzyme loses its activity. It is synthesized by the liver and secreted into the blood circulation, where its concentration is 1 μ M.

► Fibrinolytics

Plasmin(ogen)

Plasmin, a serine protease (83 kDa), can degrade fibrin, and its degradation products (FDP) are soluble in the blood. Plasmin is formed from its proenzyme (zymogen, precursor), plasminogen (92 kDa), synthesized by the liver, and secreted into the blood circulation, where its concentration is $\sim 2 \mu$ M. Plasminogen is converted to plasmin by plasminogen activators (serine proteases).

Plexins

THOMAS WORZFELD, STEFAN OFFERMANN
Institute of Pharmacology, University of Heidelberg,
Heidelberg, Germany

Definition

Plexins comprise a family of transmembrane proteins that serve as receptors for ► **semaphorins**. On the basis

Plexins. Figure 1 Mammalian plexins and their semaphorin ligands. The mammalian plexins are grouped into four subfamilies (A–D). The mammalian semaphorin family is divided into five classes (3–7). Both plexins and semaphorins are characterized by the presence of an extracellular Sema domain which contains a seven-blade β -propeller. In addition, all Plexins share a highly conserved intracellular moiety that carries a segmented GAP-domain. Additional domains include PSI (plexin, semaphorin, integrin)-domains and IPT (Ig-like, plexins and transcription factors)-domains. The plexins of the B-family have a PDZ-binding-motif at their C-terminus. Some B-Plexins exhibit a protease cleavage site. While class-3-semaphorins are secreted, class 4–6 are transmembrane proteins. Class-7-semaphorins are attached to the plasma membrane by a GPI-anchor. Class-5-semaphorins are characterized by seven thrombospondin domains.

of homology they are grouped into four subfamilies (A–D). Semaphorins are a large family of secreted and membrane-associated proteins. In the mammalian system, five structurally different classes of semaphorins (3–7) have been found (Fig. 1). While the semaphorin–plexin system was initially discovered as a regulator of **axonal guidance** in the developing nervous system, it has become clear that its physiological and pathophysiological relevance is much larger including organogenesis, angiogenesis, the immune system as well as cancer.

Basic Characteristics

Both plexins and semaphorins are structurally characterized by the presence of an extracellular **sema domain** which contains a seven-blade β -propeller. The

cytoplasmic moieties of plexins (~600 amino acids) are highly conserved and do not show homology to any other known protein. Since semaphorins are found both in a membrane-bound form as well as in a soluble form, plexins can interact with semaphorins on other cells or with semaphorins in solution. The interaction between semaphorins and plexins is mediated by the Sema domains (Table 1). However, the class 3 semaphorins do not bind directly to plexins but to **neuropilins**, which interact with plexins of the A-family. In this complex, neuropilins are responsible for binding the class 3 semaphorins while the A-plexins are required for transferring the signal over the plasma membrane. In contrast to the A-plexins, B-, C- and D-plexins bind semaphorins directly via their Sema domain.

Plexin-D1	Sema3E

Activation of plexins results in the induction of a variety of signalling pathways. All plexins contain a GTPase-activating protein (GAP) domain within their cytoplasmic domain which has been shown to promote the guanine nucleotide exchange of R-Ras. Inhibition of R-Ras has been suggested to result in the inhibition of integrin signalling. In addition, plexins of the A-family have been shown to interact with cytosolic tyrosine kinases like Fes or Fyn as well as with the GTP-bound form of the small GTPase Rac. Plexins of the B-family carry at their C-terminus a PDZ-binding motif which mediates a stable interaction with the Rho guanine nucleotide exchange factors (RhoGEFs) LARG and PDZ-RhoGEF. Activation of B-plexins results in the activation of RhoA via this pathway (Fig. 2). There is evidence that receptor tyrosine kinases like c-Met and c-ErbB-2 directly interact with B-plexins and are involved in plexin-B-dependent signalling.

Semaphorins and plexins were first described to be involved in the guidance of axonal growth cones during

Plexins. Figure 2 Intracellular signalling processes induced via plexins. Both the activation of A-Plexins (left) and B-Plexins (right) lead to an inactivation of R-Ras via their conserved cytoplasmic RasGAP domains, thereby inhibiting the activation of integrins by RasGTP. Binding of class-3-semaphorins to neuropilin activates A-plexins, which in turn results in an activation of the cytosolic tyrosine kinases Fes and Fyn. Binding of class-4-semaphorins to B-plexins stimulates the kinase activity of the receptor tyrosine kinases Met and ErbB-2. In addition, activation of B-plexins leads to an activation of RhoA via the RhoGEF (Rho guanine nucleotide exchange factors) activity of PDZ-RhoGEF or LARG.

development. *Sema3A* (formerly collapsin-1) was in fact one of the first repulsive axonal guidance factors described. Various semaphorins have been shown to induce axonal growth cone repulsion by activation of plexins. The axonal growth cone retraction induced by semaphorins is mediated by small GTPases. Both plexin A- and plexin B-family members are able to sequester GTP-bound Rac which normally induces the formation of cell extensions (lamellipodia). In addition, activation of the A- and B-plexin families results in an inhibition of R-Ras via their R-Ras-GAP domain. Since GTP-bound R-Ras activates integrins, the activation of plexins via the inhibition of R-Ras activity results in integrin inhibition which may promote axonal growth cone collapse and neurite retraction. Moreover, B-family plexins activate the Rho/Rho-kinase-mediated signalling pathway which results in the stimulation of actomyosin-based contractility to induce cell retraction and axonal growth cone collapse. Besides the repulsive activity of semaphorins, there is also evidence that semaphorins regulate axon branching and in some cases may have attractive activity.

There is increasing evidence that class 3 semaphorins play a role in the regulation of guidance and remodelling of the vascular system. Similar to the situation in the nervous system, the semaphorin–plexin system also appears to be involved in the guidance of specialized endothelial cells at the tip of navigating vascular sprouts during vascular development. In addition to a repulsive effect on endothelial cells in developing blood vessels, class 3 semaphorins have also been shown to be required for the fusion of vessels to create large blood vessels.

Various semaphorins and plexins are found to be expressed in the immune system. *Sema4D* (=CD100), e.g. is expressed by T-cells as well as by activated B-cells and antigen-presenting cells. In the immune system, *Sema4D* appears to primarily act via the non-plexin receptor CD72. *Sema4D* stimulates the activation and maturation of dendritic cells. There is evidence that *Sema4D* in immune cells may itself be involved in signal transduction processes, and it has been shown to associate with the protein tyrosine phosphatase CD45. One of the first indications for the importance of semaphorins in the immune system came from studies on viral semaphorins. Vaccinia virus e.g. carries a gene closely resembling the mammalian *Sema7A* which is expressed by activated T-cells and which binds to plexin-C1 on dendritic cells or monocytes. Expression of the viral *Sema7A* homologue has been shown to suppress migration of host antigen-presenting dendritic cells and monocytes to various infected cells.

The semaphorin–plexin system has been shown to be involved both in tumour suppression and tumour progression. The genes encoding *Sema3B* and *Sema3F*

are candidate tumour suppressors often found to be inactivated in small cell-lung cancer. Class 3 semaphorins may be repulsive for endothelial cells thereby inhibiting angiogenesis and appear to inhibit integrin activation resulting in impaired attachment and metastasis. Other class 3 semaphorins like *Sema3C* and *Sema3E* as well as *Sema4D*, *Sema5C* and *Sema6A/B* have been suggested to contribute to tumorigenesis or to tumour progression. Several semaphorins and plexins have been found to be overexpressed in human tumours.

Pharmacological Intervention

The semaphorin–plexin system has been shown to play multiple roles in the nervous system, the immune system, during the development of various organ systems as well as in the progression of certain tumours. Further studies are needed to more clearly define the role of individual semaphorins and plexins in various physiological and pathophysiological processes. There is some evidence that interfering with semaphorin–plexin signalling could improve regeneration after neuronal injury, and recent data indicate that a *Sema3A* inhibitor improves regenerative responses and functional recovery in a rat model of spinal cord injury. Blockade of the action of some semaphorins should have interesting immunomodulatory effects as shown by the action of various viral semaphorins or in mice lacking *Sema4D*. Finally, the activation or inhibition of defined semaphorin–plexin systems may be a useful approach for the treatment of certain cancers.

Polyamines

Polyamines are low molecular weight aliphatic nonprotein nitrogenous bases. Putrescine (Put), cadaverine (Cad), spermidine (Spd) and spermine (Spm) are the most common natural polyamines. They are synthesized by decarboxylation of ornithine and methionine. At physiological pH, these polyamines can be considered as organic polycations, Put²⁺, Cad²⁺, Spd³⁺ and Spm³⁺. Polyamines are essential for many growth-related processes such as DNA replication, RNA synthesis and translation, as well as for block of some ion channels. Putrescine and spermidine are ubiquitous in living organisms, while spermine is rare or even nonexistent in prokaryotes. In neurons they exert an activity-dependent block of the channel pore of Ca²⁺-permeable AMPARs.

Polyethylene Glycol

Polyethylene glycol is a water-soluble polymer that can be covalently attached to certain molecules, e.g., filgrastim. Addition of polyethylene glycol does not change the identity, purity, or biological activities of filgrastim, but plasma clearance is decreased and the circulating half-life of filgrastim is increased.

- ▶ Hematopoietic Growth Factors

Polymorphism

Polymorphism describes a naturally occurring variation in the DNA sequence among individuals which leads to the occurrence of two or more allelic forms of a gene.

Examples of a polymorphism include single nucleotide substitutions, insertions and deletions of nucleotides, and repetitive sequences. While most polymorphisms are harmless and part of normal human genetic variations, studies have established links between certain gene polymorphisms and metabolic alterations or human diseases.

Poor Metabolizer Phenotype

P

Synonyms

PM phenotype

Definition

A drug metabolism phenotype characterized by much slower biotransformation rate compared to the average population who exhibits an extensive metabolizer (EM) phenotype. Usually the PM phenotype is genetically determined by the lack of a functional gene copy of the drug metabolizing enzyme that catalyzes the respective metabolic step. For example, PMs for debrisoquine or sparteine carry two null-alleles of *CYP2D6*, the enzyme that oxidizes both drugs but they are also genetically determined PMs of many antidepressants or beta-blockers which are also substrates of this enzyme. Additional phenotypes are possible, for example due to alleles with partially reduced activity (intermediate metabolizer, IM) or due to alleles with enhanced activity (ultrarapid metabolizer, UM). In contrast to the permanent genetically determined PM

phenotype, a transient PM phenotype can also be caused by enzyme inhibition (also referred to as *phenocopying*).

Positron Emission Tomography

Positron emission tomography (PET) is an imaging technique that relies on the emission of positrons from radionucleotides tagged to an injectable compound of interest. Each positron emitted by the radioisotope collides with an electron to emit two photons at 180° from each other. The photons are detected and the data processed so that the source of the photons can be identified and an image generated showing the anatomical localization of the compound of interest.

Post-translational Modification

Post-translational modification (PTM) is the enzymatic processing of a protein into the biologically active form following release from the ribosome. This includes removal and/or derivatization of specific amino acid residues, proteolytic cleavage, loss of signal sequences, and formation of disulfide crosslinks. Other common posttranslational modifications are phosphorylation, glycosylation, acetylation, hydroxylation, myristylation, isoprenylation, and many other reactions. All amino acid side chains except those of alanine, glycine, isoleucine, leucine, and valine can be modified.

Potassium Channels

CHAR-CHANG SHIEH, MURALI GOPALAKRISHNAN
Global Pharmaceutical Research and Development,
Abbott Laboratories, Abbott, Park, IL, USA

Synonyms

K⁺ channels

Definition

Potassium channels are a diverse and ubiquitous family of membrane proteins present in both excitable and nonexcitable cells that selectively conduct K⁺ ions across the cell membrane along its electrochemical gradient at a rate of 10⁶–10⁸ ions/s.

Basic Characteristics

Under physiological conditions, the concentration of K⁺ ions inside the cell is around 25-fold greater than that outside the cell membrane. An outward current is generated due to the efflux of K⁺ ions by the opening of K⁺ channels that bring membrane potential close to the resting state (repolarization) of the cells. K⁺ channels set the resting membrane potential, shorten the action potential, terminate periods of intense activity, and determine the interspike intervals during repetitive firing [1]. Activators of K⁺ channels tend to stabilize cellular excitability or dampen the effectiveness of excitatory inputs whereas blockers tend to have the opposite effects. In addition to controlling cellular excitability, K⁺ channels can regulate fluid and electrolyte transport and cell proliferation.

About 78 human genes encoding a variety of K⁺ channels and auxiliary subunits have been identified (Fig. 1; Table 1). While the K⁺ channels are diverse, they share with a unique conducting pore highly selective for K⁺ ions. The K⁺ channels are tetramers composed of four α subunits that form the conducting pore. On the basis of primary amino acid sequence of α subunit, K⁺ channels can be classified into three major families (Fig. 2).

Six Transmembrane One-Pore Channels

Molecular biology studies have identified a loop containing 20–25 amino acid residues between S5 and S6 (or M1 and M2, Fig. 2) forming the pore. The G(Y/F)G motif located in the pore represents the K⁺-selectivity signature, which is common to all K⁺ channels. The external entry to the channel pore and its adjacent residues constitute binding sites for toxins and blockers. The internal vestibule of the pore and the adjacent residues in S5 and S6 contribute to binding sites for compounds such as 4-aminopyridine and quinidine. The S4–S5 linker lies close to the permeation pathway and is required for

inactivation. The S4 segment containing 5–7 positive charges at approximately every third position serves as voltage-sensor governing the channel opening.

Two Transmembrane One-Pore Channels

The inward rectifier K⁺ channels (Kir) represent this family of channels that conduct K⁺ ions preferentially in the inward direction than outward. The occlusion of internal vestibule of the pore by Mg²⁺ and polyamines contribute to this inward rectification. These channels

are tetrameric, although a more complex octameric arrangement has been described for ATP-sensitive K⁺ (K_{ATP}) channels derived from four inward rectifiers contributing to the ion conducting pore and four regulatory sulfonylurea receptor subunits.

Four Transmembrane Two-Pore Channels

This family of K⁺ channels, with >50 distinct gene members, typically contains four putative transmembrane and two pore domains. The G(Y/F)G motif is

preserved in the first pore loop, but this motif is replaced by GFG or GLG in the second pore loop. The two-pore K⁺ channel family plays an important role in conducting K⁺ leak currents that regulate cellular excitability by shaping the duration, frequency, and amplitude of action potentials through their influence over the resting membrane potential [2].

K⁺ Channelopathies

Genetically Linked Diseases

Genetic linkage analyses have identified inherited human disorders due to abnormal function of K⁺

channel subunits. Such naturally occurring mutations result in losses or changes in K⁺ channel function [3].

Cardiac diseases: In the heart, multiple K⁺ channels regulate cardiac excitability and determine cardiac action potential duration. Both KvLQT1 and ▶MinK have wide distribution in different tissues. These two subunits coassemble to form a slowly activating delayed rectifier K⁺ channel (IK_S) that participates in repolarization of cardiac action potential, and regulates transepithelial K⁺ ion secretion in the inner ear. Mutations in either KvLQT1 or MinK have been linked to cardiac arrhythmia as in the dominant ▶Long-QT

syndromes (LQT) or to recessive LQT, in which cardiac arrhythmia is associated with congenital deafness. Another cardiac rapid delayed rectifier K⁺ channel (I_{K_R), in contrast to I_{K_S, is composed of *hERG* and MiRP1, and is responsible for repolarization of cardiac action potential. Aberrant function of hERG/MiRP1 resulting from mutations in either subunit has been identified from families associated with LQT. Mutations in *KCNJ2* encoding Kir2.1 lead to ►**Andersen's syndrome**.}}

CNS diseases: In the CNS, the mutations in *KCNA1* (Kv1.1) impair the capacity of the affected neurons to repolarize effectively following an action potential and are linked to the type 1 ►**episodic ataxia/myokymia** (EA1). KCNQ3 and KCNQ2 or KCNQ5 constitute diverse ►**M-channels** that play important roles in determining the excitability threshold, firing properties, and responsiveness of neurons to synaptic inputs. Mutations in both KCNQ2 and KCNQ3 subunits have been identified in families associated with ►**benign familial neonatal convulsions** [4].

Deafness: KCNQ4 is expressed in vestibular system, brain, and cochlea sensory hair cells. KCNQ4 has been

mapped to human chromosome 1p34, in which DFNA2 (The DFNA2 locus for autosomal dominant nonsyndromic hearing impairment, the one of over 30 loci for dominant deafness, is located in chromosome 1p34. In DFNA2 locus, at least mutations in two genes, GJB3 encoding connexions to form gap junction and KCNQ4 encoding K⁺ channels have been linked to progressive hearing loss.) is located. Loss of KCNQ4 function due to deletion or mutation contributes to progressive hearing loss [4].

Renal diseases: Mutations in *KCNJ1* disrupt the function of Kir1.1 in apical renal outer medulla of the kidney. The loss of tubular K⁺ channel function and impaired K⁺ flux could prevent apical membrane potassium recycling and lead to antenatal ►**Barter's syndrome**.

Metabolic diseases: In the pancreatic β -cells, K_{ATP} channel derived from ►*SUR1* and Kir6.2, links cellular metabolism to electrical activity and regulates insulin secretion. Mutations in SUR1 and Kir6.2 that result in loss of K_{ATP} channel function have been identified in families with ►**familial persistent hyperinsulinemic hypoglycemia of infancy** (PHHI).

Potassium Channels. Figure 2 Schematic representation of the structural classification of K⁺ channel subunits. (a) Six-transmembrane one-pore subunits. This represents a class of the K⁺ channels composed of four subunits each containing six transmembrane segments (S1–S6) and a conducting pore (P) between S5 and S6 with a voltage sensor (positive charge of amino acid) located at S4. Some of the voltage-gated K⁺ channels include an auxiliary β -subunit (Kv β), which is a cytoplasmic protein with binding site located at the N-terminus of the α -subunit. The inset shows the general assembly of K⁺ channels. The homotetrameric K⁺ channel consists of four identical subunits while different α -subunits form heterotetrameric K⁺ channels. (b) Two-transmembrane one-pore subunits. The inward rectifier K⁺ channel belongs to a superfamily of channels with four subunits each containing two-transmembrane segments (M1 and M2) with a P-loop in between. (c) Four-transmembrane two-pore subunits. This represents a class of K⁺ channel that has four transmembranes with two P-loops. This figure is adapted from [3].

Acquired Aberrant K⁺ Channel Function

In addition to naturally occurring mutations in K⁺ channels leading to various human disorders, acquired dysfunction of K⁺ channels induced by drugs or diseases can also occur [3]. Blockade of hERG channel by certain H1 antagonists, antipsychotics, tricyclic antidepressants, antibiotics, and anti-emetic agents contributes to the drug-induced LQT leading to polymorphic ventricular dysrhythmia, the **torsade de pointes**. H1 receptor antagonists such as loratadine and rupatadine can also induce cardiac arrhythmia by blocking Kv1.5. Up- or down-regulation of K⁺ channel

gene expression has been shown to be involved in cardiac hypertrophy, atrial fibrillation, apoptosis, oncogenesis, and Alzheimer's disease. In neuromuscular junction, inhibition of delayed rectifier K⁺ channels (Kv1.1 and Kv1.6) by autoantibodies is the underlying mechanism leading to muscle twitching observed in **► Isaacs' syndrome**, an acquired neuromyotonia.

Drugs

Concurrent with the progress in our understanding of molecular diversity, structure, and function of K⁺ channels, and their role in genetically linked and acquired

diseases, interest in the discovery and development of selective modulators of various classes of K^+ channels has evolved [5].

Voltage-Gated K^+ Channels

Kv1.3: The Kv1.3 channel plays a critical role in controlling Ca^{2+} influx that regulates proliferation in human T lymphocytes. Blocking Kv1.3 inhibits activated T cell proliferation, thereby making this channel an attractive target for immunosuppressant agents. In addition to correolide, other known Kv1.3 blockers include H-37, WIN-17317-3, CP-339818, UK-78282, ShK (L5)-amide (SL5), and PAPI (Table 2).

Kv1.5: In human atria, the Kv1.5 represents the ultrarapid delayed rectifier that contributes to the repolarization in the early phase of cardiac action potential. Selective blockers of Kv1.5 channels could be potentially beneficial in the treatment of atrial fibrillation because blocking Kv1.5 could delay repolarization and prolong refractoriness selectively in cardiac myocytes. Examples for Kv1.5 blockers include AVE0118, S9947, and analogs of diphenyl phosphine oxide (DPO).

hERG: hERG/MiRP is the major target for the class III antiarrhythmic agents. Novel and selective agents include dofetilide, ibutilide, and azimilide that block

Potassium Channels. Table 2 Potassium channel openers^a

Channel family	Therapeutic Indications	Compounds
ATP-sensitive K^+ channels (K_{ATP})		
Cardiac Mitochondria K_{ATP} (SUR2A/Kir6.2)	Myocardial ischemia	BMS-180448

hERG, prolong cardiac action potential, and represent useful agents for the treatment of arrhythmias (Table 2).

KvLQT1: KvLQT1/MinK has been considered a promising avenue for class III antiarrhythmic approach. As noted above, most known class III antiarrhythmic drugs block hERG/MiRP and lead to prolongation of cardiac action potentials. However, hERG/MiRP blockade typically causes excessive prolongation of action potentials at slow heart rates, whereas at higher rates, blockade is much less effective. This so-called reverse use-dependent action can lead to life-threatening arrhythmias. Thus, selective KvLQT1/MinK blockers may be regarded as a more promising approach with reduced proarrhythmic potential. Chromanol 293B is a prototypical inhibitor of KvLQT1/MinK. Other blockers include HMR-1556 and L-73582.

Other KCNQ-derived channels: The M-channel has emerged as an attractive target for cognitive disorders. Several neurotransmitter release enhancers initially shown to be cognition enhancers such as linopirdine, DMP-543, and XE-991 are M-channel blockers. Mutations in KCNQ2 and KCNQ3 linking to benign familial neonatal convulsions suggest that M-channel openers may have as potential as antiepileptic agents. The antiepileptic agent retigabine has been shown to activate KCNQ2/KCNQ3 channels, indicating that M-channel activation may be another mode of action for anticonvulsant drugs.

K_{ATP} Channels

As noted previously, SUR1/Kir6.2 constitutes the pancreatic K_{ATP} channel. The molecular composition of the cardiac/skeletal muscle K_{ATP} channel is SUR2A/Kir6.2, whereas SUR2B/Kir6.2 is thought to form the predominant K_{ATP} channel in smooth muscle cells. Like sarcolemmal K_{ATP} channels, mitochondria K_{ATP} channel also couples the energy metabolism to cellular activities although its molecular composition remains to be elucidated.

SUR1/Kir6.2: Glibenclamide and glipizide that block pancreatic K_{ATP} channels have been used for the treatment of type II diabetes. New class of insulin secretagogues includes repaglinide and nateglinide, which improve insulin secretion, action and reduce carbohydrate absorption.

Mitochondria K_{ATP} channels: Cardiac K_{ATP} channel opening has a role in myocardial preconditioning, a paradoxical form of cardioprotection wherein brief ischemic episodes can protect the heart from subsequent lethal ischemic injury. Openers including BMS-180448 and BMS-191095 have been reported to possess preferential cardioprotective effects over vasorelaxant effects by activating mitochondria K_{ATP} channels.

SUR2B/Kir6.2: Efforts have also focused on the development of selective K_{ATP} channel openers for vascular and nonvascular indications including angina, airway hyperactivity, bladder overactivity, and erectile

dysfunction (Tables 2 and 3). Examples of structurally diverse smooth muscle active K_{ATP} channel openers include ZD-6169, WAY-133537, A-278637, A-151892, and A-251179.

Ca²⁺-Activated K⁺ Channels

This subfamily including the large- (BK_{Ca}), intermediate- (IK_{Ca}), and small-conductance (SK_{Ca}) Ca²⁺-activated K⁺ channels are activated by increases in intracellular free Ca²⁺ concentration. The opening of IK_{Ca} and SK_{Ca} channels are less voltage-dependent, whereas the activation of BK_{Ca} channel has steep voltage sensitivity.

BK_{Ca}: The diversity of BK_{Ca} channels can be attributed to the assembly of pore-forming α subunit together with four different auxiliary subunits (β 1– β 4). BMS-204352 has been identified as a BK_{Ca} channel opener for the treatment of acute ischemic stroke although it has also been shown as an M-channel activator. Therapeutic applications for channel openers include epilepsy, bladder overactivity, asthma, hypertension, and psychosis. Other known BK_{Ca} channel openers include NS-8, NS-1619, NS-4, and certain aminoazaindole analogs.

IK_{Ca}: The IK_{Ca} channel corresponds to the *Gardos* channel described in red blood cells. Blockers of IK_{Ca} channels have been suggested for the treatment of sickle cell anemia, diarrhea, and rheumatoid arthritis. Blockers of IK_{Ca} channels may be used as immunosuppressive agents because these channels are upregulated following antigenic or mitogenic stimulation in T-cells. IK_{Ca} channel blockers include clotrimazole, ICA-15451, and TRAM-34. Openers of IK_{Ca} channels may be therapeutically beneficial in cystic fibrosis and peripheral vascular diseases. Although not highly specific, 1-EBIO (1-ethyl-2-benzimidazolinone) chlorzoxazone and zoxazolamine have been shown to activate IK_{Ca} channels.

SK_{Ca}: The SK_{Ca} channels are responsible for the slow after hyperpolarization and play important roles in determining the firing frequency. Distinct genes are known to encode SK_{Ca}1, SK_{Ca}2, and SK_{Ca}3, in which SK_{Ca}2 and SK_{Ca}3 are highly apamin-sensitive. Overexpression of SK_{Ca}3 can induce abnormal respiratory responses to hypoxic challenge and compromised parturition, suggesting the SK_{Ca}3 as potential target for sleep apnea and for regulating uterine contractions during labor. Other indications for SK_{Ca} channel modulators include myotonic muscular dystrophy, gastrointestinal dysmotilities, memory disorders, and epilepsy. SK_{Ca} channel blockers include dequalinium analogs and more potent agents such as UCL-1684 and UCL-1530.

Two-Pore K⁺ Channels

The two-pore K⁺ channels are thought to function as background channels involved in the resting membrane

Potassium Channels. Table 3 Potassium channel blockers^a

Channel family	Therapeutic Indications	Compounds
Voltage-gated K ⁺ channels

potential regulation. Certain neuroprotective agents such as riluzole and volatile general anesthetics can activate two-pore K⁺ channels, suggesting these channels might be attractive targets for novel neuroprotective and anesthetic agents. The endocannabinoid, anandamide, is a blocker of the TASK channel.

Conclusions

Defects and dysfunction of K⁺ channels have emerged as the molecular basis for a number of diseases. Enhanced knowledge of K⁺ channel structure and function, together with further analysis of genetic- and disease-induced dysregulation of K⁺ channels could undoubtedly improve diagnosis and offer specific candidate genes for the development of appropriate therapies. Technologies to

refine high throughput assay techniques for K⁺ channel modulators should be helpful to identify potent, and more importantly, selective drug candidates.

Progesterone Receptor.

- ▶ Sex Steroid Receptors

Pregnane X Receptor

The pregnane X receptor (PXR) is a promiscuous nuclear receptor, that has evolved to protect the body from toxic chemicals. It is activated by a wide variety of xenobiotics including several drugs like rifampicin, hyperforin (the active ingredient of St. John's wort), clotrimazole and others. PXR heterodimerizes with the retinoid X receptor (RXR) and is also activated by various lipophilic compounds produced by the body such as bile acids and steroids. PXR heterodimerized with RXR stimulates the transcription of cytochrome P450 3A monooxygenases (CYP3A) and other genes involved in the detoxification and elimination of the potentially harmful substances. PXR appears to be the key regulator of CYP3A induction by xenobiotics.

Prenylation

Prenylation is the post-translational addition of 15- or 20-carbon isoprenyl lipids to the C-terminus of proteins. Prenylation is an irreversible modification that anchors proteins to the membrane fraction of cells.

- ▶ Lipid Modifications

Prepro-opiomelanocortin

Prepro-opiomelanocortin (POMC) is a huge precursor protein, from which several peptides are generated by

proteolytic cleavage (melanocyte-stimulating hormone, adrenocorticotrophic hormone (ACTH), β -endorphin, methionine enkephalin).

- ▶ Anti Obesity Drugs
- ▶ Opioid System

Primary Hemostasis

Primary hemostasis is the first phase of hemostasis consisting of platelet plug formation at the site of injury. It occurs within seconds and stops blood loss from capillaries, arterioles, and venules. Secondary hemostasis, in contrast, requires several minutes to be complete and involves the formation of fibrin through the coagulation cascade.

Prolactin

Prolactin is peptide hormone secreted by the pituitary gland. It acts on prolactin receptors in breast tissue where it stimulates production of casein and lactalbumin. It also acts on the testes and ovaries to inhibit the effects of gonadotrophins. Since the secretion of prolactin is under tonic dopaminergic inhibition by the hypothalamus, dopamine D_2 -receptor antagonists

cause prolactin release through a process of disinhibition, leading to elevated prolactin levels resulting in gynaecomastia, galactorrhoea, anovulation, and impotence.

- ▶ Antipsychotic Drugs
- ▶ JAK-STAT Pathway

Proopiomelanocortin

Proopiomelanocortin (POMC) is the precursor peptide of hormones and neuropeptides expressed in the pituitary and the hypothalamus (adrenocorticotrophic hormone (ACTH), lipotropin, α -melanocyte-stimulating hormone (α MSH), γ MSH, β -endorphin, and others). The main clinical consequences of POMC deficiency are adrenal insufficiency (due to absence of ACTH), red hair pigmentation (due to absence of MSH) and severe early-onset obesity (due to the lack of α MSH).

Definition

▶ **Prostanoids**, or prostaglandins, are potent mediators of a wide range of physiological actions including pain, inflammation, modulation of smooth muscle tone as well as water and ion transport. Prostaglandins are oxygenated metabolites of the essential fatty acid ▶ **arachidonic acid**. Four of the principal prostaglandins are analogs of the 20 carbon unnatural fatty acid prostanic acid, distinguished by its five carbon “prostane” ring group comprised of carbons five through eight. The fifth prostanoid, thromboxane, has an inserted ether oxygen and thus has a six-member ring structure and is an analog of the unnatural fatty acid thrombanoic acid [1].

Basic Characteristics

Biosynthesis

PGs act locally in an autocrine or paracrine fashion in the tissues in which they are synthesized, rather than as circulating hormones, which act at a distant site. For this reason, studies localizing the enzymatic machinery, which synthesize prostaglandins, are informative with respect to the site of PG actions. PG synthesis is

initiated by ►cyclooxygenase (COX) mediated metabolism of the unsaturated 20 carbon fatty acid arachidonic acid to PGG₂/H₂, generating five primary bioactive prostanoids: PGE₂, PGF_{2α}, PGD₂, PGI₂ (prostacyclin), and TXA₂ (thromboxane; Fig. 1). Arachidonic acid is esterified in the lipid bilayer of most cells, and is liberated by the action of specific phospholipases, for example, PLA₂. Mobilization of arachidonic acid by phospholipases is regulated by a number of hormones and signal transduction pathways and represents a critical control point of prostanoid synthesis. Upon liberation, arachidonic acid is rapidly metabolized by a number of enzymatic pathways including the cyclooxygenase pathway. Cyclooxygenase, also known as PGH synthase, catalyzes two sequential reactions, a *bis* oxygenase, or cyclooxygenase, reaction leading to the formation of PGG₂ and a subsequent peroxidase activity at the C15 position leading to the conversion of PGG₂ to PGH₂ [2]. Two isozymes of cyclooxygenase have been identified, designated COX-1 and COX-2, which catalyze the formation of identical products, but have different patterns of expression and differential regulation. Differential blockade of the COX isozymes results in important physiological outcomes, as described below. PGH₂, the immediate product of COX

activity, is an unstable product that spontaneously degrades to other prostaglandin metabolites; however, in vivo, PGH₂ is acted upon by specific PG synthases leading to differential shunting of PGH₂ to one of the five principal prostanoid products. Following their formation, PGs cross the cell membrane where local concentrations of PGs may be modulated by specific transporters including the recently described specific PG transporter (PGT). Although PGT's role is incompletely understood, it has been proposed to facilitate the reuptake of PGs to allow vectorial transport of PGs synthesized in polarized cells.

Receptor Pharmacology

The local action of PGs depends, in part, on activation of a family of specific G-protein coupled receptors (►GPCRs), designated EP for E-prostanoid receptors, FP, DP, IP, and TP receptors, respectively, for the other prostanoids [3]. The EP receptors are unique in that four receptors, designated EP1 through EP4, have been described for PGE₂ each encoded by a distinct gene. A second class of Prostaglandin D receptor designated Chemoattractant Receptor-Homologous molecule expressed on ►Th2 cells (CRTH2) which has no sequence homology to the remaining PG receptors has been

Prostanoids. Figure 1 Biosynthesis of prostaglandins. Arachadonic acid is metabolized by cyclooxygenase-1 or 2 to the unstable endoperoxide PGH₂, the common precursor for the five principle prostaglandins. PGD₂, PGE₂, PGF_{2α}, PGI₂, and thromboxane A₂ are generated by individual prostaglandin synthase enzymes and elicit their biological effects by activating cell surface G-protein coupled receptors.

identified. This receptor has been unofficially designated “DP2.” Each of the other PGs has a single receptor, and taken together, there are nine PG GPCRs, each encoded by distinct genes (Table 1). Alternative mRNA splice variants have been cloned for the EP1, EP3, TP, and FP receptors. In each case, these splice variants generate receptor sequence diversity in the intracellular C-terminal tail of the receptor protein (Fig. 2). Functionally, these splice variants appear to modulate the specificity of G-protein coupling, as well as regulation of receptor desensitization by encoding alternate phosphorylation sites. Pharmacologically, the PG receptors are distinguished by their ligand binding selectivity as well as the signal transduction pathways they activate. In general, a PG receptor may have significant affinity for PGs other than its principal ligand. Moreover, multiple PG receptors are frequently coexpressed in a single cell type or tissue. COX activation and resulting PG production may lead to complex effects in the target tissue by activation of multiple PG receptor subtypes. Thus, a given PG ligand may elicit multiple, and at times apparently opposing, functional effects on a given target tissue. For example, prostaglandin receptors were initially characterized by their actions on smooth muscle, where they may lead to either smooth muscle contraction or relaxation. The vasodilator effects of PGE₂ have long been recognized in both arterial and venous beds. Smooth muscle relaxation by PGE₂ is, however, not uniformly observed, and PGE₂ is a potent constrictor in other smooth muscle beds, including trachea, gastric fundus, and ileum. Importantly, some structural analogs of

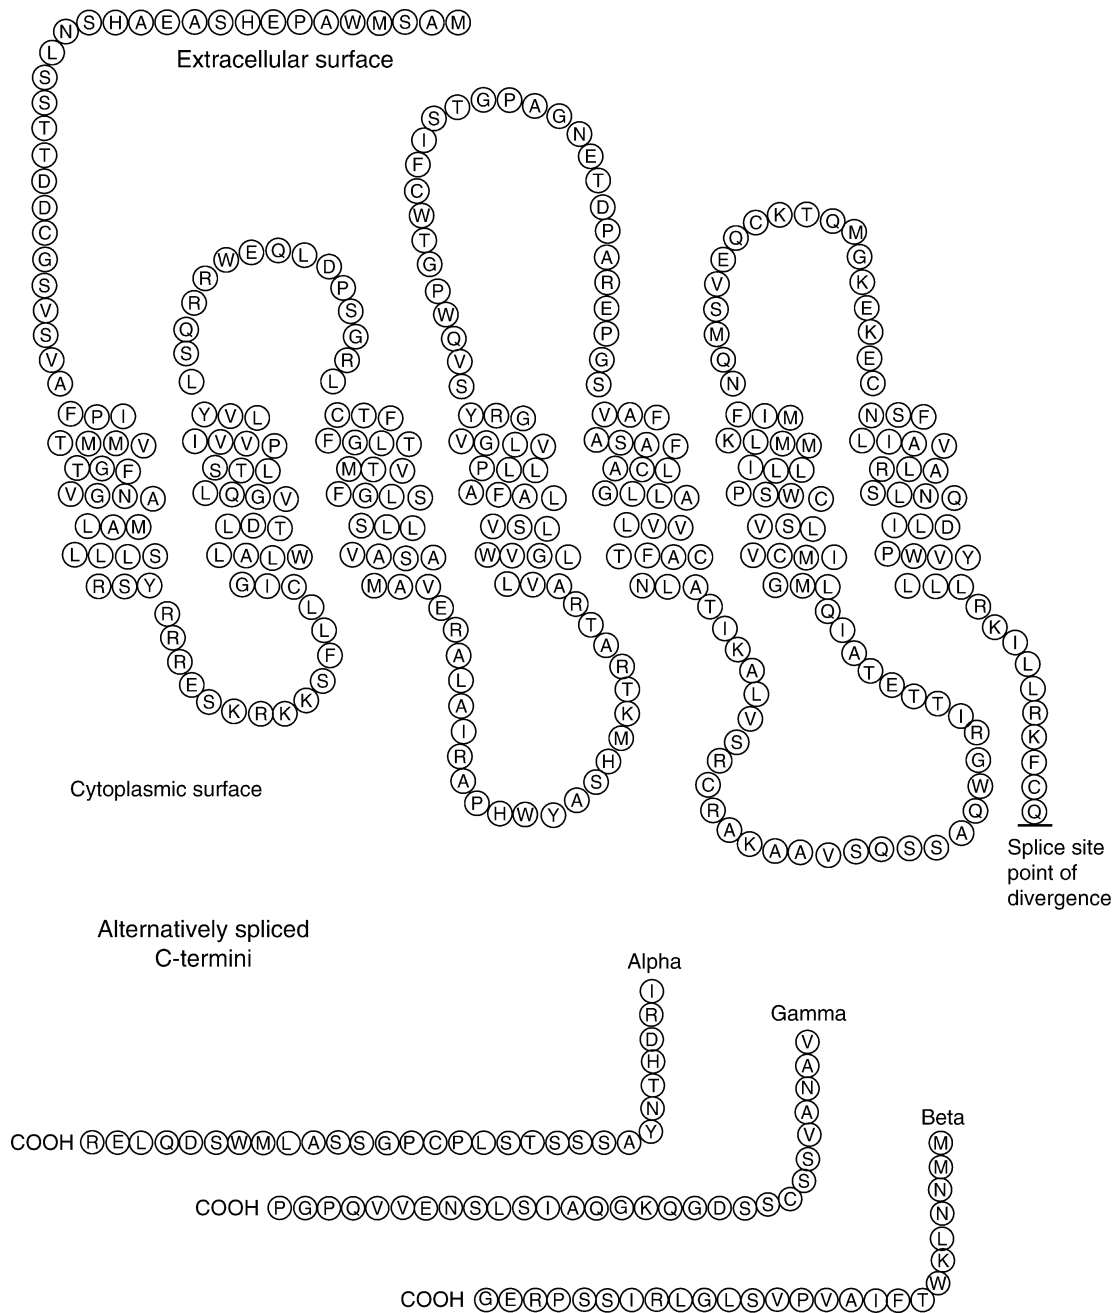

PGE₂ are capable of reproducing the dilator effects of PGE₂, but are inactive on tissues where it is a constrictor. Conversely, analogs that reproduce the constrictor effects of PGE₂ may fail to affect tissues where PGE₂ is a dilator. The EP receptor mRNAs exhibit differential expression in a number of tissues with distinct functional consequences of activating each receptor subtype. Functional antagonism among PGs can also be observed in platelet aggregation, where TXA₂ activation of the TP receptor causes platelet aggregation. Conversely, prostacyclin activates platelet IP receptors which oppose this platelet aggregation. Thus, the balance of PGs synthesized as well as the complement of PG receptors expressed determines the COX effect on platelet function.

In addition to the GPCR mediated effects, there is evidence that prostaglandin metabolites are capable of activating some nuclear transcription factors. This action is exemplified by the cyclopentenone prostaglandins of the J-series, for example, 15-deoxy- Δ 12, 14-PGJ₂ (15d-PGJ₂) which is derived from PGD₂. 15d-PGJ₂ activates a nuclear hormone receptor designated peroxisome proliferator activator receptor gamma (►PPAR- γ). There is also evidence that prostacyclin (PGI₂) also activates another member of this family designated PPAR- δ . It is unclear whether the PGs represent true endogenous ligands of these receptors, as their affinity is generally in the micromolar range, two to three orders of magnitude lower affinity than the nanomolar affinities observed for PGs at the GPCRs, yet nonetheless concentrations that could be achieved in the intracellular environment.

*Partial agonist

Prostanoids. Figure 2 EP₃ receptor sequence of three mouse EP₃ receptor splice variants differing only in their intracellular carboxyl termini. The predicted amino acid sequences of each splice variant are represented by the one letter amino acid code. The common region is comprised of two exons, which are spliced to three possible C-terminal tails. The carboxyl variable tails are designated alpha, beta, and gamma, each encoded by distinct exons.

Prostanoid Catabolism

Prostaglandins are short lived and endogenous PGs circulating at extremely low levels. Once synthesized and released, PGs are rapidly inactivated by one pass through the pulmonary circulation. The principal inactivating step of PGs is the oxidation of the 15-OH group to the corresponding ketone by prostaglandin 15-OH dehydrogenase [4]. Consequently many

synthetic PG analogs have modifications at the 15 carbon to decrease inactivation of these compounds and increase their half-life in vivo.

Drugs

Two distinct classes of drugs are important in modulating PG signaling: those that inhibit PG synthesis and those that act directly on the receptor as either agonists

or antagonists. Drugs that inhibit PG synthesis are a particularly widely utilized class of therapeutic agents designated as ►**non-steroidal anti-inflammatory drugs** (NSAIDs). These drugs act as either competitive inhibitors of COX (e.g., ibuprofen, indomethacin, diclofenac) or as irreversible inactivators of COX enzymes (aspirin). Classical nonselective NSAIDs inhibit the cyclooxygenase activity of both COX-1 and COX-2, thereby suppressing PG synthesis. These drugs are utilized for their antipyretic, anti-inflammatory, and analgesic properties, and as a class, they represent one of the most widely prescribed and economically important groups of drugs. Although generally safe and effective, because of their widespread use, significant numbers of patients develop undesirable side effects from these drugs. The most common serious side effects are gastrointestinal bleeding and renal failure. PGE₂ is a major PG in the gastrointestinal (GI) tract, and NSAID mediated suppression of PGE synthesis is thought to be responsible for NSAID induced gastrointestinal injury. Coadministration of the PGE₂ analog misoprostol with NSAIDs is cytoprotective. Nonetheless, misoprostol itself can have unwanted GI side effects such as cramping and diarrhea. An alternative approach for developing NSAIDs with decreased gastrointestinal side effects has been the identification of isozyme selective inhibitors that selectively target the COX-2 enzyme, while leaving the COX-1 isozyme functional. COX-2 expression is inducible, and its expression level is elevated in response to many inflammatory stimuli. COX-2 selective inhibitors such as valdecoxib, rofecoxib, and celecoxib have significantly reduced the unwanted side effects of NSAIDs such as gastrointestinal bleeding, while retaining their antipyretic, analgesic, and anti-inflammatory properties [5]. Moreover, these drugs can be administered at doses sufficient to allow essentially complete blockade of COX-2 without the acute side effects of dual COX-1 and COX-2 blockade. Clinical studies have identified a unique profile of unwanted side effects of selective inhibition of COX-2, resulting in the withdrawal of many COX-2 selective inhibitors from the market. Selective COX-2 inhibition has been associated with an increase in cardiovascular events including stroke and myocardial infarction. The observation that prothrombotic platelet derived TXA₂ is primarily synthesized by COX-1, whereas antithrombotic prostacyclin is, at least in part, a COX-2 product may underlie this profile of side effects.

Because of the complexities resulting from the use of these relatively broadly acting COX inhibitors, the use of selective PG synthase inhibitors or receptor agonists and antagonists could provide therapeutic alternatives devoid of these side effects and therefore with therapeutic value. At this point, there are no potent and selective PG synthase inhibitors or receptor

antagonists in routine clinical use [1]. Development of selective agonists for PG receptors has been limited. Use of PG receptor agonists is complicated because these ►**autacoids** normally act locally and systemic administration of PG agonists may have profound adverse side effects. Nonetheless, several PG agonists are in clinical usage, and they are particularly effective when they can be delivered directly to the site of action.

For example, PGF_{2α} agonists such as latanoprost have been developed as eyedrops to reduce intraocular pressure for the treatment of glaucoma. Topical instillation of these agonists is effective in lowering intraocular pressure and may be used as a first-line therapy for the treatment of glaucoma.

PGE₂ was initially characterized by its actions on female reproductive tissue, and this has been an area of considerable pharmaceutical development activity. PGE₂ (dinoprostone) and PGE₁ (alprostadil) have been used as abortifacients in early pregnancy, and they facilitate labor at term by promoting ripening and dilatation of the cervix. PGE₁ may be used for the treatment of impotence by direct intracavernous injection. As noted above, the PGE₁ analog, misoprostol, has been utilized for the treatment of NSAID induced GI bleeding and presumably acts by replacing the loss of the endogenous PGE₂.

Prostacyclin (epoprostanol) is one of the few drugs effective for the treatment of Primary Pulmonary Hypertension (PPH) a rare but frequently fatal illness of young adults. Increased blood pressure in the pulmonary circulation leads to right-heart failure. Continuous infusion of epoprostanol leads to a decrease in blood pressure; however, it is unclear whether this is due to direct dilator activity of the IP receptor acting on smooth muscle, or a more indirect mechanism.

It is worth noting that in many cases, PG drugs have found greatest use where they may be applied locally and directly rather than systemically. Glaucoma is treated with latanoprost eyedrops, induction of labor with dinoprostone vaginal suppositories, GI ulcers with oral misoprostol. In contrast, in treatment of PPH with epoprostanol and use of PG analogs as abortifacients, the drugs are given systemically.

Ramatroban is a PG receptor antagonist in use for the treatment of allergic rhinitis in Japan. This compound was initially identified as a TP receptor antagonist, although more recently it has been determined that it is also antagonizes the CRTH2 (DP2) receptor.

Proteases

Proteases (proteinases, peptidases, or proteolytic enzymes) are enzymes that break peptide bonds between amino acids of proteins. The process is called peptide cleavage, a common mechanism of activation or inactivation of enzymes. They use a molecule of water for this, and are thus classified as hydrolases.

Protein Folding Problem

Proteins fold on a time scale from μ s to s. Starting from a random coil conformation, proteins can find their stable fold quickly although the number of possible conformations is astronomically high. The protein folding problem is to predict the folding and the final structure of a protein solely from its sequence.

The protein structure prediction problem refers to the combinatorial problem to calculate the 3D structure of a protein from its sequence alone. It is one of the biggest challenges in structural bioinformatics.

Protein Kinase A

Protein kinase A (PKA) is a cyclic AMP-dependent protein kinase, a member of a family of protein kinases that are activated by binding of cAMP to their two regulatory subunits, which results in the release of two active catalytic subunits. Targets of PKA include L-type calcium channels (the relevant subunit and site of phosphorylation is still uncertain), phospholamban (the regulator of the sarcoplasmic calcium ATPase, SERCA) and key enzymes of glucose and lipid metabolism.

C kinase; PKC

Definition

Protein kinase C (PKC) is an enzyme family whose members are activated by agonists that cause receptor-mediated generation of lipid second messengers. The activated enzymes transduce information from such agonists by phosphorylating relevant downstream substrates.

Basic Characteristics

PKC is a family of enzymes whose members play central roles in transducing information from external stimuli to cellular responses. Members of this family of serine/threonine kinases respond to signals that cause lipid hydrolysis. PKC isozymes phosphorylate an abundance of substrates, leading to both short-term cellular responses such as regulation of membrane transport and long-term responses such as memory and learning.

The PKC Family

There are ten mammalian PKC isozymes that fall into three classes: conventional (α , γ , and the two alternative splice variants, β I and β II, which differ only in the C-terminus), novel (δ , ϵ , η , θ), and atypical (ζ , λ) PKC isozymes [3]. As shown in Fig. 1, all isozymes comprise an N-terminal regulatory moiety and a C-terminal kinase core. The regulatory moiety contains two important functional segments: an autoinhibitory pseudosubstrate sequence that allosterically regulates access to the substrate-binding cavity, and one or more membrane-targeting modules. It is the nature of the membrane-targeting modules that defines the classes of PKC isozymes. All PKCs have a version of the C1 domain, the ▶diacylglycerol sensor. This domain binds diacylglycerol and the potent functional analogues, phorbol esters, in all isozymes except atypical PKCs. For these isozymes, an impaired ligand-binding pocket does not support the binding of diacylglycerol or phorbol esters and, as a consequence, the hallmark of atypical PKCs is their complete lack of response to phorbol esters. Rather, these isozymes appear to be regulated following activation of PI 3 kinase. They also contain a PB1 (for Phox and Bem1p) protein interaction domain. Conventional and novel PKCs have a C2 domain; this domain binds anionic lipid in a Ca^{2+} -dependent manner for conventional PKCs. However, an impaired Ca^{2+} binding pocket in the novel PKCs makes them unresponsive to Ca^{2+} . Phosphorylation on tyrosine controls protein interactions of this domain in the novel PKC δ .

Regulation

PKC isozymes are regulated by three mechanisms: phosphorylation, second messenger binding, and protein-protein interactions. First, a series of ordered phosphorylations renders newly synthesized PKC catalytically competent. The upstream kinase, the ▶phosphatidylinositol kinase-1 (PDK-1), phosphorylates the activation loop of PKC, triggering phosphorylation at two conserved sites in the C-terminus, the turn motif and the hydrophobic motif, the latter occurring via intramolecular autophosphorylation. The positions of these sites on the recently solved structure of the kinase domain of PKC β II are shown in Fig. 1. Second, the mature, fully phosphorylated species of PKC is allosterically activated following engagement of the membrane-targeting

Protein Kinase C. Figure 1 Domain structure of PKC family members showing regulatory modules (pseudosubstrate sequence and C1, C2, and PB1 domains) and the kinase core. Shown below are the structures of the C1 domain of PKC δ with bound phorbol (purple), the C2 domain of PKC β with bound Ca^{2+} (pink spheres), and the recently solved structure of the kinase domain by Grant and coworkers [1] of PKC β II with phosphorylation sites indicated in pink. Figure adapted from Newton (2003).

modules to the membrane. For conventional PKCs, Ca^{2+} pretargets PKC to the membranes by binding the C2 domain and increasing this domain's affinity for anionic lipids. At the membrane, the C1 domain binds DAG, an event that provides the energy to release the autoinhibitory pseudosubstrate sequence from the substrate binding cavity. Novel PKC isoforms respond to DAG alone because their C1 domain has a sufficiently high-affinity binding to DAG such that pretargeting by the C2 domain is not required. Unlike the diacylglycerol-regulated isoforms, the priming phosphorylations of the atypical PKCs appear to be agonist-driven, and phosphorylation by PDK-1 is, so far, the best characterized activation mechanism of these kinases. Third, scaffold proteins position PKC near its activators or substrates, allowing specificity in signaling by distinct isoforms.

Signaling by PKC is terminated by concentrations of its ligands dropping to basal levels (i.e., Ca^{2+} and diacylglycerol) and by dephosphorylation of the three processing sites. Dephosphorylation is controlled, in part, by a recently discovered hydrophobic phosphorylation motif phosphatase. This phosphatase, ►PHLPP (for PH domain Leucine-rich repeat Protein Phosphatase) dephosphorylates conventional and novel PKC isoforms, initiating their downregulation.

Function

PKC isozymes are involved in a wide array of diverse cellular functions [5]. Most isozymes (e.g., PKC β) are involved in proliferative responses, and hyperactivation with phorbol esters most typically results in cell growth and differentiation. However, isozymes can have opposing functions. PKC δ is well-characterized as an apoptotic kinase, whereas the closely related PKC ϵ is antiapoptotic. PKC also plays a key role in learning and memory.

Atypical PKC isozymes have more clearly defined roles. Their best characterized function is in regulating cell polarity by binding two polarity proteins, Par3 and Par6. Consistent with a key role in cell polarity, knockout of PKC λ is embryonic lethal. The atypical PKC isozymes also play a role in glucose homeostasis. These isozymes control insulin-stimulated glucose transport in muscle and adipocytes by promoting the translocation of glucose transporters to the plasma membrane. In liver, atypical PKC isozymes promote insulin-dependent lipid synthesis.

Pathophysiology

The levels of PKC in cells control the amplitude of PKC signaling pathways. Thus, defects in the regulation of PKC that result in altered levels of the kinase impact the

magnitude and duration of downstream signaling. Altered levels of PKC are associated with a number of diseased states, most notably cancer [2]. Here, levels of specific PKC isozymes are frequently upregulated. Best characterized are the roles of PKC β II and PKC ι in colon cancer: both isoforms are grossly upregulated in this disease. These isozymes promote colon carcinogenesis; mice lacking these enzymes are resistant to carcinogen-induced preneoplastic lesions whereas overexpression in the colonic epithelium results in enhanced colon carcinogenesis. Because of their roles in glucose homeostasis and insulin signaling, defects in atypical PKC signaling contribute both to obesity and Type II diabetes.

Drugs Activators

Conventional and novel PKC isozymes are potently activated by phorbol esters, heterocyclic compounds found in the milky sap exuded by plants of the Euphorbiaceae family. This sap was used medicinally as a counterirritant and cathartic agent over the millennia; we now know that the active ingredients, phorbol esters, specifically bind to the C1 domain, the diacylglycerol sensor described above. In fact, their ability to recruit PKC to membranes is so effective that phorbol esters cause maximal activation of conventional PKCs, bypassing the requirement for Ca^{2+} . This module is found in a number of other proteins in addition to PKC, so the profound effects of phorbol esters on cells are mediated by other proteins in addition to PKC.

Bryostatins are another class of compounds that bind to the C1 domain and result in acute activation of PKC. However, unlike phorbol esters, these marine natural products have antitumor effects. Bryostatins are currently in phase II clinical trials and show promise as anticancer drugs, particularly when combined with other adjuvant therapy.

Inhibitors

A number of inhibitors directed towards the active site of PKC have been developed [4]. Many of these have therapeutic potential and some are in clinical trials. The drug enzastaurin (LY317615) shows selectivity towards inhibiting PKC β and is currently in clinical trials for cancer. This drug has particular potential as a treatment for colon cancer because of the specific role of PKC β II in this disease (see above). A separate PKC β inhibitor, ruboxistaurin (LY333531) has been developed as a drug to treat the microvasculature complications of diabetes; hyperactivation of both PKC β II and PKC β I contribute to diabetic retinopathy and microvasculature complications.

Synonyms

Phosphate transferring enzyme inhibitors

Definitions

▶ **Protein kinases** constitute a class of enzymes that transfer a γ -phosphoryl group of ATP donor molecules to acceptor hydroxyl groups of serine, threonine and tyrosine residues in proteins. Many protein kinases are components of signal transduction pathways that regulate cellular processes such as division, differentiation, migration and survival. Their perturbed function often contributes to the development of cancer and other diseases. Therefore, molecules that can inhibit the activity of protein kinases, protein kinase inhibitors (PKIs), can be used both in investigating the function of a specific kinase in a particular signalling pathway, as well as in preventing the aberrant action of protein kinases in pathophysiological conditions [1, 2].

Mechanism of Action

After their synthesis (translation), most proteins go through a maturation process, called post-translational modification that affects their activity. One common post-translational modification of proteins is phosphorylation. Two functional classes of enzymes mediate this reversible process: protein kinases add phosphate groups to hydroxyl groups of serine, threonine and tyrosine in their substrate, while protein phosphatases remove phosphate groups. The phosphate-linking

reaction requires the presence of three specific sites within the protein kinase: an ATP-binding site, a domain catalyzing the transfer of the phosphate group, and a substrate-binding site that recruits the phosphoaccepting target protein. In order to prevent the activity of a particular kinase, PKI are often directed against one or several of these three sites [4, 5]. The diversity of mechanisms of action of PKI are outlined here and summarized in Fig. 1. Examples of PKI that possess promising therapeutic potentials and that are currently being successfully applied in clinical trials or as therapy against diseases (e.g. cancer, inflammation, autoimmune diseases, diabetes, cardiovascular disease and viral infections) are given in Clinical use [3, 5].

Antibodies can prevent a ligand to bind to its cognate receptor tyrosine kinase either by interacting directly with the ligand (i) or by blocking the binding site on the receptor (ii). This will avoid activation of the receptor [4]. Small molecules can dock at the phosphotyrosine motifs of the intracellular part of the receptor tyrosine kinase and abolish subsequent activation of the signalling cascade (iii). Alternatively, PKI may target degradation of the transcript encoding a protein kinase (iv). Moreover, competitive inhibitors for the ATP-binding site (v) or the substrate-binding site (vi) or both (vii) will prevent phosphorylation of the substrate by the protein kinase [4]. Finally, small molecules can bind to a specific conformation of the protein kinase and inhibit the protein activity or they may influence the stability of the protein kinase by disrupting its interaction with stabilizing chaperone proteins (viii).

Molecules that Interfere with Receptor Tyrosine Kinase Activity

Besides cytoplasmic protein kinases, membrane receptors can exert protein kinase activity. These so-called ▶receptor tyrosine kinases (RTK) contain a ligand-binding extracellular domain, a transmembrane motif, and an intracellular catalytic domain with specificity for tyrosine residues. Upon ligand binding and subsequent receptor oligomerization, the tyrosine residues of the intracellular domain become phosphorylated by the intrinsic tyrosine kinase activity of the receptor [3, 4]. The phosphotyrosine residues function as docking sites for other proteins that will transmit the signal received by the RTK.

One strategy to interfere with RTK activity is to prevent ligand binding to its cognate receptor. This may be achieved by antagonists that block the accessibility of the receptor for its natural ligand or by antibodies that associate with the ligand or the extracellular part of the receptor, thereby avoiding ligand–receptor interaction. To increase the therapeutic potential of antibodies against RTK, toxic proteins are conjugated to the antibodies. These fusion proteins simultaneously block aberrant signalling from the receptor and destroy the target cells. However, a potential immune response against the toxin complicates the clinical application of such inhibitors. Monoclonal antibodies exist that bind both a specific RTK and an immunologic effector cell. Molecules that efficiently prevent receptor oligomerization, and subsequently abrogate RTK activity and downstream signalling have been

Protein Kinase Inhibitors. Figure 1 Major mechanism by which inhibitors can prevent the activity of protein kinases.

designed as well. However, such PKI have not yet entered clinical trials.

Inhibitors that Interfere with Docking Sites

The RTK activity phosphorylates tyrosine residues within the intracellular domain of the receptor. These phosphorylated residues function as docking sites for proteins that will convey the signal to downstream signal transduction components. PKI can be developed that bind these phosphorylated docking sites in order to abrogate inappropriate downstream signalling.

Inhibitors Targeting Protein Kinase Transcripts

Another strategy to inhibit the expression of a specific protein kinase exists in preventing translation of its transcripts. One mode to accomplish this relies on the use of ribozymes, which are modified RNA molecules that can cut other RNA molecules. Ribozymes consist of a central catalytic domain with RNA degrading activity, flanked by RNA sequences that are complementary to the target mRNA. In this way, a catalytic domain with no particular specificity can be made to cut up the mRNA encoding a specific protein kinase. Another way to thwart translation is by degradation of target RNA by RNA interference (►siRNA). Synthetic RNA sequences that are complementary to target protein kinase mRNA will form dsRNA structures with their target. These dsRNA molecules will be recognized and digested by specific RNA degrading enzyme complexes.

Competitors of ATP-Binding Sites

Most of the PKIs currently in clinical trials are small molecules that compete for the ATP-binding site [3, 5]. They prevent the phosphate donor ATP to bind to the protein kinase, and hence the target protein will not become phosphorylated and the perturbed signalling can be terminated.

Competitors of Substrate-Binding Sites

The rationale behind substrate-mimicking molecules lies in their ability to compete with the genuine substrate for binding to the protein kinase. They occupy the binding site for the natural substrate, and therefore terminate the signal transduction event that contributes to the pathogenic state of the cell [3]. Thymidylate synthase is an enzyme that is frequently overexpressed in tumours. The substrate-mimicking compound ThymectacinTM (a phosphoramidate derivative of brivudin) inhibits this enzyme and has successfully entered clinical evaluation against colon cancer. Although not a PKI, this example illustrates the therapeutic potential of substrate-mimicking compounds for PKI. Indeed, substrate-binding site compounds have been synthesized that efficiently ablate protein kinase activity in cell cultures, but none of them have been submitted to clinical trials so far.

Bisubstrate Competitors

Bisubstrate analogue inhibitors form a special group of PKIs that mimic both the phosphate donor (ATP) and the acceptor components (serine-, threonine-, and tyrosine-containing peptides). They can provide enhanced specificity for protein kinases as they block both the ATP- and the substrate-binding site of their target. Bisubstrate analogues that effectively inhibit the insulin receptor tyrosine kinase activity in vitro have been designed, and may thus comprise a new class of therapeutically useful agents.

Inhibitors of Chaperones

Another way to restrain protein kinases is by altering their stability. Heat shock proteins, like e.g. heat shock protein 90 (Hsp90), function as molecular ►chaperones by binding to various cellular proteins, including protein kinases, thereby regulating the folding, stability and function of their substrates. Thus, chaperone-based inhibitors may prevent the associated chaperone to maintain the activated conformation state of the protein kinase and help to quench the oncogenic activity of this kinase in tumour cells. The inhibition of Hsp90 results in the proteasomal degradation (►proteasome) of the client protein and in cell death of the targeted cancer cells.

Molecules that Selectively Bind a Specific Conformation of the Protein Kinase

An alternative strategy to inhibit a protein kinase relies on different conformations that active and inactive protein kinase can acquire. Antagonists for a protein kinase can be selected that exclusively bind to the inactive form of the kinase, so as to sequester the molecule in a state that cannot participate in signal transduction.

Clinical Use

Inhibitors that Block the Action of RTK

Antibodies that bind the ligand have been successfully used as inhibitors of RTK [3]. Bevacizumab (Avastin) is a recombinant humanized monoclonal antibody that binds the vascular endothelial growth factor (VEGF), and thereby prevents activation of the VEGF receptor and the assembly of new blood vessels (►angiogenesis), which ultimately leads to tumour growth regression. Bevacizumab seems beneficial in several clinical trials as an antiangiogenic strategy in cancer patients and has been approved by the Food and Drug Administration as first-line treatment for metastatic colorectal cancer (Table 1). Bevacizumab has low toxicity, but patients possessed an increased risk of encountering thromboembolic events. Ranibizumab (Lucentis, another anti-VEGF monoclonal antibody) is used to treat macular degeneration, a medical condition leading to blindness [3–5]. HerceptinTM (Trastuzumab) is a monoclonal antibody directed against the epidermal growth factor receptor 2 (EGFR2,

Protein Kinase Inhibitors. Table 1 Examples of PKI currently investigated in clinical trials or administered in the clinic

HER-2, Neu, ErbB-2), which is overexpressed in ~25% of invasive human breast cancer and is associated with an aggressive tumour phenotype and reduced survival rate. Herceptin is now administered to treat metastatic breast cancer and tested in **clinical trials** with osteosarcoma and endometrium cancer patients. Most patients do not experience side effects, although some cases of temporary dizziness, fever or chill, headache, skin rash, nausea and shortness of breath have been reported. Despite its initial beneficial response, most patients develop resistance within 1 year. Combined therapy of Herceptin and conventional chemotherapy resulted in a synergistic effect on tumour regression and improved survival rates in patients [1, 3, 5]. Pertuzumab is a monoclonal antibody that blocks dimerization of HER-2 with other EGFR receptors and has entered phase III clinical trials with breast cancer and other solid tumour patients. MDX-447, a bispecific antibody that binds EGFR and immunologic effector cells, is analysed in phase II studies on patients with squamous cell carcinoma of the head and neck. Currently, a phase III trial with MDX-210 (inhibits EGFR2) in combination with monocyte-derived activated killer cell technology against ovarian cancer is under way [3]. To increase the therapeutic potentials of antibodies against RTK, toxic proteins are fused to the antibodies. For example, anti-HER-2 antibodies linked to the fungal toxin maytansine DM-1 are being tested in preclinical studies. Peptides that occupy the receptor are also a strategy to prevent the natural ligand from binding to its receptor. The platelet-derived growth factor (PDGF) receptor is overexpressed in many carcinomas and some cancer patients have elevated serum levels of PDGF compared with healthy individuals. GFB-111 or its second-generation derivative GFB-204 bind the PDGF receptor and block PDGF-induced receptor autophosphorylation and downstream signalling. The GFB compounds

possessed antiangiogenic and anticancer activity against human tumour **xenografts** in mice and showed no signs of gross toxicity. However, these compounds still await to enter clinical trials. DAB₃₈₉EGF is a fusion of a specific peptide sequence of EGF and diphtheria toxin. This fusion molecule efficiently binds the EGFR that is overexpressed on tumour cells. DAB₃₈₉EGF was cytotoxic for tumour cell cultures and caused tumour regression in animal models, but no clinical trials have been reported.

Blocking the Phosphotyrosine Docking Sites in RTK

Preventing docking of signalling molecules to the phosphotyrosine motifs in the intracellular domain of the activated RTK may form another mode to interrupt aberrant signalling. CGP78850 can impede the usual SH2-phosphopeptide interactions upon activation of the EGFR, thereby blocking signalling downstream of this receptor. However, CGP78850 has not yet been tested on patients with inappropriate EGFR activity.

Targeting Protein Kinase Transcripts RNA Interference

The antisense oligonucleotide L_ErafAON against the serine/threonine kinase c-Raf has been tested in phase I clinical trials. The antisense oligonucleotides ISIS-5132, which also inhibits c-Raf, and ISIS-3521, which inhibits PKC, went through different phase clinical trials with solid tumour patients. Unfortunately, no objective responses occurred with these PKI. GEM-231, an oligonucleotide targeting the RI α subunit of protein kinase A is currently undergoing phase I/II clinical trials alone or in combination with traditional therapy for the treatment of solid cancers [3].

Ribozymes

Angiozyme is a ribozyme that specifically recognizes the mRNA for FLT-1, one of the most important VEGF

receptors involved in angiogenesis. Angiozyme, which has gone through phase I and II clinical trials, showed biological activity in metastatic breast cancer, although it could not be used as monotherapy. Angiozyme is now being investigated in combination therapy for metastatic colorectal cancer. Herzyme is also a ribozyme in phase I clinical trial for the treatment of HER2-overexpressing breast cancer [3].

Competitors of the ATP-Binding Site

Imatinib (STI-571 or Gleevec) was one of the first PKI developed to treat Philadelphia chromosome positive leukaemia, and gastrointestinal stromal tumours (GIST). This small compound occupies the ATP-binding site and prevents access of donor ATP to the kinase and subsequent phosphorylation of the substrate. Although the inhibitor was well tolerated in clinical trials and showed high bioavailability and mild side effects, resistance to the drug quickly arose. This resistance lies in functional inactivation of the compound, loss of BCR-ABL kinase target, mutations in the target protein kinase. Second-generation derivatives that circumvent resistance are being developed and tested [1, 3, 4].

Erlotinib (Tarceva™) competes with ATP in the HER1/EGFR ATP-binding pocket. It is used in the clinic in locally advanced or metastatic non-small cell lung cancer after failure of at least one chemotherapy regime [1, 3, 5].

Inhibitors of Chaperones

Destabilization of an abnormally functioning protein kinase by interrupting the association of the kinase with its chaperone may be beneficial in pathogenic conditions. Encouraging *in vitro* results with the histone deacetylase inhibitor LBH589 and an analogue of geldanamycin (17-allyl-amino-demethoxy geldanamycin or 17-AAG) demonstrated that both compounds disrupt the chaperone association of Hsp90 with its targets proteins BCR-ABL and mutant FLT-3, resulting in ►ubiquitination and proteasomal degradation of both proteins. Currently, both 17-AAG and LBH589 are in Phase I and II clinical trials as treatment for a variety of solid tumours [3].

Molecules that Selectively Bind a Specific Conformation of the Protein Kinase

KC706 stabilizes the inactive conformation of the mitogen-activated protein kinase p38 α , a protein kinase involved in inflammatory reactions and cardiovascular functions. KC706 therefore holds the potential to treat conditions such as rheumatoid arthritis, psoriasis, inflammatory bowel disease and cardiovascular disease. This compound is currently being tested in phase II clinical trials with patients suffering from rheumatoid arthritis.

Protein Phosphatases

SUSANNE KLUMPP, MARIE-CHRISTIN THISSEN,
JOSEF KRIEGLSTEIN
Institut für Pharmazeutische und Medizinische
Chemie, Westfälische Wilhelms-Universität, Münster,
Germany

Definition

Protein phosphatases are several classes of enzymes that catalyze the hydrolysis of phospho-amino acids within a peptide or protein, thus resulting in dephosphorylation.

Basic Characteristics

Protein phosphatases are obligate counterparts of protein kinases. Originally considered boring enzymes, it is clear by now that phosphatases are playing dynamic regulatory and decisive roles. Protein phosphatases are involved in many fundamental physiological events, including growth, proliferation, survival, differentiation of cells, stress response and the cell cycle, hormone action, ion channel activity, cytoskeleton function, neurotransmission, protein synthesis, gene expression, and metabolic pathways.

Nomenclature

Protein phosphatases are classified according to their activity toward phospho-amino acids they act on (Fig. 1). Nomenclature is independent of regulation simply because stimuli were unknown. Protein phosphatases hydrolyzing *O*-phospho-monoesters are currently subdivided into two major classes: (i) phosphatases acting on phosphoserine (pSer) and phosphothreonine (pThr), and (ii) the second class

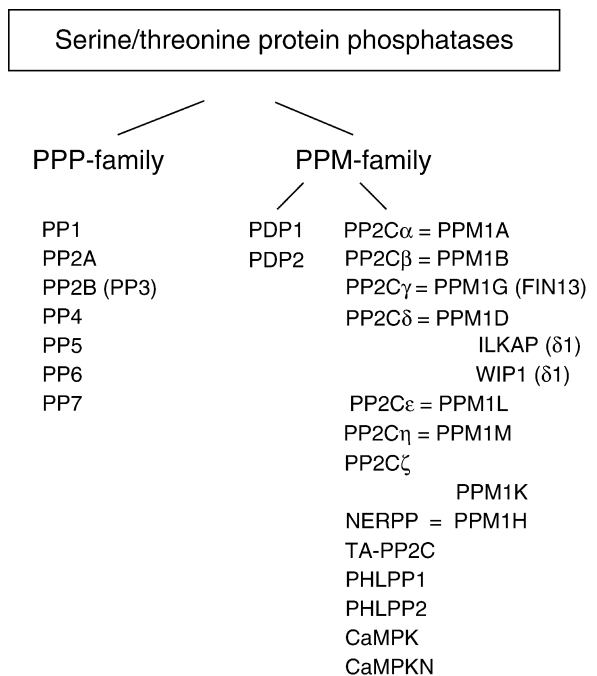

Protein Phosphatases. Figure 1 The diversity of protein phosphatases.

of enzymes acting on phosphotyrosine (pTyr). In addition, there are protein phosphatases hydrolyzing N-phospho-amidates such as phosphohistidine (pHis), phosphatases acting on acyl-phosphates, and those hydrolyzing phospho-thioesters.

Serine/Threonine Protein Phosphatases

Protein phosphatases acting on pSer/pThr were initially defined using biochemical assays as either type 1 (PP1) or type 2 (PP2). Type 1 phosphatases are preferentially inhibited by heat-stable inhibitor proteins while type 2 enzymes are much less affected. The type 2 phosphatases were further subdivided on the basis of divalent cation requirement. PP2A is independent of metal ions whereas PP2B (calcineurin) depends on Ca^{2+} , and PP2C requires Mg^{2+} or Mn^{2+} for activity. Cloning and genetics called for major revision. Nowadays, pSer/pThr protein phosphatases are classified into two groups on the basis of sequence, structure, and catalytic mechanism [1] (Fig. 2): the phospho-protein phosphatase family (PPP), and the family of protein phosphatases that require Mg^{2+} - or Mn^{2+} -ions for activity (PPM).

PPP family members: PP1, PP2A, PP3 (=PP2B, ►calcineurin), PP4, PP5, PP6, and PP7 (Fig. 2). Many of them acquire specificity and are controlled by association with polypeptides that not only localize the enzymes to different cellular compartments but also impart regulation of enzyme activity and substrate recognition. For instance, in higher eukaryotes the catalytic subunit of PP1 interacts with an estimated 200 structurally unrelated proteins to form distinct holoenzymes. Regulatory and targeting subunits typically bind to PP1 via short degenerate sequences, e.g. the RVXF and SILK motifs. Similar complexity is observed with PP2A. Mammals have two PP2A catalytic subunit genes (PPP2C α and PPP2C β – they are not the same as PP2C α and PP2C β of the PPM family, *vide infra*), two structural A subunit genes and four classes of regulatory B subunits with multiple genes in each group. PP2A exists as a heterotrimer. PP4 and PP6 are relatives of PP2A. PP5 has several N-terminal tetratricopeptide

Protein Phosphatases. Figure 2 Families and subtypes of serine/threonine protein phosphatases. PP: protein phosphatases; PPP: phospho protein phosphatases; PPM: protein phosphatases Mg^{2+} -dependent.

(TPR) domains. PP2B (calcineurin) is a heterodimer of a catalytic A-subunit together with a regulatory, Ca^{2+} -binding B-subunit. The A-subunit additionally carries a calmodulin binding site and an autoinhibitory domain. PP7 also contains EF-hand motifs. Both, PP2B and PP7 are stimulated by Ca^{2+} -ions.

PPM family members are characterized by the requirement of Mg^{2+} or Mn^{2+} -ions for activity. The group consists of two pyruvate dehydrogenase phosphatases (PDP1, PDP2) plus 15 protein phosphatase type 2C (PP2C) isozymes (Fig. 2). The 2C enzymes vary in molecular mass, function, and localization. Specific inhibitors are not available. Discovery of the prototypes PP2C α (PPM1A) and PP2C β (PPM1B) of 42 and 45 kD goes back to the 1980s. PP2C isozymes are involved in a variety of processes, e.g., apoptosis, cell cycle, and stress response. Strikingly, at least 23 kinases have been identified as substrates of PP2C enzymes. PP2C members are not evolutionary related to PP1, PP2A, and PP2B, which are all multisubunit enzymes, and its members are not inhibited by okadaic acid.

Protein Tyrosine Phosphatases

Genome sequencing revealed approximately 100 human PTP genes [2], compared with 90 human protein tyrosine kinase genes, suggesting similar levels of complexity among the opponents. The catalytic domain

of all PTPs contains an essential cysteine residue embedded within a conserved signature motif ((I/V)-HCxxGxxR(S/T)) – briefly HC(x)₅R – and catalyzes hydrolysis via a thio-phosphate intermediate.

The classical PTPs can be subdivided into receptor-like PTPs and nonreceptor, cytosolic PTPs. The second category of PTPs are broadly defined as dual specificity phosphatases (DSPs), which dephosphorylate pSer/pThr as well as pTyr. MAP kinase phosphatases (MKPs) (▶MAP kinase cascades) and ▶PTEN are examples of DSP family members. Remarkably, PTEN also has lipid phosphatase activity that is specific for ▶phosphatidylinositol-3,4,5-trisphosphate generated in response to the actions of PI3K. Finally, the class of low molecular mass (LM-) PTPs and that of CDC25 PTPs accomplish the cells repertoire of PTPs (Fig. 3).

Protein Histidine Phosphatases

Histidine phosphatases and aspartate phosphatases are well established in lower organisms, mainly in bacteria and in context with “two-component-systems”. Reversible phosphorylation of histidine residues in vertebrates is in its infancy. The first protein histidine phosphatase (PHP) from mammalian origin was identified just recently. The soluble 14 kD protein does not resemble any of the other phosphatases. ATP-citrate lyase and the β-subunit of ▶heterotrimeric GTP-binding proteins are substrates of PHP thus touching both, metabolic pathways and signal transduction [4].

FCPs, SCPs, and HAD Protein Phosphatases

This is an emerging field that has not reached its final position yet. Members of the novel class of FCP, SCP, and HAD phosphatases require Mg²⁺ for catalysis. An aspartate residue within the active site signature motif (DxDx(T/V)) is essential to form an acyl-phosphate intermediate. Many members of the the HAD (haloacid dehalogenase) superfamily have phosphoesterase activity [3]. Some of those protein phosphatases act on

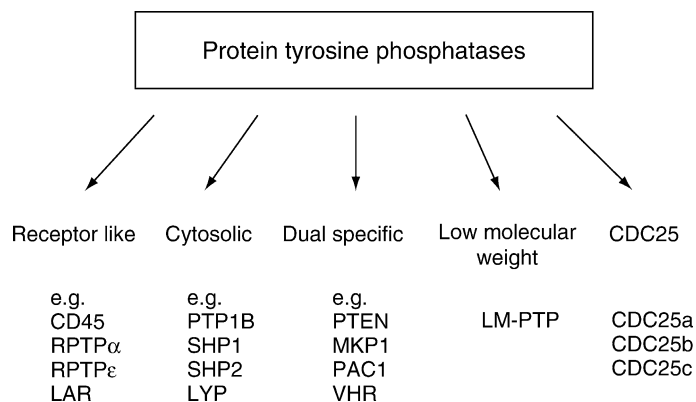

pSer, others on pTyr. Phosphatases dephosphorylating the carboxyl-terminal domain of RNA polymerase II are termed FCPs (TFIIF-associating CTD phosphatase; CTD, carboxyl-terminal domain of the largest subunit of RNA polymerase II). So far all FCPs act on pSer. Small C-terminal domain phosphatases (SCPs) accomplish this novel class of phosphatases. SCPs in addition dephosphorylate the regulatory linker regions of Smad2 and Smad3 to enhance transforming growth factor-β (▶TGFβ) signaling.

Regulation

For in vitro studies there are a number of compounds available to block protein phosphatase activity. Phosphate buffers inactivate all of these enzymes. Several naturally occurring toxins are potent inhibitors of PPPs, e.g., okadaic acid or microcystin, and are frequently used tools. PPM and PTP family members are not affected by these toxins. Vanadate containing solutions are competitive inhibitors of PTPs, pervanadate is an irreversible inhibitor of PTPs.

In vivo, protein phosphatases are tightly regulated by diverse mechanisms including

- Oxidation (e.g., PTPs; inactivation via oxidation of the active site cysteine)
- Divalent cations (e.g., PP2B, PP7: Ca²⁺; PPM-enzymes: Mg²⁺ or Mn²⁺)
- Fatty acids (e.g., PP5; PP2Cα and β)
- Methylation (e.g., PP2A; carboxylgroup of the C-terminal Leu-308)
- Dimerization (e.g., some receptor-PTPs such as CD45 and RPTPα)
- Proteolysis (e.g., activation of PP5 by limited proteolysis)
- Phosphorylation (e.g., LM-PTPs, PP1 and inhibition of PP1; the inhibitor protein I1 becomes inhibitory to PP1 only after phosphorylation on Thr-35 by PKA)

Protein Phosphatases. Figure 3 Classification of protein tyrosine phosphatases. See text for details. Common names for selected PTPs are used according to Ref. [2].

- Regulatory subunits (e.g., PP1, PP2A, PP2B; note that inhibitor proteins may, in turn, be further regulated by phosphorylation and dephosphorylation).

Scaffolding Proteins

Numerous protein phosphatases are targeted to their substrates and regulators through the interaction with specific ► **scaffolding proteins**. Some of these anchoring proteins bind both, kinases and phosphatases. This applies to ser/thr protein phosphatases as well as to tyrosine phosphatases.

Drugs and Diseases

The introduction of PP2B (calcineurin) inhibitors revolutionized kidney transplantation. Cyclosporine A and tacrolimus (FK506) are the principal immunosuppressants prescribed for adult and pediatric renal transplantation. Cyclosporine A was in use clinically long before its mechanism of action was elucidated.

Acid- and alkaline phosphatases act on a variety of mono- and multiple phosphate carrying low molecular mass molecules. In addition, they hydrolyze many, but not all, phosphoproteins. They are in use for decades to easily screen for diseases, however, somewhat unspecifically. For instance, acid phosphatase is used as biomarker for prostate cancer, and alkaline phosphatase to monitor bone (de-) mineralization and liver tumors.

In the meantime, aberrant phosphorylation levels of proteins have been linked to many human diseases. The discovery of tyrosine kinases as potential oncogenes had great impact on drug development. Corresponding tyrosine phosphatases can either induce transformation (e.g., oncogenic role of PTP1B in breast cancer) or act as tumor suppressor (e.g., PTEN which is mutated in a large number of cancers). Protein kinase inhibitors are on the market; studying phosphatases as targets has just begun.

Important advances have been made recently from genomic studies. Our understanding of the (patho-) biochemical functions of phosphatases originates from human single-nucleotide polymorphisms (SNPs) and knockout mice. Only few examples will be highlighted here. Knowledge is most advanced within members of the PTP-family. Abnormal PTP genes are also associated with diseases other than cancer. For instance, an SNP of the *PTPN22* gene of lymphoid PTP LYP is associated with diabetes mellitus type I. Variants encoded by the two alleles *1858C* and *1858T* result in a point mutation at position 620 from arginine to tryptophane. This single amino acid exchange is a common risk factor for autoimmune diseases, including type I diabetes and rheumatoid arthritis. Furthermore, PTP1B is an outstanding target for the treatment of diabetes type II and obesity. Antisense-based therapeutics that target PTP1B have normalized blood glucose levels and improved insulin sensitivity, and are now in phase II clinical trial. Among

ser/thr protein phosphatases PP1 and PP2B are involved in neuronal signaling, learning and memory. PP2A accounts for most of the tau phosphatase activity. Abnormal hyperphosphorylation of tau is mainly due to downregulation of PP2A activity in Alzheimer's disease brain. Finally, PP2C seems to be linked to cystic fibrosis, stress response, and atherosclerosis.

Synonyms

Protein transport; Protein sorting

Definition

Protein trafficking is the transport of proteins to their correct subcellular compartments or to the extracellular space (“secretory pathway”). Endo- and exocytosis describe vesicle budding and fusion at the plasma membrane and are by most authors not included in the term protein trafficking. Protein quality control comprise all cellular mechanisms, monitoring protein folding and detecting aberrant forms.

Basic Mechanisms

General Transport Routes and Quality Control

The intracellular protein transport and quality control mechanisms ensure that proteins are delivered to their correct subcellular compartment and are thus a prerequisite for both cell architecture and function. Trafficking processes are not only important for proper protein sorting. Together with biosynthesis and degradation mechanisms, they play also an important role in maintaining specific protein concentrations in the various subcellular compartments. Since protein transport is of vital importance, these mechanisms are tightly regulated. Trafficking processes have also drawn the attention of clinicians since many diseases have been shown to be caused by transport deficient proteins.

The pharmacological manipulation of protein folding, trafficking, and quality control is still challenging, but a lot of progress has been made recently.

The general transport routes of proteins are well established (Fig. 1a) [1]. Initially, every protein is synthesized at cytoplasmic ribosomes. Its destination within the cell is then determined by transport signals. If the nascent chain does not contain transport signals, it becomes a cytosolic protein.

Transport signals can be of the import or the export type. Import signals are contained in proteins that are transported into the individual compartments of mitochondria (matrix, inner membrane, intermembrane compartment, outer membrane), peroxisomes (lumen, boundary membrane) and into the interior of

Protein Trafficking and Quality Control. Figure 1 Intracellular protein transport (a) General transport routes of proteins starting with the initial synthesis at cytoplasmic ribosomes (Ri). The export (secretory) pathway to the plasma membrane (PM) via the endoplasmic reticulum (ER), the ER/Golgi intermediate compartment (ERGIC) and the Golgi apparatus (Golgi) is indicated in red. The different import pathways are indicated in blue. Import pathways direct proteins into the individual compartments of mitochondria (Mi) (matrix, inner membrane, intermembrane compartment, outer membrane), peroxisomes (Pe) (lumen, boundary membrane), and into the interior of the nucleus (Nu). Note that transport is posttranslational in the case of all import pathways but cotranslational in the case of the export pathway. (b) Types of signal sequences in the export pathway for translocation across (secretory proteins) or integration into (membrane proteins) the ER membrane. The signal sequences are indicated in red. Lu, ER lumen; Mem, ER membrane; Cy, cytoplasm. Upper panel: secretory proteins contain signal peptides which are removed by signal peptidases in the ER lumen. A subset of the membrane proteins with an extracellular N terminus may also contain signal peptides (type I proteins). Lower panel: the second group of membrane proteins with an extracellular N terminus use signal anchor sequences for ER insertion (type III proteins). Membrane proteins with an intracellular N terminus contain invariably signal anchor sequences (type II proteins).

the nucleus. They mediate transport to the target compartment when protein biosynthesis is complete (posttranslational transport).

Export signals direct proteins to the secretory pathway which runs from the ►endoplasmic reticulum (ER) via the ►ER/Golgi intermediate compartment (ERGIC) and the different compartments of the ►Golgi apparatus to the plasma membrane. The occurrence of export signals leads to the stop of the cytoplasmic protein translation (elongation arrest) by the binding of the ►signal recognition particle (SRP). The resulting nascent chain/ribosome/SRP complex is then targeted to the ►translocon complex at the ER membrane. Here translation restarts and the export signals mediate integration into (membrane proteins) or translocation across the ER membrane (secretory proteins) through the main component of the translocon, the protein-conducting Sec61p channel protein. At the ER membrane, protein integration or translocation takes place while protein synthesis is in progress (cotranslational transport). Secretory proteins contain N-terminal signal peptides as export signals. The signal peptides are cleaved off by the ►signal peptidases of the ER after translocation of the nascent chain. Secretory proteins consequently become part of the ER lumen. In membrane proteins, two different types of export signals were found to mediate ER targeting/insertion (Fig. 1b): (i) proteins with an extracellular N terminus may contain cleavable signal peptides similar to that of secretory proteins (type I proteins); (ii) the vast majority, however, use the first transmembrane domain of the mature protein as a so-called signal anchor sequence (type III proteins). Membrane proteins with an intracellular N tail invariably contain signal anchor sequences (type II proteins). In contrast to secretory proteins, membrane proteins laterally leave the Sec61p protein and thus become part of the ER membrane. Their extracellular domains are translocated into the ER lumen, their intracellular domains remain in the cytoplasm.

In the secretory pathway, the ER is the compartment where protein folding takes place [2]. Proteins called ►chaperone play an important role in protein folding and in the quality control of this process. Chaperones like ►BiP assist in protein folding by their repeated binding to hydrophobic patches of the nascent chain. Moreover, they retain misfolded proteins by their prolonged association, monitor ER stress induced by accumulating aberrant proteins, and induce the unfolded protein response (UPR). The UPR represents a complex adaptation reaction of the cell leading to major changes in transcription and translation of stress-related (increase) and stress-unrelated proteins (decrease). The UPR also induces the ER-associated degradation pathway (ERAD): misfolded proteins are retrotranslocated to the cytosol, ubiquitinated, and finally degraded by the proteasom.

In the case of membrane proteins, the chaperone-based quality control system outlined above seems to be supported or complemented by quality control mechanisms in the ERGIC [3]. Here, subunits of some multimeric proteins (such as ATP-sensitive potassium channels; K_{ATP} -channels) expose short dibasic retrieval signals as long as they are unassembled (consensus sequence = RXR). The RXR signals mediate sorting into retrograde (ERGIC to ER) transport vesicles and consequently reroute the unassembled subunits back to the ER. Upon assembly, the RXR signals are masked and the resulting complex is able to complete the secretory pathway. This system guarantees that only completely assembled multimeric proteins can finalize the secretory pathway. It remains to be determined whether similar quality control mechanisms occur outside the ER and ERGIC, e.g., in the Golgi apparatus.

Once the proteins have passed the quality control system of the early secretory pathway, they are transported in vesicles via the individual compartments of the Golgi apparatus to the plasma membrane. Soluble proteins are transported in the vesicle lumen, membrane proteins are integrated in the vesicle membrane. The transport to the cell surface is the “default” pathway for secretory and membrane proteins. Proteins may also become part of one of the intracellular compartments along the secretory pathway, but only if they contain specific retention signals.

It is thought that soluble proteins enter the transport vesicles of the secretory pathway by bulk flow. In contrast, the recruitment of membrane proteins into the vesicles seems to require sorting signals. Whereas the sorting signals mediating the transport through the intracellular compartments seem to be identical in different cell types, those for the plasma membrane may be variable. In polarized epithelial cells, for example, the cell surface is not homogenous but consists of two different compartments, the apical and the basolateral membranes. Here, additional sorting information is required in the trans-Golgi to deliver proteins correctly. The same holds true for neurons containing dendritic and axonal membranes or endothelial cells, containing luminal and abluminal membranes.

Diseases Caused by Transport-Deficient Proteins

Many diseases are known to be caused by the intracellular retention of mutant proteins or by the impairment of components of the secretory pathway [4]. The disease-causing mechanisms include:

1. Disorders caused by misfolded mutant proteins that fail to pass the quality control system of the ER (e.g., mutations of the cystic fibrosis transmembrane regulator protein (CFTR) causing ►cystic fibrosis). The mutant proteins are retrotranslocated into the cytosol and finally subjected to proteolysis. In some

cases, inefficient proteasomal degradation may lead to the accumulation of proteins in the ER causing severe ER stress and cell damage.

- Disorders caused by the impairment of the Golgi apparatus and further vesicular trafficking (e.g., mutations in the Rab escort protein Rep1 leading to ►**choroideremia**).
- Disorders caused by mislocalization of lysosomal proteins (e.g., mutations in the N-acetylglucosamine 1-phosphotransferase leading to ►**inclusion cell disease**).
- Disorders affecting the import pathways to mitochondria, peroxisomes, and the nucleus (e.g., mutations in the peroxisomal Pex proteins leading to ►**Zellweger syndrome**).

Among the many diseases known to be caused by transport defective proteins, cystic fibrosis is one of the most frequent and best characterized. It is caused by mutations in the gene for the CFTR protein, a cAMP-regulated chloride channel belonging to the ABC transporter family. The CFTR protein is expressed in the apical membrane and in subapical endosomal compartments of secretory epithelial cells, where it regulates the chloride transport over the apical membrane. In about 70% of the patients, the $\Delta F508$ mutation of the CFTR protein is found. The intracellularly retained $\Delta F508$ CFTR protein has some residual function, i.e., the quality control system seems to be overprotective in this case. The $\Delta F508$ CFTR protein is a widely used model for developing drugs which may be useful for the treatment of diseases caused by transport and folding-defective proteins.

Drugs

Most pharmacological strategies for the treatment of protein transport diseases aim to rescue mutant proteins

retained by the quality control system of the ER [5]. The idea is to develop substances favoring correct folding of the mutant proteins, thereby allowing them to pass the quality control system. Although the new pharmacological approaches for the causal treatment of these protein transport diseases are promising, none of the substances made its way out of the experimental or the early clinical trial level as yet. Two groups of substances favoring correct protein folding are examined at the moment: the chemical and the pharmacological chaperones.

Chemical Chaperones

The observation that reduction of temperature sometimes favors correct protein folding led to the idea that this effect may also be achieved by the addition of chemical compounds acting as “chemical chaperones”. Indeed, protein folding can be improved in cells by a wide range of substances acting more or less unspecifically. Osmolytes such as glycerol or trimethylamins may increase solvent density and consequently decrease protein movements and their ability to aggregate. Hydrophobic compounds such as phenylbutyrate (PBA) may prevent protein aggregation by masking exposed hydrophobic domains of misfolded proteins. Aside from their unspecific mode of action, the most important disadvantage of the various chemical chaperones is that they must be used in very high (toxic) concentrations precluding an in vivo application.

Pharmacological Chaperones

The disadvantages of the chemical chaperones led to the idea that correct protein folding may also be stabilized by small compounds binding specifically to the patients target proteins. For example, addition of an agonist or an antagonist to a mutant receptor protein may help to establish the correct conformation of the ligand binding

Protein Trafficking and Quality Control. Table 1 Examples of diseases associated with folding-defective, mutant proteins, and pharmacological chaperones used to correct misfolding in vitro

Disease	Protein affected	Substance
Congenital Long QT syndrome	Human-ether-a-go-go-related protein (HERG)	E-4031, astemizole, cisapride
Cystic fibrosis	Cystic fibrosis transmembrane conductance regulator (CFTR)	Benzo(c)quinolizinium derivatives, VRT-325
Persistent hyperinsulinemic hypoglycemia of infancy (PHHI)	SUR1 subunits of ATP-sensitive potassium channels (K_{ATP})	Sulfonylurea
Hypogonadotropic hypogonadism	Gonadotropin-releasing hormone (GnRH) receptor	GnRH peptidomimetic antagonist
GM2-gangliosidosis	Lysosomal, heterodimeric α -hexosaminidase A (Hex A)	Pyrimethamine
Pompe disease	Acid α -glucosidase (GAA)	Deoxynojirimycin
Retinitis pigmentosa	Opsin	11-cis-7-ring retinal
X-linked nephrogenic diabetes insipidus	Vasopressin V2 receptor (V2R)	SR121463, SR49059

pocket and consequently the correct structure of the full length protein. In nonreceptor proteins, these “pharmacological chaperones” may specifically interact with other protein domains. If such high affinity molecules interact with the extracellular domains of membrane proteins or with secretory proteins, they must, however, be hydrophobic enough to pass not only the plasma but also the ER membrane. At the translocon complex of the ER membrane, transcription, translation, and folding of proteins are closely synchronized processes. Recent data indicate that pharmacological chaperones do not act cotranslationally, but exert their function after translation is complete. It is conceivable that the efficiency of pharmacological chaperones increase with their affinity, the best substances even binding irreversibly to their targets. Thus, studies addressing improved folding and transport of mutant proteins by pharmacological chaperones must always be accompanied by activity and washout experiments.

In the past 5 y, many pharmacological chaperones have been described promoting correct folding of disease-causing, mutant proteins in transfected cells (see [Table 1](#) for examples). It is conceivable that modern high throughput screening methods using activity assays or even automated microscopes will help to identify many additional substances in the near future.

Neither chemical nor pharmacological chaperones lead to wild-type expression levels of the mutant proteins at the cell surface. Alternative or additional strategies are needed to improve the intracellular transport of the mutant proteins. In the future, drugs may also be developed that influence those components of the quality control system that are involved in the retention of misfolded proteins.

Protease-activated receptors, PAR-1, PAR-2, PAR-3, PAR-4; Thrombin receptors; Thrombin-related receptors, Trypsin receptor

Definition

►Proteinase-activated receptors (PARs) are a unique family of G-protein-coupled receptors (GPCRs) that are activated in response to ►serine proteinases. There are four PAR family members; PAR-1 through to PAR-4. PAR-1 and PAR-3 respond to ►thrombin, PAR-2 responds to ►trypsin, whilst PAR-4 is sensitive to both thrombin- and trypsin-related proteinases.

Basic Characteristics

Mechanism of PAR Activation

PARs are distinguished from other GPCRs by their mechanism of activation. Unlike other GPCRs which are activated reversibly by a freely diffusible ligand, PARs are activated by serine proteinases through irreversible proteolytic cleavage at specific residues upon the N-terminal of the receptor. A new N-terminal ‘tethered’ ligand region is created that interacts intramolecularly with the second extracellular loop (ECL-2) of the receptor to initiate signal transduction via G-protein-dependent pathways ([Fig. 1](#)). PAR-1, PAR-3 and PAR-4 become activated in response to thrombin whilst PAR-2, and to a lesser extent PAR-4, become activated by trypsin-related proteinases. In addition to thrombin and trypsin, other activators of PARs have been reported including coagulation factors, leukocyte and mast cell proteinases, pancreatic and extrapancreatic trypsins and the anchoring protein anticoagulant protein C (APC). Non-mammalian proteinases also display efficacy at PARs, namely those generated from dust mites (Der P3/9), bacteria and fungi ([Table 1](#)). Depending upon the consensus PAR cleavage site and abundance, some proteinases are capable of both activating and deactivating PARs. Cathepsin G can activate PAR-1, however, when cleavage occurs

Proteinase-activated Receptors. Figure 1 Activation of proteinase-activated receptors (PARs) through proteolytic cleavage with serine proteinases (1) and independent of cleavage through PAR-specific activating peptides (2).

downstream of the N-terminal **tethered ligand** region, proteolytic deactivation of the receptor results.

PAR activation can also take place independent of N-terminal cleavage through the direct interaction of synthetic activating peptides (APs) with the extracellular loop. These peptides are derived from the sequence of the freshly cleaved tethered ligand and mimic the intramolecular docking to ECL-2 to induce cell signalling (Table 1). Structure–activity relationship (SAR) studies investigating PAR-activating peptides identified that peptide sequences encompassing the tethered ligand domain as short as 5 or 6 amino acids are adequate for maximal potency. However, in comparison with the nanomolar activity of endogenous proteinases, peptide agonists require micromolar concentrations to elicit a response of comparable magnitude. Furthermore, given the sequence similarity within ECL-2 for all PARs there is considerable potential selectivity problems with peptides previously assumed to be selective for the earlier discovered subtypes. Thus, the development of highly potent agonists and antagonists has been achieved for only PAR-1, whilst for other PAR studies are still ongoing [1].

The Physiological and Pathophysiological Roles of the PAR Family

PARs are coupled to multiple G-proteins and mediate a number of well-defined cellular responses via classical second messenger and kinase pathways. PARs are differentially expressed in cells of the vasculature as well in the brain, lung, gastrointestinal tract, skin as well as other highly vascularised tissues and evidence suggests distinct physiological functions and roles in disease states [2].

PAR-1

Activation of PAR-1 results in intracellular calcium mobilisation and cytoskeletal rearrangement that mediates platelet activation and aggregation. Early studies identified a dual receptor system involving activation of both PAR-1 and PAR-4 in human platelet aggregation. Recent studies have now confirmed that activation of PAR-1/PAR-4 heterodimers act synergistically to activate platelets. In addition to platelets, thrombin also interacts with PAR-1 expressed on other cells of the vasculature such as leukocytes, endothelial cells and smooth muscle cells. In endothelial cells PAR-1 stimulation results in contraction, the activation of von Willebrand factor and up-regulation of cell surface adhesion molecules such as ICAM and VCAM and also tissue factor (TF). Activation of PAR-1 expressed in aorta and coronary endothelial cells mediates relaxation, through the release of nitric oxide (NO) and prostaglandin I₂ (PGI₂), important events in the control of vascular tone. In addition, activation of PAR-1 expressed in vascular endothelial, smooth muscle cells and fibroblasts mediates cellular migration and proliferation through mitogenic pathways, the release of matrix metalloproteinases (MMPs) and subsequent induction of angiogenesis. Thus PAR-1 is intimately involved in the coordination of wound healing responses. Other functions include effects upon the brain, where depending upon the physiological level of thrombin, PAR-1 activation may be both protective against or induce neuronal cell death during trauma.

PAR-2

PAR-2 is strongly expressed in cells of epithelial origin, for example in vascular endothelial cells, airway epithelium, keratinocytes, neutrophils, T cells, synoviocytes and chondrocytes. In blood vessels PAR-2 causes relaxation via NO or PGI₂ release, regulates local tissue perfusion, and mediates inflammatory responses associated with wound healing, for example, expression of adhesion molecules. PAR-2 is also strongly expressed in several layers of the skin and has effects upon keratinocyte differentiation and pigmentation via effects upon melanosome incorporation. PAR-2 has multiple effects upon the intestine stimulating prostaglandin release and chloride ion transport in enterocytes and modulating intestinal motility though differential effects upon ciliary and longitudinal muscle. PAR-2 is also expressed in discrete areas of the brain where it activates Ca²⁺ transiently however, in this system the functional role of PAR-2 remains obscure. Whilst a number of studies have implicated PAR-2 as playing a protective role in the airways, coronary vessels and the heart by mediating vessel relaxation, the majority of evidence strongly implicates PAR-2 in inflammation. PAR-2 mediates neurogenic inflammation via release of CGRP and

substance P, whilst studies utilising PAR-2 knockout mice indicate a role in both acute and chronic joint inflammation. PAR-2 also mediates type IV and allergic dermatitis, whilst in the intestine luminal proteinases severely compromise the integrity of the intestinal barrier through PAR-2 activation, implicating a role for PAR-2 in the pathophysiology of the intestinal inflammatory conditions including Crohn's disease and ulcerative colitis. These findings correlate well with a number of cellular events associated with inflammation: release of PAR-2 mediators such as trypsin by mast cells, upregulation of PAR-2 following inflammatory challenge and coupling of PAR-2 to the release of

cytokines and expression of adhesion molecule via pro-inflammatory signalling pathways such as nuclear factor kappa B (NFκB) and the MAP kinases. However, PAR-2-mediated release of prostaglandins from enterocytes, and gastric mucus secretion which may also protect against intestinal inflammation, again exemplifying a potential dual effect.

PAR-3

The PAR-3 subtype of the PAR family is truncated at the C-terminus limiting its potential to signal intracellularly. Furthermore, other than thrombin, there have been no specific activating peptides developed that

result in PAR-3 activation. As a result, exploration into the functional expression of PAR-3 has been limited to scenarios where physiological levels of thrombin exist. Such studies have identified PAR-3 to act as a cofactor for the thrombin activation of PAR-4 in murine platelets, where this dual receptor system results in platelet aggregation in mice. The cooperative interaction between PAR-3 and PAR-4 occurs through thrombin anchoring to the ▶**hirudin** domain of PAR-3, where it facilitates in the cleavage of PAR-4.

PAR-4

A number of techniques including Northern blotting, PCR (polymerase chain reaction) and functional studies have shown PAR-4 to be expressed in a variety of cell types including platelets, smooth muscle cells, endothelial cells, leukocytes, cardiomyocytes and neurons. As outlined above, PAR-4 is a low affinity thrombin receptor and functions in synergy with PAR-1 to regulate human platelet activation and interacts with PAR-3 in mouse platelet aggregation. PAR-4 is also expressed in smooth muscle cells where it mediates proliferation and thus contributes to wound healing initiated by thrombin via PAR-1. However in some instances PAR-4 acts in opposition to PAR-1. This has been demonstrated the regulation of contractile motility in the oesophagus, where thrombin activation of PAR-1 mediates muscle contraction, whilst PAR-4 activation results in muscle relaxation, with the dominant effect dependent upon the physiological thrombin concentration. Since the characterisation of PAR-4, many of the original studies investigating possible roles for PAR-1 activation have now been revisited for the possible implication of PAR-4 activation. Such roles include vascular inflammation and cerebrovascular damage. PAR-4 activation results in the release of TNF- α , and activation of MAP kinases and the NF κ B pathway in microglial cells, suggesting a possible role for PAR-4 in inflammation in the brain.

Drugs

The PAR family represents a novel target for drug therapy. Therapeutic approaches with most clinical benefit may rely upon the development of both agonists and antagonists, either of which could be utilised depending upon the disease condition [3].

The most promising prospect of PARs as a therapeutic target remains in vascular biology for the treatment of cardiovascular diseases. Numerous studies have confirmed the potential of PAR inhibition in the treatment of disease states. Several PAR-1 antagonists have been developed (Table 1), in particular the non-peptide antagonist SCH-205831 currently in phase II/III clinical trials as a candidate for anti-thrombotic therapy. Other strategies under investigation include targeting the PAR-1/PAR-4 heterodimeric complex in human platelets using

PAR1/4-specific antagonists. This dual inhibition strategy has been demonstrated in animal models utilising a combination of PAR-1 antagonist and palmitoylated peptide pepducins which inhibit PAR-4 signalling, suggesting the potential of combination therapy for the management of thrombosis [4]. In addition to thrombosis, antagonist pepducins directed at PAR-1 have also shown potential in targeting PAR-1 mediated breast cancer tumorigenesis and metastasis, inflammation and sepsis. The potential of antagonising PAR-4 in other conditions where PAR-1 is not co-expressed has not been examined, however such antagonism may be an affective anti-inflammatory therapy for the treatment of neurotrauma.

Studies utilising PAR-2 deficient mice have supported the proposed physiological and pathological roles of PAR-2 in a number of disease states. Although research in this area is in progress, PAR-2 antagonists such as novel small molecule antagonist ENMD-1068, may prove to be of therapeutic value in joint inflammation, when used alone or in combination with other therapies. However, ENMD-1068 is of very low-affinity and until high-affinity compounds are developed, other strategies for example, using humanised PAR-2 blocking antibodies may be more successful. PAR-2 antagonists may also prove beneficial in the suppression the proliferative responses that underlie tumour metastasis.

Given the potential protective effects of PARs in some situations the potential of utilising agonists therapeutically has been considered but not as yet exploited clinically. For example, the PAR-2 activating peptide 2f-SLIGKV-NH₂ has been shown to be cytoprotective in intestine and thus prove to be a worthwhile therapeutic target in the treatment of gastritis or gastric ulcers. PAR agonists may also have a limited role in asthma and in ischemic damage [5].

From these studies it is clear that the progression of PAR-based therapy relies upon the future development of new specific agonists and antagonists for PARs 2–4 with much higher potencies than those currently available, with an efficient mode of delivery to target sites. However despite these problems the PARs still represent one of the most attractive therapeutic targets for a number of disease states.

Definition

The 14-3-3s are a family of ~30 kDa proteins that exist as homo- and heterodimers within all eukaryotic cells. 14-3-3 proteins bind target proteins containing phosphothreonine or phosphoserine motifs, however exceptions do exist. The docking of 14-3-3s to their target can: (i) cause conformational changes in the target protein, (ii) block sequence-specific or structural features on the target protein, or (iii) function as a scaffold allowing other proteins to dock.

Basic Mechanisms

Recognizing Covalent Modifications

Evolution has provided the cell with a repertoire of 20 amino acids to build proteins. The diversity of amino acid side chain properties is enormous, yet many additional functional groups have been selectively chosen to be covalently attached to side chains and this further increases the unique properties of proteins. These additional groups play a regulatory role allowing the cell to respond to changing cellular conditions and events. Known covalent modifications of proteins now include phosphorylation, methylation, acetylation, ubiquitylation, hydroxylation, uridylation and glycosylation, among many others. Intense study in this field has shown the addition of a phosphate moiety to a protein

can result in several potential effects including control of enzymatic activity, the shuttling of proteins between cellular compartments and regulation of proteolytic degradation. More recently the study of signal transduction events has provided a new understanding of the regulation of cellular activities by protein: protein interaction and many of the covalent modifications mentioned above perform their function by providing specific docking sites for other proteins. Again, the field to protein phosphorylation was a forerunner in recognizing and characterizing this property of covalent modifications and the 14-3-3 proteins were the first protein shown to specifically bind a phosphoserine or -threonine motif. Thus, the generation of specific docking sites for other proteins is an additional, regulatory function for protein phosphorylation. Other ▶ **phospho-specific binding modules** that can be recognized by amino acid sequence within proteins include leucine rich repeats (LRR), forkhead-associated (FHA), WW, FF, tetratricopeptide repeat (TPR), MH2, WD40, polobox and BRCA1 carboxyl-terminal (BRCT) domains for serine and threonine phosphorylation and Src homology two (SH2) and protein tyrosine binding (PTB) domains for phosphotyrosine. It is likely that additional phospho-specific binding modules exist.

The 14-3-3 proteins were initially catalogued as abundant brain proteins and designated 14-3-3 based on their chromatography column elution fraction and position after starch gel electrophoresis [1]. Defining the role for these proteins began many years later when they were identified initially as activators of tryptophan and tyrosine hydroxylases, and then as regulators of protein kinase C and the protein kinase Raf-1, and as a direct binding protein for the polyoma virus middle T-antigen. This was followed by the key observation that binding of 14-3-3 to its target protein was dependent on the phosphorylation of the target protein. Since this discovery, 14-3-3s have continuously surfaced as regulators of a multitude of phosphorylation dependent cellular events [1–4].

14-3-3 Sequence Conservation, Structure and Function

Cloning and genome sequencing has shown there to be multiple 14-3-3 genes in all eukaryotic organisms with 12 in *Arabidopsis*, 7 in mammals and 2 in *Saccharomyces cerevisiae*, *C. elegans* and *D. melanogaster*. No 14-3-3 or 14-3-3-like genes have been noted any archaeal or bacterial genomes. The *S. cerevisiae* 14-3-3 isoforms are encoded by *BMH1* and *BMH2* and deletion of either does not cause growth defects, but the double deletion of both is lethal. The 14-3-3s are highly conserved across species Fig. 1(a) with divergence occurring on the N- and C-termini. The 14-3-3s have acidic pI values, are small in size (~28–32 kDa) and form homo- and heterodimers. Crystal structures have been elucidated for the unliganded form, and in complex with a high affinity phosphopeptide

from a known target protein. Dimers form a cup shape with the most highly conserved amino acids lining the inside of the cup Fig. 1(b). It is this conserved inner surface that functions as docking site for the phosphoprotein(s). Each subunit has the ability to bind a phosphopeptide and as shown in Fig. 1(c), phosphopeptides dock in an extended anti-parallel orientation. Residues equivalent to Lys⁴⁹, Arg⁵⁶, Arg¹²⁷ and Tyr¹²⁸ of human 14-3-3ζ are completely conserved in every 14-3-3 known and it is these residues that are responsible for direct interaction with the phosphate moiety of the bound phosphoprotein (Fig. 1c, d). It is interesting to note that crystallization of the nonsense mediated decay regulatory protein, ▶SMG7 (suppressor with morphogenetic effects on genitalia 7), revealed structural resemblance of one its ▶TPR domains to one monomer of a 14-3-3 protein even with very limited (<10%) sequence homology. Additional work showed that this region, like 14-3-3 binds peptides in a phosphorylation dependent manner.

When 14-3-3s were first identified as phosphorylation dependent binding proteins (note that a selection of non-phosphorylated targets are known), target protein phosphorylation sites were mapped and it was immediately apparent that 14-3-3s bound preferentially to specific phosphorylation motifs. The advent of oriented

peptide libraries and their application to 14-3-3 binding specificity confirmed this first motif (RSXpSXP; where R is arginine, X is any amino acid, S is serine, pS is phosphoserine and P is proline) that is now described as mode I binding. The peptide library method also pulled out another high affinity binding motif now designated mode II (RXXXpSXP).

In addition to these initially characterized 14-3-3 binding motifs, other studies identified 14-3-3 binding to the C-termini of proteins and this mode or mode III is now recognized as a significant target for 14-3-3s. This motif was first identified in the plant plasma membrane H⁺-ATPase, where the C-terminal sequence QSYpTV-COOH was found to bind 14-3-3 resulting in relief of inhibition of the enzyme by the C-terminus. Binding and relief of inhibition is dependent upon phosphorylation of the second to last residue; in this case a phosphothreonine. In a genetic screen of random peptides aimed to identify C-terminal signal motifs that override endoplasmic reticulum (ER) retention of proteins destined for the cell plasma membrane, a group of C-terminal peptides that function through an interaction with 14-3-3 were identified and this is much like the sequence of the H⁺-ATPase where the C-terminal sequence. The genetic screen suggested preference for a

hydrophobic amino acid at the C-terminus and a serine or threonine at -2 from the C-terminus. Further work has defined this binding motif as SWpTX_{Pro}-COOH (where pT is phosphothreonine, X is any amino acid except proline and COOH is the carboxyl-terminus of the protein). Interestingly, a number of plasma membrane receptor proteins carry this motif.

Another novel 14-3-3 binding motif was recently uncovered during studies on histones and should be designated Mode IV [5]. Histones are among the most conserved proteins known with covalent modification of their tails, which includes lysine acetylation and methylation, arginine methylation and serine phosphorylation, being responsible for altering access to DNA by charge neutralization and for generating high affinity binding sites for other proteins. Acetylated lysine and methylated lysine residues are known to dock bromo and chromodomains, respectively. Histone H3 is phosphorylated at Ser-10 and 28, which are both preceded by the sequence for Ala-Arg-Lys (ARK). The precise function of this modification was unknown until the N-terminal 20 amino acids were synthesized as unmodified, acetylated (Lys-9 and 14), and acetylated plus Ser-10 phosphorylated peptides and were used for affinity chromatography with HeLa cell nuclear extracts. The only proteins found to bind specifically to the phosphorylated and acetylated (and not acetylated only) versions were 14-3-3 proteins ϵ , ζ and γ . The crystal structure of 14-3-3 ζ complexed with the acetylated and phosphorylated peptide (AR_{Ac}-KpSTGG_{Ac}K, where _{Ac}K is acetylated lysine and pS is phosphoserine) revealed that the basic residues lining the binding pocket as shown in previous structures bind the phosphate moiety. Mode I and II binding motifs have a proline at $+2$ that allows the bound peptide or protein to change direction and exit the binding cleft. Here positions $+2$ and $+3$ have glycine residues that perform the same function. Interestingly, peptides with a glycine at the $+2$ position were identified as 14-3-3 binding in the original oriented peptide binding studies. The acetyl group at lysine 9 is folded back and hydrogen bonded to the backbone amide. The exit from the cleft after the two glycines means that acetyl-lysine 14 is not in the binding cleft. Although making no contacts with 14-3-3, acetyl-lysine 14 is thought not to be accessible in any way to proteins that bind acetyl-lysine motifs, through motifs such as bromodomains. This structural study nicely demonstrates how 14-3-3 binding can mask another structural feature altering a property of the protein (see below for 14-3-3 roles).

Modes of Action

Early work on 14-3-3 proteins placed researchers in a peculiar position of trying to define the precise function of 14-3-3s. This came from the large number of, and apparently diverse type of targets proteins. Continued work has brought more and more insights and it is

fairly well accepted that 14-3-3s play potentially three functions when bound to a target. They are: (i) 14-3-3 directed conformational changes, (ii) 14-3-3 blockage of sequence-specific or structural features, and (iii) scaffolding.

14-3-3 directed conformational changes. The 14-3-3 proteins are primarily α -helical and are thus described as rigid in nature. The 14-3-3 structure in the presence of phosphopeptides or the target enzyme **▶serotonin-N-acetyltransferase** support this notion as no change in 14-3-3 shape is observed in the co-crystals. This has led to the molecular anvil or clamping hypothesis for 14-3-3 function whereby the sturdy 14-3-3, upon binding certain targets, cause them to be re-shaped and thus altering their function. This is best described for the enzyme serotonin-N-acetyltransferase. Serotonin-N-acetyltransferase is normally catalytically inefficient and after phosphorylation and 14-3-3 binding displays increased V_{max} and increased substrate affinity. The binding of 14-3-3 causes a local alteration in enzyme, re-shaping the active site. This concept can also be extended to long distance re-shaping of proteins as well where it is thought that 14-3-3 binding can expose or hide protein features or motifs distant from the site binding. For instance, data now support the idea that 14-3-3 binding to several nuclear histone deacetylases (HDACs) causes exposure of a nuclear export sequence (NES) and shuttling from the nucleus.

14-3-3 blockage of sequence-specific or structural features. The physical association of 14-3-3 with a target can also mask or occlude sequence-specific motif or structural features. Examples include the masking of nuclear localization or export sequences and as introduced above, it has been well characterized that the C-terminus of the plant plasma membrane H⁺-ATPase inhibits the activity of the enzyme. After phosphorylation on a mode III motif, 14-3-3 binding removes the tail of the enzyme and the ATPase is activated. Another example of 14-3-3 function by sequence masking has been noted for several proteins synthesized in the endoplasmic reticulum (ER) and destined for the plasma membrane. Many proteins synthesized in the ER are retained there by a diarginine motif that is “recognized” by the coat protein complex I (COPI) retention machinery. Using an affinity-binding method, 14-3-3s were identified as interacting proteins for the dibasic motif of the C-terminus of the potassium channel α subunit, Kir6.2. 14-3-3 Proteins do not recognize the monomeric form of the Kir6.2 tail, but do bind the multimeric Kir6.2 complex, and compete for binding to the dibasic region with the COPI machinery. This suggests that bound 14-3-3 masks the COPI interaction site and thus causes release of Kir6.2 from the ER.

Scaffolding. Because 14-3-3s can bind potentially bind more than one phosphoprotein at once due the presence of two phosphopeptide-binding sites in a

dimer, it has been postulated that they play this role in vivo. Direct observation of this phenomenon is difficult to show, but data from several groups support this idea.

Binding Specificity Among 14-3-3 Isoforms

It is not clear why some organisms have two 14-3-3 isoforms while others have up to 12. Binding 14-3-3 inhibits the plant enzyme nitrate reductase and there appears to be no selectivity between plant 14-3-3 isoforms; in fact yeast and human isoforms appear to work equally as well in vitro. The best example where selectivity has been demonstrated is human ▶14-3-3 σ . 14-3-3 σ Preferential homodimerizes with itself and crystallization revealed a structural basis for this isoform's dimerization properties as well as for its specific selectivity for target binding proteins. Here partner specificity is the result of amino acid differences outside of the phosphopeptide-binding cleft.

14-3-3 Interactome

With more than 350 proteins identified in global 14-3-3 interaction studies the most astounding thing to emerge is the vast repertoire of cellular processes that 14-3-3 plays a role in [2]. Several early studies purified 14-3-3 as an effector molecule that regulated some assayable property of a protein, or 14-3-3 was simply found as a co-purifying protein with some specific target. One of the best-characterized examples is the purification of 14-3-3 as inhibitor of plant nitrate reductase. In the first global study to find new 14-3-3 interactors yeast 14-3-3s (BMH1 and 2) were coupled to a matrix and a plant extract passed over this affinity column to allow proteins to bind. These were affinity eluted with mode I phosphopeptide and released proteins identified. This work found mostly higher abundance metabolic enzymes as the primary targets. More recent studies have employed a similar approach or used specific human 14-3-3-isoforms. Identified targets include proteins involved many metabolic pathways, protein trafficking, signal transduction and transcriptional regulation. Undoubtedly, many more 14-3-3 targets exist and the roles they play in regulating biological function will be uncovered in years to come.

Pharmacological Intervention

The 14-3-3s are abundant eukaryotic proteins that have emerged as key regulators of a vast number of cellular functions. As the list of 14-3-3 interacting proteins grows links with human disease are becoming clearer. Structural studies have defined the interaction surfaces of 14-3-3s with several targets and have now placed them as future potential drug targets. The disruption of protein: protein interactions are now being recognized as a feasible target for pharmacological intervention with several excellent examples demonstrating the feasibility of this approach.

Definition

The proteome has been defined as the entire protein complement expressed by a genome. Thus the field of proteomics involves the extensive study of the dynamic protein products of the genome and includes

the identification, characterization and quantitation of proteins and their interactions.

Description

Genome and Proteome: The term proteome was introduced in 1995 [1], and has spread world wide within just a few years. Proteome is the linguistic equivalent of the term genome and describes the whole complement of proteins expressed by a cell at any given time. In contrast to the genome, the proteome is dynamic and very complex (Fig. 1). The expression of a gene has no definitive relationship to the expression or abundance of its protein product. In addition, ►**post-translational modifications** (PTM), such as processing, phosphorylation and glycosylation as well as other modifications cannot be deduced from genomic data. Post-translational protein modifications (PTMs) are important for structure, localization, function, and turnover of proteins, and have been shown to be involved in disease states. Proteomics involves extensive protein analysis and is intimately involved with protein chemistry. In the early work, proteomics was associated with the cataloging of a large number of proteins separated by two-dimensional gel electrophoresis. Now that the human genome and the genomes of several species have been determined, proteomics is expected to contribute to the understanding of gene function. The field of proteomics is currently in a rapid state of development [2]. The main areas of research include: (i) identification of proteins, (ii) determination of details of the primary structure characterization and PTM, (iii) studies of protein interactions and complex formation, and (iv) differential display effects for the comparison of protein expression. Functional proteomics is defined as the use of the methods of proteomics to analyze the molecular networks in cells, for example the identification of specific proteins of these networks following functional stimulation. Large-scale data sets provided by proteomics are needed for the growing field of systems biology research.

The Tools of Proteomics: A variety of methods and techniques including ►**two-dimensional gel electrophoresis** (2DE), capillary liquid chromatography, stable isotope labeling, and mass spectrometry has been developed for qualitative and quantitative protein

analysis. One of the most challenging steps in proteome research is the separation, visualization, and quantification of proteins. Current methodology suffers from the lack of an amplifying method analogous to the polymerase chain reaction. If a given cell at a given time expresses 5,000 genes, approximately 15,000 cellular proteins can be expected as a result of mRNA splicing and PTM. In addition, the broad dynamic range of protein expression (10^8 and higher) and the physico-chemical diversity of proteins makes the visualization of an entire proteome an unresolved problem. Unfortunately, there is no universal separation method, although 2DE is commonly used for the quantitative analysis of the state of expression of large numbers of proteins in a cell. Proteins are separated electrophoretically in the first dimension according to their isoelectric point (isoelectrofocusing, IEF) and in the second dimension according to their mobility in the porous polyacrylamide gel (SDS-PAGE). A standard 2DE of 150 μ g of cell lysate allows the resolution of more than 2,000 proteins on the basis of charge and mass. Sample prefractionation techniques prior to 2DE aim to reduce the complexity of protein mixtures found in cells or tissues and may enhance sensitivity for the more interesting low-abundance proteins by removing the house-keeping proteins that are present at higher concentrations. Sensitive staining methods that do not covalently modify proteins are available for the detection of gel-separated proteins. In particular, fluorescent staining methods that offer a broader dynamic range of detection than silver staining, and computer image analysis methods enable quantification of proteins at least over the range of a few orders of magnitude and allow comparative proteome mapping. The weakness of 2DE is that it does not work well with very large, very small, or hydrophobic proteins (especially membrane-bound and cytoskeletal proteins), and those exhibiting extreme isoelectric points. An alternative approach is to use affinity-based protein purification combined with one-dimensional SDS gel electrophoresis, a technique that is able to visualize even extremely hydrophobic as well as acidic and basic proteins.

Nongel separation techniques such as multidimensional capillary chromatography in combination with

Proteomics. Figure 1 Genome versus proteome.

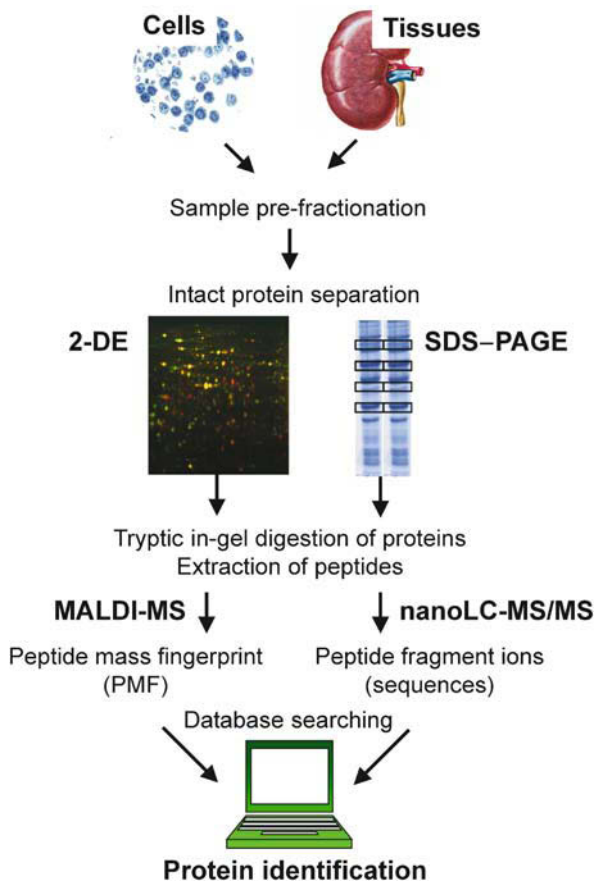

stable isotope labeling methods circumvent the disadvantages of 2DE. Using stable isotope labeling relative quantitation can be achieved by comparing peptide ion intensities which differ only by their isotopic composition. Stable isotope labeling of proteins and peptides can be performed metabolically, chemically, or enzymatically [3]. In the SILAC method (stable-isotope labeling of amino acids in cell culture), two sets of cells are grown independently with one set having ^{13}C -labeled amino acids substituted into the culture media. ICAT (isotope-coded affinity tag) and iTRAQ (isobaric tags for relative and absolute quantitation) are the widely used chemical labeling techniques. The trypsin-catalyzed digestion of proteins in the presence of H_2^{18}O can be used for incorporation of two ^{18}O atoms into the C-terminal carboxyl groups of peptides and does not require chemical derivatization steps. Stable-isotope labeling methods enable quantitative cataloging and comparison of protein expression by mass spectrometry and are therefore useful a wide range of differential proteomics applications. Further advances in proteomics can be expected from the miniaturization of separation techniques (microfluidic chip-based LC) that lead to increased sample concentration, reduced loss of analyte and improved compatibility with mass spectrometry.

The study of proteomes also requires efficient methods for the identification and characterization of separated proteins. Recent advances in mass spectrometric instrumentation and techniques have revolutionized protein analysis; see [4] for review. The development of so-called “soft” ionization methods such as ►electrospray ionization (ESI) and ►matrix-assisted laser desorption/ionization (MALDI) have enabled the generation of gas-phase ions of peptides and proteins without significant fragmentation. Various mass analyzers such as the time-of-flight (TOF), quadrupole, ion trap, linear ion trap, orbitrap, and ion cyclotron resonance (ICR) systems as well as various combinations thereof can be used. MALDI-TOF remains a robust and reliable mass spectrometry (MS) technique for accurate and sensitive mass measurements of peptides as well as high molecular weight proteins. Advanced TOF design and mass analyzer such as ICR and orbitrap have improved the resolution and sensitivity of MS. Triple quadrupole, ion trap, linear ion trap or in particular, hybrid mass analyzers such as quadrupole-TOF, linear ion trap-ICR, and linear ion trap-orbitrap systems have been applied to ►tandem mass spectrometry in which peptide ions are selectively separated in the first step and then fragmented by collision-induced dissociation (CID) and analyzed in the second step in the mass spectrometer. These types of mass spectrometers typically use ESI. MALDI-MS including fragmentation of high-energy ions by TOF-TOF techniques also yield informative fragment ion spectra of peptides. CID spectra obtained by these methods mainly show

sequence-specific N-terminal “b” and C-terminal “y” ions. Such fragmentation by MS gives at least partial information about the peptide sequence and can be used to identify proteins from databases of expressed sequence tags. Very recently new fragmentation techniques have been developed. Implemented on ICR and linear ion trap instruments electron capture dissociation (ECD) and electron transfer dissociation (ETD) will enable a more reliable MS analysis of PTM and intact proteins. In contrast to Edman sequencing, which fails in the analysis of subpicomole quantities or of N-terminally blocked proteins, MS provides accurate mass measurements at a very high level of sensitivity even of protein mixtures. For protein identification the sensitivity limit is in the low femtomole range. Suitable sample volumes are in the range from 500 nL to 1 μL . Although MS is now the method of choice for protein analysis, there is a need for instrumentation that allows greater sensitivity, reliability, and speed. Thus sample preparation methods, the ionization process, mass analyzers, and data processing are fields of rapid development.

Besides sensitive methods for the analysis of proteins, bioinformatics is one of the key components of proteome research. This includes software to monitor and quantify the separation of complex samples, e.g., to analyze 2DE images. Web-based database search engines are available to compare experimentally measured peptide masses or sequence ions of protein digests with theoretical values of peptides derived from protein sequences. Websites for database searching with mass spectrometric data may be found at ►<http://www.expasy.ch/tools>, ►<http://prospector.ucsf.edu/> and ►<http://www.matrixscience.com>.

Identification of proteins, PTM and protein–protein Interactions: Currently, two different methodologies are used for the mass spectrometric analysis of proteins. In the “top-down” approach, the molecular mass as well as backbone fragment ions of intact proteins are measured by high performance MS (ESI-FTICR-MS). Although it has been shown that highly informative fragmentation for proteins with molecular masses greater than 50 kDa could be obtained, the broad applicability of this approach for protein identification and characterization of PTM has yet to be proven. In the “bottom-up” approach, separated proteins or protein mixtures are digested with an enzyme, and the resulting peptides are analyzed by MS and MS/MS methods (Fig. 2). Trypsin is the most commonly used enzyme for digestion since it is inexpensive and the cleavage rules are well known (peptide bonds after lysine and arginine are cleaved selectively). In case of gel-separated proteins, digestion can be performed directly in gel, followed by elution of the peptide mixture. The enzyme normally generates peptides between 600 and 2000 Da, a mass range suitable for sensitive and accurate MS. Once digested, the peptide mixtures can either be

Proteomics. Figure 2 A strategy for mass spectrometry (MS)-based identification of proteins.

directly analyzed by MALDI-MS or can be separated by capillary reversed-phase liquid chromatography coupled to tandem MS instruments such as quadrupole-TOF, TOF-TOF, ion trap, FTICR, or orbitrap. From the mass spectra a set of experimentally obtained peptide masses, the ►peptide mass fingerprint (PMF), can be extracted and used for database searches. Depending on protein molecular weight, the detection of even a small number of peptides (20–30% sequence coverage) provides sufficient data for reliable identification. Peptide mass mapping using MALDI-MS works satisfactorily, if a complete genomic sequence database is available. The method can be automated and makes possible the identification of hundreds of 2DE-separated proteins. In case peptide mass mapping is unsuccessful, tandem MS has to be used. The method utilizes the fragmentation of individual peptides of the protein digest by CID in a collision cell of the mass spectrometer (see above). Protein identification using this approach is particularly useful for proteins from species with incompletely sequenced genomes. MS/MS spectra may yield an amino acid sequence or at least a partial sequence that is specific

for a protein and can be used to search protein sequence databases or nucleotide databases (EST).

More than 200 different naturally occurring PTMs have been described. Most of these modifications are accessible to analysis via MS. Despite numerous reports of MS analysis of phosphorylation and glycosylation, the detection of such modifications in mass fingerprints still presents a serious challenge. Because the modification is frequently labile, MS has to be performed under very mild conditions in terms of sample preparation and ionization. Furthermore, the identification of PTMs requires determination of the specific peptide that contains the modified amino acid. In principle, procedures used for protein identification are also applicable to the determination of PTMs. A mass difference compared to the expected mass after enzymatic degradation of the protein by specific endoproteases (peptide mass mapping) can be used as a sign for the presence of modified peptides, even though this indication is not very specific. Selection and preconcentration of modified sequences by immunoprecipitation or binding to a chelating column are techniques that have been described for phosphopeptides. To determine the site of modification, i.e., the modified amino acid side chain, fragmentation by CID, ECD, or ETD (see above) must be performed.

Because it is well accepted that cellular processes are controlled by multiprotein complexes and such complexes are actual molecular targets of drugs, a further key aim of proteomics is to study protein–protein interactions. The characterization of complexes in which several proteins are associated to perform their biological function can be achieved by purification of the entire protein complex using affinity-based methods, such as glutathione S-transferase (GST)-fusion proteins. The tandem-affinity-purification-tag (TAP-tag) techniques use two high-affinity binding sequences separated by a highly specific cleavage site for a protease to capture and purify a protein complex. After separation by gel electrophoresis proteins are identified by capillary LC-tandem MS. As an example, more than two hundred distinct multiprotein complexes of the yeast proteome [5] as well as several new factors of the human spliceosome were obtained by these techniques and analyzed further.

Pharmacological Relevance

The identification and quantitation of large numbers of proteins by proteomics approaches directly contributes to the validation of diagnostic and prognostic disease biomarkers and to the identification of novel drug targets. Extensive protein identifications has been performed in the framework of numerous proteome projects to study human pathogens (e.g., comparative proteome analysis of *Helicobacter pylori*), to identify disease-associated proteins (e.g., cancer or heart proteomics), and to analyze proteins involved in signal transduction cascades. Although the main goal of

proteomics is the mapping of proteins of cells or tissues, there are further tasks beyond the identification of proteins. PTM of proteins are important for biological processes, particularly in cellular signal transduction. The processing generates functional proteins, lipid modifications determine the location of proteins, and the attachment of phosphate can activate or inactivate reaction cascades. Because of its regulatory importance, protein phosphorylation has received the most attention. Several receptor-mediated signal transduction pathways result in tyrosine phosphorylation of various proteins. A functional proteomics approach that focuses on the isolation, separation, and identification of phosphorylated proteins following stimulation of wild-type and/or modified receptors provides insights into the quality and quantity of signaling proteins. Examples include EGF and PDGF receptor signaling, which involve activation or inactivation by endogenous or exogenous factors and interactions between different signal pathways. Postgenomic proteomics also includes areas such as the determination of protein function, structural analysis, analysis of metabolic pathways, drug mode-of-action and toxicity studies

Proteosomal Degradation

Proteosomal degradation is the process by which improperly folded proteins or proteins with altered post-translational modifications are removed from a cell before they have a detrimental effect on cellular function. This is performed in small organelles known as proteosomes. Proteins are targeted for destruction in the proteosome by having a number of small ubiquitin molecules added.

Proton Pump Inhibitors and Acid Pump Antagonists

JAI MOO SHIN, GEORGE SACHS
David Geffen School of Medicine, University of California at Los Angeles and Veterans Administration Greater Los Angeles Healthcare System, Los Angeles, CA, USA

Synonyms

Gastric H,K-ATPase inhibitors; Potassium competitive acid blockers

Definition

The proton pump is the ► **gastric H,K-ATPase**, which secretes hydronium ions, H_3O^+ , in exchange for K^+ into the secretory canaliculus generating a pH of <1.0 in

lumen of the stomach. Pump-targeted inhibitors of acid secretion can be classified into two groups: covalent inhibitors (proton pump inhibitors, PPIs) and reversible inhibitors (acid pump antagonists, APAs or potassium competitive acid blockers, PCABs). The covalent binding inhibitors are prodrugs, activated by acid catalysis. Their structures are substituted 2-pyridine-methylsulfanyl benzimidazoles. The reversible inhibitors are K^+ -competitive.

Mechanism of Action

The gastric H,K-ATPase consists of a α -subunit of about 1,034 amino acids and a β -subunit having about 290 amino acids. The gastric H,K-ATPase is a membrane protein having ten transmembrane segments in the α -subunit and one transmembrane segment in the β -subunit. The gastric H,K-ATPase transports H_3O^+ ion from cytoplasm to lumen and then reabsorbs K^+ from the lumen due to conformational changes induced by phosphorylation and dephosphorylation of the large α -subunit. In the first step, the E_1 form of the H,K-ATPase binds hydronium ion and MgATP with the ion site facing the cytoplasm. The enzyme is then phosphorylated to form $E_1P \cdot H_3O^+$ and the conformation changes from $E_1P \cdot H_3O^+$ to $E_2P \cdot H_3O^+$ form, where the ion site faces exoplasmically. H_3O^+ is released and K^+ binds on the extracytoplasmic surface of the enzyme, resulting in the $E_2P \cdot K^+$ conformation. This conformation dephosphorylates forming $E_2 \cdot K^+$ with the cation occluded within the membrane domain and then this conformation converts to E_1K^+ that releases K^+ to the cytoplasmic side with binding of MgATP. The H,K-ATPase has a very similar structural motif when

compared with other P_2 -type ATPases such as the Na, K- and \triangleright Ca-ATPases.

Since a substituted benzimidazole was first reported to inhibit the H,K-ATPase by covalent binding [1], many PPIs have been synthesized and are in clinical use. These all have a similar core structure, 2-pyridylmethylsulfanyl benzimidazole moiety except tenatoprazole. Tenatoprazole has 2-pyridylmethylsulfanyl pyridoimidazole moiety.

It was known that the K^+ -competitive imidazopyridine compound, SCH28080, inhibits acid secretion. Then, many reversible inhibitors were developed. These contain protonatable nitrogens but have a variety of core structures such as imidazopyridines, piperidinopyridines, substituted 4-phenylaminoquinolines, pyrrolo [3,2-c]quinolines, guanidinothiazoles, and 2,4-diaminopyrimidine derivatives. Several reversible inhibitors have been in clinical trials.

Proton Pump Inhibitors

The first compound of this class with inhibitory activity on the enzyme and on acid secretion was the 2-(pyridylmethyl)sulfanylbenzimidazole, timoprazole, and the first pump inhibitor used clinically was omeprazole, 2-[[[3,5-dimethyl-4-methoxy-pyridin-2-yl]methylsulfanyl]-5-methoxy-1H-benzimidazole. Omeprazole is an acid-activated prodrug. Omeprazole and the other PPIs are accumulated in the acidic space of the parietal cell due to the pK_a of the pyridine nitrogen and these are converted due to protonation of the benzimidazole nitrogen first to a thiol-reactive cationic sulfenic acid and then dehydrated to form the sulfenamide (Fig. 1). These thiophilic cations then bind to lumenally

Proton Pump Inhibitors and Acid Pump Antagonists. Figure 1 Irreversible proton pump inhibitors (PPIs).

domain are important for inhibition of acid secretion by the PPIs [3]. This covalent mechanism extends their duration of action to far beyond their presence in the blood. Also, since active pumps are required and not all pumps can be activated at once, their effect is cumulative, reaching steady state after about 3 days on once a day dosing. The steady state reflects the balance between inhibition of active pumps and restoration by activation of silent pumps after the drug has left the circulation, by de novo synthesis of the pump with a half-life of ~ 54 h and by partial reversal of the enzyme-S-S-inhibitor complex by endogenous glutathione [4].

Acid Pump Antagonists or Potassium Competitive Acid Pump Blockers

SCH28080, a substituted imidazo[1,2a] pyridine, is the best defined among other reversible PPIs. SCH 28080, 3-cyanomethyl-2-methyl-8-(phenylmethoxy) imidazo [1,2a]pyridine, inhibited the H,K-ATPase competitively with K^+ . SCH 28080 binds to free enzyme extracytoplasmically in the absence of substrate to form $E_2(\text{SCH 28080})$ complexes. SCH 28080 inhibits ATPase activity with high affinity in the absence of K^+ by binding to the E_2P form. SCH 28080 has no effect on spontaneous dephosphorylation but inhibits K^+ -stimulated dephosphorylation, presumably by forming a $E_2\text{-P}\cdot[\text{I}]$ complex. Hence SCH 28080 inhibits K^+ -stimulated ATPase activity by competing with K^+ for binding to E_2P . Steady state phosphorylation is also reduced by SCH 28080, showing that this compound

also binds to the free enzyme. The important difference between this class of inhibitor and the PPIs is that that this type does not require acid activation and inhibits the pump by blocking it in mid-cycle (Fig. 3). Hence it is expected that inhibition of acid secretion will be more rapid and more complete. However, the inhibition will last only as long as the drug is present in the blood and therefore will be of shorter duration unless a long dwell time compound is developed or timed release formulation introduced. Soraprazan, one imidazopyridine compound, is under clinical trial and revaprazan, one of 2,4-diaminopyrimidine derivative, is now clinically used in Korea.

Clinical Use

PPIs are used for the therapy of gastric ulcer, duodenal ulcer, **gastroesophageal reflux disease**, **Zollinger-Ellison syndrome** and for eradication of *Helicobacter pylori* in combination with two antibiotics. The primary effect of these PPIs is gastric acid suppression. The degree of acid suppression correlates with healing rates for reflux oesophagitis and peptic ulcer. Omeprazole, lansoprazole, pantoprazole, and rabeprazole show generally equivalent potency of gastric acid suppression. S-omeprazole has become available for clinical use. Omeprazole is a racemate consisting of S- and R-enantiomers. The R-form of omeprazole is sensitive to CYPs 2C19 and 3A4 enzymes, while S-form is less sensitive to these **CYP enzymes** [5]. S-omeprazole has longer plasma half-life compared to omeprazole, providing longer duration of acid suppression when

given at 40 mg compared to 20 mg of the racemate. Tenatoprazole also has longer plasma half-life, providing longer inhibitory activity.

PPIs are used in triple therapy for eradication of ►*Helicobacter pylori*. Their effect may be due to acid inhibition that results in a greater proportion of the infecting organisms being moved into growth rather than stationary phase. The usual antibiotics used in triple therapy, clarithromycin and amoxicillin (targeting protein or cell wall biosynthesis), require growth phase for efficacy and are not effective against bacteria in stationary phase.

Proton-sensing GPCRs

KLAUS SEUWEN, MARIE-GABRIELLE LUDWIG
Novartis Institutes for Biomedical Research,
Switzerland

Synonyms

GPR4; Ovarian cancer G protein-coupled receptor 1 (OGR1, GPR68); T cell death-associated gene 8 (TDAG8, GPR65)

Definition

GPR4, OGR1, and TDAG8 are GPCRs regulated by extracellular pH in the physiological range. These receptors are silent at pH 7.8, and fully activated at pH 6.8.

Basic Characteristics

The receptors GPR4, OGR1, and TDAG8 form a subfamily of GPCRs distantly related to purinergic and

angiotensin receptors. They had first been described as receptors for bioactive lipids, however, the publications regarding activation of GPR4 and OGR1 by ►sphingophosphorylcholine (SPC) and ►lysophosphatidylcholine (LPC) have been withdrawn. Activation of TDAG8 by galactosylsphingosine (psychosine) (potential signaling lipid accumulating in krabbe disease. No receptors known.) could not be reproduced in our hands and by other laboratories. Instead, work in our laboratory and by other research groups has established that GPR4, OGR1, and TDAG8 are activated by neutral to slightly acidic extracellular pH [1, 2], suggesting that protons are the activating ligands. Recent developments in this field are summarized in [3]. See Table 1 for overview.

A fourth molecule, the receptor G2A (GPR132), is also related to this group. However, recent data suggest that G2A is a receptor for oxidized free fatty acids. Activation by acidic pH could not be confirmed.

GPR4 and TDAG8 are Gs-coupled GPCRs, they stimulate cAMP formation inside cells. OGR1 is Gq-coupled, leading to activation of phosphoinositide turnover and release of calcium from intracellular stores [1, 2]. The response of these receptors to extracellular pH in recombinant cell systems is shown in Fig. 1. OGR1 appears slightly more sensitive to extracellular protons than GPR4 and TDAG8. In the experimental setup used, halfmaximal activation of receptors was observed at pH 7.45 ± 0.04 for OGR1 (*n* = 14), pH 7.18 ± 0.02 for GPR4 (*n* = 3), and pH 7.15 ± 0.02 for TDAG8 (*n* = 6). As described in [1], the pH values refer to buffers adjusted at room temperature. To obtain pH at 37°C, ca. 0.15 pH units should be subtracted.

To date, we could not identify other GPCRs showing a similar pH-dependent response. Without exception, all receptors studied so far in our hands show a rather stable signal output over the extracellular pH range of 6.5–7.8 following activation by their cognate ligand. However, the existence of other pH-sensing GPCRs is not excluded.

In the light of the earlier studies implying GPR4 and OGR1 as lipid receptors, it was proposed that lipids might act as inhibitory ligands on these receptors. However, as described in detail in [3], our data do not support the notion of a specific modulation of OGR1, GPR4, or TDAG8 by the lipid messengers SPC, LPC, or psychosine.

Structure-Function

OGR1 and GPR4 exhibit a cluster of histidines exposed to the extracellular space, and these amino acids are conserved across mammalian species. Site-directed mutagenesis experiments confirmed the importance of five histidine residues for normal pH sensing of the receptor OGR1 [1]. No detailed studies are yet available for GPR4 and TDAG8. In the latter receptor, three of the histidine residues shown to be relevant in OGR1

Proton-sensing GPCRs. Table 1 pH-sensing receptors

Name	Chromosomal location	Signal transduction	Comment
GPR4	19q13.2–q13.3	cAMP ↑ (G _s)	pH sensor of endothelial cells
OGR1 (GPR68)	14q31	cAMP ↑ (G _s)	pH sensor of osteoblasts, osteoclasts, smooth muscle cells
TDAG8 (GPR65)	14q31–q32.1	IP ₃ /Ca ²⁺ (G _{q/11})	pH sensor of thymocytes

Proton-sensing GPCRs. Figure 1 pH-dependent activation of recombinant receptors expressed in host cells. GPR4 was stably expressed in HeLa cells, OGR1 and TDAG8 in CCL39 hamster fibroblasts. For OGR1, formation of inositol phosphates was measured, for GPR4 and TDAG8, cAMP formation was determined. Data were normalized to maximal stimulation (100%). Untransfected host cells show no pH-dependent activation of second messenger formation. Experimental details are as described in [1].

are replaced by basic amino acids. It is possible that these Arg and Lys residues, in the context of other surrounding amino acids in TDAG8, can function in pH sensing.

Potential Physiological Roles of pH-Sensing Receptors

The pH-sensing properties of GPR4, OGR1, and TDAG8 were discovered relatively recent and only limited information is as yet available regarding the physiological function of these receptors. A role in pH homeostasis is likely. Surprisingly little is known today about the molecular mechanisms governing pH homeostasis of higher organisms. Overall control is achieved through regulation of respiration and renal handling of bicarbonate and protons. Bone plays an important role as a reserve for hydroxyl ions, bicarbonate, and phosphate. Cardiovascular function and immune responses are influenced by ►acidosis.

The three ►pH-sensing receptors are found in vertebrates – orthologues for OGR1 and GPR4 are detected in zebrafish, chicken, and in all sequenced mammalian species, but not in *Drosophila*, *C. elegans*, or *plasmodium*. TDAG8 is not found in zebrafish, but in the mammalian species analyzed to date. The receptors thus appear to be relevant for physiological processes developed relatively late in evolution.

The first data on genetically modified mice were reported very recently. Animals deficient in GPR4, OGR1, and TDAG8 are viable and fertile, and show no major defects. A short summary of available information is given in the following (see also Table 1).

GPR4 is found in kidney and lung, and recent more detailed analysis showed that it is significantly expressed in endothelial cells. Yang et al. [4] reported that adult GPR4^{-/-} mice appear normal, however, increased perinatal lethality was observed which was associated with vascular abnormalities. Experiments on aortic rings ex vivo showed that microvessel outgrowth was less inhibited by acidic pH in preparations obtained from GPR4^{-/-} mice compared to control. These data indicate that GPR4 functions as a vascular pH sensor.

OGR1 is significantly expressed in lung, kidney, bone, and the nervous system [1 and references cited therein]. We and others demonstrated pH-dependent signaling of the receptor in bone-forming ►osteoblasts as well as in bone-resorbing ►osteoclasts [1, 3]. Despite clear evidence for function in these cell types, OGR1-deficient mice show a normally developed skeleton and normal bone mineral density (preliminary data). Further analysis is required to assess the response of the skeleton of OGR1^{-/-} mice to ►acidosis and hormonal changes. Recently, expression and function of OGR1 were also described in human aortic smooth muscle cells, and the receptor was reported to control acid-induced PGI₂ production. PGI₂ is a vasodilating mediator and may contribute to acidosis-induced vasorelaxation [3].

TDAG8 appears restricted to the immune system. As tissue inflammation is usually followed by local ►hypoxia and acidosis, the pH-sensing property of TDAG8 appeared of particular interest in this context. Unexpectedly, however, the phenotype of mice

deficient in TDAG8 appears rather mild. The animals develop an apparently normal immune system, and major immune functions are unaffected [5].

Drugs

OGR1, but not GPR4 or TDAG8, is sensitive to inhibition by zinc and copper ions [1]. Agonistic or antagonistic modulators of receptor function are not yet published. As described above, we do not consider lipid messengers as specific modulators of these receptors.

Conclusions

The data available to date identify GPR4, OGR1, and TDAG8, but not G2A, as genuine pH-sensing receptors. Activation by neutral to acidic pH is strong, comparable to activation of other GPCRs by their cognate ligands. The existence of additional specific positive or negative modulators of these receptors can not be excluded, but remains to be demonstrated.

Proto-oncogene

Normal cellular gene, usually concerned with the regulation of cell proliferation that can be converted to a cancer promoting oncogene by mutation.

► Cancer, Molecular Mechanisms of Therapy

PRRs

Pattern recognition receptors (PRRs) are receptors expressed by cells from the innate immune system

acting as sensors to rapidly detect invading pathogens. PRRs recognize conserved pathogen-associated molecular patterns (PAMPs) and distinguish foreign organisms such as bacteria, viruses, fungi, or parasites, from cells of the host. PRRs are divided into three families. The most studied family is the Toll-like receptors (TLRs). TLRs are membrane proteins anchored in the plasma membrane or at the surface of endosomes. TLRs are characterized by a common ligand-binding domain, which is composed of leucine-rich repeats (LRRs). Their recognition of either extracellular pathogens or PAMPs present in endosomes activates the innate and adaptive immune responses through signaling cascades controlling selective activation of NF- κ B and other inducible transcription factors. The other two families of PRRs, the NOD-like receptors (NLRs) and the RIG-like helicases (RLHs) are soluble receptors present in the cytosol and act as sensors to detect a variety of viral and bacterial products. NOD1 and NOD2 (two NLRs) detect bacterial peptidoglycan while the retinoic acid inducible gene-1 (RIG-1) and the melanoma differentiation associated gene-5 (MDA-5) are RNA helicases that sense viral double-stranded RNA (dsRNA).

Pseudogene

Pseudogenes are nonfunctional relatives of known genes that have lost their ability to encode proteins.

The conversion of a functional into a pseudogene most frequently results from mutations such as frameshift mutations or deletions. Even though pseudogenes might still have some retained functionality such as promoter- or enhancer-like features, they are usually classified as pseudogenes upon their lack of protein-coding ability.

P-Site Ligands

P-site ligands are characteristically adenine nucleosides or adenine nucleoside 3'-phosphates. The term > P-site = was historically used to describe that > site = in the adenylyl cyclase system through which a selected class of agents reduced enzyme activity. As originally described, P-site ligands required an intact purine moiety, but tolerated modifications to the ribose group. (This was contrasted with another class of inhibitors that required an intact ribose moiety, but tolerated substitutions to the purine ring. This latter group was later identified and further refined as adenosine and purine receptor agonists.)

P-site ligands inhibit adenylyl cyclases by a noncompetitive, dead-end- (post-transition-state) mechanism (cf. Fig. 6). Typically this is observed when reactions are conducted with Mn^{2+} or Mg^{2+} on forskolin- or hormone-activated adenylyl cyclases. However, under some circumstances, uncompetitive inhibition has been noted. This is typically observed with enzyme that has been stably activated with $GTP\gamma S$, with Mg^{2+} as cation. That this is the mechanism of P-site inhibition was most clearly demonstrated with expressed chimeric adenylyl cyclase studied by the reverse reaction. Under these conditions, inhibition by 2'-d-3'-AMP was competitive with cAMP. That is, the P-site is not a site *per se*, but rather an enzyme configuration and these ligands bind to the post-transition-state configuration from which product has left, but before the enzyme cycles to accept new substrate. Consequently, as post-transition-state inhibitors, P-site ligands are remarkably potent and specific inhibitors of adenylyl cyclases and have been used in many studies of tissue and cell function to suppress cAMP formation.

► Adenylyl Cyclases

Psoralens

Psoralens are naturally occurring substances, which are used for photochemotherapy, e.g. for treatment

of psoriasis or vitiligo. The local application of e.g. 8-methoxypsoralen on the skin and subsequent irradiation with UVA-light is called PUVA. Psoralens are absorbed rapidly after oral administration and photosensitivity is maximal about 1–2 hours after ingestion.

Psychedelic Hallucinogen

The term “psychedelic” literally means “mind manifesting” and was applied to hallucinogens like LSD or mescaline to emphasize the intensification of awareness and sensory perception that is associated with these drugs.

Psychostimulants

ION ANGHELESCU, ISABELLA HEUSER
Department of Psychiatry and Psychotherapy, Charité,
CBF, Berlin, Germany

Synonyms

Stimulants; Stimulant drugs; Psychomotor stimulant drugs

Definition

Psychostimulants are drugs that substantially influence cognitive and affective functioning and behaviors. Effects are increased motivational desire, agitation, heightened vigilance, euphoria, hyperactivity, and

decreased sleepiness as well as appetite. Traditionally, mainly cocaine and amphetamines are considered psychostimulants. However, nicotine, caffeine, and even certain antidepressants could be included in this class. Methylphenidate, amphetamine (like dextroamphetamine) and also pemoline – the latter was retracted from the market due to hepatotoxicity – are or have been widely used for the treatment of ► **attention deficit/hyperactivity disorder (ADHD)**. Another psychostimulant indicated in ► **narcolepsy** and sleep apnea is modafinil.

Mechanism of Action

General Remarks

The final pathway of psychostimulants on the behavioral level is an increased mobilization of the normal fight/flight/fright reaction that is mediated by the biogenic amines epinephrine, norepinephrine, serotonin, and dopamine. The most widespread extraclinically used psychostimulant is ecstasy (3,4-methylenedioxymethamphetamine; MDMA), which also exhibits perceptual distortions due to 5-HT_{2A}-receptor agonism like lysergic acid diethylamide (LSD).

The main target of action of methylphenidate, the most widespread clinically used psychostimulant, is the dopamine transporter (DAT); its inhibition increases intrasynaptic dopamine concentrations. The subcortical dopamine system (mesolimbic and nigrostriatal parts) mediates the unconditioned and conditioned responses toward reinforcement.

Within the striatum, dopamine terminals have direct synaptic contacts with the spines of striatal neurons. These synaptic contacts appear to provide the anatomical substrate for both compartmental (synaptic) and volume (extrasynaptic) transmission. The DAT is located intra- or perisynaptically, suggesting that dopamine has a limited ability to escape the striatal synapse. Moreover, dopamine D2 and, to a lesser extent, D1 receptors are located postsynaptically from dopamine terminals, suggesting compartmental transmission. However, there is a significant cohort of D1 and D2 receptors that are not directly opposed to dopamine terminals, suggesting some component of volume transmission within the striatum. Therefore, tonic and phasic changes in dopamine transmission are critical in producing behavioral effects associated with the striatum. In contrast, in cerebral cortex, volume transmission appears to be more critical in mediating the effects of dopamine. DAT density is reduced in the ► **frontal cortex (FC)** relative to the striatum, and it is localized extrasynaptically. Moreover, D1-immunoreactivity within FC is virtually never opposed to tyrosine hydroxylase immunopositive terminals suggesting that the effect of dopamine on D1 receptors is by volume transmission. This hypothesis has direct relevance to the neurochemistry of

ADHD because cognitive functions known to be affected in this disorder, namely working memory and inhibitory control, are sensitive to manipulations of D1 receptor-mediated dopamine transmission [1]. Thus, the tonic component might be more critical for the behavioral functions of the FC.

Several classes of drugs modulate the firing rates or patterns of midbrain dopamine neurons by direct, monosynaptic, or indirect, polysynaptic, inputs to the cell bodies within the ventral mesencephalon (i.e., nicotine and opiates). In contrast, amphetamine, cocaine, and methylphenidate act at the level of the dopamine terminal interfering with normal processes of transmitter packaging, release, reuptake, and metabolism.

Methylphenidate, Amphetamine, and Cocaine

Methylphenidate like cocaine largely acts by blocking reuptake of monoamines into the presynaptic terminal. Methylphenidate administration produces an increase in the steady-state (tonic) levels of monoamines within the synaptic cleft. Thus, DAT inhibitors, such as methylphenidate, increase extracellular levels of monoamines. In contrast, they decrease the concentrations of the monoamine metabolites that depend upon monoamine oxidase (MAO), that is, HVA, but not catecholamine-*o*-methyltransferase (COMT), because reuptake by the transporter is required for the formation of these metabolites. By stimulating presynaptic autoreceptors, methylphenidate induced increase in dopamine transmission can also reduce monoamine synthesis, inhibit monoamine neuron firing and reduce subsequent phasic dopamine release.

The pharmacology of amphetamine is considerably more complex. It does not only block monoamine reuptake, but also directly inhibits the vesicular monoamine transporter, causing an increase in cytosolic but not vesicular dopamine concentration. This may lead to reverse transport of the amines via the membrane-bound transporters. Further mechanisms of amphetamine action are direct MAO inhibition and indirect release of both dopamine and serotonin in the striatum.

Mild increases in tonic dopamine release – as a consequence of the administration of both methylphenidate and amphetamine – could have important impact on subsequent phasic release by feedback mechanisms (lowering the concentration).

As pointed out before there are some major differences between the striatal and cortical dopamine terminals (Table 1).

Therefore, dopamine transporter inhibitors exhibit less effect in the FC. There, dopamine seems to be reuptaken by the norepinephrine transporter, which dopamine actually has a higher affinity for than norepinephrine itself.

Amphetamine administration produces a marked increase in cortical dopamine, norepinephrine, and

serotonin release that is impulse independent. Methylphenidate can produce significant increases in dopamine and norepinephrine release (Table 2).

Dopaminergic mechanisms within the ventral striatum (i.e., nucleus accumbens) subserves the ability of amphetamine and methylphenidate in low to moderate doses to increase locomotor activity. In contrast, very low dosages in animals seem to cause hypoactivity presumably by stimulation of autoreceptors, a finding that would be compatible with the clinical impression that methylphenidate might be useful in some patients with mania.

At low doses, both psychostimulants could theoretically stimulate tonic, extracellular levels of monoamines, and the small increase in steady state levels would produce feedback inhibition of further release by stimulating presynaptic autoreceptors. While this mechanism is clearly an important one for the normal regulation of monoamine neurotransmission, there is no direct evidence to support the notion that the doses used clinically to treat ADHD are low enough to have primarily presynaptic effects. However, alterations in phasic dopamine release could produce net reductions in dopamine release under putatively altered tonic dopaminergic conditions that might occur in ADHD and that might explain the beneficial effects of methylphenidate in ADHD.

Repeated intermittent exposure to stimulants can produce sensitization, where subsequent drug exposures produce increased behavioral and neurochemical responses. The ability of the drug and ultimately of related stimuli to elicit behavior may be increased with repeated administration or intake of the drug. Dopaminergic sensitization within the amygdala has also been found after repeated exposure to amphetamine and this

can enhance appetitive and aversive learning even after drug cessation.

Cocaine- and amphetamine-regulated transcript (CART) peptides are putative neurotransmitters are found in those dopaminergic brain regions. Stimulants seem to alter CART mRNA and peptide levels [2].

Besides the dopaminergic system, the noradrenergic nucleus, locus coeruleus (LC) may be another structure involved in the mode of action of psychostimulants. Electrophysiological recordings from this area demonstrate a relationship between behavior and response of the LC to targets versus distractors in an attention task. Baseline firing shows a constant increase paralleling the conditions from drowsiness to hyperarousal. In contrast, phasic responses are maximal in an optimal alert attentive state and minimal in drowsiness as well as hyperarousal that may be associated with poor cognitive performance due to high distractibility.

Finally, the cerebellum has recently become a focus of interest in the context of the pathophysiology of ADHD and as a possible target for psychostimulants since it is not only important for motor coordination but also for processing cognitive situations.

In summary, main structures involved in the action of psychostimulants can be divided into cortical (mainly prefrontal cortex) and subcortical (basal ganglia and related structures, LC and cerebellum) ones. Figure 1 gives a schematic overview of the connections between these structures, omitting the cerebellum due to lack of precise information.

Modafinil

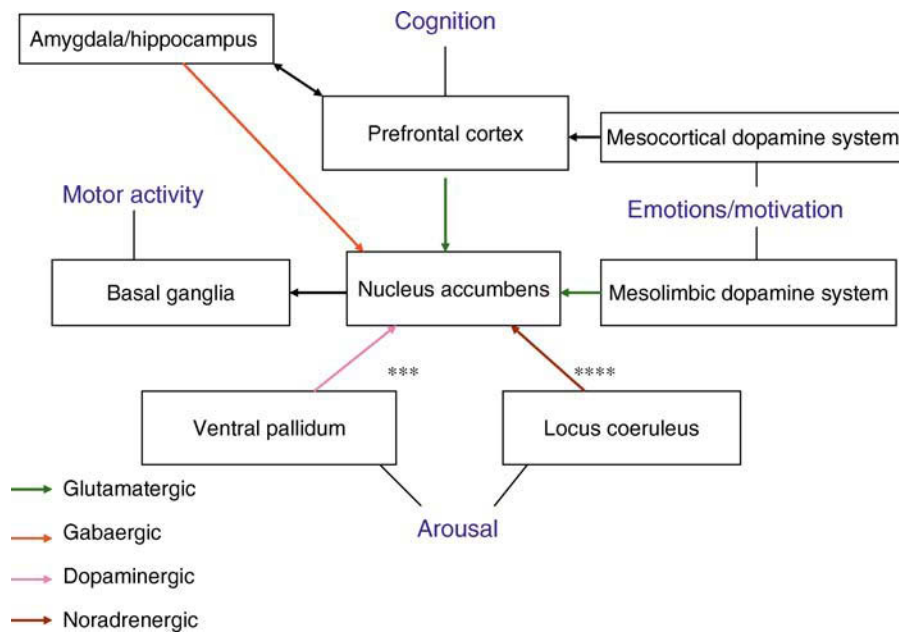

The mode of action of modafinil, a new arousal-promoting compound used in the treatment of sleepiness associated with narcolepsy, is not fully understood.

Psychostimulants. Table 1 Properties of cortical versus striatal dopamine system

	Cortical	Striatal

Dopamine	++	++	++
Norepinephrine	++	++	+
Serotonin	+	++	(+)

Psychostimulants. Figure 1 Nucleus accumbens as a major intersection of cognitive, motor and arousal processes.

It has been suggested that modafinil increases wakefulness by activating α_1 noradrenergic receptors or hypothalamic cells that contain the peptide ►[hypocretin](#) [3], or that it may act by modulating the GABAergic tone that might lead to an increased dopamine release in the nucleus accumbens. On the other hand, modafinil does not have any effect in DAT knockout mice.

Nicotine

Nicotine is the main psychoactive ingredient of tobacco and is responsible for the stimulant effects and abuse/addiction that may result from tobacco use. Cigarette smoking rapidly (in about 3 sec!) delivers pulses of nicotine into the bloodstream. Its initial effects are caused by its activation of ►[nicotinic acetylcholine \(nACh\) receptors](#). nACh receptors are ligand-gated ion-channels and pre- and postsynaptically located. Reinforcement depends on an intact mesolimbic dopamine system (VTA). nACh receptors on VTA dopamine neurons are normally activated by cholinergic innervation from the laterodorsal tegmental nucleus or the pedunculopontine nucleus.

Clinical Use

The main indication for certain psychostimulants is ADHD in children and adults [4]. Recent research shows that the clinical effect and benefit are dramatic even in adults. About 60% of adult patients receiving stimulant medication showed moderate-to-marked improvement, as compared with 10% of those receiving placebo. The core symptoms of hyperactivity,

inattention, mood lability, temper, disorganization, stress sensitivity, and impulsivity have been shown to respond to treatment with stimulant medications.

The characteristic behavioral effects of acute and chronic psychomotor stimulant drugs are locomotor activation, stereotypy, and conditioned reward and stimulus-reward learning. The most important brain regions involved in these effects are summarized in [Table 3](#).

Each of these processes depends upon increases in dopaminergic transmission within the striatum, and possibly, amygdala. Moreover, neurochemical actions within the FC may contribute to the ability to modulate some of these basic motivational processes. This data is based primarily on studies in rodents given systemic injections of moderate to high doses of stimulants, and it is not known whether lower doses applied orally would produce similar behavioral and neurochemical effects. Nevertheless, when given acutely or chronically to animals, stimulants appear to alter the neurochemistry of the striatum in such a way as to augment the control of behavior by conditioned or unconditioned stimuli associated with reinforcement processes. These effects may be consistent with the suggestion that amphetamine or methylphenidate may exert some of their beneficial clinical effects by augmenting conditioned reinforcement and stimulus-reward associations that could enhance aspects of task performance.

A simple decrease in striatal dopamine transmission produced by even low clinical doses of the drugs according to current data seems an untenable

hypothesis. However, if the tonic control of phasic release by dopamine is abnormally low in ADHD, then a high phasic dopamine response may be associated with ADHD and treatment efficacy. Moreover, alterations in corticolimbic tonic/phasic balance may also provide an explanation of why chronically administered psychostimulants in ADHD produce a behavioral profile and response associated with subcortical dopamine neuronal hyperactivity and cortical hypoactivity, though issues of dose and route of administration should be considered in this context.

Another theory for the action of stimulant drugs in ADHD involves effects on nonstriatal monoamine systems. Frontal cortical dopamine, norepinephrine, and serotonin are clearly important in cognitive functioning and impulse control. These neurotransmitters directly modulate reward-related behaviors associated with the striatal dopamine system. Moreover, the amygdala may be pharmacologically influenced leading to enhanced

associative learning and recall. Thus, the net behavioral effects of stimulant drugs may promote changes in reward-motivated behaviors and impulsivity, as well as neuromodulation of inhibitory control (FC), working memory, and incentive learning (amygdala).

Dysfunction of cortical–subcortical dopamine systems is associated with an impaired inhibitory control after chronic drug administration.

Since there is some evidence that the dopaminergic system might also play an important role in the pathophysiology of depression, methylphenidate has also been successfully used as an augmentation strategy in the treatment of depressive disorders. Modafinil might be useful in this indication, too, besides its effect in narcolepsy and ADHD. It is usually well tolerated, although hyperkinesias and switch into mania might rarely occur.

Figure 2 [2] illustrates the acute and chronic actions of methylphenidate. By blocking DAT, methylphenidate

Psychostimulants. Table 3 Acute effects of psychostimulants and the brain regions that are mainly involved in these effects

Acute effects	Mainly involved brain region
Locomotion	Ventral striatum (i.e., nucleus accumbens)
Motor stereotypy	Dorsal striatum (i.e., caudate putamen)
Reinforcement	Ventral striatum
Conditioned reward	Ventral striatum/amygdala
Stimulus-reward learning	Amygdala

Psychostimulants. Figure 2 Dopamine molecules have two different possible targets. Both ways are initially increased by DAT inhibition caused by methylphenidate: pre- and postsynaptic dopamine receptors. Stimulation of postsynaptic receptors results in inhibition of presynaptic action potential generation. On the other hand, presynaptic receptor stimulation leads to a transmission inhibition of action potentials. Therefore, both mechanisms are responsible for a decrease in vesicular depletion of dopamine into the synaptic cleft (adapted from [2]).

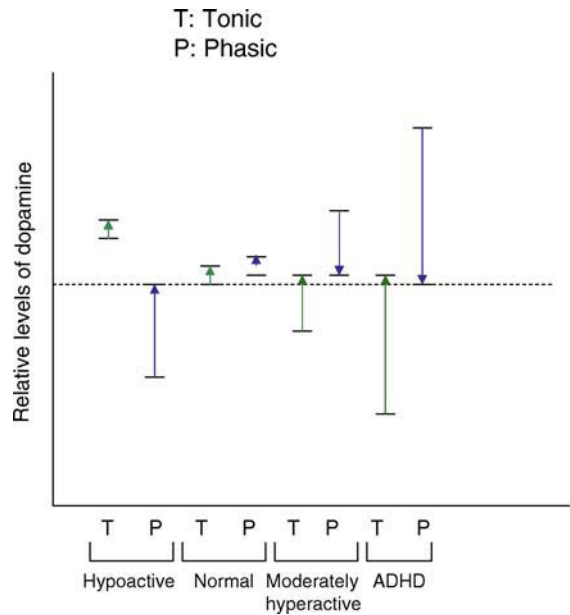

causes an accumulation of dopamine in the synaptic cleft. Although this may initially increase the stimulation of postsynaptic DA receptors, in the long term the consequence is rather a down-regulation of dopamine release. First, there is feedback inhibition of dopamine neuron firing to decreased spike-dependent dopamine release. Second, much larger quantities of dopamine are enabled to escape from the cleft and accumulate in the extrasynaptic space. Presynaptic receptors are stimulated and thus firing rate is reduced. The amount of phasic dopamine that can be released is subsequently diminished.

Moreover, no significant differences could be found between the efficacy of methylphenidate and amphetamine. Methylphenidate is faster metabolized and seems to be associated with fewer side effects regarding appetite loss and insomnia. From a clinical point of view, dosage and route of administration are the most important features influencing the spectrum of effects and side effects. ADHD drugs and cardiovascular risk (especially via increased blood pressure) has recently become a major issue with regard to sudden death. Summarizing, more selective and restricted use to clear-cut diagnoses are advocated.

An important clinical clue connected with the difference between tonic and phasic dopamine release is the so-called “rate dependence” of psychostimulant action. That means, it depends on the actual dopaminergic state (tonic and phasic) how an individual will react to psychostimulants. Figure 3 illustrates this rule by some examples [2]. The arrows represent the response of each component to methylphenidate for each of the classes of subjects tested, with the horizontal dashed line representing the baseline tonic and phasic levels present in control individuals. Summarizing, methylphenidate tends to normalize dopamine transmission regardless what the baseline rate is.

Despite their clinical use, psychostimulants are strongly reinforcing and their long-term use is linked to potential abuse and addiction, especially when they are rapidly administered. Nevertheless, long-term use is rather associated with emotional and motivational than with physical dependence. This is also true for cocaine and amphetamine. Methylphenidate might also be abused, although it is far less potent, possibly due to its specific mode of action (see above). Two drugs with low, if at all, abuse potential that are used in ADHD are atomoxetine [5], a noradrenalin reuptake inhibitor and bupropion, a dopamine- and noradrenalin reuptake inhibitor. By their mode of action they would rather fit into the group of antidepressants than psychostimulants.

Nicotine differs from cocaine in that it is powerfully reinforcing in the absence of subjective euphoria. The high incidence of cancerogenicity associated with long-term tobacco use is associated with compounds other than nicotine that are also contained in tobacco. Main

Psychostimulants. Figure 3 Effect of methylphenidate depending on baseline tonic (T) and phasic (P) dopamine levels. In a “normal” state only minimal changes are noted (which points to a rather low abuse potential). From a “hypoactive” state, methylphenidate increases both T and P levels. However, this is much more true for the strongly lowered P tone. In contrast, in moderately hyperactive states and ADHD, T levels are increased and P levels are decreased, respectively, correlating with the baseline levels (adapted from [2]).

short-term effects of nicotine are increased alertness, muscle relaxation, nausea, and increased psychomotor activation. Typical withdrawal symptoms include dysphoria, increased appetite, hyperventilation, and concentration difficulties. If the $\alpha 4\beta 2$ nicotinic partial agonist varenicline that is used for smoking cessation is also to be regarded as a stimulant drug still remains to be elucidated.

Psychotogenic

► Psychotomimetic Drugs

Psychotomimetic Drugs

GEORGE K. AGHAJANIAN
Yale School of Medicine, New Haven, CT, USA

Synonyms

Hallucinogenic; Psychotogenic

Definition

Psychotomimetic drugs can be defined as chemical agents that reliably and dose-dependently induce a psychosis, often including hallucinations and delusions in normal individuals. Implicit in this term is a mimicking of naturally occurring psychosis.

Mechanism of Action

There are remarkable qualitative differences in the types of psychoses induced by different classes of psychotomimetic drugs. Some drugs cause such profound deficits in cognitive functioning that the resulting psychosis is associated with gross disorientation and confusion; a state sometimes called “dementia” or “organic psychosis.” A psychotomimetic effect of this kind is seen, for example, after high doses of atropine or scopolamine, drugs which block muscarinic cholinergic receptors. Drugs of this type serve to mimic or model Alzheimer’s disease and other severe brain disorders. There are other types of drugs that produce hallucinations and delusions without marked disorientation or confusion. Examples are ►**psychedelic hallucinogens** such as lysergic acid diethylamide (LSD) and mescaline and, in low doses, the ►**dissociative anesthetics** phencyclidine (PCP) and ketamine. This essay will focus upon the psychedelic hallucinogens and dissociative anesthetics, which are of

special interest because they are believed to model some important features of ►**schizophrenia** [1, 2].

For many years it was believed that the brain mechanisms underlying the effects of psychedelic hallucinogens and dissociative anesthetics were separate and distinct. Indeed, there has been considerable debate about which represents the best drug model of schizophrenia. However, recent data show that the two classes of psychotomimetic drugs share a common final pathway involving an increase in the release of the excitatory neurotransmitter ►**glutamate**.

Mechanism of Action of Psychedelic Hallucinogens

In the early 1950s, not long after the discovery of the powerful hallucinogenic properties of LSD, it was proposed that this drug interacted with a structurally related endogenous brain substance named ►**serotonin**. As seen in Fig. 1, LSD and serotonin (5-hydroxytryptamine; 5-HT) share an indolethylamine moiety, as do certain simpler indoleamine hallucinogens such as psilocin. On the other hand, the hallucinogen mescaline, despite having psychological or behavioral effects virtually identical to LSD, has a phenethylamine—rather than indoleamine—based structure. Nevertheless, mescaline does share certain other structural features

Psychotomimetic Drugs. Figure 1 Chemical structures of *serotonin* (5-hydroxytryptamine; 5-HT), the ergoline hallucinogen LSD (lysergic acid diethylamide), the simple indoleamine hallucinogen psilocin, and the phenethylamine hallucinogen mescaline. The letters A–D denote the four rings of LSD which are shared in varying aspects by the other hallucinogens as well as serotonin.

with LSD (Fig. 1), consistent with the hypotheses that these two drugs have a common site of action. In the mid-1980s it was shown that the hallucinogenic potency of indoleamine and phenethylamine hallucinogens could be predicted by their affinity for a subtype of serotonin receptor, the 5-HT_{2A} receptor [3]. The recognition of an association between hallucinogens and the 5-HT_{2A} receptor has formed the foundation for contemporary research in the field. Presently there is much evidence from biochemical, electrophysiological, and animal as well as human behavioral studies that the effects of hallucinogens are mediated through a partial agonist action at 5-HT₂ receptors, particularly of the 5-HT_{2A} subtype [4].

The effects of hallucinogens on an array of complex integrative processes such as cognition, perception and mood suggest the involvement of the cerebral cortex. In support of this idea, histochemical mapping by receptor autoradiography, mRNA in situ hybridization, and immunocytochemistry shows a high expression of 5-HT_{2A} receptors in the cerebral cortex, particularly within the apical dendrites of cortical ►pyramidal cells. At an electron microscopic level, an association has been observed between 5-HT_{2A} immunoreactivity and the postsynaptic density of excitatory synapses in the neocortex.

The high density of 5-HT_{2A} receptors in the cerebral cortex has stimulated study of the physiological role of this receptor in that region of brain [4]. A striking effect of serotonin in the cerebral cortex is to increase the release of ►glutamate onto layer V ►pyramidal cells of neocortex, as measured by electrophysiological recording of “spontaneous” excitatory postsynaptic potentials (►EPSPs). In vitro studies in brain slices show that EPSPs are induced by serotonin through a focal action at the apical dendrites of pyramidal cells. This effect is blocked by low concentrations of highly selective 5-HT_{2A} antagonists and is virtually absent in mice where there has been a genetic deletion of the 5-HT_{2A} receptor. While a serotonin-induced increase in ►EPSPs occurs throughout the neocortex, this effect is most pronounced in frontal areas such as the medial prefrontal cortex where there is an increased density of 5-HT_{2A} receptors as compared to more posterior regions. It has been postulated that the effect of serotonin is mediated indirectly by a ►retrograde messenger since 5-HT_{2A} receptors have a predominantly postsynaptic localization. Recently, it has been found that LSD and other hallucinogenic drugs, while having relatively low efficacy in inducing spontaneous ►EPSPs, dramatically increase the probability of occurrence of a late component of EPSPs evoked by electrical stimulation of the subcortical white matter. In contrast, serotonin itself usually does not promote the late component of electrically evoked EPSPs, probably due to opposing actions at 5-HT₁ or other non-5-HT_{2A}

receptors. It has been proposed that excessive induction of late EPSPs may underlie the disruptive effects of hallucinogens upon cortical function. The opposition by non-5-HT_{2A} receptors of this effect may explain why treatments that elevate endogenous serotonin (e.g., monoamine oxidase inhibitors or selective serotonin uptake blockers) are not hallucinogenic and may in fact attenuate the subjective effects of hallucinogens in humans.

Mechanism of Action of Dissociative Anesthetics

The most commonly used (or abused) drugs in this category are the structurally related drugs, PCP and ketamine (Fig. 2). At high doses these drugs produce a delirium-like state as seen in stage I anesthesia. Lower, subanesthetic doses are capable of producing a psychotomimetic state in normal subjects that stops short of frank delirium. Both PCP and ketamine are known to act as non-competitive antagonists of the ►NMDA receptor; a subtype of ionotropic ►glutamate receptor [5]. The NMDA receptor belongs to the general class of ligand-gated nonselective cation channels and is distinguished within this group by its high permeability for calcium in addition to sodium and potassium ions. Because of its high calcium permeability, the NMDA receptor has been linked to various intracellular calcium signaling pathways. Another notable characteristic of NMDA receptor channels is blockade by magnesium ions under resting or hyperpolarized conditions, a block that is relieved under excitatory, depolarizing conditions. As suggested by the noncompetitive nature of the blockade, these drugs do not act directly at the glutamate ligand binding site, but rather interact with a separate site within the pore of the open channel, hence their designation as “open channel” blockers. While other actions also have been described, it is generally believed that the primary mechanism by which PCP and ketamine produce their adverse behavioral effects is through blockade of NMDA receptors. The net effect of these drugs has sometimes been thought of in terms of a general

Psychotomimetic Drugs. Figure 2 Chemical structures of the *dissociative anesthetics* phencyclidine (PCP) and ketamine. Both are arylcycloalkylamine derivatives that are open channel blockers of the NMDA channel.

impairment of glutamatergic transmission. However, it should be noted that these drugs do not block non-NMDA glutamate receptors, including other ionotropic glutamate receptors (i.e., AMPA and kainate) and all three major groups of metabotropic glutamate receptors. Recently, it has been shown that many of the effects of NMDA antagonists may be mediated through increased release of glutamate in prefrontal cortex and other regions, causing excessive activation of non-NMDA receptors. Suppression of excessive glutamate release ameliorates many of the resulting adverse behavioral effects. The mechanism by which NMDA antagonists increase glutamate release appears to be distinct from that of 5-HT_{2A} agonists since local application of phencyclidine to brain slices, in contrast to local serotonin application, does not result in an increase in EPSCs in layer V pyramidal cells of prefrontal cortex.

Conclusions

This essay has highlighted both differences and similarities in the mechanism of action of the psychedelic hallucinogens and ▶[dissociative anesthetics](#). The initial sites at which these two classes of psychotomimetics act are quite different: the psychedelic hallucinogens acting via 5-HT_{2A} receptors and dissociative anesthetics through blockade of NMDA receptors. However, recent evidence reveals intriguing common features downstream from the initial receptors. Most notably, both hallucinogens and dissociative anesthetics indirectly produce an enhancement of glutamate release in the cerebral cortex. However, it would not be expected that the effects of the two classes of drugs would be identical since in the case of the psychedelic hallucinogens, NMDA receptors are not blocked. Blockade of NMDA receptors may account for the progressive disorientation or delirium seen clinically with near-anesthetic doses of the phencyclidine/ketamine class of drugs, effects that are not characteristic of the psychedelic hallucinogens. Nevertheless, evidence for an increase in glutamate transmission for both psychedelic hallucinogens and dissociative anesthetics points to a convergence upon a final common glutamatergic pathway to account for overlapping aspects of their psychotomimetic effects.

PTEN

PTEN is a phosphatase, which is a product of a tumor suppressor gene. This phosphatase has an unusual broad specificity and can remove phosphate groups attached to serine, threonine, and tyrosine residues. It is believed that its ability to dephosphorylate phosphatidylinositol (PI) 3,4,5-triphosphate, the product of PI-3 kinase, is responsible for its tumor suppressor effects.

Purinergetic System

GEOFFREY BURNSTOCK
Autonomic Neuroscience Centre, Royal Free and
University College Medical School, London, UK

Definition

The purinergetic system is a signalling system, where the purine nucleotides, ▶ATP (Adenosine 5'-triphosphate) and ADP (Adenosine diphosphate), and the nucleoside, ▶adenosine, act as extracellular messengers. This concept, which was first proposed over 30 years ago [1], met with considerable resistance for many years, because ATP had been established as an intracellular energy source involved in various metabolic cycles and it was thought that such a ubiquitous molecule was unlikely to be involved in selective extracellular signalling. However, ATP was one of the first molecules to appear in biological evolution so that it is not really surprising that it should have been utilized early for extracellular, as well as intracellular, purposes. The existence of potent extracellular enzymes that regulate the amount of ATP

and adenosine available for signalling, also provides support that ATP has extracellular actions.

Basic Characteristics Purinoreceptor Subtypes

Implicit in purinergetic signalling is the presence of receptors for ATP [2]. A basis for distinguishing adenosine receptors (P1), from ATP/ADP receptors (P2), was proposed in 1978. This helped resolve some of the earlier ambiguous reports, which were complicated by the breakdown of ATP to adenosine by ectoenzymes, so that some of the actions of ATP were directly on P2 receptors while others were due to indirect action via P1 receptors. Four subtypes of P1 receptors have been cloned, namely, A₁, A_{2A}, A_{2B} and A₃ (Fig. 1a). P2 receptors belong to two families based on molecular structure and second messenger systems, namely P2X ionotropic ligand-gated ion channel receptors and P2Y metabotropic G protein-coupled receptors. This framework allows for a logical expansion as new receptors are identified. There are currently seven subtypes of P2X receptors and eight subtypes of P2Y receptors identified and characterized in mammals (Table 1). P2X receptors are characterized by two transmembrane domains, short intracellular N- and C-termini and an extensive extracellular loop with conservation of ten cysteines (Fig. 1b). Broadly, P2X₁ receptors are strongly represented in smooth muscle, P2X₂, P2X₄ and P2X₆ receptors in the central nervous system, P2X₃ receptors on sensory neurones, P2X₅ receptors are associated with cell proliferation and differentiation and P2X₇ receptors with cell death. The ion pores appear to consist of three subunits forming homomultimers or heteromultimers, including P2X_{1/2}, P2X_{1/4}, P2X_{1/5}, P2X_{2/3}, P2X_{2/6} and P2X_{4/6}. P2Y receptors, in common with other G protein-coupled receptors, have seven transmembrane domains, an extracellular N, and intracellular C-terminus (Fig. 1c). P2Y₁ receptors are ADP-selective in mammals and 2-methylthioADP and MRS 2179 are selective agonists and antagonists, respectively. At P2Y₂ and P2Y₄ receptors in the rat, ATP and UTP are equipotent, but the two receptors can be distinguished with antagonists. P2Y₆ is UDP-selective. P2Y₁₁ is unusual in that there are two transduction pathways, adenylate cyclase as well as inositol triphosphate, which is the second messenger system used by the majority of the P2Y receptors. The P2Y₁₂ receptor is found on platelets. P2Y₁₃ is ADP-selective and acts via adenylate cyclase, while P2Y₁₄ receptors are selective for UDP-glucose and UDP-galactose.

Physiology

Short-Term Neuronal Signalling

There was early evidence that ATP was a ▶neurotransmitter in non-adrenergic, non-cholinergic (NANC) nerves supplying the gut and bladder. There is now

Purinergic System. Figure 1 Membrane receptors for extracellular ATP and adenosine. P1 family of receptors for extracellular adenosine are G protein-coupled receptors signalling by inhibiting or activating adenylate cyclase (a). The P2 family of receptors bind extracellular ATP or ADP, and is comprised of two types of receptors (P2X and P2Y). The P2X family of receptors are ligand-gated ion channels (b), and the P2Y family are G protein-coupled receptors (c). (a, reproduced from [2] with permission from the American Society for Pharmacology and Experimental Therapeutics; b, from Brake AJ, Wagenbach MJ, Julius D (1994) New structural motif for ligand-gated ion channels defined by an ionotropic ATP receptor. *Nature* 371:519-523, reproduced with permission from Nature; c, modified from Barnard EA, Burnstock G, Webb TE (1994) G protein-coupled receptors for ATP and other nucleotides: a new receptor family. *Trends Pharmacol Sci* 15:67-70, reproduced with permission from Elsevier).

supporting evidence that ATP is a cotransmitter in many nerve types [1], probably reflecting the primitive nature of purinergic signalling. Thus, there is now evidence for ATP as a cotransmitter with:

- Noradrenaline (NA) and neuropeptide Y (NPY) in sympathetic nerves
- ATP with acetylcholine and vasoactive intestinal peptide in some parasympathetic nerves
- ATP with nitric oxide and vasoactive intestinal peptide in enteric NANC inhibitory nerves
- ATP with calcitonin gene-related peptide and substance P in sensory-motor nerves

There is also evidence for ATP as a cotransmitter with γ -aminobutyric acid or with glutamate, serotonin, NA or dopamine in nerves in the central nervous system.

In sympathetically innervated tissues, such as vas deferens or blood vessels, ATP produces fast responses mediated by P2X receptors followed by a slower component mediated by G protein-coupled α -adrenoceptors (Fig. 2); NPY usually acts as a pre- or postjunctional modulator of the release and/or action of NA and ATP. Similarly, for parasympathetic nerves supplying the urinary bladder, ATP provokes a fast, short-lasting twitch response via P2X receptors, whereas the slower component is mediated by G

P2X	P2X ₁	Smooth muscle, platelets, cerebellum, dorsal horn spinal neurons	α,β-meATP = ATP = 2-MeSATP, L-β,γ-meATP (rapid desensitization)	TNP-ATP, Ip ₅ l, NF023, NF449	Intrinsic cation channel (Ca ²⁺ and Na ⁺)
	P2X ₂	Smooth muscle, CNS, retina, chromaffin cells, autonomic and sensory ganglia	ATP ≥ ATPγS ≥ 2-MeSATP > > α,β-meATP (pH + zinc sensitive)	Suramin, isoPPADS, RB2, NF770, NF279	Intrinsic ion channel (particularly Ca ²⁺)
	P2X ₃	Sensory neurones, NTS, some sympathetic neurons	2-MeSATP ≥ ATP ≥ α,β-meATP ≥ Ap ₄ A (rapid desensitization)	TNP-ATP, PPADS, A317491, NF110, Ip ₅ l, phenol red	Intrinsic cation channel
	P2X ₄	CNS, testis, colon	ATP > > α,β-meATP, CTP ivermectin potentiation	TNP-ATP (weak), BBG (weak), phenolphthalein	Intrinsic ion channel (especially Ca ²⁺)
	P2X ₅	Proliferating cells in skin, gut, bladder, thymus, spinal cord	ATP > > α,β-meATP, ATPγS	Suramin, PPADS, BBG	Intrinsic ion channel
	P2X ₆	CNS, motor neurons in spinal cord	– (does not function as homomultimer)	–	Intrinsic ion channel
	P2X ₇	Apoptotic cells in, for example, immune cells, pancreas, skin	BzATP > ATP ≥ 2-MeSATP > > α,β-meATP	KN62, KN04, MRS2427, O-ATP Coomassie brilliant blue G	Intrinsic cation channel and a large pore with prolonged activation
P2Y	P2Y ₁	Epithelial and endothelial cells, platelets, immune cells, osteoclasts	2-MeSADP = ADPβS > 2-MeSATP = ADP > ATP, MRS2365	MRS2179, MRS2500, MRS2279, PIT	G _q /G ₁₁ ; PLC-β activation

Purinergic System. Table 1 Receptor subtypes for purines and pyrimidines: distribution, agonists, antagonists and transduction mechanisms (updated and reprinted from Burnstock G (2003) Introduction: ATP and its metabolites as potent extracellular agonists. In: Schwiebert EM (ed) Current topics in membranes, vol 54. Purinergic receptors and signalling. Academic Press, San Diego, pp 1–27, with permission from Elsevier) (Continued)

Receptor		Main distribution	Agonists	Antagonists	Transduction mechanisms
	P2Y ₂	Immune cells, epithelial and endothelial cells, kidney tubules, osteoblasts	UTP = ATP, UTP γ S, INS 37217, INS 365	Suramin > RB2, AR-C126313	G _q /G ₁₁ and possibly G _i ; PLC- β activation
	P2Y ₄	Endothelial cells	UTP \geq ATP, UTP γ S, INS 37217	RB2 > suramin	G _q /G ₁₁ and possibly G _i ; PLC- β activation
	P2Y ₆	Some epithelial cells, placenta, T cells, thymus	UDP > UTP > > ATP, UDP β S, IDP	MRS2578	G _q /G ₁₁ ; PLC- β activation
	P2Y ₁₁	Spleen, intestine, granulocytes	AR-C67085MX > BzATP \geq ATP γ S > ATP	Suramin > RB2, NF157, 5'-AMPS	G _q /G ₁₁ and G _s ; PLC- β activation
	P2Y ₁₂	Platelets, glial cells	2-MeSADP \geq ADP > > ATP	CT50547, AR-C69931MX, INS49266, AZD6140, PSB0413, ARL66096, 2-Me-SAMP	G _{i/o} ; inhibition of adenylate cyclase
	P2Y ₁₃	Spleen, brain, lymph nodes, bone marrow	ADP = 2-MeSADP > > ATP = 2-Me-SATP	MRS2211, 2-Me-SAMP	G _{i/o}
	P2Y ₁₄	Placenta, adipose tissue, stomach, intestine, discrete brain regions	UDP glucose = UDP-galactose	–	G _q /G ₁₁

Ap₄A, diadenosine tetraphosphate; BBG, Brilliant blue green; BzATP, 2'-&3'-O-(4-benzoyl-benzoyl)-ATP; cAMP, cyclic AMP; CCPA, chlorocyclopentyl adenosine; CPA, cyclopentyl adenosine; CTP, cytosine triphosphate; DPCPX, 8-cyclopentyl-1,3-dipropylxanthine; IP₃, inosine triphosphate; Ip₅I, diinosine pentaphosphate; α,β -meATP, α,β -methylene ATP; β,γ -meATP, β,γ -methylene ATP; 2-MeSADP, 2-methylthio ADP; 2-MeSAMP, 2-methylthio AMP; 2-MeSATP, 2-methylthio ATP; NECA, 5'-N-ethylcarboxamido adenosine; PPADS, pyridoxal-phosphate-6-azophenyl-2', 4'-disulfonic acid; PLC, phospholipase C; RB2, reactive blue 2; TNP-ATP, 2',3'-O-(2,4,6-trinitrophenyl) ATP.

protein-coupled muscarinic receptors. In the gut, ATP released from NANC inhibitory nerves produces the fastest response, nitric oxide gives a less rapid response, and vasoactive intestinal peptide produces slow tonic relaxations. In all cases of **▶cotransmission**, there are considerable differences in the proportion of the cotransmitters in nerves supplying different regions of the gut or vasculature, in different developmental or pathophysiological conditions and between species.

The first clear evidence for nerve-nerve purinergic **▶synaptic transmission** was in 1992, when it was

shown that excitatory postsynaptic potentials in the celiac ganglion and in the medial habenula in the brain were reversibly antagonized by suramin, a P2 receptor antagonist. Since then, there have been many articles describing either the distribution of various P2 receptor subtypes in the brain and spinal cord or electrophysiological studies of the effects of purines in brain slices, isolated nerves and glial cells. Synaptic transmission has also been found in the myenteric plexus and in various sensory, sympathetic and pelvic ganglia.

Purinergic System. Figure 2 Schematic of sympathetic cotransmission. ATP and NA released from small granular vesicles (SGV) act on P2X and α_1 receptors on smooth muscle, respectively. ATP acting on inotropic P2X receptors evokes excitatory junction potentials (EJPs), increase in intracellular calcium ($[Ca^{2+}]_i$) and fast contraction; while occupation of metabotropic α_1 -adrenoceptors leads to production of inositol triphosphate (IP_3), increase in $[Ca^{2+}]_i$ and slow contraction. Neuropeptide Y (NPY) stored in large granular vesicles (LGV) acts after release both as a prejunctional inhibitory modulator of release of ATP and NA and as a postjunctional modulatory potentiator of the actions of ATP and NA. Soluble nucleotidases are released from nerve varicosities, and are also present as ectonucleotidases. (Reproduced from Burnstock G (2007) Neurotransmission, neuromodulation: cotransmission. Short-Term Non-Neuronal Signalling

There are many examples of purinoceptor-mediated responses in non-neuronal cell types [3]. ► **Endothelial cells**, which express P2Y₁, P2Y₂ and probably P2Y₆ and P2X₄ receptors, when occupied, release nitric oxide leading to vasodilatation (Fig. 3). The more recent discovery of P2X receptors in endothelial cells suggests a role regulating gap and tight junctions involved in permeability and in cell adhesion. P2Y₁ receptors in pancreatic β -cells have been shown to be involved in insulin secretion, and P2Y₂ receptors are present on hepatocytes. P2Y₁₂, P2X₁ and P2Y₁ receptors are expressed in platelets and P2Y₁ and P2Y₂ receptors on non-myelinating and myelinating Schwann cells, respectively. Purinergic receptors are also involved in signalling to endocrine cells, leading to hormone secretion and in neuron-glia cell interactions.

Long-Term (Trophic) Signalling

Purinergic signalling is also concerned with long-term events, such as cell proliferation, migration, differentiation and death associated with development and regeneration [1, 3, 4]. For example, α,β -methylene ATP produces proliferation of glial cells, whereas adenosine inhibits proliferation. A p2y8 receptor was

cloned from the frog embryo, which appears to be involved in the development of the neural plate. P2Y₁ receptors seem to have a role in cartilage development in limb buds and in development of the mesonephros. P2X₅ and P2X₆ receptors have been implicated in the development of chick skeletal muscle. In recent studies of purinoceptor expression in developing mouse myotubes, there was progressive expression of P2X₅, P2X₆ and P2X₂ receptors. The P2X₁ receptor is prominent in contractile smooth muscle phenotype, but is absent in the synthetic smooth muscle phenotype grown in culture, while P2Y receptor expression is substantially increased. There are several reports showing that P2X and P2Y receptors in ► **osteoclasts** and ► **osteoblasts** are involved in bone development and remodelling.

Pathophysiology and Therapeutic Potential

There is increasing interest in the therapeutic potential of purinergic compounds in relation to both P1 and P2 receptors [4]. A number of purine-related compounds have been patented.

It is well established that the ► **autonomic nervous system** shows marked plasticity. The expression of cotransmitters and receptors shows dramatic changes during development and ageing, in nerves that remain

Purinergic System. Figure 3 A schematic representation of the interactions of ATP released from perivascular nerves and from the endothelium (ENDOTH.). ATP and UTP are released from endothelial cells during changes in blood flow (sheer stress) and hypoxia to act on endothelial P2Y and P2X receptors leading to production of EDRF (nitric oxide) and subsequent vasodilatation (-). In contrast, ATP released as a cotransmitter with noradrenaline (NA) from perivascular sympathetic nerves at the adventitia (ADVENT.)/muscle border produces vasoconstriction (+) via P2X receptors on the muscle cells. Adenosine (ADO), resulting from rapid breakdown of ATP by ectoenzymes, produces vasodilatation by direct action on the muscle via P1 receptors and acts on the perivascular nerve terminal varicosities to inhibit transmitter release. (Modified from Burnstock G (1987) Local control of blood pressure by purines. *Blood Vessels* 24:156–160, reproduced with permission from Karger AG).

after trauma or surgery and in disease conditions. There are now a number of examples where the purinergic component of cotransmission is increased in pathological conditions [4]. Purinergic nerve-mediated contractions of the human bladder are increased up to 40% in pathophysiological conditions such as interstitial cystitis, outflow obstruction and probably also neurogenic bladder. ATP plays a significantly greater cotransmitter role in sympathetic nerves supplying hypertensive blood vessels. Upregulation of P2X₁ and P2Y₂ receptor mRNA

in hearts of rats with congestive heart failure has been reported. Adenosine modulates long-term synaptic plasticity in the hippocampus; it attenuates long-term potentiation (LTP); P1 receptor antagonists facilitate LTP. It is suggested that adenosine-related compounds might prove helpful in the treatment of memory disorders and intellectual performance related to caffeine intake.
