Preface to the First Edition

The era of pharmacology, the science concerned with the understanding of drug action, began only about 150 years ago when Rudolf Buchheim established the first pharmacological laboratory in Dorpat (now, Tartu, Estonia). Since then, pharmacology has always been a lively discipline with “open borders”, reaching out not only to other life sciences such as physiology, biochemistry, cell biology and clinical medicine, but also to chemistry and physics. In a rather successful initial phase, pharmacologists devoted their time to describing drug actions either at the single organ level or on an entire organism. Over the last few decades, however, research has focused on the molecular mechanisms by which drugs exert their effects. Here, cultured cells or even cell-free systems have served as models. As a consequence, our knowledge of the molecular basis of drug actions has increased enormously. The aim of *Encyclopedic Reference of Molecular Pharmacology* is to cover this rapidly developing field.

The reductionist approach described above has made it increasingly important to relate the molecular processes underlying drug actions to the drug effect on the level of an organ or whole organism. Only this integrated view will allow the full understanding and prediction of drug actions, and enable a rational approach to drug development. On the molecular or even atomic level, new disciplines such as bioinformatics and structural biology have evolved. They have gained major importance within the field but are particularly relevant for the rational development and design of new drugs. Finally, the availability of the complete genome sequence of an increasing number of species provides a basis for systematic, genome-wide pharmacological research aimed at the identification of new drug targets and individualised drug treatment (pharmacogenomics and pharmacogenetics). All these aspects are considered in this encyclopedia.

The main goal of the *Encyclopedia* is to provide up-to-date information on the molecular mechanisms of drug action. Leading experts in the field have provided 159 essays, which form the core structure of this publication.

Most of the essays describe groups of drugs and drug targets, with the emphasis not only on already exploited drug targets, but also on potential drug targets as well. Several essays deal with the more general principles of pharmacology, such as drug tolerance, drug addiction or drug metabolism. Others portray important cellular processes or pathological situations and describe how they can be influenced by drugs. The essays are complemented by more than 1600 keywords, for which links are provided. By looking up the keywords or titles of essays highlighted in each essay, the reader can obtain further information on the subject. The alphabetical order of entries makes the *Encyclopedia* very easy to use and helps the reader to search successfully. In addition, the names of authors are listed alphabetically, together with the title of their essay, to allow a search by author name.

Apart from very few exceptions, the entries in the main text do not contain drug names in their titles. Instead, drugs that are commonly used all over the world are listed in the Appendix. Also included in the Appendix are four extensive sections that contain tables listing proteins such as receptors, transporters or ion channels, which are of particular interest as drug targets or modulators of drug action.

The *Encyclopedia* provides valuable information for readers with different expectations and backgrounds (from scientists, students and lecturers to informed lay-people) and fills the gap between pharmacology textbooks and specialized reviews.

All the contributing authors as well as the editors have taken great care to provide up-to-date information. However, inconsistencies or errors may remain, for which we assume full responsibility. We welcome comments, suggestions or corrections and look forward to a stimulating dialog with the readers of the *Encyclopedic Reference of Molecular Pharmacology* whether their comments concern the content of an individual entry or the entire concept.

We are indebted to our colleagues for their excellent contributions. It has been a great experience, both personally and scientifically, to interact with and learn from the 200 plus contributing authors. We would also like to thank Ms. Hana Deuchert and Ms. Katharina Schmalfeld for their excellent and invaluable secretarial assistance during all the stages of this project. Within Springer-Verlag, we are grateful to Dr. Thomas Mager for suggesting the project and to Frank Krabbes for his technical expertise. Finally, we would like to express our gratitude to Dr. Claudia Lange for successfully managing the project and for her encouraging support. It has been a pleasure to work with her.

Heidelberg/Berlin, June 2003

STEFAN OFFERMANN AND WALTER ROSENTHAL

Preface to the Second Edition

The first edition of the *Encyclopedic Reference of Molecular Pharmacology* was well received by its readers, thanks to the excellent work done by the authors, of whom most have contributed to the second edition as well. The basic structure of the Encyclopedia has remained unchanged. It is primarily based on essays, which have been updated, and their number has been increased to 225 to include many new exciting areas. These essays cover important drugs and drug targets, but also general principles of pharmacology as well as cellular processes and pathological situations which are relevant for drug action. In addition, there are about xy key words linked to the essays. The Encyclopedia is complemented by an Appendix, which has been greatly enlarged, listing more than 700 drugs and more than 4,000 proteins that act as receptors, membrane transport proteins, transcription factors, enzymes or adhesion molecules.

During the preparation, we greatly enjoyed the interaction with all our colleagues who contributed to this reference work. It has been a pleasure and an enriching experience to deal with so many facets of pharmacology. We are very thankful to the contributing authors for the careful updating of their essays, and, in particular, we would like to express our gratitude to the more than xy new authors who have written excellent essays on novel topics. Finally, we would like to thank Dr. Michaela Bilic and Simone Giesler from Springer for their enthusiasm throughout the project and their constant support.

- ▶ Two-dimensional Electrophoresis
- ▶ Proteomics

14-3-3 σ

The 14-3-3 proteins constitute a family of abundant, highly conserved and broadly expressed acidic polypeptides. One member of this family, the 14-3-3 σ isoform {sigma}, is expressed only in epithelial cells and is frequently down-regulated in a variety of human cancers and plays a role in the cellular response to DNA damage. The 14-3-3s generally form heterodimers with other family members, but 14-3-3 σ preferentially forms homodimers in cells. Three amino acids that are completely conserved in all other 14-3-3s, are not present in 14-3-3 σ . These amino acids unique to 14-3-3 σ confer a second ligand-binding site involved in 14-3-3 σ -specific ligand discrimination.

Protein kinase A anchoring proteins

Definition

AKAPs are a diverse family of about 75 scaffolding proteins. They are defined by the presence of a structurally conserved protein kinase A (PKA)-binding domain. AKAPs tether PKA and other signalling proteins to cellular compartments and thereby limit and integrate cellular signalling processes at specific sites. This compartmentalization of signalling by AKAPs contributes to the specificity of a cellular response to a given external stimulus (e.g. a particular hormone or neurotransmitter).

Basic Mechanisms

AKAP-dependent Control of cAMP/PKA Signalling

A large variety of extracellular stimuli including hormones and neurotransmitters elicit the generation of the second messenger cyclic adenosine monophosphate (cAMP). Cyclic AMP binds to several effector proteins including ion channels, cAMP-dependent guanine-nucleotide-exchange factors (Epacs) and PKA. The latter is the main effector of cAMP. Binding of four molecules of cAMP activates the kinase. Activated PKA transfers a phosphate group from adenosine triphosphate (ATP) to consensus sites on many different substrate proteins and thereby modulates their activity. It appears that different external stimuli mediate activation of specific pools of PKA located at defined sites within cells (compartments) including, for example mitochondria, nuclei, exocytic vesicles, sarcoplasmic reticulum and the cytosol [1]. A kinase anchoring proteins (AKAPs; Fig. 1) tether PKA to such cellular compartments and allow for its local activation, and consequent phosphorylation of particular substrates in close proximity [2]. Spatial and temporal coordination of PKA signalling through compartmentalization by AKAPs is considered essential for the specificity of PKA-dependent cellular responses to a particular external stimulus [3, 4]. AKAP-PKA interactions play a role in a variety of cellular processes including β -adrenoceptor-dependent regulation of cardiac myocyte contraction (Fig. 2), vasopressin-mediated water reabsorption, proton secretion from gastric parietal cells, modulation of insulin secretion from pancreatic β cells and T cell receptor signalling. A typical AKAP is AKAP18 α , also termed AKAP15. It tethers PKA to ▶L-type Ca²⁺ channels in

A Kinase Anchoring Proteins (AKAPs).

Figure 1 Model of an A kinase anchoring protein (AKAP). The unifying characteristic of AKAPs is the presence of a structurally conserved binding domain for the dimer of regulatory (R) subunits of PKA (RBD, regulatory subunit binding domain). In the inactive state, PKA forms a tetramer consisting of a dimer of R subunits each bound to one catalytic subunit (C). Binding of two molecules of cAMP to each R subunit causes a conformational change and release of the C subunits, which in the free form phosphorylate substrate proteins in close proximity. The RBD in all AKAPs with pericentrin as the only exception forms an amphipathic helix that docks into a hydrophobic pocket formed by the dimerization and docking domain of R subunits. The targeting domain, which tethers the AKAP complex to cellular compartments and docking domains, which bind further signalling proteins (e.g. phosphodiesterases, phosphatases or other kinases) are specific for individual AKAPs. A few AKAPs possess catalytic activity such as the RhoGEF-activity in AKAP-Lbc conferred by a DH domain. The proteins within the AKAP family are without obvious sequence homology.

cardiac myocytes and skeletal muscle cells and facilitates their phosphorylation in response to β -adrenoceptor activation. The phosphorylation increases the open probability of the channel.

The tethering of PKA through AKAPs by itself is not sufficient to compartmentalize and control a cAMP/PKA-dependent pathway. Cyclic AMP readily diffuses throughout the cell. Therefore, discrete cAMP/PKA signalling compartments are only conceivable if this diffusion is limited. ► **Phosphodiesterases** (PDE) establish gradients of cAMP by local hydrolysis of the

A Kinase Anchoring Proteins (AKAPs).

Figure 2 β -adrenoceptor-induced increases in cardiac myocyte contractility depend on AKAP–PKA interactions. Stimulation of β -adrenoceptors (β_1 AR) on the surface of cardiac myocytes by binding of adrenergic agonists such as norepinephrine (NE), epinephrine or isoproterenol increases contractility of the heart. Agonist binding to the receptors activates the G protein G_s and adenylyl cyclase (AC), and consequent synthesis of cAMP which binds to regulatory (R) subunits of protein kinase A (PKA) inducing dissociation of catalytic (C) subunits (see also Fig. 1). The C subunits phosphorylate L-type Ca^{2+} channels located in the plasma membrane (plasmalemma) and ryanodine receptors (RyR_2) embedded in the membrane of the sarcoplasmic reticulum (SR). Phosphorylation of the two channel proteins increases their open probability and leads to an increase in cytosolic Ca^{2+} causing increased contractility. For the relaxation of cardiac myocytes, Ca^{2+} has to be removed from the cytosol. A pivotal role in this plays sarcoplasmic Ca^{2+} ATPase (SERCA). It pumps Ca^{2+} back into the SR. SERCA is inhibited when bound to phospholamban (PLB) and activated upon dissociation from PLB, which is induced by β -adrenoceptor-mediated PKA phosphorylation. Collectively, the PKA phosphorylation events increase cardiac myocyte contractility. The efficient phosphorylation of L-type Ca^{2+} channels occurs only if PKA is anchored to the channel by AKAP18 α . For the phosphorylation of RyR , PKA anchoring to this channel by mAKAP is a prerequisite. Further AKAPs are likely to be involved in PKA-dependent phosphorylation events in response to β -adrenoceptor stimulation (e.g. PLB).

second messenger and thereby regulate PKA activity locally. Several AKAPs interact with PDEs and thus play a role at this level of control. For example, the interaction of muscle-specific mAKAP with cAMP-specific PDE4D3 and the ► **ryanodine receptor** (RyR)

facilitates hydrolysis of cAMP in the vicinity of RyR at the sarcoplasmic reticulum of cardiac myocytes. Local cAMP hydrolysis keeps mAKAP-associated PKA activity low. An increase in the cAMP level exceeding the PDE4D3 hydrolyzing capacity activates PKA, which phosphorylates RyR and increases the open probability of this Ca²⁺ channel. PKA also phosphorylates mAKAP-bound PDE4D3 and thereby enhances PDE4D3 activity. This again increases local cAMP hydrolysis, switches off PKA, and eventually reduces RyR phosphorylation. This negative feedback loop regulating RyR phosphorylation is completed by association of mAKAP with protein phosphatase 2A (PP2A), dephosphorylating RyR. Dephosphorylation decreases the channel open probability of RyR.

AKAP-dependent Integration of Cellular Signalling

In addition to PKA, PDEs and protein phosphatases involved in cAMP signalling, AKAPs interact with other signalling proteins whose activation depends on second messengers other than cAMP, e.g. Ca²⁺. AKAPs may bind additional kinases such as protein kinases C (PKC) and D (PKD), and further protein phosphatases such as calcium/calmodulin-dependent phosphatase (calcineurin, protein phosphatase 2B, PP2B). This scaffolding function allows AKAPs to integrate cellular signalling processes. For example, rat AKAP150 and its human ortholog AKAP79 bind PKA, PKC and calcineurin. In neurons, AKAP150-bound PKC is activated through a M₁ muscarinic receptor-induced pathway that depends on the G protein G_q and leads to elevation of cytosolic Ca²⁺ and diacylglycerol. AKAP150 interacts directly with M channels (K⁺ channel negatively regulating neuronal excitability) and facilitates PKC phosphorylation and thereby inhibition of this channel. AKAP79 coordinates the phosphorylation of ▶AMPA channels. Cyclic AMP-activated AKAP79-bound PKA phosphorylates and thereby activates the channels. A raise of cytosolic Ca²⁺ activates AKAP79-bound calcineurin, which in turn dephosphorylates the channels. The dephosphorylation mediates the rundown of AMPA channel currents.

AKAP-Lbc binds PKA, PKC and PKD and possesses intrinsic catalytic activity (Rho guanine nucleotide exchange factor (RhoGEF) activity). Through its RhoGEF activity it catalyses the exchange of GDP for GTP on the ▶small GTPase Rho. The GTP form of Rho is active and induces the formation of F-actin-containing stress fibres. Agonists stimulating receptors coupled to the G protein G_s may mediate activation of AKAP-Lbc-bound PKA, which in turn phosphorylates AKAP-Lbc. Subsequently, a protein of the ▶14-3-3 family binds to the phosphorylated site and inhibits the RhoGEF activity. In contrast, agonists stimulating receptors coupled to the G protein G₁₂ increase the RhoGEF activity.

AKAPs Optimise the Limited Repertoire of Cellular Signalling Proteins

Intriguingly, the same AKAP may coordinate regulation of different target proteins. In hippocampal neurons, AKAP150 positions PKA and calcineurin to modulate AMPA channels and maintains PKC inactive. In superior ganglial neurons, AKAP150 facilitates PKC phosphorylation of M channels while keeping PKA and calcineurin inactive. The difference is due to the interaction of AKAP150 with the scaffolding protein SAP97, which occurs in hippocampal neurons but not in superior ganglial neurons. SAP97 positions AKAP150 such that PKA and calcineurin are in close proximity to AMPA channels. Thus by variation of a single interacting partner an AKAP optimises the usage of the limited set of cellular signalling proteins.

In summary, the function of AKAPs goes far beyond controlling cAMP/PKA signalling by simply tethering PKA to cellular compartments and confining the access of PKA to a limited set of local substrates. AKAPs are scaffolds forming multiprotein signal transduction modules, recently termed “AKAPosomes” that coordinate and integrate cellular signalling processes.

Pharmacological Intervention

Disturbances of compartmentalized cAMP signalling in processes such as the ones mentioned above cause or are associated with major diseases including congestive heart failure, diabetes insipidus, diabetes mellitus, obesity, diseases of the immune system (e.g. AIDS), cancer and neurological disorders including schizophrenia. However, AKAPs participating in compartmentalized cAMP signalling networks are not targeted by drugs which are currently applied for the treatment of such diseases.

Recently, clinically relevant intracellular protein–protein interactions have gained much interest as potential drug targets. The cell-type specificity of such interactions and the finding that mostly only selected isoforms of proteins interact with each other offers great opportunities for highly selective pharmacological intervention. For targeting AKAP-dependent protein–protein interactions, peptides non-selectively displacing PKA from all AKAPs have been developed so far. For example, the peptides functionally uncouple PKA from L-type Ca²⁺ channels in cardiac myocytes by disruption of the AKAP18α–PKA interaction that facilitates L-type Ca²⁺ channel phosphorylation (see above). This prevents β-adrenoceptor-induced increases in cytosolic Ca²⁺, an effect resembling that of β-blockers. In renal collecting duct principal cells, vasopressin regulates water reabsorption from primary urine by triggering the PKA phosphorylation and subsequent redistribution of aquaporin-2 (AQP2) from intracellular vesicles into the plasma membrane. The redistribution depends on

the compartmentalization of PKA by AKAPs, one of which is AKAP18 δ . The PKA anchoring disruptor peptides displace PKA from AQP2-bearing vesicles and inhibit vasopressin-mediated water reabsorption, i.e. have an aquaretic effect. These examples suggest that cell-type specific pharmacological intervention at selected AKAP–PKA interactions is a feasible concept for the treatment of human diseases (e.g. cardiovascular disease or diseases associated with water retention).

Synonyms

ATP-binding cassette proteins; ABC-proteins

Definition

The ►ABC-transporter superfamily represents a large group of transmembrane proteins. Members of this family are mainly involved in ATP-dependent transport processes across cellular membranes. These proteins are of special interest from a pharmacological point of

view because of their ability to transport numerous drugs, thereby modifying intracellular concentrations and hence effects.

Basic Characteristics

ATP-binding cassette (ABC-) proteins have been identified in all living organisms; they are present in plants, bacteria, and mammals. In humans the ABC-superfamily comprises about 50 members; on the basis of homology relationships this superfamily is organized in several subfamilies named ABCA to ABCF. Not all of them are pharmacologically important, for example, members of the A branch are mainly involved in lipid trafficking. ABCB2 as well as ABCB3, which are also termed as *transporter associated with antigen processing* (TAP), are involved in the transport of peptides presented by Class I HLA molecules. However, other ABC-transporters like ABCB1 (►P-glycoprotein, P-gp), ABCG2 (*breast cancer resistance protein*, BCRP) and several members of the C-branch are of high pharmacological relevance because they are involved in transport of several drugs; thereby affecting pharmacokinetic parameters.

ABCB1, for example, which is also known as P-glycoprotein (P-gp) and probably the best characterized ABC-transporter, has been identified as the underlying mechanism of a cancer-related phenomenon called ►multidrug resistance (therefore, P-gp is also termed *multidrug resistance protein* (MDR1)), which is characterized by the resistance of cancer cells against drug therapy. Interestingly, this phenomenon is not directed against a single drug or structurally related entities, but comprises unrelated compounds with different target structures. Meanwhile, besides P-gp further ABC-transporters have been identified to be involved in this process. For example, in 1992 Cole et al. identified the first member of the so-called *multidrug resistance related proteins* (MRP). The ►MRP-proteins (MRP1–MRP9) belong to the C-branch of the ABC-superfamily, which currently consists of a total of 13 members (ABCC1–ABCC13). In addition to ABCB1 and the ABCC family, a member of the ABCG family has recently been demonstrated to confer drug resistance. This protein called *breast cancer resistant protein* (►BCRP/ABCG2) was first identified in mitoxantrone resistant cell lines, which lack expression of P-gp or MRP1.

Topology and Structure

Most ABC-transporters, especially those located in the plasma membrane, are phosphorylated and glycosylated transmembrane proteins of different molecular weights (e.g., P-gp: 170 kDa; MRP2: 190 kDa; BCRP: 72 kDa). Topologically, most ABC-transporter show a similar structure: they are organized in two transmembrane domains (TMD), each consisting of six

α -helical, transmembranal segments and two ATP binding domains linked to the C-terminus of the TMDs. These domains, which are also termed *nucleotide binding folds* (NBFs), contain the highly conserved Walker A and B consensus motifs and the LSGGQ motif (also called C- or signature motif). While the Walker A and B motifs are also found in other ATP-hydrolyzing ATP proteins, the LSGGQ motif is unique for the ABC-transporters. The ATP hydrolysis catalyzed by the NBFs is a prerequisite for substrate binding and enables transport against a substrate gradient. In addition to these general characteristics, several members of the ABCC-family (e.g., ABCC1–3) contain a further N-terminal TMD, which, however, is not required for transport activity. In contrast to the other TMDs, this N-terminal TMD contains five transmembranal segments and lacks the NBF. Besides this structural variant some other ABC-transporters (e.g., ABCB2, 3 (TAB1 and 2), as well as ABCG2) contain only one

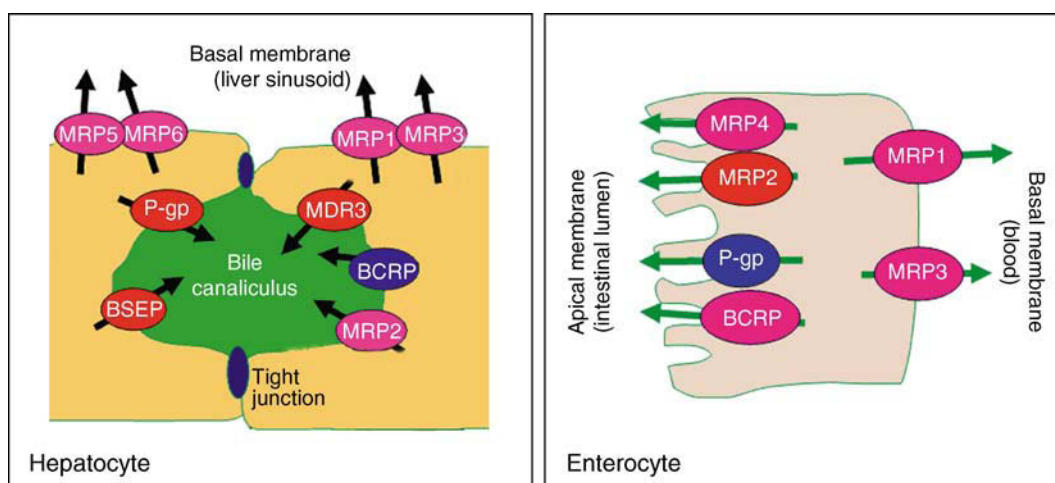

TMD and NBF (Fig. 1). Therefore, these transporters are termed *half transporter* (in contrast to *full transporter*); however, to achieve functional activity they have to form hetero- or homodimers.

Tissue Distribution and Expression

Although initially detected in cancer cell lines ABC-transporters show a wide tissue distribution. Several members of drug transporting ABC-proteins, for example, are highly expressed in physiological barriers such as the apical membrane of gut enterocytes, the endothelial cells of the blood–brain barrier or the maternal facing (apical) membrane of the placental syncytiotrophoblast. In all of these organs they protect sensitive tissues like brain or the growing fetus against potentially toxic compounds. In addition, ABC-transporter expression is highly abundant in hepatocytes (Fig. 2). Here, ABC-transporters are involved in detoxification of many endogenous and exogenous

ABC Transporters. Figure 1 Structure of ABCB1, ABCC1, and ABCG2 (NBF: *nucleotide binding fold*; TMD: *transmembrane domain*). Modified according to www.iwaki-kk.co.jp/bio/specialedition/se02.htm.

ABC Transporters. Figure 2 ABC-transporter expression in hepatocytes and enterocytes (modified according to www.iwaki-kk.co.jp/bio/specialedition/se02.htm).

agents and are therefore expressed both in the canalicular and sinusoidal membrane. The canalicular expression is a prerequisite for biliary elimination. For example, the *bile salt export pump* (BSEP/ABCB11) is transporting bile salts, MRP2 (ABCC2) is involved in the elimination of organic anions like bilirubin-glucuronide or glutathione-conjugates and finally, P-gp (ABCB1) eliminates a wide variety of drugs into the bile. In contrast, other ABC-transporters like MRP1 (ABCC1) and 3 (ABCC3) are mainly located in the basal membrane of hepatocytes. They transport xenobiotics and several conjugates back to the blood and seem to be important under certain pathophysiological conditions, for example, hepatic expression of both transporters is enhanced during cholestasis, thereby protecting the hepatocytes against toxic bile acid concentrations by transport into the blood followed by increased renal elimination.

Various ABC-transporters are expressed in organs like heart, lung, pancreas, or cellular blood compounds. They may be important both for physiological processes and local drug concentrations. In this context, it is noteworthy that many of these transporters not only eliminate xenobiotic and toxic compounds from the cell, but also endogenous compounds. For example, MRP4, 5, and 8 (ABCC4, 5, and 11), which are expressed in many tissues and cancer cells, not only transport xenobiotics like nucleotide-based anticancer drugs but also the second messenger molecules cAMP and cGMP. Thereby, these transporters may play a role in regulating intra- and extracellular cyclic nucleotide concentrations.

ABC-Transporters and Disease

Based on their physiological function it is not surprising that genetic polymorphisms affecting expression and

function of ABC-proteins have been identified as the underlying mechanisms for some diseases. For example, mutations in the MRP2 (ABCC2) gene, which lead to the loss of this protein from the canalicular membrane of hepatocytes, are the mechanism of the **Dubin–Johnson Syndrome**. Here, the biliary elimination of MRP2 substrates like bilirubin and bilirubin-glucuronide is blocked; therefore the respective plasma levels are elevated leading to the disease. Another example is ABCC7, which is also called *cystic fibrosis transmembrane conductance regulator* (CFTR) and forms an anion channel in different tissues like the epithelial surfaces of the respiratory and intestinal tract. As its alias indicates, ABCC7 is involved in the pathogenesis of *cystic fibrosis*, because mutations in the ABCC7 gene associated with dysfunction or epithelial absence of the transporter are the underlying reason for the incorrect ion homeostasis, especially for chloride, which is the predominate anion transported by ABCC7 under physiological conditions.

Drugs

In this context, two aspects are important. First, many drugs are substrates of ABC-transporters and therefore these transporters might affect the bioavailability of these substances. Tissues like liver, intestine, and kidney exhibit high expression levels of different transport proteins. Therefore, substrates of these transporters may be intensively eliminated to the bile and urine or transported back to the intestine, thereby limiting oral bioavailability. Besides these pharmacokinetic important organs, ABC-transporters are expressed in target tissues of certain drugs. As already mentioned this point carries an unsolved problem in chemotherapy because many anticancer drugs are ABC-transporter substrates and tumor cells often show an enhanced

transporter expression and therefore MDR. However, this problem is not restricted to cancer therapy. For example, ABC-transporters are also expressed in the ►blood–brain barrier; thereby limiting the access of drugs to the brain. While this is useful for drugs like loperamide, a morphine-based drug against diarrhea, it might be a problem in the case of antipsychotic and antiepileptic drugs. A list of ABC-transporters and their substrates is given in Table 1.

Second, as already shown for P450 enzymes before, there is also a drug-interaction potential on the transporter level. The promoter regions of some ABC-transporter genes (e.g., P-gp) contain transcription factor binding sites like the *pregnane X receptor* (PXR), the *constitutive androstane receptor* (CAR), the *farnesoid X receptor* (FXR), the *steroid and xenobiotic receptor* (SXR) or the *peroxisome proliferator-activated receptor* (PPAR). Therefore, these proteins are not only regulated by endogenous compounds like bile acids or steroid hormones but also by therapeutic agents like phenobarbital, rifampicin, or dexamethasone. This regulation might be accompanied by an altered bioavailability of transporter substrates, when coadministered with these compounds. For example, the decreased bioavailability of digoxin, a P-gp substrate, after coadministration of rifampicin is due to an enhanced intestinal P-gp expression. On the other hand, many compounds are inhibitors of ABC-transporters (in the case of P-gp, for example, verapamil, ketoconazole, amiodarone, progesterone, indinavir, clarithromycin, cyclosporine, chlorpromazine, or methadone), which in turn leads to higher

plasma levels after coadministration of substrates for these transporters.

In addition, ABC-transporters demonstrate interindividual variability caused by genetic polymorphisms. Again, the *ABCB1* (P-gp) is the best characterized transporter in this field. Here, various synonymous and nonsynonymous polymorphisms as well as deletions and insertions have been described. Some of the nonsynonymous *single nucleotide polymorphisms* (SNPs) have already been shown to be associated with an altered transport activity of the protein. Interestingly, this observation has also been made for the C- to T-variant at position 3435, which represents the most frequent synonymous SNP of *ABCB1*. This C3435T polymorphism could be associated with an altered protein expression and function of P-gp, because individuals homozygous for this polymorphism show a significant lower intestinal P-gp expression. This finding was underlined by elevated digoxin plasma levels in patients homozygous for this SNP in comparison with the wild type. Recent data suggest that the altered protein expression and function of this variant may be due to the presence of a rare codon, which affects the timing of cotranslational folding and insertion of the protein into the membrane.

Taken together ABC-transporters represent a large family of proteins affecting the pharmacokinetic parameters of various drugs. Here, P-gp is currently the best characterized member and it may also be one of the most important ABC-transporters with regard to drug transport. However, it becomes more and more apparent that ABC-transporter act in a coordinated

ABC Transporters. Table 1 Substrates of ABC-transporters involved in multidrug resistance (MDR)

ABC-transporter	Transporter substrates
P-gp (ABCB1)	Verapamil, digoxin, mitoxantrone, vinblastine, doxorubicin, losartan, talinolol, cortisol, dexamethasone, colchicine, loperamide, domperidone, indinavir, erythromycin, tetracycline, itraconazole, cyclosporine, methotrexate, amitriptyline, phenobarbital, morphine, cimetidine, and others
MRP1 (ABCC1)	Glucuronides and sulfate conjugates of steroid hormones and bile salts, colchicine, doxorubicin, daunorubicin, epirubicin, folate, irinotecan, methotrexate, paclitaxel, vinblastine, vincristine, and others
MRP2 (ABCC2)	LTC ₄ , bilirubin-glucuronide, estradiol 17 β -glucuronide, dianionic bile salts, anionic conjugates, glutathione disulfide, and others
MRP3 (ABCC3)	Organic anions including bile salts
MRP4 (ABCC4)	PMEA, PMEG, ganciclovir, AZT, 6-mercaptopurin, thioguanine, methotrexate, cAMP, cGMP, estradiol 17 β -glucuronide, DHEAS, sulphated bile acids, glutathione, PGE1, PGE2, and others
MRP5 (ABCC5)	PMEA, PMEG, cladribine, gemcitabine, cytarabine, 5-FU, 6-mercaptopurine, thioguanine, cAMP, cGMP, glutathione, DNP-SG, CdCl ₂ , and others
BCRP (ABCG2)	Cisplatin, folate, methotrexate, mitoxantrone, topotecan, irinotecan, steroids (cholesterol, testosterone, progesterone), certain chlorophyll metabolites, and others

fashion with other detoxification systems like P450 enzymes and **▶uptake transporters**. In particular, P-glycoprotein and Cytochrome P450 3A4 are closely intertwined in terms of regulation and function. Thus, further reviews have to address the combined action of various systems.

Absence Epilepsy

Absence Epilepsies are a group of epileptic syndromes typically starting in childhood or adolescence and characterized by a sudden lack of attention and mild automatic movements for some seconds to minutes. Absence epilepsies are generalized, i.e. the whole neocortex shifts into a state of sleep-like oscillations.

- ▶Antiepileptic Drugs

Absorption

Absorption is defined as the disappearance of a drug from the site of administration and its appearance in the

blood (“central compartment”) or at its site of action. The main routes of administration are oral or parenteral (injection). After oral administration, a drug has to be taken up (is absorbed) from the gut. Here, the main site of absorption is the small intestine. In this case, only a portion of drug reaches the blood and arrives at its site of action.

- ▶Pharmacokinetics

Abstinence Syndrome

The abstinence syndrome (synonym, withdrawal symptom) is observed after withdrawal of a drug to which a person is addicted. For example, the abstinence syndrome after alcohol withdrawal is characterized by tremor, nausea, tachycardia, sweating and sometimes hallucinations.

Synonyms

Angiotensin-converting enzyme inhibitors

Definition

Angiotensin converting enzyme (ACE) plays a central role in cardiovascular hemostasis. Its major function is the generation of angiotensin (ANG) II from ANG I and the degradation of bradykinin. Both peptides have profound impact on the cardiovascular system and beyond. ACE inhibitors are used to decrease blood pressure in hypertensive patients, to improve cardiac function, and to reduce work load of the heart in patients with cardiac failure.

Mechanism of Action

ACE inhibitors inhibit the enzymatic activity of ►angiotensin converting enzyme (ACE). This enzyme cleaves a variety of pairs of amino acids from the carboxy-terminal part of several peptide substrates. The conversion of ANG I to ANG II and the degradation of bradykinin to inactive fragments are considered the most important functions of ACE [1–3]. ACE inhibitors are nonpeptide analogues of ANG I. They bind tightly to the active sites of ACE, where they complex with a zinc ion and interact with a positively charged group as well as with a hydrophobic pocket. They competitively inhibit ACE with K_i values in the range between 10^{-10} and 10^{-11} [3].

Effects of ACE Inhibitors Mediated by the Inhibition of ANG II Generation

ANG II is the effector peptide of the renin–angiotensin system [1, 2]. ANG II is one of the most potent vasoconstrictors, facilitates norepinephrine release, stimulates aldosterone production, and increases renal sodium retention. In addition, ANG II is considered to be a growth factor, stimulating proliferation of various cell types. The actions of ANG II are mediated through two ►angiotensin receptors, termed AT_1 and AT_2 . Most of the cardiovascular functions of ANG II are mediated through the AT_1 receptor.

In some patients with hypertension and in all patients with cardiac failure, the renin–angiotensin system is activated to an undesired degree, burdening the heart. The consequences of diminished ANG II generation by ACE inhibitors are multiple. In patients with hypertension, blood pressure is reduced as a result

of (i) decreased peripheral vascular resistance, (ii) decreased sympathetic activity, and (iii) reduced sodium and water retention. In patients with cardiac failure, cardiac functions are improved as a result of (i) reduced sodium and water retention (preload and afterload reduction), (ii) diminished total peripheral resistance (afterload reduction), and (iii) reduced stimulation of the heart by the sympathetic nervous system. A reduction of cardiac hypertrophy appears to be another desired effect of ACE inhibitors. It is mediated at least partially by the reduction of intracardiac ANG II levels. ACE inhibitors furthermore protect the heart from arrhythmia during reperfusion after ischemia, and improve local blood flow and the metabolic state of the heart. These effects are largely mediated by Bradykinin (see below).

In the vasculature, ANG II not only increases contraction of smooth muscle cells, but is also able to induce vascular injury. This can be prevented by blocking ►NF κ B activation [3] suggesting a link between ANG II and inflammation processes involved in the pathogenesis of arteriosclerosis (see below). Thus, ACE inhibitors not only decrease vascular tone but probably also exert vasoprotective effects.

In the kidney, ANG II reduces renal blood flow and constricts preferentially the efferent arteriole of the glomerulus with the result of increased glomerular filtration pressure. ANG II further enhances renal sodium and water reabsorption at the proximal tubulus. ACE inhibitors thus increase renal blood flow and decrease sodium and water retention. Furthermore, ACE inhibitors are nephroprotective, delaying the progression of glomerulosclerosis. This also appears to be a result of reduced ANG II levels and is at least partially independent from pressure reduction. On the other hand, ACE inhibitors decrease glomerular filtration pressure due to the lack of ANG II-mediated constriction of the efferent arterioles. Thus, one important undesired effect of ACE inhibitors is impaired glomerular filtration rate and impaired kidney function.

Another effect of ANG II is the stimulation of ►aldosterone production in the adrenal cortex. ANG II increases the expression of steroidogenic enzymes, such as aldosterone synthase and stimulates the proliferation of the aldosterone-producing zona glomerulosa cells. Aldosterone increases sodium and water reabsorption at the distal tubuli. More recently it has been recognized that aldosterone is a fibrotic factor in the heart. ACE inhibitors decrease plasma aldosterone levels on a short-term scale, thereby not only reducing sodium retention but also preventing aldosterone-induced cardiac fibrotic processes. On a long-term scale, however, patients with cardiac failure exhibit high aldosterone levels even when taking ACE inhibitors.

In this context, it is important to note that circulating ANG II levels do not remain reduced during long-term treatment with ACE inhibitors. This is likely the result of activation of alternative, ACE-independent pathways of ANG II generation. The protective effects of ACE inhibitors on a long-term scale, therefore, are not explained by a reduction of circulating ANG II levels. They are either unrelated to inhibition of ANG II generation, or a result of the inhibition of local generation of ANG II. Indeed, due to the ubiquitous presence of ACE in endothelial cells, large amounts of ANG II are generated locally within tissues such as kidney, blood vessels, adrenal gland, heart, and brain, and exert local functions without appearing in the circulation [2]. Membrane-bound endothelial ACE, and consequently local ANG II generation, has been proved to be of greater significance than ANG II generated in plasma by the circulating enzyme. Experimental evidence also indicates that plasma ACE may in fact not be relevant to blood pressure control at all.

Effects of ACE Inhibitors Mediated by the Inhibition of Bradykinin Degradation

Kinins are involved in blood pressure control, regulation of local blood flow, vascular permeability, sodium balance, pain, inflammation, platelet aggregation and coagulation. Bradykinin also exerts antiproliferative effects [4]. In plasma, bradykinin is generated from high molecular weight (HMW) kininogen, while in tissues lys-bradykinin is generated from HMW and low molecular weight (LMW) kininogen. Several effects of bradykinin are explained by the fact that the peptide potently stimulates the NO-pathway and increases prostaglandin synthesis in endothelial cells. In smooth muscle cells and platelets, NO stimulates the soluble guanylate cyclase, which increases cyclic GMP that in turn activates protein kinase G. As a consequence, vascular tone and subsequently systemic blood pressure is decreased, local blood flow is improved, and platelet aggregation is prevented.

ACE inhibitors inhibit the degradation of bradykinin and potentiate the effects of bradykinin by about 50–100-fold. The prevention of bradykinin degradation by ACE inhibitors is particularly protective for the heart. Increased bradykinin levels prevent postischemic reperfusion arrhythmia, delays manifestations of cardiac ischemia, prevents platelet aggregation, and probably also reduces the degree of arteriosclerosis and the development of cardiac hypertrophy. The role of bradykinin and bradykinin-induced NO release for the improvement of cardiac functions by converting enzyme inhibitors has been demonstrated convincingly with use of a specific bradykinin receptor antagonist and inhibitors of NO-synthase.

In the kidney, bradykinin increases renal blood flow, whereas glomerular filtration rate remains unaffected.

Bradykinin stimulates natriuresis and, through stimulation of prostaglandin synthesis, inhibits the actions of antidiuretic hormone (ADH), thereby inhibiting water retention. Bradykinin further improves insulin sensitivity and cellular glucose utilization of skeletal muscle cells in experimental models. This, however, appears not to be relevant in the clinical context.

Bradykinin exerts its effects via B₁ and B₂ receptors. The inhibition of bradykinin degradation by ACE inhibitors compensatory leads to increased conversion of bradykinin to des Arg-9-bradykinin by kininase I. This peptide still has strong vasodilatory properties and a high affinity to the B₁ receptor. The clinical relevance of this aspect is not clear. The cardioprotective effects of bradykinin are mediated via B₂ receptors, since they can be blocked by a specific B₂ receptor antagonist [4]. On the other hand, kinins increase vascular permeability with the consequence of edema, exhibit chemotactic properties with the risk of local inflammation and they are involved in the manifestation of endotoxic shock. Increased bradykinin levels are thus thought to cause some of the undesired effects observed with ACE inhibitors, such as cough, allergic reactions, and anaphylactic responses, for instance angioneurotic edema [5].

Clinical Use (Including Side Effects)

ACE inhibitors are approved for the treatment of hypertension and cardiac failure [5]. For cardiac failure, many studies have demonstrated increased survival rates independently of the initial degree of failure. They effectively decrease work load of the heart as well as cardiac hypertrophy and relieve the patients symptoms. In contrast to previous assumptions, ACE inhibitors do not inhibit aldosterone production on a long-term scale sufficiently. Correspondingly, additional inhibition of aldosterone effects significantly reduces cardiac failure and increases survival even further in patients already receiving diuretics and ACE inhibitors. This can be achieved by coadministration of spironolactone, which inhibits binding of aldosterone to its receptor.

In the treatment of hypertension, ACE inhibitors are as effective as diuretics, β -adrenoceptor antagonists, or calcium channel blockers in lowering blood pressure. However, increased survival rates have only been demonstrated for diuretics and β -adrenoceptor antagonists. ACE inhibitors are approved for monotherapy as well as for combinational regimes. ACE inhibitors are the drugs of choice for the treatment of hypertension with renal diseases, particularly diabetic nephropathy, because they prevent the progression of renal failure and improve proteinuria more efficiently than the other drugs.

More than 15 ACE inhibitors are presently available. They belong to three different chemical classes: sulfhydryl compounds such as captopril, carboxyl compounds such as enalapril, and phosphorus compounds

such as fosinopril. Sulfhydryl compounds exert more undesired, but also desired effects, since they additionally interact with endogenous SH groups. For instance, these compounds may potentiate NO-actions or act as scavengers for oxygen-derived free radicals. Carboxyl compounds are in general more potent than captopril. Phosphorous compounds are usually characterized by the longest duration of action.

Most ACE inhibitors are prodrugs, with the exceptions of captopril, lisinopril, and ceranapril. Prodrugs exert improved oral bioavailability, but need to be converted to active compounds in the liver, kidney, and/or intestinal tract. In effect, converting enzyme inhibitors have quite different kinetic profiles with regard to half time, onset and duration of action, or tissue penetration.

In general, ACE inhibitors at the doses used to date are safe drugs. In contrast to many antihypertensive drugs, ACE inhibitors do not elicit a reflex tachycardia and do not influence lipid or glucose metabolism in an undesired manner. Glucose tolerance is even increased. Most undesired effects are class-specific and related to the inhibition of ACE. Less dangerous, but often bothersome, are dry cough, related to increased bradykinin levels and loss of taste or impaired taste. The more severe undesired effects are hypotension, hyperkalemia, and renal failure, but those can be easily monitored and appropriately considered. The risk for hypotension increases in combination with diuretics, particularly when ACE inhibitors are initiated in patients who already receive diuretics. The risk of hyperkalemia increases with coadministration of spironolactone and the risk of renal failure is higher in volume-depleted patients or those already exhibiting impaired renal function. Seldom (0.05%) the development of angioneurotic edema occurs (usually) during the first days of treatment and is life threatening. Allergic responses and angioneurotic edema are related to bradykinin. Recently, specific AT₁ receptor antagonists have become available and are used in the management of hypertension and are presently tested for use in cardiac failure. They are believed not to exhibit the bradykinin-related undesired effects. Indeed, undesired effects of AT₁ receptor antagonists are lower than seen with ACE inhibitors. On the other hand, AT₁ receptor antagonists are probably less effective since the patients do not profit from the cardioprotective effects of bradykinin. Studies comparing the effects of ACE inhibitors with AT₁ receptor antagonists are presently underway. ACE inhibitors are contraindicated in pregnancy (risk of abortion, acute renal failure of the newborn) and patients with bilateral stenosis of the renal artery. Special caution should be taken if patients have autoimmune local systemic diseases.

Acetylcholine

Acetylcholine (ACh) is an ester of acetic acid and choline with the chemical formula $\text{CH}_3\text{COOCH}_2\text{CH}_2\text{N}^+(\text{CH}_3)_3$. ACh functions as a chemical transmitter in both the peripheral nervous system (PNS) and central nervous system (CNS) in a wide range of organisms, humans included. Neurotransmitter involved in behavioral state control, postural tone, cognition and memory, and autonomous parasympathetic (and preganglionic sympathetic) nervous system.

Acetylcholine Hydrolase

- ▶ Cholinesterase

Acetylcholinesterase

Acetylcholine serves as a neurotransmitter. Removal of acetylcholine within the time limits of the synaptic transmission is accomplished by acetylcholinesterase (AChE). The time required for hydrolysis of acetylcholine at the neuromuscular junction is less than a millisecond (turnover time is 150 μ s) such that one molecule of AChE can hydrolyze 6×10^5 acetylcholine molecules per minute. The K_m of AChE for acetylcholine is approximately 50–100 μ M. AChE is one of the most efficient enzymes known. It works at a rate close to catalytic perfection where substrate diffusion becomes rate limiting. AChE is expressed in cholinergic neurons and muscle cells where it is found attached to the outer surface of the cell membrane.

Acetyltransferase

Acetyltransferase is an enzyme that catalyses the transfer of an acetyl group from one substance to another.

- ▶ Histon Acetylation

N-Acetyltransferases

N-Acetyltransferases (NATs) catalyze the conjugation of an acetyl group from acetyl-CoA on to an amine, hydrazine or hydroxylamine moiety of an aromatic compound. NATs are involved in a variety of phase II-drug metabolizing processes. There are two isozymes NAT I and NAT II, which possess different substrate specificity profiles. The genes encoding NAT I and NAT II are both multi-allelic. Especially for NAT II, genetic polymorphisms have been shown to result in different phenotypes (e.g., fast and slow acetylators).

Acidosis

State of deviation of plasma pH (systemic acidosis) or tissue extracellular pH (tissue or local acidosis) from normal (ca. pH 7.4) towards lower values. Deviation of 0.1 pH units is significant. Systemic acidosis can be caused by lung or kidney failure. Local acidosis can be the consequence of injury, inflammation, or tumor growth, due to disruption of blood supply. Local acidosis is normally associated with hypoxia.

Action Potential

An Action Potential is a stereotyped (within a given cell) change of the membrane potential from a resting

(intracellular negative) value to a depolarized (intracellular positive) value and then back to the resting value. The durations of Action Potentials range from a couple of milliseconds in nerve cells to hundreds of milliseconds in cardiac cells. Action Potentials may be propagated along very elongated cells (skeletal muscles, axons of neurons, etc) or from one cell to another via electrical gap junctions (e.g. in cardiac tissue).

Activator Protein-1

Activator Protein-1 (AP1) comprises transcriptional complexes formed by dimers of members of the Fos, Jun, and ATF family of transcription factors. These proteins contain basic leucine zipper domains that mediate DNA binding and dimerization. They regulate many aspects of cell physiology in response to environmental changes.

► [NFAT Family of Transcription Factors](#)

Active Site

Active site of an enzyme is the binding site where catalysis occurs. The structure and chemical properties of the active site allow the recognition and binding of the substrate. The active site is usually a small pocket at the surface of the enzyme that contains residues responsible

for the substrate specificity (charge, hydrophobicity, and steric hindrance) and catalytic residues which often act as proton donors or acceptors or are responsible for binding a cofactor such as pyridoxal, thiamine, or NAD. The active site is also the site of inhibition of enzymes.

Active Transport

Permeation of a drug through biological membranes against the electrochemical gradient. This type of drug transport requires energy produced by intracellular metabolic processes.

- ▶ Drug Interaction

Activins

Activins are growth and differentiation factors belonging to the transforming growth factor- β superfamily. They are dimeric proteins, consisting of two inhibin- β subunits. The structure of activins is highly conserved during vertebrate evolution. Activins signal through type I and type II receptor serine/threonine receptor kinases. Subsequently downstream signals such as Smad proteins are phosphorylated. Activins are present in many tissues of the mammalian organism, where they function as autocrine and/or paracrine regulators of various physiological processes, including reproduction. In the hypothalamus, activins are thought to stimulate the release of gonadotropin-releasing hormone. In the pituitary, activins increase follicle-stimulating hormone secretion and up-regulate gonadotropin-releasing hormone receptor expression. In

the ovaries, activins regulate processes such as folliculogenesis, steroid hormone production and oocyte maturation. During pregnancy, activin-A is also involved in the regulation of placental functions.

Adaptive Immunity

The adaptive or specific arm of the immune system consists of T- and B-lymphocytes and antibodies. T- and

B-cells carry antigen receptors that are generated by random genetic rearrangement during the ontogeny of lymphocytes in the bone marrow (B cells) or the thymus (T-cells). The hallmarks of adaptive immunity are the improved and specific defenses by T and B memory cells and antibodies after repeated exposure (immunological memory) to the eliciting antigen.

Scaffold; Docking protein; Anchoring protein

Definition

Adaptor proteins are multi-domain proteins (Fig. 1) that interact with components of signaling pathways [1]. As a consequence of these interactions, adaptor proteins are able to regulate signaling events within the cell, providing spatiotemporal control and specificity, and influencing how a cell responds to a particular stimulus.

Basic Mechanisms

Adaptor proteins function by simultaneously interacting with multiple components of a signaling pathway (Fig. 2). In order to be able to bind to more than one target protein at the same time, adaptor proteins contain at least two specific protein-protein interaction domains. These domains recognize specific motifs in the target proteins and can act completely independently, like beads on a string, or interact with another domain within the same molecule. Such intramolecular interactions can regulate the ability of each domain to bind to its target.

Adaptor Protein Function

In their simplest form, adaptor proteins perform a straightforward function: the formation of multi-protein complexes. However, they often provide more than a static scaffold support for signaling components, instead enabling dynamic regulation to control propagation of pathways and networks. Consequently, adaptor proteins can act as signaling modules, directing propagation of the pathway, influencing downstream events and even modifying the cellular response to a specific stimulus. Some of the different roles played by adaptor proteins are described below. These functions are not mutually exclusive and more than one of these roles can be performed by a particular adaptor protein at one time.

Assembly of Signaling Complexes

This is perhaps the simplest function provided by adaptor proteins and involves bringing together

Adaptor Proteins. Figure 1 Adaptor protein domains. A scheme of the domain structures of some well-characterized adaptor proteins is shown. Descriptions of domain characteristics are in main text except: C2, binds to phospholipids; GTPase activating protein (GAP) domain, inactivates small GTPases such as Ras; Hect domain, enzymatic domain of ubiquitin ligases and GUK domain, guanylate kinase domain. For clarity, not all domains contained within these proteins are shown.

individual components of a pathway. These complexes promote propagation, and often amplification, of the signal. Examples of this are found in the ►MAP kinase cascade pathway, where the adaptor proteins IQGAP1 and kinase suppressor of Ras-1 bind to multiple ►kinases. Consequently, they enable efficient signaling from one kinase to the next.

Spatial Regulation

Adaptor proteins can assemble the complexes in particular subcellular compartments. For example, following activation of a ligand-bound receptor, adaptor proteins can localize downstream signaling targets to the intracellular domains of the receptor (Fig. 2a), thereby facilitating propagation of the signal through the cell. Note that signaling events occur in all cell

organelles and subcellular compartments and adaptor proteins appear to function throughout the cell. Through their ability to localize signaling targets to specific subcellular compartments, adaptor proteins not only facilitate signaling events, but also influence how these signals are interpreted by the cell, and consequently the cellular response. For example, in the MAP kinase pathway, signaling from the plasma membrane activates different signaling components to those activated when the signal originates from the Golgi.

Temporal Regulation

The duration of signaling influences how a cell responds to a particular stimulus. For example, brief activation of the MAP kinase cascade in the neuronal cell line, PC12, results in proliferation, while sustained

Adaptor Proteins. Figure 2 Examples of adaptor protein function. Selected examples of how adaptor proteins facilitate signaling are shown. (a) Growth factor signaling. Many growth factor receptors contain an intrinsic tyrosine kinase. Following stimulation by cognate ligand binding, the intracellular domains of the transmembrane receptor autophosphorylate on key tyrosine (Y) residues. The SH2 domain of the adaptor protein Grb-2 associates with the phosphorylated tyrosine residues on the receptor, while the SH3 domain binds to the Ras activator Sos. Consequently, Sos is localized to the receptor and the plasma membrane where it activates the small GTPase Ras, which results in activation of the mitogen-activated protein (MAP) kinase cascade. By this mechanism, Grb-2 facilitates the transduction of an extracellular stimulus to an intracellular signaling pathway. (b) The adaptor protein PSD-95 associates through one of its three PDZ domains with the N-methyl-D-aspartic acid (NMDA) receptor. Another PDZ domain associates with a PDZ domain from neuronal nitric oxide synthase (nNOS). Through its interaction with PSD-95, nNOS is localized to the NMDA receptor. Stimulation by glutamate induces an influx of calcium, which activates nNOS, resulting in the production of nitric oxide.

MAP kinase signaling promotes differentiation of PC12 cells. Adaptor proteins are able to regulate the time course of signaling events, and therefore the cellular outcome.

Activation of Signaling Components

The binding of an adaptor protein may activate the target molecule. An example of this is the adaptor protein insulin receptor substrate-1 (IRS-1), which is activated during insulin signaling. Following binding by insulin, the insulin receptor (which contains an intrinsic tyrosine kinase) catalyzes phosphorylation of selected tyrosine residues on IRS-1. A subset of these phosphorylated tyrosines act as docking sites for SH2 (see below) domains on p85, the regulatory subunit of phosphoinositide 3-kinase. As a consequence of the interaction between IRS-1 and p85, phosphoinositide 3-kinase is activated.

Inactivation of Kinases

▶**A-kinase anchoring proteins (AKAPs)** are a well-studied class of adaptor proteins that regulate protein kinase A (PKA) signaling [2]. PKA is activated in response to 3′5′-cyclic-adenosine monophosphate (cAMP). ▶**AKAPs** provide spatiotemporal specificity for PKA activity by forming multi-protein complexes and localizing them to the appropriate subcellular compartment. These complexes contain kinases and phosphatases, as well as phosphodiesterases, which catalyze the hydrolysis of cAMP to AMP. Therefore AKAPs anchor both positive and negative regulators of PKA signaling.

Sequestering Signaling Components

Specificity in signal transduction is also achieved by selective separation of signaling components. By associating with specific proteins and bringing them together, adaptor proteins can determine how the pathway propagates through the cell. This is important for ▶**Ras** signaling, for example. Ras, which can be activated in response to large number of growth factors and signaling cues, regulates multiple pathways. Therefore, by sequestering specific proteins, adaptor proteins ensure that a particular stimulus activates the appropriate pathway(s). Sequestration of proteins also enables adaptor proteins to negatively regulate signaling. An example of this can be found in T cell activation. The adaptor protein, c-Cbl, sequesters the tyrosine kinase, Syk, preventing recruitment to IgE receptors. Consequently, T cell activation is attenuated.

Domains

In order to bind to target proteins, adaptor proteins contain protein-protein interaction domains which recognize specific target motifs (Fig. 1). Through combinations of these domains, adaptor protein can interact with multiple

target proteins, potentially forming large signaling complexes. Whilst many different protein binding domains have been identified, adaptor proteins often utilize the well characterized domains described below.

Src Homology 2 (SH2) and Src Homology 3 (SH3)

▶**SH2** domains are common protein modules that recognize short motifs containing a tyrosine residue that has been phosphorylated by a tyrosine kinase. Other residues outside of this motif provide specificity to determine which SH2 domain-containing protein associates with that particular site. ▶**SH3** domains bind to polyproline motifs with the sequence PXXP. These two domains are often found independently in adaptor proteins such as ▶**Src**-homologous and collagen (Shc) and ▶**PSD-95** (Fig. 1). However, the SH2/SH3 adaptors ▶**Crk** and ▶**Grb-2** contain both SH2 and SH3 domains (Fig. 1). In these proteins, the SH2 domain recognizes a binding motif in activated transmembrane receptors, while the SH3 recognizes other signaling proteins, such as the Ras activator ▶**Sos** (Fig. 2). Consequently, these proteins couple an activated receptor to signaling components downstream, thereby facilitating signal propagation.

Post Synaptic Density Protein/*Drosophila* Disc Large Tumor Suppressor/*Zonula Occludens-1* Protein (PDZ)

▶**PDZ** domains bind to short peptide motifs at the C-terminal end of target proteins, and are particularly important in spatial organization of receptors and ion channels [3]. Many adaptor proteins contain multiple PDZ domains, which have important implications for their functions. By interacting with subunits from different receptors, adaptor proteins containing multiple PDZ domains can promote formation of homogenous receptor complexes. This clustering can be further enhanced through the ability of PDZ domains to self-associate, enabling oligomerization of the adaptor proteins. Conversely, individual PDZ domains can associate with different target proteins, enabling the formation of large heterogeneous complexes of proteins. Examples of PDZ containing adaptor proteins include ▶**PSD-95** (Fig. 1), Lim kinase and membrane-associated guanylate kinases (MAGUKs).

Phosphotyrosine-binding (PTB)

▶**PTB** domains recognize small peptides containing a phosphotyrosine, usually with the consensus sequence, NPXpY. Some PTB-containing proteins, such as Numb, are able to bind to the consensus peptide in the absence of phosphorylated tyrosine, suggesting phosphotyrosine is dispensable for the function of certain PTB domains. Hydrophobic residues N-terminal to the phosphotyrosine provide some specificity of target and distinction from SH2 domains. PTB domains appear to be particularly important in docking

proteins to activated receptors. Examples of PTB containing proteins include Numb, IRS-1 and Shc [4] (Fig. 1).

WW

► WW domains (named after the one letter abbreviation for the amino acid tryptophan) are small regions of around 30 residues, which, like SH3 domains, bind to polyproline sequences. These sequences often contain the consensus sequence PPXY or PPLP. Examples of proteins that contain WW domains include Nedd4 E3 ubiquitin ligase (Fig. 1) and IQGAP1.

Pleckstrin Homology (PH)

► PH domains consist of about 120 amino acid residues. They do not interact with other proteins, but associate with specific polyphosphoinositides. Consequently, PH domains appear to be important for localizing target proteins to the plasma membrane. Examples of PH domain-containing proteins include phospholipase C and p120/RasGAP (Fig. 1).

Regulation of Adaptor Proteins

The interactions between adaptor proteins and their targets are often regulated (see below). By these mechanisms, specific signals are able to control which adaptor proteins, and consequently which target proteins, are recruited to a particular signaling complex. Common methods of adaptor protein regulation are described here.

Phosphorylation

Phosphorylation is a common method of regulation. As described above, SH2 domains bind to phosphorylated tyrosine residues. Conversely, phosphorylation of serines and threonines proximal to SH3 and PDZ domains uncouples them from their target motifs. Therefore modulation of protein kinase activity in cells regulates interactions between adaptor proteins and their target proteins.

Chemical Regulation

Cellular messengers, such as calcium, also regulate adaptor protein function. The adaptor protein IQGAP1 binds multiple members of the MAP kinase cascade, including B-Raf, MAPK/extracellular-regulated kinase (MEK) and extracellular-regulated kinase (ERK). Binding of calcium to its effector, calmodulin, increases the association of calmodulin with IQGAP1 and inhibits the interaction with B-Raf.

Intramolecular Interactions

Another way in which the function of adaptor proteins is regulated is through modulation of intramolecular interactions. Often one domain will bind to another domain in the same adaptor molecular, preventing

further interactions with other proteins. An example of this is found in the adaptor protein, Crk. Crk contains an N-terminal SH2 domain, followed by two SH3 domains. The SH3 domains are separated by a linker region containing a tyrosine residue. When Crk is phosphorylated by a tyrosine kinase, such as Abl, the intrinsic SH2 domain binds to the phosphotyrosine, attenuating Crk signaling activity.

Conformational Changes

Changing the conformation of adaptor proteins can also alter their function. p130Cas, which is a target for ► Src kinase, serves as an example. The central region of p130Cas contains multiple ► Src phosphorylation sites that, when phosphorylated, promote the binding and recruitment of other target proteins. Under resting conditions, these phosphorylation sites are hidden due to the folded conformation of p130Cas. When mechanical stress is applied to the cell, this central region is stretched exposing the Src phosphorylation sites. This alteration in conformation results in increased phosphorylation of p130Cas and recruitment of the adaptor protein ► CrkII, leading to activation of the Ras family GTPase, Rap1.

Pharmacological Intervention

Adaptor proteins are attractive targets for the design of new therapies against diseases in which signaling pathways are deregulated. For example, many cancers and inflammatory disorders display hyperactive MAP kinase signaling. This may be due to increased growth factor/cytokine stimulation or increased intracellular kinase activity. Adaptor proteins play well-established roles in controlling MAP kinase activation, and so provide a potential target for novel therapies [5]. For example, Grb-2 has been the focus of research to identify compounds which target either its SH2 or SH3 domains. The importance of Grb-2 in the activation of Ras, and therefore stimulation of the MAP kinase pathway, suggests compounds that inhibit Grb-2 function could potentially be useful in the treatment of many cancers.

At present no compounds targeting adaptor proteins have been approved for clinical use.

Therapies for treatment of diseases caused by hyperactive intracellular signaling may utilize inhibitors targeted against a specific kinase. However, this approach has several problems, such as inhibition of other non-target kinases and inhibition of signaling events not related to the disease. Consequently, the use of kinase inhibitors is not always effective and often produces side effects. However, as described above, adaptor proteins provide specificity to signaling pathways. Therefore, disrupting adaptor protein function may allow more specific targeting of the aberrant cellular response which contributes to the disease, such

as cell proliferation or cytokine production. By selectively interfering with adaptor interactions, these agents are likely to have fewer side effects and increased efficacy.

- Drug Addiction

Addison's Disease

An endocrine disorder first described by the British Physician Thomas Addison in the mid 1800's. The adrenal glands fail to produce sufficient amounts of glucocorticoid hormones (cortisol) and sometime mineralocorticoid (aldosterone). If left untreated it is life-threatening, the patient will show muscle weakness, hyperpigmentation and even depression. Typical treatment is hydrocortisone replacement therapy.

- Melanocortin

Additive Interaction

Interaction in which the combined effect is the sum of the effects of each drug administered separately.

- Drug Interaction

Adenosine

Adenosine is produced by many tissues, mainly as a by-product of ATP breakdown. It is released from neurons, glia and other cells, possibly through the operation of the membrane transport system. Its rate of production varies with the functional state of the tissue and it may play a role as an autocrine or paracrine mediator (e.g. controlling blood flow). The uptake of adenosine is blocked by dipyridamole, which has vasodilatory effects. The effects of adenosine are mediated by a group of G protein-coupled receptors (the $G_{i/o}$ -coupled A_1 - and A_3 receptors, and the G_s -coupled A_{2A} -/ A_{2B} receptors). A_1 receptors can mediate vasoconstriction, block of cardiac atrioventricular conduction and reduction of force of contraction, bronchoconstriction, and inhibition of neurotransmitter release. A_2 receptors mediate vasodilatation and are involved in the stimulation of nociceptive afferent neurons. A_3 receptors mediate the release of mediators from mast cells. Methylxanthines (e.g. caffeine) function as antagonists of A_1 and A_2 receptors. Adenosine itself is used to terminate supraventricular tachycardia by intravenous bolus injection.

Definition

Extracellular adenosine acts through a class of ► **G protein-coupled receptors** (GPCRs), defined across mammalian species as A_1 , A_{2A} , A_{2B} , and A_3 ARs (adenosine receptors). Adenosine has a cytoprotective role in the body, both in the periphery and in the central nervous system. Following binding of adenosine, or another naturally occurring ► **agonist**, the receptor

interacts with heterotrimeric G proteins to stimulate or inhibit downstream signaling cascades.

Basic Characteristics

The purine nucleoside adenosine, as a natural local modulator of cell action, increases the ratio of oxygen supply to demand, suppresses excessive inflammation, and promotes tissue protection against apoptosis or ischemic damage. ARs also have effects on proliferation and differentiation. Nearly every cell type in the body expresses one or more of these receptors, indicating the fundamental nature of adenosine as a cytoprotective mediator. In the cardiovascular system, ARs present on myocardial, vascular, and inflammatory cells respond to the stress of ischemia and other damaging conditions. Adenosine has been termed a “retaliatory” metabolite of ATP, in that its extracellular level rises in response to excessive energy demand in relation to the available energy supply, i.e., utilization of intracellular ATP. Adenosine aids in correcting this imbalance between energy supply and demand by causing vasodilation, increasing vascular integrity and angiogenesis, and counteracting the lethal effects of prolonged ischemia on cardiac myocytes. In the brain, activation of presynaptic A₁ARs suppresses the release of excitatory neurotransmitters and counteracts excitotoxicity by both presynaptic and postsynaptic mechanisms.

The affinity and selectivity of nucleosides as adenosine ►agonists has been extensively explored, resulting in thousands of selective agonists, of which many are useful in pharmacological studies [1]. Selected agonists of A₁, A_{2A}, and A₃ receptors are shown in Fig. 1. Highly selective ►antagonists of A₁, A_{2A}, A_{2B}, and A₃ receptors have been reported both as research tools and as experimental therapeutic agents (Fig. 2) [3, 4]. Caffeine and other naturally occurring alkylxanthines act as nonselective competitive antagonists of adenosine with respect to at least three of the four subtypes of the ARs. In fact, antagonism of ARs is the most likely mechanism of action of ingested caffeine. These simple xanthine antagonists are of micromolar affinity, but these lead molecules have been optimized for affinity and selectivity. Library screening has pointed the way for the identification of a variety of chemically novel lead structures that have been optimized by medicinal chemists for affinity and selectivity as adenosine antagonists.

Sources of Adenosine, its Transport Mechanisms, and Metabolism

Adenosine production in the synapse is not through vesicular release in response to nerve firing, as is the case for classical neurotransmitters. Rather, adenosine acts as a local autacoid, the release of which increases upon stress to an organ or tissue. Most cells in culture and in situ produce and release adenosine extracellularly. This

endogenous adenosine released tends to influence the outcome of pharmacological studies and can cause misleading results if not properly controlled. Depending on stress factors present, the levels of extracellular adenosine in a given tissue or organ may vary widely, leading to highly variable basal levels of stimulation of the ARs by endogenous adenosine. The level of adenosine may be as low as ~20 nM in the resting brain and as high as 100 μM in severe ischemic conditions. The half-life of adenosine in the blood is short (~1 s), and the peripheral administration of adenosine has no effect on the extracellular concentration of adenosine in the brain. Both neuronal and glial cell function are regulated by adenosine.

One source of extracellular adenosine may be both from inside the cell, where it is present in millimolar concentrations. As a hydrophilic small molecule, adenosine does not diffuse freely through the intact plasma membrane; rather, it may pass through an equilibrative transporter such as the ENT1 nucleoside transporter, for which there are well characterized inhibitors [7]. Levels of extracellular adenosine may also rise as a result of the enzymatic hydrolysis of extracellular adenine nucleotides or cell lysis. Nucleotide precursors of adenosine, notably ATP and ADP, have their own extracellular signaling properties that are mediated by P2 receptors. ►Ectonucleotidases, which are also ubiquitously expressed on the cell surface, but with characteristic distribution patterns, cleave adenine nucleoside 5'-phosphate derivatives (including activators of P2X and P2Y nucleotide receptors) to eventually form adenosine. There are many classes of ectonucleotidases; however, the most relevant species in the family of ectonucleoside triphosphate dihydrolases (E-NTPDases) that act to breakdown P2 agonists are apyrase or NTPDase1 (which converts ATP and ADP to AMP) and NTPDase2 (which converts ATP to ADP). A separate enzyme, ecto-5'-nucleotidase (CD73), converts AMP to adenosine. CD73 is characteristically found on the surface of astrocytes but not neurons.

Unlike classical neurotransmitters, adenosine does not have a rapid synaptic uptake system (as for the biogenic amines), and its chemical inactivation system is not as rapid as for the transmitter acetylcholine, for example. Adenosine may be metabolized extracellularly and inactivated with respect to the ARs in a more general fashion by the widespread enzymes adenosine kinase (AK, to produce AMP) and adenosine deaminase (AD, to produce inosine). Both AMP and inosine are only weakly active at ARs, depending on the subtype.

Inhibition of the metabolism of extracellular adenosine or its uptake proteins is being explored for therapeutic purposes. AK inhibitors have been proposed for the treatment of pain and seizures; however, the promising clinical development of these efficacious compounds was discontinued due to toxicity.

Adenosine Receptors. Figure 1 Structures of widely used AR agonists, both nonselective and selective. Affinities/potencies at the ARs are found in [Table 2](#). (a) Nucleoside derivatives that are either nonselective or selective for A_1 receptors (1–12). (b) Nucleoside derivatives that are selective for A_{2A} , A_{2A}/A_{2B} (mixed), or A_3 receptors (13–19).

Adenosine Receptors. Figure 2 Structures of widely used AR agonists, both nonselective and selective. Affinities/potencies at the ARs are found in Table 2. (a) Nonnucleoside derivatives that are either nonselective or selective for A₁ or A_{2A} receptors. (b) Nonnucleoside derivatives that are selective for A_{2B} or A₃ receptors.

Receptor Structure, Signaling Pathways Coupled to ARs, and AR Regulation

The four mammalian ARs are members of the rhodopsin-like Class A family of **GPCRs**, which contain seven transmembrane helical domains (**TMs**). Characteristics of the four subtypes of the human ARs, length of their primary sequences, their chromosomal localization, and their signaling pathways are given in Table 1. The A_{2A} receptor is considerably longer than the other three subtypes, due to its extended carboxy-terminal.

Two AR subtypes, A₁ and A₃, couple through G_i to inhibit adenylate cyclase, while the other two subtypes, A_{2A} and A_{2B}, stimulate adenylate cyclase through G_s or G_{olf} (for A_{2A}). The A_{2B}AR is also coupled to the activation of PLC through G_q. Furthermore, each of these receptors may couple through the β,γ subunits of the G proteins to other effector systems, including ion channels and phospholipases. Levels of intracellular

calcium increase upon stimulation of ARs, which interact with other second messenger systems. ARs have been found to couple to mitogen-activated protein kinases (MAPKs) in a variety of circumstances, leading to effects on differentiation, proliferation, and cell death.

Crosstalk occurs between ARs and other receptors. For example, an otherwise subthreshold concentration of acetylcholine, as might be present in the Alzheimer's brain, still produces a strong calcium signal when the A₁ AR is costimulated. Crosstalk occurs with the striatal dopamine receptor system, in which a direct physical association (dimerization) occurs between A_{2A} and D₂ receptors, and between other subtypes. The A₁AR forms functional heterodimers with the P2Y₁ nucleotide receptor, which may be stimulated by P2Y₁ receptor agonists but is not blocked by P2Y₁ receptor antagonists.

Downregulation of ARs should be considered in pharmacological studies and in the development of

b

Adenosine Receptors. Figure 2 (Continued)

agonists for therapeutic purposes. Responses of all four subtypes have been found to desensitize, and down-regulated the receptors. The most rapid downregulation among the AR subtypes is generally seen with the A_{3A} AR.

Ligands and Mechanisms Involved in Ligand Binding

The structure activity relationships (►SAR) of newly synthesized analogues of nucleosides, xanthine heterocycles, and nonxanthine heterocycles have been explored at the ARs. Potent and selective AR antagonists have been prepared for all four subtypes [3, 4], and selective agonists are known for three subtypes [1]. Thus, numerous pharmacological tools are available for in vitro and in vivo use (Table 2). Potent and selective A_{2B} AR agonists are yet to be reported, although several research groups have identified lead compounds.

Agonists: Medicinal chemists have extensively explored the ►SAR of adenosine derivatives as agonists of the ARs. Until recently, with the synthesis of atypical adenosine agonists that are pyridine-3,5-dicarbonitrile derivatives, nearly all AR agonists have been purine nucleoside derivatives. In general, for the adenine moiety of adenosine, modifications at the N^6 position have led to selectivity for the A_1 AR, and modifications at the 2 position, especially with ethers, secondary amines, and alkynes, have led to selectivity for the A_{2A} AR. Commonly used A_1 AR agonists that are N^6 -cycloalkyl

derivatives are the 2-chloro analogue CCPA **6** and S(-)-ENBA **8**, which are more highly selective than R-PIA **11**. When using the human ARs, S(-)-ENBA is more highly A_1 AR-selective than CCPA or its 2-H analogue CPA. Substitution of the 2' position of the ribose moiety of CCPA with a methyl group results in **7**, with a high selectivity for the A_1 AR. The hydroxy derivative **10** of CPA is a clinical candidate selective for the A_1 AR. The A_1 AR agonist SPA **12** contains a sulfonate group, which tends to prevent passage across the blood–brain barrier. Some N^6 derivatives are not selective for the A_1 AR; for example, the arylamino derivative APNEA **2**, which is an analogue of **3**, and metrifudil **4**, are relatively nonselective. 2-Chloroadenosine **5** is a nonselective agonist that is subject to cellular uptake and nonreceptor-mediated effects.

The substitution at the 2 position may also lead to A_{2A} AR enhancing effects, which are further boosted with an uronamido substitution at the 5' position of adenosine. When the 5'-*N*-alkyluronamide group alone is present, high affinity [at the A_{2A} AR but not selectivity] is typically observed, similar to the nonselective agonist NECA **1**. By combination of this-uronamide group with the appropriate 2 position substitution, selectivity may be achieved for the A_{2A} AR. For example, the 5'-*N*-ethyl derivatives CGS21680 **13** and ATL-146e **15** are both selective in

Adenosine Receptors. Table 1 Characteristics of the four subtypes of adenosine receptors (human, unless noted)

The A₁AR is found in the brain (cortex, cerebellum, hippocampus), dorsal horn of the spinal cord, eye, adrenal gland, heart (atrium), skeletal muscle, liver, kidney, adipose tissue, salivary glands, esophagus, colon, antrum, and testis. The A_{2A}AR is found in spleen, thymus, leukocytes (both lymphocytes and granulocytes), and blood platelets. In the brain it is restricted to the striatum, nucleus accumbens, olfactory tubercle, and large striatal cholinergic interneurons. The message for A_{2B} and A₃ARs occurs throughout the CNS and in many peripheral tissues.

binding to the rat A_{2A}AR, but are less selective at the human subtypes. CGS21680 crosses the blood–brain barrier to only a small degree. The aminoethyl derivative APEC **14**, however, crosses the blood–brain barrier and is more potent than CGS21680 in causing locomotor depression through a central mechanism.

There are not yet any agonists that are truly selective for the A_{2B}AR, known as the “low affinity” adenosine A₂ receptor. A novel agonist, the 2-(6-bromotryptophol) ether derivative MRS3997 **16**, is a full agonist with mixed selectivity at A_{2A} and A_{2B}ARs.

The A₃ agonists CI-IB-MECA **17** and its corresponding 2-H analogue IB-MECA are widely used as selective agonists of the A₃AR, although even more selective agents are now known, including those in which the ribose-like ring has been conformationally locked in the receptor-preferring north conformation, such as MRS3558 **18**. HEMADO **19** is a human A₃AR-selective agonist, but its selectivity does not generalize across species.

Antagonists: The classical AR ▶antagonists are ▶xanthines derivatives such as caffeine **21** and theophylline (1,3-dimethylxanthine). The micromolar affinity of the naturally occurring antagonists has been greatly exceeded with the introduction of selective antagonists, even reaching subnanomolar affinity. For example, the A₁AR-selective antagonists **23** and **24** are xanthine derivatives. The 8-cyclopentyl derivative DPCPX **23** is highly A₁AR selective in the rat and less A₁AR selective among the human AR subtypes. DPCPX is an ▶inverse

agonist at the A₁AR, while the adenine derivative N-0840 **25** is a ▶neutral antagonist. In general, modifications of the xanthine scaffold at the 8 position with aryl or cycloalkyl groups have led to selectivity for the A₁AR, although the water soluble 8-sulfophenyl derivative **22** is nonselective. Persistent problems in the use of xanthine derivatives as AR antagonists of the A₁AR are their low aqueous solubility and their interaction at the A_{2B}AR. Use of adenine derivatives, such as the inverse agonist WRC-0571 **26**, provides A₁AR-selective antagonists that have low affinity at the A_{2B}AR.

Modifications of ▶xanthines at the 8 position with alkenes (specifically styryl groups) have led to selectivity for the A_{2A}AR. The 8-styrylxanthine derivatives KW6002 **27**, MSX-2 **28**, and CSC **29** are moderately potent A_{2A}AR antagonists [3]. Some 8-styrylxanthine derivatives, especially CSC, have been discovered to inhibit monoamine oxidase-B as well. High selectivity of ▶xanthines at the A₁, A_{2A}, and A_{2B} (e.g., MRS1754 **35** and its *p*-COCH₃ analogue MRS1706) ARs has been achieved. ▶Xanthines that are selective for the A₃AR remain to be designed, however, PSB-II **40** contains an elaborated xanthine ring system.

In recent years, an enormous diversity of heterocyclic structures has been reported as AR antagonists (Table 2) [2]. For example, the nonselective triazoloquinoline antagonist CGS15943 **20**, first introduced in the early 1990s, has given rise to numerous derivative

^bAffinity determined at rat ARs.

^cPotency in a cyclic AMP functional assay.

Alloxazine **38** is a weak, nonxanthine antagonist that is slightly selective for the $A_{2B}AR$.

Although the simple xanthine antagonists have not provided suitable analogues with A_3AR selectivity, a cyclization of the xanthine nucleus, leading to imidazopurinones **39**, **40**, and their congeners has. For A_3AR , most of the successful leads have come from chemically diverse heterocycles. The dihydropyridine derivatives MRS1191 **43**, its nitro analogue MRS1334 **44b**, and the pyridylquinazoline derivative VUF5574 **47** are potent, selective A_3AR antagonists in the human, but are weak at the rat A_3AR . Nevertheless, MRS1191 has been used successfully in murine species. MRS1220 **42** is very potent and selective at the human A_3AR but not at the rat or the mouse receptor. There is a marked species dependence of antagonist affinity at the A_3AR . Commonly used A_3AR antagonists must be treated with caution in non-human species other than human. In general, one must be cognizant of potential species differences for both AR agonists and antagonists. The pyridine derivative MRS1523 **45** is a moderately selective A_3AR antagonist units for both the rat and human.

Variations in the relative efficacy of nucleosides, depending on structure, have been noted. This is especially pronounced for the A_3AR , at which changes on the adenine moiety (N^6 and 2 positions) and ribose moiety can either reduce efficacy to the point of pure antagonism (i.e., combination of 2-Cl and N^6 -(3-iodobenzyl)) or guarantee a robust, nearly full activation of the A_3AR (i.e., 5'-uronamide) [2]. Such nucleoside-derived A_3AR antagonists tend to have selectivity that is more general across species.

Radioligands: Radioligands commonly used for the ARs are: A_1 agonist [3H]CCPA **6**, antagonist [3H]

DPCPX **23**; A_{2A} agonist [3H]CGS21680 **13**, antagonist [3H]ZM241,385 **32** or [3H]SCH58261 **31**; A_3 agonist [^{125}I]I-AB-MECA (the N^6 -(4-amino-3-iodobenzyl) 2-H analogue of **17**) and antagonist [3H]PSB-11 **40**. Ligands for in vivo positron emission tomographic imaging of A_1 and $A_{2A}AR$ s have been developed [3]. Potent fluorescent ligands have been reported for A_1 and $A_{2A}AR$ s.

Allosteric modulation: In addition to AR agonists and antagonists that interact directly with the primary (orthosteric) site of the receptor, **allosteric modulators** of agonist action are also under consideration for disease treatment. Such modulators, either positive enhancers or negative allosteric inhibitors might have advantages over the directly-acting (orthosteric) receptor ligands. The action of the allosteric compounds would depend on the presence of a high local concentration of adenosine, which often occurs in response to a pathological condition [4]. In some cases (dependent on tissue, receptor subtype, and other conditions), one would wish to boost the adenosine effect, and therefore, an allosteric enhancer would be useful. In other cases, the elevated adenosine may be detrimental, in which instance one would want to apply a negative modulator. **Allosteric modulators** have been explored and are under development for the A_1 and A_3 AR subtypes [4].

Receptor modeling: Each of the ARs has been modeled based on homology to bovine rhodopsin (the only GPCR with an available crystal structure) or by other methods. Several such theoretical models are now available (Table 1). Molecular modeling of the ARs and **ligand docking** have provided insights into the putative binding sites of all of the subtypes, which has aided in ligand design [1, 3]. Essential residues for the binding of ligand and activation of the receptors have

Adenosine Receptors. Figure 3 An alignment of the primary sequences of the four human AR subtypes. Regions of conservation are highlighted. * indicates the most conserved (X.50) residue in each TM region. Bold residues correspond to those indicated in Table 1. The A2A receptor is truncated in the carboxy-terminal region.

been defined through both modeling and site-directed mutagenesis. Similar to other GPCRs having small molecular ligands, ►TMs 3, 5, 6, and 7 of the ARs are thought to be most closely associated with bound agonists and antagonists. An alignment of the primary sequences of the four human AR subtypes (Fig. 3) indicates a high degree of homology within the ►TMs. The second extracellular loop (EL2) is highly variable in sequence and contains a relatively high content of charged residues, in addition to the connection point (Cys residue) of a conserved disulfide bridge.

Key functional residues for ligand binding and activation that have been identified are listed in Table 1 (also in bold in 3). Extensive mutagenesis of the ARs has helped in defining a putative, hydrophilic ribose-binding region spanning ►TMs 3 and 7. The putative adenine-binding region contains more hydrophobic residues, particularly in the vicinity of the N⁶ substituent. The EL2 also is thought to coordinate the ligands.

The binding and activation steps of receptor action have been dissected computationally, although not yet in a global fashion. The conformational dynamics of the activation of the A₃AR have been approximated with respect to isolated portions of the receptor.

Drugs

Presently, only adenosine itself is approved for clinical use. It is used widely in the treatment of supraventricular tachycardia and in cardiac stress imaging to assess coronary artery disease [5]. Other agonists and antagonists and an ►allosteric modulator of the A₁ receptor are in clinical trials for a variety of indications.

Selective AR agonists are undergoing clinical trials for cardiac arrhythmias and pain (A₁); cardiac imaging and inflammation (A_{2A}); colon cancer, rheumatoid arthritis, psoriasis, and dry eye (A₃). Selective AR antagonists are either in or advancing toward clinical trials for kidney disorders (A₁); Parkinson's disease (A_{2A}); diabetes and asthma (A_{2B}); cancer and glaucoma (A₃).

Adenylyl Cyclases

ROGER A. JOHNSON

Department of Physiology and Biophysics, State University of New York, NY, USA

Synonyms

Adenylyl cyclase (preferred); Adenylate cyclase; Adenyl cyclase (original); ATP:pyrophosphate lyase; Cyclizing (E.C.4.6.1.1.)

Definition

Adenosine 3':5'-monophosphate (►cAMP) regulates effects in all eukaryotic cells, principally through activation of cAMP-dependent protein kinase (►PKA), but also through cAMP-gated ion channels (►CNGs) and select guanine nucleotide exchange factors (►Epacs) (Fig. 1). Cellular levels of cAMP reflect the balance of activities of adenylyl cyclases (AdCy: 5'-ATP $\{$ cAMP + PP_i) and cAMP ►phosphodiesterases (PDE: cAMP $\{$ 5'-AMP). Adenylyl cyclases occur throughout the animal kingdom and play diverse roles in cell regulation [1].

Basic Characteristics

Classes of Adenylyl Cyclases

Adenylyl cyclases belong to the larger class of purine nucleotide cyclases. These have been divided into classes I–VI [2]. Class I cyclases include those in gram negative bacteria, e.g. *Escherichia coli* and *Yersinia pestis*, in which cAMP levels respond to external

nutrient levels and mediate effects on transcription factors and gene expression. Class II cyclases comprise the extracellular soluble toxins of certain pathogens (see below under “*Bacterial and other adenylyl cyclases*”), e.g. those of *Bacillus anthracis*, *Bordetella pertussis*, and *Pseudomonas aeruginosa*. Class III cyclases (with subclasses IIIa–IIIc) include most adenylyl and guanylyl cyclases (Fig. 2). These enzymes respond to changes in the extracellular environment. In mammals this occurs via hormones, neurotransmitters, odorants, or tastes. In lower organisms influences may be via changes in ionic factors, glucose, bicarbonate, or serum factors, and through osmoregulation, chemotaxis, phototaxis, or pH, in various bacteria. Class IV–VI cyclases are tentative assignments with few members each, but contain soluble and smallest adenylyl cyclases (~180 amino acids). The Class IV adenylyl cyclase of *Y. pestis* has been crystallized and its structure determined. The enzyme in *Prevotella ruminicola* was designated as a Class V cyclase [2]. And the enzyme found in the nitrogen-fixing bacterium *Rhizobium etli* was designated as a Class VI adenylyl cyclase.

Mammalian Adenylyl Cyclases

Of the ten known ►isozymes of mammalian adenylyl cyclase (AC1–AC10; Table 1) all but one are membrane-bound and are regulated via cell-surface receptors linked to heterotrimeric ($\alpha\beta\gamma$) stimulatory (G_s) and inhibitory (G_i) guanine nucleotide-dependent regulatory proteins (►G-proteins) (Fig. 3, Table 2) [1]. These receptors are referred to as G-protein coupled receptors, or GPCRs, and mediate effects of stimulatory and inhibitory hormones and neurotransmitters. $G\alpha_s$ stimulates all of these isozymes save the soluble AC10, and the plant-derived diterpene, ►forskolin, stimulates all isozymes, save AC9 and AC10, by binding within the cleft formed by the enzyme's two cytosolic domains ($C_1\cdot C_2$; see below). The several isozymes differ more significantly in their responses to $G\alpha_i$ and $G\beta\gamma$ and in the physiological responses they control (Table 2). For example, $G\alpha_i$ inhibits some but not all isozymes and $G\beta\gamma$ inhibits AC1 and AC8, but significantly stimulates AC2, AC4, and AC7, and has reportedly different effects on AC5 and AC6 (Table 2).

Stimulation and inhibition of the enzyme by the GPCR-G-protein cycle occur by analogous mechanisms. Agonists induce hormone receptors to increase a $G\alpha$ -GDP-GTP exchange and subsequent $G\alpha\beta\gamma$ dissociation ($GDP\cdot\alpha_x\beta\gamma + GTP \{ GTP-\alpha_x + \beta\gamma + GDP$) (Fig. 4). Consequently, agents that affect either the dissociation of either G_i or G_s , or the association of their respective α_s , α_i , or $\beta\gamma$ subunits with adenylyl cyclase could affect rates of cAMP formation in enzyme preparations or in intact cells and tissues. There are several important examples. $G\alpha_s$ is stably activated by poorly hydrolyzable analogs of GTP, e.g. GTP γ S

Adenylyl Cyclases. Figure 1 Synthesis, degradation, and actions of cAMP.

Adenylyl Cyclases. Figure 2 Domain organization of several class III adenylyl cyclases. Domains are abbreviated: CHD: cyclase homology domains for subclasses (IIIa – IIId), predicted transmembrane domains are indicated as vertical blue bars, BLUF: blue light receptor with tightly bound flavin, CHASE: (Cyclase/histidine kinase-associated sensing extracellular) domain, GAF switch domain: cGMP-binding phosphodiesterases, Adenylyl cyclases, and *E. coli* transcription factor FhlA, Rec: receiver domain; HisK: histidine kinase domain, 2Fe-2S: two iron-two sulfur cluster domain, HAMP: tandem amphoteric α -helices present in Histidine kinases, Adenylyl cyclases, Methyl-accepting chemotaxis proteins, and Phosphatases, AI: auto-inhibitory domain, leucine-rich

or GPP(NH)P, and its activation is hindered by GDP β S. A less obvious example is **fluoride**. It activates most mammalian adenylyl cyclases, indirectly through its AlF_4^- complex with $\text{G}\alpha_s \cdot \text{GDP}$. Another example includes the ADP-ribosyltransferase activities of bacterial toxins. The toxin of *Vibrio cholerae* catalyzes the ADP-ribosylation from NAD of $\text{GTP} \cdot \text{G}\alpha_s$, and that of *Bordetella pertussis* similarly ADP-ribosylates α_i of $\text{GDP} \cdot \alpha_i \beta \gamma$, preventing its dissociation. In both cases the effect is elevated adenylyl cyclase activity and contributes to the pathophysiology of these bacteria. Of therapeutic relevance, of course, are agents acting as agonist or antagonist on GPCRs coupled to adenylyl cyclase, with the prominent example being antagonists of β -adrenergic receptors (i.e. β -blockers).

Activities of all isozymes are affected by Ca^{2+} . At higher concentrations (mM) Ca^{2+} is inhibitory through competition with divalent cation required for catalysis (see below). At lower concentrations ($< \mu\text{M}$), Ca^{2+} regulates activity physiologically. This can be through: (i) a direct effect at the catalytic active site, increasing activity of AC10, or decreasing activity of AC5 and AC6; (ii) as a Ca^{2+} /calmodulin complex, activating ACs 1,3,8; (iii) with calcineurin to inhibit AC9; or (iii) indirectly through activation of PKC. Phosphorylation of adenylyl cyclase varies among the isozymes and is determined by differences in their primary sequences and is catalyzed by cAMP-dependent protein kinase (PKA) or protein kinase C (PKC) (**Protein Kinase C**) (Table 2). Activity of adenylyl cyclases can be indirectly influenced by the specific phosphorylation of hormone receptors or of **G-proteins**.

Membrane-bound forms of mammalian adenylyl cyclases exhibit a putative topology with twelve membrane-spanning regions and two largely homologous ~ 40 kDa cytosolic domains (C_1 and C_2) (cf. Fig. 2). Differences in N-terminal and other domains are significant and influence regulation by a variety of agents as noted above (cf. Table 2). AC5(C_1) and AC2(C_2) domains have been separately expressed, recombined, and the resulting structure was solved in complex with $\text{GTP} \cdot \text{G}\alpha_s$ (Fig. 5) [3]. $\alpha_s \cdot \text{GTP}$ activates the enzyme through interaction with C_2 , yielding the active enzyme: Inhibition of adenylyl cyclase may occur by interaction of $\text{G}\alpha_i$ with the C_1 domain of adenylyl cyclase, yielding $\text{GTP} \cdot \alpha_i \cdot \text{C}$, or by the recombination of $\beta \gamma$ with $\text{G}\alpha_s$. The structure obtained with $\beta\text{-L-}2',3'\text{-dd-}5'\text{-ATP}$ allowed the demonstration that the pseudo symmetric cleft formed by the $\text{C}_1 \cdot \text{C}_2$ domains binds $5'\text{-ATP}$, forskolin, and cation at

repeats are indicated a vertical grey bars, PP2C: protein phosphatase type 2C catalytic domain, RAS, RAS-associating domain, and CAP: cyclase activating protein. This figure was modified from [2].

Notes to [Table 1](#):

(a) Adenylyl cyclases have been numbered in the order in which they were cloned and sequenced. In databases they are referred to as *adcyl*#, with the exception of the soluble AC10, which is referred to variably as *Sacy* or *Sac*.

(b) Sources are those for which the database entries are given. The first source listed is the original source from which the isozyme was cloned. In some instances there are variant forms as indicated. For AC8 there are three splice variants; data are provided for variant 8A.

(c) Accession numbers are for the Reference Sequence (*RefSeq*) collection of data from the National Center for Biotechnology Information (NCBI). Values pertinent to the mammalian isozymes of adenylyl cyclases are compiled here. The link is: [▶http://www.ncbi.nlm.nih.gov/](http://www.ncbi.nlm.nih.gov/) These numbers link to a "...comprehensive, integrated, nonredundant set of sequences, including genomic DNA, transcript (RNA), and protein products for several major research organisms. *RefSeq* standards serve as the basis for medical, functional, and diversity studies; they provide a stable reference for gene identification and characterization, mutation analysis, expression studies, polymorphism discovery, and comparative analyses. *RefSeqs* are used as a reagent for the functional annotation of some genome sequencing projects, including those of human and mouse."

two sites [4]. The active site shares topology and reaction mechanism with [▶guanylyl cyclases](#), with which there is considerable homology, and with oligonucleotide polymerases.

Although there is substantial homology among the membrane-bound forms of the mammalian adenylyl cyclases, the striking differences in the character and

extent of regulation by a variety of agents imply that primary and secondary structural characteristics are important determinants in the interactions of the enzyme with cell constituents and hence will regulate enzyme activity, the rate of formation of cAMP, and the downstream effects that this will have. All the studies on mammalian adenylyl cyclases

Adenylyl Cyclases. Figure 3 Membrane localization, topology, and regulation of mammalian adenylyl cyclases.

notwithstanding it is uncertain if all forms and variants of the enzyme have been identified, whether all modes of regulation have been determined, when during development, cell life cycles, and cell–cell interactions that specific isozymes are expressed, and how these processes are regulated. Perhaps because of this, the enzyme family continues to be a focus of much research and even as targets for drug discovery.

Catalytic Mechanism

Catalysis by adenylyl cyclases involves cation-mediated attack of the 3'-OH on the α -phosphate of 5'-ATP, with PP_i as leaving group. It is a reversible bireactant sequential mechanism with free cation and cation $\cdot 5'$ -ATP as substrates and cAMP, cation $\cdot PP_i$, and

Adenylyl Cyclases. Table 2 Regulatory characteristics of mammalian adenylyl cyclases

AdCy	Effect of $G\alpha_i$	Effect of $G\beta\gamma$	Effects of Ca^{2+} and/or calmodulin	Effects of protein kinases	Tissue distribution	Physiological functions
1	↓	↓	↑	No Δ PKA	Brain (neuron), adrenal (medulla)	Neurotransmission, synaptic plasticity, LTP, memory, circadian rhythm
2	↓	↑	No Δ	No Δ PKA ↑ PKC	Brain, lung, skeletal muscle	Synaptic plasticity, arrest of cell proliferation
3	↓	no Δ	↑ (In vitro)		Olfactory epithelium, brain, adrenal, adipose, pancreas	Olfactory response to odorants
4		↑	No Δ		ubiquitous	
5	↓	↑↓	↓ (No CaM)	↓ PKA ↑ PKC α/ζ	Heart, brain (striatum)	Cardiac function, Ca^{2+} -dependent regulation
6	↓	↑↓	↓ (No CaM)	↓ PKA ↓ PKC	Heart, kidney, Brain, liver, widespread	Cardiac function, Ca^{2+} -dependent regulation, hormonal regulation of gluconeogenesis, cell proliferation, coincidence detector for NO
7		↑	No Δ	↑ PKC	Brain, platelets, heart, spleen, lung	Ethanol dependency
8		↓	↑		Brain, lung	Neurotransmission, LTP, synaptic plasticity, memory
9			↓ (Ca^{2+} /calmodulin)	↓ PKC	Skeletal muscle, heart, brain, pancreas	Neurotransmission
10	No Δ	No Δ	↑ (no CaM)		Testes (germ cells), widespread	HCO_3^- sensor; defect associated with absorptive hypercalciuria

Notes for Table 2:

(a) Empty cells imply that no information was available. Effects of additions on adenylyl cyclase activity are as indicated: up (↑) arrow: increase, down (↓) arrow: decrease, or "no Δ " (tested, but no effect on activity seen).

(b) Effects of $G\alpha_i$ or $G\beta\gamma$ are on enzyme stimulated by either $G\alpha_s$ or forskolin. In some instances differences were noted in the effects of different isoforms of β or γ . These are not distinguished here. For AC5 and AC6 both stimulation and inhibition have been reported, the difference being conditionally dependent on stimulation and whether or not full-length enzyme has been expressed.

(c) For effects of Ca^{2+} and/or calmodulin, stimulation of adenylyl cyclase by Ca^{2+} usually requires calmodulin, except in the case of AC10 [Sacy; no calmodulin (CaM)]. All adenylyl cyclases are inhibited by high (mM) concentrations of Ca^{2+} , through competition with divalent cation required for catalysis (cf. Figs. 6 and 7). The inhibition indicated here occurs with low ($<\mu M$) concentrations of Ca^{2+} , without calmodulin, but with AC9 Ca^{2+} inhibition is with calcineurin.

(d) Ca^{2+} /calcineurin has been observed to inhibit mouse AC9 but not human AC9.

(e) AC10 (Sacy/Sac), a soluble adenylyl cyclase discovered in testes is widely distributed and functions as a HCO_3^- ion sensor. It is also stimulated by Ca^{2+} , independently of calmodulin.

(f) LTP: long term potentiation in neuronal function, PKA: cAMP-dependent protein kinase, PKC: protein kinase C, CaM: calmodulin.

Adenylyl Cyclases. Figure 4 Regulation of adenylyl cyclases by G-proteins. Abbreviations: H_s , H_i , R_s , and R_i denote hormones and receptors that lead to stimulation or inhibition, respectively, of adenylyl cyclases. C_a and C_i are active and inactive configurations of adenylyl cyclase, F_o : forskolin binding site, G_s and G_i are GTP-dependent regulatory proteins comprising their respective α_s , α_i , and $\beta\gamma$ subunits.

free cation as products (Fig. 6; transition state is depicted as $E \leftrightarrow E^*$). Cation participation in catalysis through two sites was predicted from enzyme kinetics and was later confirmed in the solved enzyme structure (Fig. 5) [3]. Available data suggest that for some isozymes substrate binding and product release are ordered and for others random. Typically, reaction velocities are considerably greater with Mn^{2+} as cation than with Mg^{2+} . Maximal velocities observed with various ATP analogs follow the order: 2'-d-5' ATP > ATP > ATP γ S > APP(NH)P > APP(CH $_2$)P. K_m values for rat brain cyclase are: $K_{MnATP} \sim 9\mu M$; $K_{Mn^{2+}} \sim 4\mu M$; $K_{MgATP} \sim 60\mu M$; and $K_{Mg^{2+}} \sim 860\mu M$. Notably, activation of adenylyl cyclases by hormones or by G_{α_s} , via the active enzyme configuration $GTP \cdot \alpha_s \cdot C_a$, causes a reduction in $K_{Mg^{2+}}$ of more than an order of magnitude to $\sim 50\mu M$, without a change in K_{MgATP} .

Miscellaneous Observations

Since its first description, adenylyl cyclase has been an intensely investigated enzyme family. Consequently, numerous observations have been made of agents that affect its activity, principally in isolated membranes, but also of purified enzyme. Some of these effects would be of importance for investigators intending to work with the enzyme. First, typical enzyme preparations, whether from native or recombinant sources, are of membranes or membrane extracts that contain enzyme activities that can alter concentrations of substrate or product of adenylyl cyclases. These include activities of cyclic nucleotide phosphodiesterases, ATPases, among others, that must be taken into consideration in assays of adenylyl cyclase activities. In addition, it has been universally observed that the enzyme is protected by thiols, with β -mercaptoethanol, 2,3-dimercaptopropanol, and dithiothreitol being the most commonly used. Conversely, adenylyl cyclases are generally susceptible to oxidants, e.g. H_2O_2 , ($IC_{50} \sim 3\mu M$) and benzoquinone ($IC_{50} \sim 3\mu M$), and alkylating

agents, e.g. *N*-ethylmaleimide ($IC_{50} \sim 100\mu M$), *p*-aminophenylarsenoxide ($IC_{50} \sim 40\mu M$), *p*-aminophenyldichloroarsine ($IC_{50} \sim 80\mu M$), or *o*-iodosobenzoate ($IC_{50} \sim 10\mu M$ for AC1 against calmodulin stimulation). Not surprisingly, the crude membrane-bound enzyme is susceptible to thermal inactivation (e.g. 50% inactivation at 35° in 10 min) and purified enzyme is more labile, but protection is afforded by forskolin, substrate, \blacktriangleright P-site ligands, Ca^{2+} /calmodulin (e.g. with AC1), and by $GTP\gamma S \cdot G_{\alpha_s}$. Proteases also elevate adenylyl cyclase activity. For example, acrosin, trypsin, and thrombin can cause 5–10-fold activation, and these exhibit some isozyme selectivity (AC2 > AC3 \gg AC5). The basis for this activation in each case is not clear, though serine proteases are known to cleave G_{α_i} , and this could lead to indirect effects on adenylyl cyclase activity.

Bacterial and Other Adenylyl Cyclases

Adenylyl cyclases are found throughout the animal kingdom and serve a variety of roles. Structures of enzyme from but a few of these sources have been determined, although amino acid sequences and domain structures have been deduced for an ever increasing number. Available evidence indicates that there is little sequence homology between these adenylyl cyclases and the membrane-bound mammalian form. As is evident from the varied domain structure just of class III adenylyl cyclases (Fig. 2) [2], although the enzyme is principally membrane bound in metazoan species, it may or may not be in lower organisms. Furthermore, those forms that are membrane bound are more often than not regulated by means quite different from that described above for mammalian systems.

A comprehensive summary of these enzyme families is beyond the scope of this chapter, but a few examples are worth emphasis. The Class I adenylyl cyclases of the enterobacteria *Salmonella typhimurium*, *Yersinia pestis*, and *Escherichia coli* are membrane bound yet sequences do not give ready evidence of typical

Adenylyl Cyclases. Figure 5 Catalytic cleft and active site of a chimeric mammalian adenylyl cyclase. The cleft is formed by the pseudosymmetric interaction of enzyme cytosolic domains, C_1 and C_2 . Panel A: part of the crystal structure of the chimeric adenylyl cyclase AC5C₁•AC2C₂ with G_{α_s} , indicating binding sites for substrate (5'ATP) and forskolin (FSK). The Switch II domain of G_{α_s} interacts with the C_2 domain of adenylyl cyclase. Panel B: the catalytic active site modeled with 5'ATP and amino acids involved in catalysis; based on structure with β -L-2',3'-dd-5'-ATP (C). Panel C: structure with β -L-2',3'-dd-5'-ATP and loci for two metal sites, A and B. Panel D: enlargement of C with Zn^{2+} (metal A) and Mn^{2+} (metal B) used in forming the crystal. Catalysis occurs with the metal catalyzed attack of the ribosyl 3'-OH group of the substrate α -phosphate. Adapted from [3].

Adenylyl Cyclases. Figure 6 Adenylyl cyclase catalytic cycle. Points during the catalytic cycle of adenylyl cyclases at which inhibition by competitive and noncompetitive nucleotides occur; E^* represents the catalytic transition state.

transmembrane domains. The enzymes comprise two principal domains, with the catalytic domain being N-terminal to a glucose-sensing regulatory domain; the enzyme is inhibited the presence of glucose. Its regulation is coordinated with that of carbohydrate permeases by the phosphoenolpyruvate:sugar phosphotransferase system. This is important for bacterial responses to changes in nutrient levels. In other bacteria, the enzyme may be regulated in response to nutrients and/or it may constitute a toxic factor in mammals, as with Class II forms of adenylyl cyclase of *Bordetella pertussis*, *Bacillus anthracis*, *Pseudomonas aeruginosa*, or *Yersinia pestis*. These enzymes constitute the 'toxin class' of adenylyl cyclases. The well-studied adenylyl cyclases of *Bordetella pertussis* and *Bacillus anthracis* are both soluble, Ca^{2+} /calmodulin-dependent, but G-protein independent enzymes that are exported from the respective bacteria. (The adenylyl cyclase of *P. aeruginosa* is not calmodulin-dependent.) Because these enzymes are then transported into infected cells, adenylyl cyclase actually constitutes a virulence and toxic factor in mammals. The *B. pertussis* adenylyl cyclase is a large (1706 amino acids) bifunctional enzyme, the N-terminal end constituting the adenylyl cyclase activity fused to a C-terminal end exhibiting hemolytic activity and its capacity for being secreted into external medium. The *B. anthracis* adenylyl cyclase (800 amino acids), also known as 'edema factor' (EF), exhibits four domains, a signal peptide essential for protein secretion, a docking domain allowing binding to the protective antigen (PA), the adenylyl cyclase catalytic site, and a fourth region of unknown function. The *B. anthracis* adenylyl cyclase has been crystallized and its structure determined.

The Class III adenylyl cyclases are sometimes referred to as the ancestral form of the enzyme and

include numerous variants (cf. Fig. 2). Among these there are a couple of noteworthy examples. The adenylyl cyclase of *Saccharomyces cerevisiae* was the first to have been cloned and sequenced and is a prototypical Class III enzyme, with a sequence in the catalytic domain distinct from those of Class I and Class II enzymes and with the catalytic core located at the C-terminal part of the protein (Fig 2). In such yeast/fungi (e.g. *Candida albicans*) the enzyme is membrane bound and is regulated by a G-protein, in these cases Ras. As in mammalian systems it is involved in metabolic control, in mating responses, but also constitutes a virulence factor. In *C. albicans*, for example, which contains only one form of the enzyme, the cAMP signaling pathway is essential for hyphae formation and hence virulence. Sequences have been deduced for a number of enzymes of this family, including *Schizosaccharomyces pombe*, *Saccharomyces kluyveri*, *Trypanosoma brucei*, and *T. equiperdum*, *Neurospora crassa*, and *Dictyostelium discoideum*, where the adenylyl cyclase generates the cAMP that provides the signal for aggregation into a multicellular organism and the development of fruiting bodies.

Given that in many of these systems additional proteins and cofactors participate in the regulation of adenylyl cyclase activity, the full elucidation of the roles in which this enzyme activity participates in their growth, development, and function, is a long way off. This notwithstanding, the fact that the mammalian adenylyl cyclases differ so substantially from those of numerous pathogens in which the enzyme is an essential virulence factor gives motive to the idea that new classes of small molecule inhibitors of the pathogen adenylyl cyclases may be discovered that do not interact with mammalian forms of the enzyme.

Drugs

Although agents which indirectly activate or inhibit mammalian adenylyl cyclases are common and are even used in the treatment of disease, especially drugs targeting G-protein-coupled receptors, drugs acting directly on the enzyme have been less well explored. And for most compounds acting directly on adenylyl cyclases, high selectivity for specific isozymes has not been demonstrated. The main classes of such agents are derivatives of forskolin and of adenine nucleosides. Adenosine and derivatives of it have long been known to inhibit adenylyl cyclases and it became clear early on that certain modifications afforded substantially increased inhibitory potency. Notable are the approximately threefold increase in potency seen with the 2-fluorine substitution on adenine and the increases in potency seen with various modifications to the ribose moiety. The orientation of the ribose (α vs β) and the presence, orientation, or absence of hydroxyl groups clearly contribute to inhibitory potency

(Table 3). For example, arabinose and xylose differ from ribose only in the orientation of the 2'- and 3'-OH groups yet exhibit markedly different potencies. Whereas 9-(tetrahydrofuryl)-Ade (▶SQ 22,536) and 9-(cyclopentyl)-Ade are without hydroxyl groups and are less potent, they offer metabolic and biochemical stability useful for many types of studies. It is, however, the removal of two of the hydroxyl groups, that elicits the largest improvement in inhibitory potency, in particular the 2',5'-dideoxy- modification (Table 3). With these improvements in potency, these cell permeable compounds, in particular ▶2',5'-dd-Ado, have become useful research tools and have been used to inhibit adenylyl cyclases and to lower cAMP levels and alter function in numerous studies in isolated cells or intact tissues.

An early observation that 2'-d-3'-AMP was a more potent inhibitor of adenylyl cyclases than 2'-d-Ado suggested that the enzyme would accept substitutions at the 3'-ribose position and that phosphate was particularly well tolerated. This led to the generation of a family of 3'-phosphoryl derivatives of 2',5'-dideoxyadenosine exhibiting ever greater inhibition with the addition of an increasing number of 3'-phosphoryl groups, the most potent of which is 2',5'-dideoxyadenosine-3'-tetraphosphate (2',5'-dd-3'-A4P; Table 4) [5]. These constitute a class of inhibitors historically referred to as ▶P-site ligands that caused inhibition of adenylyl

Adenylyl Cyclases. Table 3 Nucleoside inhibitors of adenylyl cyclase. Assays were with a detergent-dispersed adenylyl cyclase from rat brain and were with 100 μ M 5'ATP and 5 mM $MnCl_2$ as substrates

cyclase that was kinetically either noncompetitive or uncompetitive (cf. Fig. 6). This implied binding of the inhibitor with either a different locus or different configuration than substrate. As it developed, these are configuration selective inhibitors and they provide an exquisite means for inhibition of this signal transduction pathway. We know now that most membrane-bound forms of the mammalian adenylyl cyclase are inhibited by adenine nucleosides and their 3'-polyphosphates derivatives. Inhibition by these ligands is conserved with varying sensitivity in all isozymes, save AC10 and those of bacteria.

Probably all adenylyl cyclases are inhibited competitively by substrate analogs, which bind at the site and to the enzyme configuration with which cation-ATP binds (cf. Fig. 4). One of the best competitive inhibitors is β-L-2',3'-dideoxyadenosine-5'-triphosphate (β-L-2',3'-dd-5'-ATP; Table 4) [4], which allowed the identification of the two metal sites within the catalytic active site (cf. Fig. 4) [3]. This ligand has also been labeled with ³²P in the β-phosphate and is a useful ligand for reversible, binding displacement assays of adenylyl cyclases [4]. The two inhibitors, ►2',5'-dd-3'-ATP and β-L-2',3'-dd-5'-ATP, are comparably potent

Adenylyl Cyclases. Figure 7 Structures of potent inhibitors of adenylyl cyclase. Structures for 2',5'-dd-3'-ATP ($IC_{50} \sim 40$ nM; noncompetitive inhibitor), β -L-2',3'-dd-5'-ATP with Mg^{2+} and Zn^{2+} ($IC_{50} \sim 24$ nM; competitive inhibitor), and 3'-MANT-GTP with Mn^{2+} ($IC_{50} \sim 90$ nM; competitive inhibitor) are from coordinates obtained for these compounds in respective crystal structures with AC5C₁•AC2C₂. Divalent cations are indicated: Mn^{2+} : purple, Mg^{2+} : green, Zn^{2+} : blue. The 3'-MANT-group fits into a hydrophobic pocket of the enzyme. Note the difference in contortion of the phosphate chains in these structures relative to positions for divalent cation.

(Table 4), but inhibit adenylyl cyclase by conformationally distinct mechanisms (cf. Fig. 6) by binding within the catalytic cleft in unique structures (Fig. 7).

It has been known for some time that the enzyme tolerated large substitutions to the 3'-ribose position. This was taken advantage of with the development of 2' (3')-O-MANT-derivatives of nucleoside 5'-triphosphates [6] (Table 4). It was surprising, though, that potent inhibition was seen with bases other than adenine, implying that base specificity is less stringent than had been generally assumed. Subsequently, fluorescent derivatives have been made with different fluorophores at 2'- and 3'-positions. 3'-Substitutions showed advantage over corresponding 2'-substitutions and 2'(3')-O-MANT-substitutions were clearly preferable to coumarin and dansyl derivatives, but followed the order of guanosine \geq inosine > adenosine (Table 4). Fluorescent phosphoryl derivatives were also well tolerated, in particular the 7-amino-coumarin. These fluorescent ligands have opened possibilities for investigations of adenylyl cyclase structure, activity, and interactions with other substances not heretofore possible.

Although the 3'- and 5'-polyphosphate derivatives mentioned above exhibit exquisite inhibitory potency these compounds are not cell permeable. To take advantage of the potency of such derivatives for studies with intact cells and tissues, there are two possibilities. One is chemically to protect the phosphate groups from exonucleotidases that also allows the compound to transit the membrane intact. The other is to provide a precursor molecule that is cell permeable and is then metabolized into an inhibitor by intracellular enzymes. The general term for such a compound is ►**prodrug**; nucleotide precursors are also referred to as ►**pronucleotides**. Families of protected monophosphate derivatives were synthesized, based on β -L- and β -D-2',5'-dd-3'-AMP, β -L-2',3'-dd-5'-AMP, and the acyclic 9-substituted adenines, ►**PMEA** and ►**PMPA**. Protective substituents were: (i) -(S-pivaloyl-2-thioethyl)=

Adenylyl Cyclases. Table 5 Prodrug inhibition of [³H]cAMP formation in intact cells. Cells were prelabeled for 2 h with [³H]adenine before 50 μ M forskolin and pronucleotides were added. After a 15 min incubation the newly formed [³H]cAMP was extracted and quantified as in (7)

Pronucleotide	OB-1771	THP1
	Preadipocytes	Monocytes
IC_{50} (nM)		
2',5'-dd-3'-AMP-bis(Me-SATE)	6.7	260
2',5'-dd-2F-Ado-3'-P-bis(Me-SATE)	9.8	110

(*t*-Bu-SATE-); (ii) -S-acetyl-2-thioethyl)=(Me-SATE-); (iii) -(S-benzyl-2-thioethyl)=(Ph-SATE-); (iv) -cyclosalicyl=(H-Sal-); and (v) -3-methyl-cyclosalicyl=(Me-Sal-). Although triphosphate forms of each of the precursor compounds inhibit isolated adenylyl cyclases with IC_{50} s in the nanomolar range, only protected forms of 2',5'-dd-3'-AMP inhibited cAMP formation in intact cells [7]. Of these the SATE-derivatives proved the most effective. None of the pronucleotide forms of 2',5'-dd-3'-AMP inhibited adenylyl cyclase *per se*, whether isolated from rat brain or OB1771 cells. Nor were identifiable extracellular metabolites of these agents responsible for the drugs' blocking effects on intact cells. These compounds exhibit all the hallmarks of prodrugs. They are taken up, are deprotected, and are converted to extremely potent inhibitors of adenylyl cyclase, *but only by intact cells and tissues*. These prodrugs have been used to block cAMP formation in isolated cells and intact tissue and elicit functional effects (Table 5). For example, pretreatment of isolated rat atria with 1 μ M 2',5'-dd-3'-AMP-bis(*t*-Bu-SATE) completely blocked the positive chronotropic effects of 1 μ M epinephrine. It is likely that pronucleotide inhibitors of adenylyl cyclases

will find applications in many intact cell systems, as an additional upstream block of the adenylyl cyclase-cAMP-PKA signaling cascade, in biochemical, pharmacological, and potentially even therapeutic contexts.

Adhesion Molecules

Adhesion molecules are transmembrane proteins, which through their extracellular part mediate the interaction of cells with other cells or with extracellular components like the extracellular matrix. On the basis of structural and functional similarities, most adhesion molecules can be grouped into families such as cadherins, integrins, selectins, the immunoglobulin superfamily or the syndecans. While some adhesion molecules are passive in their adhesive function, the adhesiveness of other adhesive molecules can be regulated. Some adhesive proteins are very similar to receptors, in that they not only bind other molecules with high selectivity and affinity, but are also able to transduce the binding into an intracellular signal.

Adipocyte

Adipocyte is the term for a fat cell which is used to store energy in the form of triacylglycerols. There are two different types of adipocytes. (i) White adipocytes contain a large lipid droplet and secrete different adipocytokines like adiponectin, and resistin. The lipid may account to 90% of cell mass. (ii) Brown adipocytes contain lipid droplets scattered throughout the single cell and are used to generate heat in a process known as nonshivering thermogenesis.

Fibroblasts, which are undifferentiated pre-adipocytes, can be stimulated and converted into adipocytes.

Adipocytokines

Definition

The term adipokine refers to any protein secreted from adipocytes [1]. Collectively, the various adipokines form the ‘adipokinome’ which together with the lipid moieties secreted from fat cells (e.g. fatty acids, cholesterol, retinol) constitute what can be referred to as the ‘secretome’ of adipocytes. Most adipokines are also secreted from other cell types in other organs, but one in particular – adiponectin – is considered to be exclusive to adipocytes.

Basic Characteristics

► **White adipose tissue**, or white fat, has been traditionally viewed essentially as an organ of fuel storage. Around half of the total cell content of adipose tissue is made up of mature ► **adipocytes**, the other cell types including fibroblasts, preadipocytes, macrophages and endothelial cells. Lipids are stored in mature white adipocytes as triacylglycerols in the form of a single large droplet. This gives a unilocular appearance under the microscope, and lipid can constitute up to 90% of the cell mass. Triacylglycerols are deposited in the tissue at a time of nutritional excess to be released during periods of negative energy balance – such as fasting and long-term starvation. Lipids allow fuel to be stored at a high energy density since their calorific value is twice that of carbohydrates, and because in contrast to carbohydrate they can be stored with little associated water.

Additional roles traditionally recognised for white adipose tissue include thermal insulation (as in the blubber of sea mammals) and mechanical protection to internal organs. However, in recent years it has become apparent that the function of white adipose tissue is much more extensive. This follows from the discovery that it is a major endocrine organ, secreting a diverse

range of protein hormones and other protein factors – the ►adipokines [1–3]. These secreted protein signals and factors were initially called adipocytokines, but the term adipokines is now generally used. This reflects the fact that the name ‘adipocytokine’ implies that the proteins are cytokines, or cytokine-like. While this is true of some, it is not so for the majority.

The first protein factor to be identified as being secreted from adipocytes was the enzyme lipoprotein lipase, which is responsible for the breakdown of circulating triacylglycerols (largely in the form of lipoproteins) to release free fatty acids and glycerol; however, no special significance was attributed to this particular secretion. The fatty acids are then taken up into the adipocytes and re-esterified to triacylglycerol. The next adipocyte secreted protein to be identified was adiponectin. This is a complement-related factor which was initially thought to play an important role in the control of energy balance and body weight as a lipostatic signal, although this was quickly recognised not to be the case. In the early 1990s adipocytes were then found to express and secrete tumour necrosis factor- α (►TNF α), a major pro-inflammatory cytokine. TNF α was immediately linked to the development of insulin resistance in fat cells, but its actions are now considered to be rather more extensive. It plays, for example, a pivotal role in the regulation of the production of a number of other adipokines, particularly those related to ►inflammation.

Leptin and Adiponectin

The protein factor whose identification induced the radical change in our understanding of the physiological role of adipose tissue was the hormone ►leptin (Greek: *leptos* – thin or small). This was discovered in 1994 as the product of the *OB (LEP)* gene, mutations in which result in the profound ►obesity of the obese (*ob/ob*) mouse [1–4]. Mutations in the leptin gene have subsequently been identified in humans, and as in mice they are associated with extreme obesity. Leptin is a key satiety factor, providing a signal from adipocytes to the hypothalamus in the neuroendocrine regulation of appetite [3, 4]. In practise, leptin is now recognised to be a pervasive hormone with multiple functions, including as a signal in the maturation of the reproductive system, in immunity and in insulin secretion and glucose utilisation. Although leptin is produced in a number of different cells and organs, the major site of production is the adipocyte, with the amount of body fat being the primary determinant of the circulating level of the hormone. There is, however, acute regulation of leptin production with an important role for insulin and the sympathetic nervous system. Indeed, the sympathetic system provides a negative feedback loop from the brain to adipocytes in the control of leptin production.

The discovery of leptin resulted in white adipose tissue being recognised as a major endocrine organ. Indeed, in many cases – particularly the obese – it is the largest endocrine organ in the body, amounting to up to 50% or more of total tissue mass. Following the identification of leptin, a rapidly expanding list of other protein hormones and factors secreted from adipocytes has been identified (Fig. 1). The total number of these adipokines is now in excess of 50 distinct molecular entities [1, 2].

The second major hormone, identified to be secreted from adipocytes, was ►adiponectin [3]. This factor was discovered by several groups in the mid 1990s and is also known as Acrp30, AdipoQ, ApM1 and GBP28. Adiponectin (the most widely used name) appears to be secreted exclusively by adipocytes, in contrast to the other adipokines. Adiponectin is involved in a wide range of functions. These include important roles in modulating insulin sensitivity, in inflammation (anti-inflammatory) and atherogenesis. Adiponectin circulates at high concentrations in the blood, occurring in high molecular weight polymeric forms. In marked contrast to other adipokines, its production and circulating levels fall in obesity.

Inflammation

A number of adipokines are linked to inflammation and immunity (Fig. 1). This includes both leptin and adiponectin, and also a number of other key inflammatory proteins, particularly cytokines and chemokines [1]. The cytokines and chemokines encompass interleukin-1 β (IL-1 β), IL-6, IL-10, TNF α , monocyte chemoattractant protein-1 (MCP-1), and macrophage migration inhibitory factor (MIF). Other major inflammation-related adipokines include nerve growth factor (NGF), and acute phase proteins such as serum amyloid A and haptoglobin. In addition, adipocytes secrete plasminogen activator inhibitor-1 (PAI-1), which is an important thrombotic factor as well as an acute phase protein.

The wide range of inflammation-related factors that adipocytes secrete is linked to the inflammatory response that the tissue exhibits in obesity [1]. Obesity in general, like an increasing number of other diseases, is characterised by a state of mild chronic inflammation, and adipose tissue plays a central role in this. The production of most inflammation-related adipokines increases markedly in obesity and there is an elevated circulating level of a number of these factors as well as of other inflammatory markers such as C-reactive protein (CRP). The increased production of inflammatory adipokines (and decreased production of adiponectin with its anti-inflammatory action) in the obese is considered to play a critical role in the development of the obesity-associated pathologies, particularly type 2 diabetes and the ►metabolic syndrome [1].

Adipokines. Figure 1 Major proteins – adipokines – secreted from white adipocytes. CETP, cholesteryl ester transfer protein; FIAF, fasting-induced adipose factor (angiopoietin like protein-4) IL, interleukin; MCP-1, monocyte chemoattractant protein-1; MIF, macrophage migration inhibitory factor; NGF, nerve growth factor; PAI-1, plasminogen activator inhibitor-1; RBP4, retinol binding protein-4; TGF β , transforming growth factor- β ; TNF α , tumour necrosis factor- α ; VEGF, vascular endothelial growth factor; ZAG, zinc α 2-glycoprotein.

An important component of the inflammatory state in adipose tissue in obesity comes from the infiltration of the tissue by macrophages. These are likely to be attracted through the secretion by adipocytes of MCP-1 and MIF. The macrophages in turn secrete factors which both directly add to the total production of inflammatory agents by adipose tissue and also catalyse the production of such agents from adipocytes – and perhaps preadipocytes as well.

The wide range of inflammatory and immune factors secreted by adipocytes has led to the view that there are many similarities between these cells and cells of the immune system.

Other Adipokines and Metabolic Processes

In addition to the regulation of energy balance and the mounting of an inflammatory response, adipokines are involved in a number of other physiological and metabolic processes [3, 4]. These include lipid metabolism (e.g. retinol binding protein, cholesteryl ester transfer protein), the control of blood pressure through the renin-angiotensin system (e.g. angiotensinogen), vascular haemostasis (e.g. PAI-1), angiogenesis, glucose homeostasis and stress responses. Several factors are involved in angiogenesis and these not only include the key angiogenic factor vascular endothelial growth factor (VEGF), but also leptin and angiopoietin-like protein 4/fasting-induced adipose factor (Angptl4/FIAF). Leptin and adiponectin – and perhaps IL-6 and MCP-1 – play an important role in glucose homeostasis and insulin sensitivity.

The current view is that through the various adipokines, adipocytes and adipose tissue are implicated in a wide range of physiological functions in a manner that far transcends the original simple paradigm of fuel storage. Indeed, there is extensive cross-talk between adipocytes and other cells and organs, including the brain, skeletal muscle and bone. Within adipose tissue itself, there is cross-talk between adipocytes, macrophages and preadipocytes, particularly in relation to the inflammatory response. The discovery of the adipokines and the endocrine role of adipose tissue has led to parallel developments with skeletal muscle; myocytes are now recognised to secrete protein factors also, in particular IL-6, leading to the concept of ‘myokines’.

Drugs

Little attempt has been made to develop drugs targeted specifically to white adipose tissue and the production of adipokines. It is likely, however, that there will be an increasing emphasis on this approach to the pharmacological treatment of obesity-related diseases, given the current views on the centrality of the adipokines to these disorders. It is, of course, the diseases that obesity leads to, rather than obesity itself, that constitute the main medical challenge.

There has been considerable focus on the development of drugs that lead to a reduction in the total amount of adipose tissue. These include agents targeted at limiting fat absorption, the inhibition of appetite, and the stimulation of energy expenditure (thermogenesis) – or a combination thereof. The best example of drugs,

targeted specifically to adipocytes, are the β_3 -adrenoceptor agonists such as the first generation compound BRL-37344 [(RR + SS)-(+)-4-[2-(2-(3-chlorophenyl)-2-hydroxyethyl)amino)propyl] phenoxyacetate]. These stimulate lipolysis and thermogenesis (in brown adipose tissue), but their use in humans has been problematic because the β_3 -adrenoceptor appears less important in man than it is in rodents and because of the differences between the human and the rodent (on which early studies were directed) receptors. Such drugs in practise also directly modulate the production of certain adipokines; a potent example is leptin, the expression and production of which is strongly inhibited by β_3 -adrenoceptor agonists.

Currently, three drugs are available clinically to treat obesity – Orlistat, Reductil (sibutramine) and Rimonabant. Orlistat inhibits pancreatic lipase, thereby reducing the digestion and subsequent absorption of fatty acids. Sibutramine, which is a serotonin and noradrenergic reuptake inhibitor, suppresses appetite and stimulates energy expenditure. Rimonabant, the most recently introduced anti-obesity drug, is targeted at the endocannabinoid system, acting as an antagonist of the CB1 receptor. Rimonabant inhibits appetite and probably also stimulates expenditure. [5] It is increasingly clear that this drug also interacts with adipose tissue, either indirectly or directly, CB1 receptors being present in the tissue [5]. Adiponectin production appears to be stimulated by Rimonabant and this has raised the possibility that this drug and other CB1 antagonists and agonists might have specific effects on adipokine synthesis, particularly those linked to inflammation and insulin sensitivity. As such, CB1 antagonists may have a potential role in the treatment of the metabolic syndrome.

The established example of current drugs which directly affect adipokine production is the ► **thiazolidinediones** (such as pioglitazone and rosiglitazone) which were developed as anti-diabetic agents. These compounds, which interact with the ► **PPAR γ nuclear receptor**, have major effects on the production of several adipokines. Thus production of leptin is strongly downregulated, whereas that of adiponectin is upregulated. Importantly, PPAR γ activators have an extensive anti-inflammatory action. As a consequence, the production of several inflammation-related adipokines has been shown to be inhibited by treatment with TZDs.

Adiponectin

A major adipokine, molecular weight 28,000 Da (monomeric form), that is secreted only from adipocytes. It exists at high levels in the plasma and has a number of functions, including an important role in insulin sensitivity, inflammation (anti-anti-inflammatory action) and atherogenesis. Unlike most adipokines, the plasma levels fall in obesity.

- Adipokines
- Arp-activated Protein Kinase

Adipose Tissue

The adipose organ consists of two distinct tissues – brown and white adipose tissue. Brown adipose tissue is specialised for thermoregulatory heat generation (thermogenesis) through the presence of the tissue-specific mitochondrial uncoupling protein-1 (UCP-1); only limited amounts are present in most humans. White adipose tissue is the major fuel storage organ in mammals and birds, the key cell type (~50% of total cell content) being the adipocytes which store large amounts of triacylglycerol; the other cell types are fibroblasts, preadipocytes, macrophages and endothelial cells.

- Adipokines

Adrenal Gland

The adrenal gland is a flattened gland situated above each kidney, consisting of a cortex (outer wall) that

secretes important steroid hormones and a medulla (inner part) that secretes adrenaline (epinephrine) and noradrenaline (norepinephrine).

▶ Glucocorticoids

Adrenaline

Adrenaline (epinephrine) is a catecholamine, which is released as a neurotransmitter from neurons in the central nervous system and as a hormone from chromaffin cells of the adrenal gland. Adrenaline is required for increased metabolic and cardiovascular demand during stress. Its cellular actions are mediated via plasma membrane bound G-protein-coupled receptors.

▶ α -Adrenergic System

▶ β -Adrenergic System

Adrenergic Receptor

Also called adrenoreceptors, are a class of G protein-coupled receptors with a widespread expression in a broad spectrum of different organs and tissues. Adrenergic receptors are activated by their endogenous agonist ligands epinephrine and norepinephrine which belong to the catecholamine transmitters. Adrenergic receptors regulate a range of physiological parameters such as blood pressure and heart rate in a very rapid manner; these rapid changes in parameters such as heart rate are essential elements of physiological defense reactions (“fight and flight”).

Definition

The α -adrenergic system consists of six subtypes of membrane receptors which mediate part of the biological actions of the catecholamines adrenaline and noradrenaline. α -Adrenergic receptors are important regulators of smooth muscle cell contraction (α_1 -adrenergic receptors) [1] and presynaptic neurotransmitter release (α_2 -adrenergic receptors) [2, 3]. In addition, adrenaline and noradrenaline activate β -adrenergic receptors, which stimulate cardiac contractility and rhythm and inhibit bronchial, vascular, and uterine smooth muscle contraction (▶ β -adrenergic system).

Basic Characteristics

The adrenergic system is an essential regulator that increases cardiovascular and metabolic capacity during situations of stress, exercise, and disease. Nerve cells in the central and peripheral nervous system synthesize and secrete the neurotransmitters noradrenaline and adrenaline. In the peripheral nervous system, ▶ noradrenaline and ▶ adrenaline are released from two different sites: noradrenaline is the principal neurotransmitter of sympathetic neurons that innervate many organs and tissues. In contrast, adrenaline, and to a lesser degree noradrenaline, is produced and secreted from the adrenal gland into the circulation (Fig. 1). Thus, the actions of noradrenaline are mostly restricted to the sites of release from sympathetic nerves, whereas adrenaline acts as a hormone to stimulate many different cells via the blood stream.

Together with dopamine, adrenaline and noradrenaline belong to the endogenous catecholamines that are synthesized from the precursor amino acid tyrosine (Fig. 1). In the first biosynthetic step, tyrosine hydroxylase generates ▶ L-DOPA which is further converted to dopamine by the aromatic L-amino acid decarboxylase (▶ Dopa decarboxylase). Dopamine is transported from the cytosol into synaptic vesicles by a vesicular monoamine transporter. In sympathetic nerves, vesicular dopamine β -hydroxylase generates the neurotransmitter noradrenaline. In chromaffin cells of the adrenal medulla, approximately 80% of the noradrenaline is further converted into adrenaline by the enzyme phenylethanolamine-N-methyltransferase.

Several mechanisms serve to terminate the biological actions of noradrenaline and adrenaline. From the

α -Adrenergic System. Figure 1 Synthesis and release of noradrenaline and adrenaline from sympathetic nerve endings (left) and from the adrenal gland (right). Noradrenaline and adrenaline are synthesized from the precursor amino acid tyrosine and are stored at high concentrations in synaptic vesicles. Upon activation of sympathetic nerves or adrenal chromaffin cells, noradrenaline and adrenaline are secreted and can activate adrenergic receptors on surrounding cells (sympathetic nerve), or they enter the blood circulation (adrenaline released from the adrenal gland). Release of noradrenaline from nerve terminals is controlled by presynaptic inhibitory α_2 - and activating β_2 -adrenergic receptors. Actions of noradrenaline are terminated by uptake into nerve terminals and synaptic vesicles by active transporters (NET, EMT, VMAT) and by uptake into neighboring cells (not shown). Abbreviations: AADC, aromatic L-amino acid decarboxylase; COMT, catechol O-methyltransferase; DBH, dopamine β -hydroxylase; EMT, extraneuronal noradrenaline transporter; MAO, monoamine oxidase; NET, noradrenaline transporter; PNMT, phenylethanolamine-N-methyltransferase; TH, tyrosine hydroxylase; VMAT, vesicular monoamine transporter.

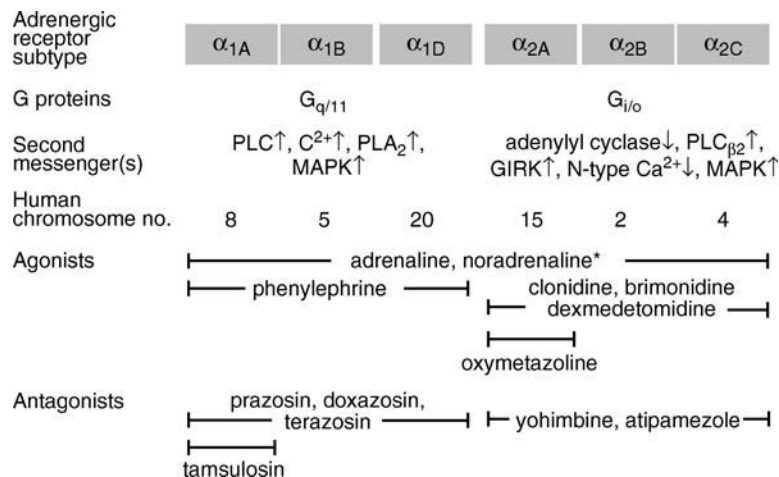

synaptic cleft, most of the released noradrenaline is recycled by reuptake into the nerve terminals via a specific **noradrenaline transporter**. This transporter is selectively blocked by cocaine, tricyclic antidepressants or selective noradrenaline reuptake inhibitors (SNRIs). After reuptake into the nerve, most of the noradrenaline is transferred into synaptic vesicles. A smaller fraction is destined for degradation by the enzymes **monoamine oxidase** (MAO, in sympathetic nerves) or **catechol-O-methyltransferase** (COMT, in neighbouring cells). COMT plays a major role in the metabolism of circulating catecholamines. MAO and COMT are widely distributed, and inhibitors of these enzymes are used for the treatment of mental depression (MAO-A inhibitor, moclobemide) or Parkinson's disease (MAO-B inhibitor, selegiline).

The biological actions of adrenaline and noradrenaline are mediated via nine different **G-protein-coupled receptors**, which are located in the plasma membrane of neuronal and nonneuronal target cells. These receptors are divided into two different groups, α -adrenergic receptors and β -adrenergic receptors (see β -adrenergic system).

The distinction between α - and β -adrenergic receptors was first proposed by Ahlquist in 1948 based on experiments with various catecholamine derivatives to produce excitatory (α) or inhibitory (β) responses in isolated smooth muscle systems. Initially, a further subdivision into presynaptic α_2 - and postsynaptic α_1 -receptors was proposed. However, this anatomical classification of α -adrenergic receptor subtypes was later abandoned.

At present, six α -adrenergic receptors have been identified by molecular cloning: three α_1 -adrenergic receptors (α_{1A} , α_{1B} , α_{1D}) and three α_2 -subtypes (α_{2A} , α_{2B} , α_{2C}) (Fig. 2). Due to the lack of sufficiently subtype-selective ligands, the unique physiological properties of these α -receptor subtypes, for the most part, have not been fully elucidated. However, recent studies in mice that carry deletions in the genes encoding for individual α -receptor subtypes have greatly advanced the knowledge about the specific functions of these receptors.

α_1 -Adrenergic receptors mediate contraction and hypertrophic growth of vascular smooth muscle cells and cardiac myocytes. The three α_1 -receptor subtypes share 75% identity in their transmembrane domains,

α -Adrenergic System. Figure 2 Subtypes of α -adrenergic receptors, their signaling pathways and agonist and antagonist binding profiles. The proposed topology of α_1 - and α_2 -adrenergic receptors with 7 transmembrane domains is illustrated. *Adrenaline and noradrenaline can also activate β -adrenergic receptors (see β -adrenergic system). PLA₂, PLC: phospholipases A, C; GIRK: G-protein-activated inwardly rectifying potassium channel, MAPK: mitogen-activated protein kinase.

whereas the degree of homology between α_1 - and α_2 -receptors is significantly smaller (35–40%). Due to discrepancies between the pharmacological subtype classification, mRNA and protein expression data and experiments with cloned α_1 -receptor subtypes, some confusion exists in the literature with respect to the assignment of α_1 -receptor subtype nomenclature. In the present terminology, α_{1A} (cloned α_{1c}), α_{1B} (cloned α_{1b}) and α_{1D} -receptors (cloned α_{1d}) can be distinguished. All three subtypes seem to be involved in the regulation of vascular tone, with the α_{1A} -receptor maintaining basal vascular tone and the α_{1B} -receptor mediating the constrictory effects of exogenous α_1 -agonists. Cardiac α_1 -receptors increase contractile force and mediate antiapoptotic and hypertrophic effects. All α_1 -receptor subtypes can activate G_q-proteins, resulting in intracellular stimulation of phospholipases C, A₂, and D, mobilization of Ca²⁺ from intracellular stores and activation of mitogen-activated protein kinase and PI3 kinase pathways. Mutagenesis of receptor subtypes has led to the identification of a number of amino acids involved in agonist binding and receptor activation as well as binding sites for antagonists within the receptor's binding crevice [4, 5] (Fig. 3).

Three genes encoding for α_2 -adrenergic receptor subtypes have been identified from several species, termed α_{2A} , α_{2B} , and α_{2C} , respectively (Fig. 2). The pharmacological profile of the α_{2A} -subtype differs significantly between species, thus giving rise to the pharmacological subtypes α_{2A} in humans, rabbits, and pigs and α_{2D} in rats, mice, and guinea pigs. Part of the pharmacological difference between α_{2A} - and α_{2D} -receptors can be explained by a Ser-Ala mutation in the

fifth transmembrane helix of the α_{2A} -receptor rendering this receptor less sensitive to the antagonists, rauwolscine and yohimbine. α_2 -Adrenergic receptors regulate a wide range of signalling pathways via interaction with multiple heterotrimeric G_{i/o} proteins including inhibition of adenylyl cyclase, stimulation of phospholipase D, stimulation of mitogen-activated protein kinases, stimulation of K⁺ currents and inhibition of Ca²⁺ currents. The three α_2 -receptor subtypes have unique patterns of tissue distribution in the central nervous system and in peripheral tissues. The α_{2A} -receptor is expressed widely throughout the central nervous system including the locus coeruleus, brain stem nuclei, cerebral cortex, septum, hypothalamus, and hippocampus. In the periphery, α_{2A} -receptors are expressed in kidney, spleen, thymus, lung, and salivary gland. The α_{2B} -receptor primarily shows peripheral expression (kidney, liver, lung, and heart) and only low level expression in thalamic nuclei of the central nervous system. The α_{2C} -receptor appears to be expressed primarily in the central nervous system (striatum, olfactory tubercle, hippocampus, and cerebral cortex), although very low levels of its mRNA are present in the kidney.

α_{2A} -, α_{2B} -, and α_{2C} -receptors are located presynaptically in order to inhibit noradrenaline release from sympathetic nerves. Activation of these receptors leads to decreased sympathetic tone, decreased blood pressure and heart rate. Central α_{2A} -receptors mediate sedation and analgesia. α_{2B} -Receptors mediate contraction of vascular smooth muscle, and in the spinal cord they are essential components of the analgesic effect of nitrous oxide. Upon stimulation by agonists, α_1 - and α_2 -receptor signalling pathways are attenuated by

α -Adrenergic System. Figure 3 Model of agonist and antagonist binding to α_1 -adrenergic receptors. The binding pocket of α_1 -receptors is depicted from an extracellular viewpoint, transmembrane domains 1–7 are numbered. Amino acids involved in agonist binding and receptor activation are depicted in blue, residues which mediate antagonist binding are shown in red (modified from 5).

several mechanisms at the receptor and postreceptor levels (see β -adrenergic system).

Drugs

Therapeutically, α_1 -receptor-mediated vasoconstriction contributes to the beneficial actions of adrenaline applied as an emergency medicine during hypotensive or anaphylactic shock. Addition of adrenaline or noradrenaline to local anaesthetics prevents diffusion of the local anaesthetic from the site of injection and thereby prolongs its action. α_1 -Receptor antagonists including prazosin, doxazosin, terazosin, and bunazosin are used to treat patients with hypertension. However, α_1 -receptor antagonists are no longer first-line antihypertensive agents since the ALLHAT clinical trial revealed that hypertensive patients taking doxazosin had a higher risk of developing congestive heart failure than patients with diuretic treatment. Tamsulosin is the first α_1 -receptor antagonist with selectivity for the α_{1A} -receptor over α_{1B} - and α_{1D} -subtypes. The α_{1A} -selectivity is thought to contribute to the beneficial actions of tamsulosin and alfuzosin in the treatment of benign prostate hypertrophy without lowering blood pressure.

At present, no drugs exist that can selectively activate α_2 -receptor subtypes. Clonidine stimulates all three α_2 -subtypes with similar potency. Clonidine lowers blood pressure in patients with hypertension and it decreases sympathetic overactivity during opioid withdrawal. In intensive and postoperative care, clonidine is a potent sedative and analgesic and can prevent postoperative shivering. Clonidine and its derivative brimonidine lower

intraocular pressure of glaucoma patients when applied locally. Moxonidine may have less sedative side effects than clonidine when used as an antihypertensive. It has been suggested that moxonidine activates “imidazoline receptors” instead of α_2 -receptors. The α_2 -receptor agonists oxymetazoline and xylometazoline are being used as nasal decongestants. At present, α_2 -receptor antagonists are not used in human medicine. However, in veterinary practice the α_2 -receptor antagonist atipamezole can rapidly reverse anaesthesia mediated by the α_2 -agonist medetomidine. In the future, subtype-selective drugs may greatly improve the therapy of diseases involving α_1 - or α_2 -adrenergic receptor systems.

β -adrenoceptor system

Definition

The β -adrenergic system defines the effects of the ► **sympathetic system** mediated via β -adrenergic receptors (synonym: β -adrenoceptors). These are G-protein-coupled receptors primarily causing an activation of adenylyl cyclases. They mediate a plethora of cardiovascular, smooth muscle and metabolic effects. β -Adrenergic receptor antagonists are used to treat various cardiovascular diseases, including hypertension, coronary artery disease, myocardial infarction and heart failure, but also glaucoma and hyperthyroidism. β -Adrenergic receptor agonists are used primarily to treat bronchial asthma and premature labour.

Basic Characteristics

The sympathetic nervous system secretes the ► **catecholamines** noradrenaline (norepinephrine) from nerve endings and adrenaline (epinephrine) from the adrenal medulla. Noradrenaline is stored in the varicosities (\approx nerve endings) of the sympathetic nervous system, often together with ATP or neuropeptide Y. Adrenaline is stored in vesicles of the chromaffin cells of the adrenal medulla together with its precursor noradrenaline at a ratio of about 4:1. Release of noradrenaline and adrenaline is subject to inhibitory control by presynaptic α_{2A} - and α_{2C} -adrenergic receptors, and to – less pronounced – stimulation via presynaptic β_2 -adrenergic receptors (see chapter on α -adrenergic system).

Adrenaline and noradrenaline act on a total of nine adrenergic receptor subtypes, three each of the α_1 -, α_2 - and β -adrenergic subfamily. The three β -adrenergic receptors are termed β_1 , β_2 and β_3 . All adrenergic receptors couple to ► **G-proteins**. G_s is the primary G-protein for all three β -adrenergic receptors and mediates activation of ► **adenylyl cyclases**, i.e. results in an increase of intracellular cAMP-levels. Activation of ► **protein kinase A** (PKA) is the main effector pathway of elevated cAMP, but cAMP can also activate cyclic-nucleotide-dependent ion channels, inhibit the metabolism of cGMP by phosphodiesterases and activate the epac proteins (exchange proteins activated by cAMP). Additional signalling pathways have been observed mainly for the β_2 -subtype, they include activation of G_i as well as stimulation of ► **MAP-kinase**

pathways (MAP-kinase cascades); activation of these “non-conventional” pathways appears to require the binding of β -arrestins to the receptors (see below). These G-protein-independent signalling pathways have been suggested by a variety of experiments, and it appears that they play a role in long-term signalling regulating cell growth [1–4].

All adrenergic receptors are heptahelical, i.e. they have seven transmembrane helices that form a ligand-binding pocket located in the central transmembrane core of the receptors. Amino acids essential for ligand binding have been mapped extensively for the β_2 -adrenergic receptor; they are located in transmembrane helices 3, 5 and 6. Receptor activation involves an agonist-induced intramolecular conformational change that causes a relative movement of the transmembrane helices 3 and 6. This is thought to lead to a rearrangement of the intracellular parts of the receptor, which couple to G-proteins, most notably the part of the third intracellular loop that is adjacent to transmembrane helix 6. These conformational changes can be directly visualized in intact cells with fluorescence techniques and occur over a few hundred milliseconds after agonist binding [5].

Recent studies indicate that – like many other receptors – G-protein-coupled receptors may form dimers, either homodimers or dimers with another type of receptor. The role of dimer formation in the cell surface expression of receptors and in their signalling and the resultant pharmacology are currently under intensive investigation [1].

In addition to agonist-induced activity, many receptors, including the β -adrenergic receptors, display spontaneous or constitutive activity. This means that the unoccupied receptor has some likelihood to adopt an active conformation, couple to G-proteins and generate an intracellular signal. Some compounds classified as antagonists (e.g. propranolol) can suppress constitutive activity and are therefore termed inverse agonists. Constitutive activity is more pronounced for the β_2 -than the β_1 -subtype, but has not yet been investigated for the β_3 -receptor.

The agonist-induced conformational change not only causes receptor activation and generation of an intracellular signal, but also a number of biochemical processes that dampen the signal and cause desensitization of the receptor [2] (Fig. 1). These include (i) phosphorylation of the receptor by members of the G-protein-coupled receptor kinase (GRK) family, followed by binding of β -arrestins, which prevents further activation of G-proteins, (ii) phosphorylation by protein kinases A and C (PKA and PKC), which directly impairs G-protein-coupling, (iii) translocation of the receptors into clathrin-coated pits and internalization into endosomes. Binding of β -arrestins and perhaps also movement of

β -Adrenergic System. Figure 1 Desensitization, internalization and recycling of β -adrenergic receptors. Activation of β -adrenergic receptors causes their phosphorylation by members of the GRKs. Cytosolic β -arrestins then bind to the phosphorylated receptors and prevent further interaction with G-proteins. β -Arrestin-bound receptors assemble in clathrin-coated pits, where the complex appears to interact with other proteins, including dynamin and src-kinase. This leads (i) to the activation of non-conventional signalling pathways (raf-kinases, MAP-kinases, JNK-kinases), and (ii) to the internalization of the receptors to endosomes. Endosomal receptors become either dephosphorylated and recycle back to the cell surface; some endosomal receptors undergo lysosomal degradation.

receptors into clathrin-coated pits appear also to be required for a subsequent “wave” of non-conventional signalling, such as activation of MAP-kinases [3]. Most internalized receptors are recycled back to the cell surface, but some are degraded. The regulatory processes described above are most pronounced for the β_2 -subtype, and least for the β_3 -subtype; they have also been demonstrated for other G-protein-coupled receptors, e.g. the α_2 -adrenergic receptors. In addition to these regulatory processes at the level of the receptor protein, the receptor mRNA-levels can be down-regulated, at least in part by destabilization via mRNA-binding proteins; this results in reduced receptor synthesis. Whereas the phosphorylation processes and the subsequent receptor desensitization can occur over a few minutes of agonist exposure, receptor down-regulation takes many hours and may even take days to reach a new steady-state level [2].

β -Adrenergic receptors mediate a plethora of cardiovascular, smooth muscle and metabolic effects (Fig. 2). Cardiac β_1 -adrenergic receptors increase the frequency, electrical conduction and force of cardiac contractions as well as cardiac relaxation; they represent the strongest stimulus for the heart. At the same time they increase the generation of ectopic impulse generation and thereby the risk of arrhythmias. These effects are mediated by \blacktriangleright PKA-mediated phosphorylation of calcium channels (resulting in enhanced calcium influx) as well as of phospholamban, a negative regulator of the sarcoplasmic calcium ATPase \blacktriangleright SERCA (resulting in

enhanced uptake of calcium into the stores of the sarcoplasmic reticulum). A second important localization of β_1 -adrenergic receptors is the cells of the juxtaglomerular apparatus, where they increase the release of renin and thus cause stimulation of the renin-angiotensin system.

β_2 -Adrenergic receptors are located primarily on smooth muscle cells and mediate relaxation. This results in bronchodilatation, relaxation of the uterus and vasodilatation (partially mediated by β_1 -adrenergic receptors). Liver β_2 -adrenergic receptors trigger a protein kinase cascade that results in inhibition of glycogen synthase and activation of phosphorylase and thereby trigger the mobilization of glucose from glycogen stores

β_3 -Adrenergic receptors stimulate lipase and cause the breakdown of triglycerides to fatty acids in fat cells. It is still not clear to what extent the β_2 -subtype participates in this process. Together with the mobilization of glucose from the liver, lipolysis provides the energy sources for the sympathetic “fight-or-flight” reaction.

Polymorphisms have been described for all β -adrenergic receptors; while initial studies, notably of the β_1 -subtype, suggested that these might be predictors of diseases as well as of therapeutic responses, these results have more recently been questioned. Alterations in responsiveness may be limited to certain compounds and a causative role in diseases has not been or remains to be substantiated in larger trials.

β -Adrenergic System. Figure 2 β -Adrenergic signalling in cardiac muscle (predominantly β_1) and smooth muscle (predominantly β_2) cells. Proteins that become more active after activation of β -adrenergic receptors are depicted in grey, those which become less active are depicted in white. Both receptors couple to G_s and lead to activation of adenylyl cyclases, generation of cyclic AMP and activation or protein kinase A (PKA). In *heart muscle cells*, PKA causes phosphorylation of L-type calcium channels (increased Ca^{2+} -influx; relevant site of phosphorylation uncertain), troponin I (TnI; diminishes affinity of troponin C for Ca^{2+} and thus enhances relaxation) and phospholamban (PLB; leads to less inhibition of the sarcoplasmic Ca^{2+} ATPase, SERCA, which pumps Ca^{2+} into the sarcoplasmic stores. This in turn enhances relaxation and enhances Ca^{2+} -release during the next beat) All this leads to more rapid and forceful contraction as well as relaxation. In *smooth muscle cell* the signalling pathways are less clear. PKA-mediated phosphorylation of myosin light chain kinase (MLCK) causes reduced activity of this kinase, which in turn leads to decreased phosphorylation of myosin light chains and, hence, reduced contraction. A second postulated mechanism for relaxation is hyperpolarization via activation of K^+ -channels; the signalling pathway is unclear and might involve coupling of β_2 -receptors to G_i .

Drugs

β -Adrenergic Receptor Agonists

Agonists as well as antagonists of β -adrenergic receptors are used for the treatment of a variety of conditions. β -Adrenergic receptor antagonists belong to the most frequently used classes of drugs.

The main use of β -adrenergic receptor agonists (β -sympathomimetic drugs) is the symptomatic treatment of bronchial asthma. Stimulation of β_2 -adrenergic receptors on smooth muscles produces dilatation of the airways and reduces airway resistance. Although β_2 -adrenergic receptor activation inhibits inflammatory mediator release from mast cells and other inflammatory cells, there is no major effect of these drugs on airway inflammation associated with asthma. β_2 -Adrenergic receptor agonists are the most effective bronchodilators known. In order to reduce unwanted systemic effects (most notably tachycardia and arrhythmia) inhaled β_2 -selective compounds are the drugs of choice; a high first-pass effect helps to reduce systemic effects of the major fraction of the inhaled drug that reaches the gastrointestinal tract. The most frequently used compounds are

fenoterol and salbutamol, which have a rapid onset and a short duration of action. Newer lipophilic compounds such as formoterol and salmeterol have a much longer duration of action (up to 12 h), presumably because they are retained in the plasma membrane after dissociation from the receptor, i.e. they remain in the immediate vicinity and can thus re-associate with the receptor.

β_2 -Adrenergic receptor agonists are also used to treat premature labour by causing uterine relaxation. Fenoterol and ritodrine are frequently used. The effectiveness of long-term tocolysis is controversial, since both desensitization of the receptors and the symptomatic nature of this treatment may limit their effects to 1–2 days according to one large study.

β_2 -Adrenergic receptor agonists, in particular clenbuterol, have been used for their hypertrophic effects on skeletal and also cardiac muscle. They can increase muscle growth in cattle (illegal in many countries) but have also been used by body-builders and athletes as anabolic drugs.

Non-selective β -adrenergic receptor agonists, particularly adrenaline (epinephrine), are used in cardiovascular

emergency situations, most importantly cardiopulmonary resuscitation and anaphylactic shock. They are given to produce stimulation of cardiac electrical activity via β_1 -receptors, inhibition of mast cell mediator release via β_2 -receptors, and bronchodilatation via β_2 -receptors as well as α_1 - and α_2 -receptor-mediated vasoconstriction.

Relatively selective stimulation of β_1 -adrenergic receptors can be achieved with dobutamine. This is a racemic drug of which both isomers activate the β_1 -receptor, and in addition the (–) isomer activates α_1 -receptors whereas the (+) isomer activates β_2 -receptors; the simultaneous activation of α_1 - and β_2 -receptors results in no major net effect on peripheral resistance, and thus the overall cardiovascular effects are mediated by β_1 -stimulation leading to increases in cardiac contractility and output. Dobutamine is used for the short-term treatment of acute cardiac failure and for diagnostic purposes in stress echocardiography.

β-Adrenergic Receptor Antagonists

Clinically used β-adrenergic receptor antagonists (“β-blockers”) are either β_1 -selective (e.g. bisoprolol, metoprolol, atenolol, betaxolol) or non-selective, i.e. with similar affinity for the β_1 - and the β_2 -subtype (e.g. propranolol, timolol, celiprolol). Many compounds classified as antagonists are in fact inverse agonists, for example metoprolol, bisoprolol, timolol or propranolol; inverse agonism is more pronounced at β_2 - than at β_1 -receptors because the latter possess a lower constitutive activity. Some compounds possess a partial agonist activity (PAA, or intrinsic sympathomimetic activity ISA); examples are pindolol or celiprolol. These drugs produce less bradycardia but may be therapeutically less efficient.

Blockade of β-adrenergic receptors are important in the treatment of many cardiovascular diseases. Supraventricular and ventricular tachycardias are treated by reducing pacemaker currents in the SA-node, slowing AV-conduction and decreasing ectopic impulse generation. This is achieved via reductions in pacemaker currents and Ca^{2+} -currents (class II antiarrhythmic drugs). Blockade of cardiac β_1 -adrenergic receptors (preferentially with β_1 -selective drugs) reduces cardiac frequency, cardiac output, cardiac O_2 -consumption and probably prevents β-adrenergically induced cardiac remodelling. Therefore, they are first-line drugs in the treatment of hypertension, angina, myocardial infarction and cardiac failure. In the latter case, treatment must be initiated with very low doses to prevent acute decompensation. While β-adrenergic receptor antagonists have become the most effective means of treatment in heart failure during the past decade, their first-line use in hypertension has recently been questioned.

Non-selective β-adrenergic receptor antagonists (e.g. propranolol) can suppress tachycardia and tremor in patients with hyperthyroidism or tremor caused by

stress or nervousness. This use is illegal in certain sports (e.g. shooting).

β-Adrenergic receptor antagonists can reduce aqueous humor production in the eye and thereby reduce intraocular pressure. This is why they represent one of the most frequently used class of drugs in glaucoma. Timolol is the best-established compound, followed by levobunolol and others. High concentrations of these compounds are applied to the eye, and it is, therefore, not really clear whether the effects are indeed mediated via specific interactions with β-adrenergic receptors. In recent years, newer drugs acting on prostaglandin or α_2 -adrenergic receptors have become more popular as first-line drugs in glaucoma.

► α -Adrenergic System

Adrenomedullin

Human adrenomedullin is a 52-amino acid peptide belonging to the calcitonin/calcitonin gene-related peptide (CGRP)/amylin peptide family. It is synthesized mainly in endothelial cells and elicits vasodilation.

► Calcitonin Gene Related Peptide

Adverse/Unwanted Reactions

All drugs, in addition to their therapeutic effects, have the potential to do harm, i.e. to cause adverse/unwanted reactions (side effects). These may or may not be related to the principal pharmacological action of the drug. Examples of the second category are toxic effects of metabolites of a drug or immunological reactions.

Affective Disorders

Affective (mood) disorders are characterized by changes in mood. The most common manifestation is depression, ranging from mild to severe forms. Psychotic depression is accompanied by hallucinations and illusions. Mania is less common than depression. In bipolar affective disorder, depression alternates with mania.

► Antidepressant Drugs

Affinity

Ligands reside at a point of minimal energy within a binding locus of a protein according to a ratio of the rate

the ligand leaves the surface of the protein (k_{off}) and the rate it approaches the protein surface (k_{on}). This ratio is the equilibrium dissociation constant of the ligand–protein complex (denoted $K_{\text{eq}} = k_{\text{off}}/k_{\text{on}}$) and defines the molar concentration of the ligand in the compartment containing the protein that is bound to 50% of the protein at any one instant. The ‘affinity’ or attraction of the ligand for the protein is the reciprocal of K_{eq} .

► Drug–Receptor Interaction

Age-related Macular Degeneration (AMD)

A disease process characterized by deterioration of the macula of the retina that results in a loss of sharp central vision. AMD is the leading cause of central vision loss in the developed countries today for those over the age of fifty years.

► Tyrosine Kinase Inhibitors

Agonist

Natural or synthetic receptor ligands that induce a conformational change (active conformation) and a signal transduction process upon receptor binding. Agonists may act as typical hormones or neurotransmitters or they may confer paracrine functions, recognize bacterial, viral or other environmental constituents via activating their dedicated receptors.

Ligands that bind to the receptor, but do not exert a maximal cellular reaction when applied at saturating concentrations are referred to as partial agonists. Their remaining activity is termed intrinsic activity ranging between 0% and 100%.

Agouti-related Protein (AgRP)

The agouti gene encodes a paracrine signalling molecule that antagonizes the effect of melanocyte-stimulating hormone (MSH) at the melanocortin-1 receptor. This effect reduces the synthesis of eumelanin, and is responsible for the agouti hair colour in rodents. Agouti-related protein (AgRP) is similar to the agouti protein (25% identical amino acids), and is an endogenous antagonist of α MSH at the melanocortin-3 and melanocortin-4 receptors. AgRP is a potent orexigen, and down-regulation of AgRP is a major mechanism of the anorexigenic effect of leptin.

AIDS

AIDS (acquired immunodeficiency syndrome) is the final stage of disease caused by infection with HIV. In this stage, the virus infection has severely affected the immune system, causing a depletion of CD4⁺ T-helper cells. AIDS is characterized by the manifestation of typical diseases caused by opportunistic infections (Pneumocystis carinii pneumonia, CMV retinitis, candidiasis of the esophagus, cerebral toxoplasmosis), neurological manifestations, cachexia, or certain tumors (Kaposi sarcoma of the skin, B-cell lymphoma).

- ▶ Antiviral Drugs

Airway Hyperresponsiveness

Airway hyperresponsiveness is an exaggerated propensity for airways to narrow too easily in response to a wide variety of stimuli. Airway hyperresponsiveness

leads to clinical symptoms of wheezing and dyspnea after exposure to allergens, environmental irritants, viral infections, cold air, or exercise.

- ▶ Glucocorticoids
- ▶ GABAergic System
- ▶ Bronchial Asthma

Airway Surface Liquid

Airway surface liquid (ASL) is the very thin fluid layer (<7 μ M) maintained at the apical membrane of airway epithelia. ASL thickness is maintained by a tight control of fluid reabsorption and/or secretion, mediated by sodium and/or chloride channels.

- ▶ Epithelial Na⁺ Channel

AKAPs

AKAPs are cyclic AMP-dependent protein kinase (PKA)-anchoring proteins, a family of about 30 proteins anchoring PKA at subcellular sites in close vicinity to a certain substrate.

- ▶ A Kinase Anchoring Proteins (AKAPs)

AKT

Synonyms

PKB

Definition

Akt also known as protein kinase B (PKB) is serine/threonine-specific protein kinase important in mammalian cellular signalling. Akt, originally identified as the oncogene in the transforming retrovirus (AKT8), controls cell survival by inhibiting apoptosis processes. Logically, Akt has been implicated as a major factor in many types of cancer. Akt plays also a crucial role in the insulin signalling pathway.

Akt is activated by binding of plasma membrane phospholipids downstream of insulin receptors, growth and survival factor receptors in a phosphoinositide 3-kinases dependent manner. In humans, there are three genes in the “Akt family”: Akt1, Akt2 and Akt3. Their respective functions are still under investigation.

Alcohol

- ▶ Ethanol

Alcohol Dehydrogenase

Alcohol dehydrogenase is a cytoplasmic enzyme mainly found in the liver, but also in the stomach. The enzyme accomplishes the first step of ethanol metabolism, oxidation to acetaldehyde, which is further metabolized by aldehyde dehydrogenase. Quantitatively, the oxidation of ethanol is more or less independent of the blood concentration and constant with time, i.e. it follows zero-order kinetics (pharmacokinetics). On average, a 70-kg person oxidizes about 10 ml of ethanol per hour.

- ▶ Ethanol

Aldehyde Dehydrogenase

Ethanol is almost entirely metabolized in the liver. The first step, oxidation by ▶ alcohol dehydrogenase, yields acetaldehyde, a reactive and toxic compound. Essentially all of the acetaldehyde is converted to acetate by the liver enzyme aldehyde dehydrogenase. Aldehyde dehydrogenase is inhibited by the drug disulfiram. Given alone, disulfiram is a nontoxic substance. However, ethanol consumption in the presence of

disulfiram causes an extremely unpleasant reaction characterized by flushing, hyperventilation, vomiting, sweating, tachycardia, hypotension, vertigo and marked distress. The altered response to alcohol is the rational basis for the use of disulfiram in the treatment of chronic alcoholism.

- ▶ Ethanol

Aldosterone

Aldosterone is a small hydrophobic molecule and belongs to the class of steroid hormones. Aldosterone is the major mineralocorticoid in the body. It binds to the mineralocorticoid receptor. This receptor belongs to the superfamily of steroid hormone receptors, which are located intracellularly and, upon binding of the agonist, translocate into the cell nucleus, where they regulate the transcription of those genes, which contain the appropriate hormone responsive regulatory elements. In the intestine and particularly in the distal tubules of the kidney, aldosterone increases the expression of proteins which modulate the activity of the sodium–potassium ATPase and the amilorid-sensitive sodium channel. As a consequence, sodium reabsorption and, secondarily, potassium excretion increase.

Alkaloid

Alkaloids are heterocyclic basic compounds and widespread in plants. Many of them have specific targets in organisms. For example, the alkaloids atropine and scopolamine of *Belladonna* are specific antagonists at ▶ [muscarinic receptors](#).

Alkylating Agents

SPIRO M. KONSTANTINOV¹, MARTIN R. BERGER²

¹Department of Pharmacology and Toxicology, Medical University in Sofia, Faculty of Pharmacy, Sofia, Bulgaria

²DKFZ, Toxicology and Chemotherapy Unit, Im Neuenheimer Feld, Heidelberg, Germany

Synonyms

Antiproliferative agents; Methylating agents; Chloroethylating agents

Definition

Alkylating agents have the ability to add alkyl groups to many electronegative groups under conditions present in cells. They stop tumor growth by introducing single strand breaks as well as by cross-linking nucleotides in DNA double-helix strands – directly attacking DNA. This makes the strands unable to uncoil and separate. As this is necessary in DNA replication, the cells can no longer divide. Alkylating agents act nonspecifically. Some of them require conversion into active substances *in vivo*.

Mechanism of Action and Clinical Use (Including Side-Effects)

Alkylating agents are DNA-interactive drugs characterized by the formation of covalent DNA adducts. The alkylating agents are the largest class of anti-cancer agents, comprising five subgroups: nitrogen

mustards, alkyl sulfonates, nitrosoureas, ethylenimines and ▶ [triazines](#) [1].

Several other drugs (e.g., procarbazine, hexamethylmelamine, estramustine, mitomycin C) are thought to act at least in part by alkylation. Alkylating agents are capable of introducing alkyl groups to nucleophilic sites (such as sulfhydryl, amino, phosphate, hydroxyl, carboxyl, and imidazole groups) of other molecules by forming covalent bonds. ▶ [Alkylation](#) damages the structure and/or function of DNA, RNA and various enzymes. The inhibition of DNA synthesis occurs at drug concentrations that are lower than those required to inhibit RNA and protein synthesis. The degree of DNA alkylation correlates well with the cytotoxicity of these drugs. The interaction with DNA also accounts for the mutagenic and carcinogenic potential of these drugs. The 7-nitrogen (N7) and 6-oxygen (O6) of guanine have been shown to be particularly susceptible to attack by ▶ [electrophilic compounds](#). There are several possible consequences of N7 guanine alkylation:

- Cross-linkage – bifunctional agents may form covalent bonds with each of two adjacent guanine residues and such inter-strand cross-links will lead to inhibition of DNA replication and transcription. Intra-strand and DNA-protein cross-links may also be formed;
- Mis-pairing of bases – alkylating at N7 changes the O6 of guanine to its enol tautomer, which can then form base pairs with thymine. As a consequence gene miscoding may be induced with adenine-thymine pairs replacing guanine-cytosine. Thus defective proteins are produced;

Alkylating agents, subgroups with examples

Alkylating agent	
Classic (nitrogen mustards)	Mechlorethamine (nitrogen mustard)
	Cyclophosphamide
	Ifosfamide
	Chlorambucil (leukeran)
	Melphalan (alckeran)
Alkyl sulfonates	Busulfan
Nitrosoureas	Carmustine
	Lomustine
	Streptozocin (streptozotocin, zanosar)
Ethylenimines	Thiotepa
Triazines	Dacarbazine
	Procarbazine
Platinum complexes	Cisplatin
	Carboplatin
	Oxaliplatin
Others	Bendamustine

- Depurination – N7 alkylation may cause cleavage of the imidazole ring and excision of the guanine residue, leading to DNA strand breakage.

Nitrogen Mustards

The first successful chemotherapy of malignant tumors was recorded in 1942 when the first cytostatic drug named mechlorethamine (▶nitrogen mustard) was used. Later, a large series of nitrogen mustard analogues was synthesized and introduced into the clinical practice (Fig. 1). These analogues are highly reactive compounds that can form covalent bonds with nucleophilic reaction partners in the cell, thus transferring alkyl groups onto nucleic acids and proteins (alkylating reactions). Most of the alkylating agents are bivalent and react by their two chloroethylamine groups. They induce intra-strand and inter-strand cross-links (bridges) within the same DNA strand or between two different DNA strands (so called cross linking). This is the main mode of action of nitrogen mustard and its derivatives. DNA replication is disturbed and eradication or damage of tumor cells is induced. This cytostatic effect is mainly exerted in cells with higher proliferative activity being in the S-phase of the cell cycle when DNA replication (doubling) is performed. Alkylating agents are not phase specific because they act during all

phases of the cell cycle. Hence, although to a lower extent, alkylating agents are able to cause cytotoxic reactions in cells outside of the cell cycle (G0 cells, nondividing cells).

Mechlorethamine (nitrogen mustard): In vivo each chloroethylamine group undergoes intramolecular cyclization with release of a chloride ion. The so formed highly reactive ethylen-immonium derivative alkylates DNA and other biomolecules and causes the cytotoxic effect.

Clinical Use (Including Side-Effects)

Nitrogen mustard is clinically used for the treatment of lymphomas and some forms of lung cancer. The major indication for mechlorethamine is Hodgkin's disease as a part of the MOPP regimen (mechlorethamine + vincristine (oncovin) + procarbazine + prednisone). The usual dose consists of 6 mg/m² on days 1 and 8. This drug has pronounced hematological toxicity (myelosuppression).

According to a hypothesis launched by Larionov et al in the 1960s, some new nitrogen mustard derivatives were developed. They contain metabolites and heterocyclic structures as carriers of the cytotoxic chloroethylamine groups. By this way the synthesis of *alkylating metabolites* started: melphalan (sarcolysine) as L- or DL-phenylalanine derivative; prospidine with a tricyclic piperazine moiety and chlorambucil as butyric acid derivative. It was proven that each alkylating metabolite has its own spectrum of selective antitumor activity.

Prospidine influenced human laryngeal tumors. Melphalan showed clinical efficacy in human seminoma and multiple myeloma. It possesses the same general spectrum of antineoplastic activity as other nitrogen mustards do. However, since it does not cause alopecia, melphalan is occasionally substituted for cyclophosphamide in the CMF regimen for breast cancer. Its bone marrow suppression tends to be more prolonged and affects both white cells and platelets. It is widely used in conditioning regimens before stem cell transplantation. Chlorambucil is used for the treatment of chronic lymphocytic leukemia, polycythemia and exerts immunosuppressive activity. It is predominantly used in the treatment of lymphomas and shares teratogenic and carcinogenic properties with the other nitrogen mustards.

German investigators (Brock et al) worked on the creation of alkylating pro-drugs that have cytostatic activity after specific biotransformation in the tumor tissue. Cyclophosphamide (CTX) has well pronounced antitumor activity with the broadest spectrum. It is metabolized to the cytotoxic phosphoamide mustard. In normal tissues with high enzyme level cyclophosphamide is converted to its inactive metabolites (Fig. 2). These differences in biotransformation can explain the relative selectivity of cyclophosphamide towards

Alkylating agents

Alkylating Agents. Figure 1 Chemical structure of some alkylating agents.

Alkylating Agents. Figure 2 Biotransformation of cyclophosphamide – formation of inactive (*) and toxic (**) metabolites.

tumor cells. It is inactive unless metabolized by the liver to 4-hydroxy-cyclophosphamide.

This drug is used for the treatment of breast carcinoma, ovarian tumors, SCLC, multiple myeloma, osteosarcoma and leukemias as a part of combination therapy. High dosages are often curative in Burkitt's lymphoma, a childhood malignancy with very fast growth rate. Oral daily dosages are useful for less aggressive tumors, such as nodular lymphomas, multiple myeloma, and chronic leukemias. Cyclophosphamide can be given orally and as intramuscular, intravenous and intra-arterial injections. Its side effects are typical for alkylating agents and include those caused by damage of cells with high proliferation rate (e.g., hematopoietic cells, gastro-intestinal and epithelial cells). A common toxic effect is the development of hemorrhagic cystitis of the urinary bladder caused by its metabolite acrolein. The risk of developing a carcinoma of the bladder is also increased. Conventional schedules contain therapeutic doses of 100–500 mg/m² within 3–14 days.

Ifosfamide is an isomeric form of cyclophosphamide with analogous mode of action.

Clinical trials showed therapeutic efficacy in a broad spectrum of tumors; these include SCLC, testicular tumors, sarcomas, breast cancer, renal cell cancer, pancreatic tumors and lymphomas. Ifosfamide is less myelosuppressive than cyclophosphamide but is more toxic to the bladder. Therefore it is recommended that ifosfamide is coadministered with the thiol compound mesna to avoid hemorrhagic cystitis and to reduce the risk of developing bladder cancer. Other side effects include neurotoxicity and myelosuppression.

Alkyl Sulfonates

British investigators (Haddow and Timmis 1951) synthesized and studied esters of the methanesulfonic acid. The most active derivative was the dimethylsulfonic ester of 1,4-butanedione, known as busulfan. Busulfan interacts with the thiol groups of proteins and amino acids; some of its metabolites can alkylate the thiols of cysteine, peptides and proteins. Busulfan exerts selective cytotoxic activity in hematopoietic bone marrow cells and inhibits the formation of granulocytes and platelets. It slightly affects the lymphoid tissue.

Clinical Use (Including Side-Effects)

Busulfan was used for the treatment of chronic myeloid leukemia and polycythemia vera.

Nitrosourea Derivatives

All members of the group ►nitrosourea derivatives are derivatives of methylnitrosourea and have mutagenic and carcinogenic properties. During the past decades nitrosoureas have been widely used for the treatment of solid tumors. Their cytostatic effects are explained by their influence on the biosynthesis of nucleic acids and proteins. They modify the chemical structure of the nucleotides. Alkyl nitrosoureas are highly reactive and alkylate strongly. Bifunctional congeners lead to DNA cross-linking. In addition, they can realize carbamoylation (introduction of the CO-NH₂ group) of biomolecules. Nitrosoureas predominantly affect the synthesis of DNA (replication) rather than synthesis of messenger, ribosomal and transport RNA (transcription). They slightly affect the synthesis of proteins

(translation). Nitrosoureas lead to great disturbances in the cell cycle and proliferation even after single exposure. Nitrosoureas can kill cells in all phases of the cell cycle. These agents undergo hepatic biotransformation to active metabolites such as isocyanates. As lipophilic compounds they easily cross the blood–brain barrier and selectively accumulate in the brain tissue at concentrations 4–5 times higher than that in hepatic and renal tissues. Nitrosoureas have been used for the treatment of gastrointestinal carcinomas. They suppress the growth of lymphoid tumors and metastatic brain tumors. Cross-resistance between nitrosoureas and classic alkylating agents was not observed. They share the feature of causing delayed bone marrow toxicity, which can be cumulative and does appear as long lasting bone marrow suppression.

Streptozotocin is a naturally occurring nitrosourea compound that was isolated from *Streptomyces achromogenes*. Its structure is related to methyl-CCNU. Streptozotocin is similar enough to glucose to be transported into the cell by the glucose transport protein GLUT2, but is not recognized by other glucose transporters. This explains its relative toxicity to beta cells, since these cells have relatively high levels of GLUT2. Streptozotocin is selectively accumulated in islet cells of the pancreas and is used for treating pancreatic islet cell cancer. It acts through methylation of nucleic acids and proteins. In addition, it produces rapid and severe depletion of the pyridine nucleotides nicotinic adenine dinucleotide (NAD) and its reduced form (NADH) in liver and pancreatic islets. Streptozotocin is used for the induction of experimental diabetes in animals.

Clinical Use (Including Side-Effects)

Carmustine is a bicyclohexylnitrosourea (BCNU, Fig. 3) with broad spectrum of antineoplastic activity (e.g., lymphomas, multiple myeloma, sarcomas, brain tumors, gastrointestinal tumors, melanomas). At doses of 80–200 mg/m² it is given i.v. at 6 week's intervals.

Lomustine (2-chlorethyl-3-cyclohexyl-1-nitrosourea, CCNU, Fig 3) is a nitrosourea for oral application. It is used for the treatment of Hodgkin's lymphomas, brain tumors and bronchial carcinomas at a dose of 3.5 mg/kg (130 mg/m²) repeated in 6–8 weeks intervals.

Carmustine and lomustine can produce remissions that last 3–6 months in 40–50% of patients with primary

brain tumors. Both drugs also are used as secondary treatment of Hodgkin's disease and in clinical trials with combination chemotherapy of various types of lung cancer.

Semustine (methyl-CCNU) is also suited for oral application but has greater toxicity and is therefore rarely used.

Nitrosoureas have been used in the treatment of non-Hodgkin's lymphomas, multiple myeloma, renal cell carcinoma, and colorectal cancer. They produce severe nausea and vomiting in most patients at 4–6 h after administration. The major site of dose-limiting toxicity is the bone marrow (leukopenia and thrombocytopenia). As alkylating agents, these drugs are mutagenic, teratogenic, and carcinogenic.

Usual dose schedules of streptozotocin involve 500 mg/m² i.v. during five consecutive days. The major toxicity is renal tubular damage. Treatment of metastatic insulinomas may result in the release of insulin from the tumor and subsequent hypoglycemic coma. Less severe toxicities include diarrhea, anemia, and mild alterations in glucose tolerance or liver function tests.

Ethylenimines

Thiotepa is chemically less reactive than the nitrogen mustards. It has antineoplastic activity against ovarian and breast cancers as well as lymphomas. However, it has been largely supplanted by cyclophosphamide and other nitrogen mustards.

Clinical Use (Including Side-Effects)

It is used by direct instillation into the bladder for multifocal local bladder carcinoma. Nausea and myelosuppression are the major toxicities of thiotepa. It is not a local vesicant and has been safely injected intramuscularly and even intra-theccally.

Triazines

Dacarbazine is activated by photodecomposition (chemical breakdown caused by radiant energy) and by enzymatic N-demethylation. Formation of a methyl carbonium ion results in methylation of DNA and RNA and inhibition of nucleic acid and protein synthesis. Cells in all phases of the cell cycle are susceptible to dacarbazine. The drug is not appreciably protein bound, and it does not enter the central nervous system.

Alkylating Agents. Figure 3 Chemical structure of some nitrosoureas.

Procarbazine is metabolized in the liver and possibly in tumor cells to yield a variety of free radical and alkylating species.

Temozolomide undergoes spontaneous hydrolysis and decarboxylation at physiological pH value and thereafter a methyl diazonium ion is released. This ion forms DNA adducts within guanine rich DNA sequences. Temozolomide has high bioavailability and is metabolized in the liver.

Clinical Use (Including Side-Effects)

Dacarbazine is the most active compound used for treating metastatic melanoma. It is also combined with anthracyclines and other cytostatics in the treatment of different sarcomas and Hodgkin's disease. Dacarbazine may cause severe nausea and vomiting. Myelosuppression results in leukopenia and thrombocytopenia. Alopecia and transient abnormalities in renal and hepatic function also occur.

Procarbazine causes myelosuppression, hypnotic and other effects on the central nervous system, e.g., vivid nightmares. Also, procarbazine causes a disulfiram like syndrome on ingestion of ethanol.

Temozolomide crosses the blood brain barrier and can be used for the treatment of brain tumors (e.g., *glioblastoma multiforme*). The most common side effects are nausea and vomiting.

Platinum Complexes

The chemical structure of the most frequently used platinum drugs (▶platinum complexes) is shown in Fig. 4.

Cisplatin was discovered fortuitously by observing that bacteria present in electrolysis solutions could not divide. It is hypothesized that in the intracellular environment, a chloride is lost and replaced by a water molecule. The resulting species is an efficient bifunctional interactor with DNA, forming platinum-based cross-links similar to that formed by alkylating agents.

Clinical Use (Including Side-Effects)

Cisplatin administration requires adequate hydration and forced diuresis to prevent kidney damage. Cisplatin is intensely emetogenic and its use requires adequate antiemetic prophylaxis. Myelosuppression is less evident than with other alkylating agents.

Carboplatin displays less nephro-, oto- and neurotoxicity. However, myelosuppression is more frequent, and as the drug is exclusively cleared through the kidney, adjustment of dose for creatinine clearance must be accomplished.

Oxaliplatin belongs to the group of diaminocyclohexane platinum complexes that can overcome platinum resistance. Its place in the primary and adjuvant treatment of colon cancers is being defined. It is prominently neurotoxic.

Alkylating Agents. Figure 4 Chemical structure of some platinum antineoplastic drugs.

Alkylating Agents. Figure 5 Chemical structure of bendamustine.

Other Alkylating Agents

Bendamustine (Fig. 5) is a representative of the group of bivalent alkylating agents and nitrogen mustard derivatives. It is supposed that bendamustine has a dual mode of action as alkylating agent and antimetabolite due to the presence of a benzimidazole ring and chloroethyl groups in its chemical structure. It is water-soluble and is widely distributed in different tissues. Bendamustine is metabolized in the liver with the formation of monohydroxy and dihydroxy derivatives and some of its metabolites are active antineoplastic compounds. It undergoes renal and biliar excretion.

Clinical Use (Including Side-Effects)

Bendamustine is a useful antineoplastic drug for the treatment of non-Hodgkin's lymphomas, multiple myeloma and as a partner drug in the combination therapy of some solid tumors. The cross-resistance with other alkylating drugs is not complete. Myelosuppression and lymphocytopenia is its main dose-limiting toxicity.

Alkylation

Alkylation is the transfer of an alkyl group from one molecule to another. The alkyl group may be transferred

as an alkyl carbocation, a free radical or a carbanion (or their equivalents).

► Alkylating Agents

Allele

Allele variant forms of the DNA sequence at a specified locus. For example, alleles at a single-nucleotide polymorphism (SNP) are characterized by the nucleotide that is changing. The combination of two alleles at a locus constitutes a genotype.

► Pharmacogenomics

Allergen

An allergen is usually an inert substance (e.g. pollen, house dust mite faeces) that in some individuals can trigger the generation of an (inappropriate) antigenic response. Mediated by TH2 lymphocytes, it causes B-Lymphocytes to produce IgE. Subsequent exposure of a sensitized individual to the allergen is therefore able to cross-link IgE antibodies on the surface of mast cells and trigger an immune response and histamine release.

Synonyms

Hypersensitivity

Definition

The term allergy describes inappropriate immune responses to foreign substances after repeated exposure giving rise to irritant or harmful, and eventually fatal reactions. Its incidence depends on two factors: the occurrence and nature of an agent eliciting immune reactions (allergen) and the reactivity of the immune system (► immune defense). In highly industrialized countries allergies may affect more than 30% of the population caused by poorly understood environmental influences. In addition, a genetically determined predisposition exists to develop an allergy.

Basic Mechanisms

Currently allergic reactions are classified into four types on the basis of different reaction patterns. Whereas types I–III are dependent on antibodies, the type IV reaction is mediated by cellular immune reactions.

Type I Reactions: Anaphylactic Reaction

This type of allergic reaction is by far the most common one, and may be responsible for more than 80% of all allergies. Often it is used synonymously with allergy.

In some individuals, exposure to an antigen – then termed allergen – leads to the increased production of specific IgE, a subclass of antibodies that physiologically is only synthesized in minute quantities. For this bias of the humoral immune response against an allergen, a subgroup of helper T-lymphocytes, Th-2 cells, plays a key regulatory role by providing the master cytokine interleukin-4 (► immune defense, cytokines). IgE binds with high affinity to receptors (Fcε-receptors) that are present on basophilic granulocytes and most prominently on the closely related mast cells. These cells thus acquire a “borrowed” (as it is, of course, synthesized by B-lymphocytes) allergen specific receptor, which can persist on these cells for long periods, at least several months, perhaps years. If that happens, an individual is “allergic”, i.e. sensitized to an allergen without exhibiting any clinical symptoms and without knowing it. Upon reexposure to this specific allergen, the mast cells (and the other IgE-bearing cells) can immediately recognize the allergen with its IgE antibodies. This results in the crosslinking of the Fcε receptors that in turn triggers activation of the mast cells (or basophils). The consequence is rapid degranulation of preformed vesicles and release of a plethora of mediators into their surrounding (see Fig. 1), the most prominent mediator is histamine which is preformed and stored in vesicles and acts immediately upon release. Within minutes, further mediators like leukotrienes are synthesized. These mediators act in concert on cells in their vicinity which bear the appropriate receptors and thereby cause the clinical symptoms of an immediate allergic reaction. These may be itching (urticaria), local swelling (edema), allergic rhinitis

Allergy. Figure 1 Type I Anaphylactic Reaction: IgE-bearing mast cells are activated by allergens to release mediators of acute allergic reactions.

(“hay fever”), constriction of bronchi (“asthma”), and when occurring in a generalized form, “anaphylactic” shock and eventual death. Activated mast cells also start synthesizing protein mediators, termed cytokines, in a process that requires some time (a few hours). These cytokines initiate an acute inflammatory response that in its late phase is characterized by the infiltration of leukocytes and especially eosinophilic granulocytes.

Type II Reactions: Cytotoxic Reaction

As a physiological response to an antigen, B-lymphocytes initially always secrete antibodies of the IgM class, only in the late stage of the primary response or upon reexposure to the same antigen, B cells switch immunoglobulin classes and produce IgG, IgA, or IgE (►immune defense). In rare situations the antigen, or a metabolite thereof, either alone or bound to a carrier protein, may bind firmly to surfaces of cells. The antigen on the cell surface is now recognized by specific IgG antibodies, and thus the whole cell is labelled as a

“foreign” particle that is consequently – but erroneously – destroyed by the complement system or cellular mechanisms. Type II reactions contribute to autoimmune mechanisms (►autoimmune diseases). They are also responsible for allergic reactions to certain drugs and may induce severe diseases such as drug-induced aplastic anemia or agranulocytosis.

Type III Reactions: Immune Complex Reactions

In the case of the Type III reaction physiologically produced antibodies, predominantly of the IgG subclasses, bind specifically the soluble antigen and form immune complexes. These immune complexes may bind directly to Fcγ receptors or be coated with complement components and thus be opsonized for uptake by phagocytic cells that normally degrade them and thus eliminate them. An “allergic” situation occurs if these immune complexes cannot be ingested appropriately and degraded. Alternatively, and more often, due to a continuous supply of allergen, the phagocytic cell is incapable of coping with the mass of

resulting immune complexes. Thus the phagocytic cells respond to the frustraneous or continuous stimulation of Fc γ receptors by secreting a variety of products into their surrounding. These include catabolic enzymes that degrade unspecifically all available biological macromolecules such as proteins, nucleic acids, carbohydrates, or lipids no matter whether these are foreign or belong to the host, resulting in continuous destruction. It should be noted that this mechanism of damage is identical with that occurring in chronic inflammatory diseases (►inflammation) such as in ►rheumatoid arthritis or nephritis. Typical allergic Type III reactions are pulmonary diseases against inhalative irritants, or “►serum sickness” occurring after administration of high molecular weight proteinaceous drugs, originally animal serum applied during passive vaccination, but also murine monoclonal antibodies or other drugs.

Type IV Reactions: Cellular Reactions

At the time when allergic reactions were classified little was known about cellular reactions, thus it appears appropriate today to divide this reaction type in two subgroups.

Type IVa Reactions: Cellular Cytotoxic Reactions

In this type of reaction an antigen elicits the generation of cytotoxic T-lymphocytes (►immune defense). Cytotoxic T-lymphocytes (T_c) destroy antigen bearing cells by inducing apoptosis. This reaction can be viewed as the cellular counterpart to the humoral Type II reactions. They play an important physiological role in the defense of viruses, and can become allergic reactions under the same conditions as described for Type II reactions.

Type IVb Reactions: Delayed Type Hypersensitivity Reactions

Antigens commonly induce the activation of T-lymphocytes of the T helper type (Th). In the case of Type IV b reactions the predominant responding cell is the Th-1 subtype. By secreting many cytokines, including ►interferon γ , Th-1 lymphocytes recruit and activate granulocytes and monocytic cells to mount an inflammatory response. In that respect the Type IVb reaction can also be viewed as a cellular counterpart of a humoral reaction, specifically of a Type III reaction, being of great importance in chronic inflammatory diseases such as rheumatoid arthritis, and glomerulonephritis, or in autoimmune diseases such as systemic lupus erythematoses. In fact, in these situations both Type III and Type IVb contribute to the chronic inflammatory reaction. With respect to allergy, Type IVb reactions are relevant for contact ekzema, i.e. the chronic response of skin to many irritants including chromate, nickel, cosmetics, fabrics, etc.

Pharmacological Intervention

General

The ideal and single curative treatment of an allergy is to strictly avoid exposure to the responsible allergen(s). This requires to elucidate the causative agent. A battery of diagnostic methods is available to achieve this including measurement of IgE in blood (RAST), various methods of eliciting allergic reactions in the skin (skin testing), and provocation of clinical symptoms (e.g. in food allergy). Unfortunately, many allergens are difficult to avoid in daily life as they occur ubiquitously or, in the case of occupational exposure, would require a change in profession. Thus, in many cases pharmacological intervention may be necessary to improve the health of the allergic patient.

Type II, III, and IV allergic reactions are variants of physiologic defense mechanisms only relevant in special situations, which follow a common pathologic pattern. In general, treatment of these forms require anti-inflammatory (►inflammation) or immunosuppressive strategies (►immunosuppression). Therefore, only therapy of Type I reactions will be described here.

Therapy of Type I Reactions

(Rush) Immunotherapy (Hyposensitization)

The inappropriate production of IgE to an allergen is caused by a Th-2 preponderance upon exposure to the allergen. Immunotherapy aims to influence the undesired Th-2 immune response and shift it to a Th-1 answer. It was found empirically and consists of the application of increasing doses of the allergen within a few days, starting with a very low, clinically inapparent, dose, and ending with a dose close to or above the one which is to be expected in a natural situation (e.g. after a bee sting). The high dose usually is applied at monthly intervals for up to three years or even longer. An absolute indication for immunotherapy are allergies to bee or wasp poison, which may result in an anaphylactic shock and may be fatal. At least partial relief may be achieved by immunotherapy in patients with allergies against defined pollen, but mostly fails with complex mixtures of allergens such as proteins of pets (epithelia, hair) or proteins in the faeces of mites (house dust allergy). With the availability of modern molecular biology and the achievements of recombinant DNA technology the identification of the responsible structures of allergens and their production in defined quality and quantities may increase the rate of success also with complex allergens or mixture of allergens in future.

Pharmacotherapy

Histamine H-1 Receptor Antagonists

Histamine H-1 receptor antagonists compete with the binding of histamine to its Type I receptors which are predominantly located in cells of the vasculature, and

Allergy. Figure 2 Histamine H-1 receptor antagonists inhibit response of target cells to histamine and relieve hay fever-like symptoms.

thus block its action (Fig. 2). H-1 receptor antagonists are effective when symptoms occur which involve peripheral blood vessels – around which the majority of mast cells are located – such as urticaria, allergic rhinitis (“hay fever”), or conjunctivitis. As histamine receptors are also present in the brain, their blockade influences the ability to focus and may result in sleepiness. However, modern second generation H-1 receptor antagonists do not cross the blood–brain barrier and thus do not show this undesired sedative side effect (examples: loratadin, fexofenadin, cetirizin).

Leukotriene Antagonists

Leukotrienes are rapidly produced and released during a Type I reaction (Fig. 3). They are responsible for a massive bronchoconstriction in allergic bronchial asthma and attract leukocytes, thus being proinflammatory. Consequently, antagonists of the LTC receptor have been proven useful in the therapy of ► bronchial asthma, often in combination with bronchodilators (example: montelukast).

Cromones

Cromones suppress the release of mediators from mast cells by a mechanism that is not known (Fig. 4). In order to achieve the complete suppressive effect, cromones have to be given prophylactically several days to weeks before exposure to seasonal allergens can be expected,

emphasizing the importance of warning systems or calendars (e.g. for pollen) as means for initiating therapy. Cromones also are effective in ongoing allergic responses, but then a few days are required to see benefits for the patient. Cromones are practically insoluble and thus are not absorbed beyond the top layers of tissues. This has the advantage that no systemic side effects occur, on the other hand cromones only act locally and must be applied at the site of action wanted. Cromones have beneficial effects in allergic rhinitis (nose drops or spray), conjunctivitis or bronchial asthma (inhalable preparations) (examples: disodium cromoglycate or nedocromil).

Glucocorticoids

Topically Applied Glucocorticoids – “Inhalable”

Glucocorticoids

Glucocorticoids are very effective anti-inflammatory drugs. In Type I allergy they affect several different target cells, the most important being the mast cells and infiltrating T-lymphocytes. In general their action is immunosuppressive (► immunosuppression). On mast cells, glucocorticoids mainly affect the synthesis and release of mediators such as the arachidonic acid metabolites and most prominently the cytokines. The molecular mechanism of glucocorticoid action is complex and can be summarized as a regulatory effect on gene induction and expression (Fig. 5).

Allergy. Figure 3 Leukotriene LT receptor antagonists inhibit the response of target cells to leukotrienes and relieve symptoms of allergic asthma bronchiale.

Allergy. Figure 4 Cromones “stabilize” mast cells.

Allergy. Figure 5 Glucocorticoids regulate gene expression, resulting in a decrease of cytokine and mediator release.

Of all glucocorticoids applied to the upper respiratory tract (nose, bronchi) more than 80% may be swallowed and finally absorbed by the gastrointestinal tract. This fraction reaches the circulation after an initial first passage through the liver. “Modern” glucocorticoids for inhalation are chemically modified in a way that they are completely inactivated metabolically by the liver. Thus inhalable glucocorticoids in therapeutic doses are effective in the respiratory tract, but do not give rise to systemic side effects (►glucocorticoids). They play an important role in the long term treatment of ►bronchial asthma. They also have beneficial effects in allergic rhinitis (“hay fever”), especially in seasonal forms (example: beclomethason, budesonid).

Glucocorticoid Ointments

Glucocorticoid ointments are used to treat allergic skin reactions locally. They should be applied only for limited periods to avoid trophic damage to the skin such as thinning (paper skin).

Systematically Applied Glucocorticoids

Because of their considerable side effects – which depend on dose and, even more relevant, on the duration of application – systemically applied glucocorticoids are only used in serious allergic diseases.

This includes ►bronchial asthma, autoimmune, and chronic inflammatory diseases.

Anti-IgE Antibodies

A modern strategy of pharmacological intervention aims at the neutralization of immunoglobulin E before it binds to the Fcε receptors on the mast cells. This is achieved by applying a monoclonal antibody recognizing the Fc part of human IgE antibodies irrespective of their antigen specificity. By this means IgE cannot bind to the Fcε receptor on mast cells, basophils, and dendritic cells. Thus activation of these cells does not take place even in the presence of allergen, because the allergen will bind to the IgE molecules kept in solution by the neutralizing antibody, and the mast cells remain quiescent (Fig. 6). The humanized monoclonal antibody of the IgG1 type is indicated in patients with moderate and severe asthma if it cannot be managed with glucocorticoids (Omalizumab, Xolair®).

Anaphylactic Shock

The most serious acute Type I reaction is the generalized reaction, the anaphylactic shock. Anaphylactic shock results from a generalized release of mediators from mast cells and basophils. The clinical symptoms are manifested predominantly in

Allergy. Figure 6 Anti IgE antibodies prevent IgE from binding to their receptors on mast cells, and thus from releasing allergic mediators.

1. Circulation: Leakage of fluid from the vasculature into the surrounding tissue causes edema, drop in blood pressure and finally hemodynamic shock.
2. Heart: Histamine (and also other mediators) induce arrhythmias which can be fatal.
3. Respiratory tract: all symptoms associated with allergy can occur, starting from profuse rhinitis to severe asthma and suffocation.
4. Gastrointestinal system: cramps and diarrhea.
5. Skin: generalized urticaria and erythema.

2. readily resorptive glucocorticoid solution (orally)
3. readily resorptive histamine H-1 receptor antagonist (**cave:** sedation!!)
4. (if available: inhalable epinephrine)

- ▶ Immunosuppressive Agents
- ▶ Humanized Monoclonal Antibodies

Treatment

The fate of the patient largely depends on the first 30 min of an anaphylactic shock reaction. Thus persons with a known history of hypersensitivity reactions towards bee or wasp poison should always carry an emergency set during the insect season (see below).

1. Intravenous infusion of epinephrin: 0.1–0.5 mg epinephrin dissolved in plasma replacement, this can be repeated after 5 min.
2. Plasma replacement (any): this should also be used as a continuous access to the intravenous blood.
3. Glucocorticoids: 300 mg to 1 g as bolus
4. Histamine H-1 receptor antagonist

Emergency Set Contains:

1. a ready to use epinephrine solution in a special syringe allowing sequential application in two doses

Allodynia

The sensation of pain, following injury or disease, in response to a previously non-noxious stimulus is termed ‘allodynia’. Tactile allodynia is caused by

recruitment of low-threshold (non-nociceptive) sensory fibres (A β) in nociceptive pathways.

Allostatic State

A state of chronic deviation of a regulatory system from its normal (homeostatic) operating level is defined as an allostatic state. In the context of drug addiction this term has been introduced by George Koob and Michel Le Moal and represents a chronic deviation of reward set point by dysregulation of reward circuits and brain stress systems that provide a negative motivational state that drives addictive behavior.

- ▶ Drug Addiction/Dependence

Allosteric Modulators

Unlike competitive antagonists that bind to the same domain on the receptor as the agonist, allosteric modulators bind to their own site on the receptor and produce an effect on agonism through a protein conformational change. Allosteric modulators can affect the affinity of the receptor for the agonist or simply the responsiveness of the receptor to the agonist. A hallmark of allosteric interaction is that the effect reaches a maximal asymptote corresponding to saturation of the allosteric sites on the receptor. For example, an allosteric modulator may produce a maximal 10-fold decrease in the affinity of the receptor for the agonist upon saturation of the allosteric sites on the receptor.

Alternative Splicing

Alternative splicing is the process occurring when eukaryotic pre-mRNA, which includes several introns and exons, is transcribed from one gene to undergo distinct cutting and pasting processes yielding different mature mRNAs. It is an important cellular mechanism that leads to temporal and tissue-specific expression of unique mRNA products from a single gene. It thereby increases protein diversity by allowing multiple, sometimes functionally distinct, proteins to be encoded by the same gene.

Synonyms

Morbus Alzheimer (most common form of dementia)

Definition

Alzheimer's disease (AD) is a progressive, degenerative and irreversible neurodegenerative disorder of the brain. The greatest risk factor for developing AD is increasing age. The likelihood of developing AD doubles almost every five years after age 65, reaching nearly 50 percent risk after age 85. ► **Familial Alzheimer's disease (FAD)** is a hereditary form of the disease that occurs earlier in life with an onset before the age of 65 and accounting for 5–10% of total AD cases. The majority of cases is sporadic without a clear inheritance pattern and occurs after age 65. So far, there is no cure for the impaired memory and the loss of mental abilities affecting normal activities of daily living. Cognitive tests and exclusion of other diseases are used to diagnose AD with a restricted accuracy in living patients. A confirmation of the diagnosis is only possible by autopsy. The key pathological hallmarks of AD are the extracellular ► **amyloid plaques** and intracellular neurofibrillary tangles and its constituent, the tau microtubule-associated protein. The principle component of plaques is the amyloid beta peptide ($A\beta$). The $A\beta$ peptide is derived from the amyloid precursor protein (APP) by two consecutive proteolytic cleavage events. Aggregates of the $A\beta$ peptide are ultimately believed to cause the neurodegeneration that leads to AD.

Basic Mechanisms

The Amyloid Hypothesis

According to the “amyloid hypothesis,” the $A\beta$ peptide plays a critical role in the pathogenesis of Alzheimer's disease [1]. Major forms of $A\beta$ produced encompass 38, 40 or 42 residues. $A\beta_{42}$ is more prone to aggregation than $A\beta_{40}$ and in animal models an increased $A\beta_{42}/A\beta_{40}$ ratio results in amyloid plaque pathology even when total $A\beta$ levels are reduced [4]. The generation of $A\beta$ is a normal process and $A\beta$ is present in the brains and body fluids of humans throughout life. Neuronal

injury appears to result from an ordered self-association of $A\beta$ monomers or dimers before plaque formation can be observed. A loss of neurons was observed in brains of transgenic mice expressing human mutant amyloid precursor protein at sites of $A\beta$ aggregation but, most importantly, was also clearly observed in brain areas distant from plaques. This finding together with the correlation found between levels of soluble $A\beta$ oligomers and the severity of synaptic loss, led to the conclusion that aggregation of $A\beta$ into oligomers is essential for toxicity. $A\beta$ monomers can spontaneously aggregate into oligomers or protofibrils on the pathway to fibril formation (Fig. 1). It seems that oligomerization is an intermediate step in the formation of protofibrils or the end point of an alternative non-fibrillar assembly process prior to plaques or tangle pathology [3].

Oligomeric forms of $A\beta$ either derived from synthetic $A\beta$ or purified from $A\beta$ -containing cell culture medium could be shown to trigger hippocampal synapse loss and are thus suspected to be the effectors of synaptic dysfunction in AD. Based on these findings and findings obtained from APP transgenic mice and human brain tissue the amyloid hypothesis of AD pathogenesis has been modified. Rather than extracellular plaque $A\beta$ causing toxicity, neuronal $A\beta_{42}$ accumulation may play a direct role in causing neuronal dysfunction, neuronal death and dementia caused by oligomer formation of $A\beta_{42}$ inside of the cells.

$A\beta$ is Derived from the Amyloid Precursor Protein (APP)

APP is a type-I transmembrane protein that is part of an evolutionarily conserved protein family, including the amyloid precursor-like proteins 1 (APLP1) and 2 (APLP2). APP and APLPs are functionally redundant and form homo- and hetero-oligomers. The absence of the $A\beta$ sequence in the APLPs underlines the importance of APP that can only give rise to the $A\beta$ species. Decreasing the formation of soluble $A\beta$

Alzheimer's Disease. Figure 1 $A\beta$ monomers can self-associate to form dimers, trimers and higher oligomers. Globular structures of synthetic $A\beta_{42}$ are known as $A\beta$ -derived diffusible ligands (ADDLs) (3–12-mers of $A\beta$). These structures are similar to the smallest protofibrils and represent the earliest macromolecular assembly of synthetic $A\beta$. The characteristic amyloid fiber exhibits a high beta-sheet content and is derived in vitro by a nucleation-dependent self-association and an associated conformational transition from random to beta-sheet conformation of the $A\beta$ molecule. Intermediate protofibrils in turn self-associate to form mature fibers.

monomers and dimers to prevent the generation of cytotoxic oligomers should prove an effective strategy against AD.

APP undergoes proteolytic processing by several ►secretases. First, the bulk of the ectodomain needs to be removed by membrane-bound α - or β -secretases leading to secreted forms of APP and membrane-bound C-terminal fragments α -CTF or β -CTF, respectively. Regulated intramembrane proteolysis (RIP) of the β -CTF by γ -secretase occurs only after ectodomain shedding and releases the A β peptide from the membrane (Fig. 2).

The γ -secretase has been reported to cleave at variable sites thus generating A β peptides of varying lengths with mainly 37–43 residues. An explanation for the multiple cleavages of γ -secretase was provided indicating a sequential proteolytic cleavage mechanism to release A β [2]. Accordingly, the first cut occurs at the cytoplasmic edge of the transmembrane sequence (TMS) at the ϵ -site, i.e. residue 49 or 48 of β -CTF. The products A β 49/A β 48 remain membrane-bound and are further processed in a sequential action mode into A β 46/A β 45, i.e. the ζ -site. A β 46 is further processed into A β 43 and finally A β 40 whereas A β 45 is the direct precursor of A β 42. The underlying mechanism for the regulation is uncertain but alterations in A β production may be reflected by the dynamic nature of the substrate and/or altered enzyme/substrate interactions. The current view is that the generation of A β 42 and A β 38 levels can be regulated by the strength of homophilic interactions within the APP TMS itself leading to the generation of the shorter species A β 37, A β 35 and A β 34 if the interaction is attenuated. Any events stabilizing dimerization would increase the production of A β 42 and vice versa. It could be considered that AD risk factors like

high cholesterol levels or disturbed lipid homeostasis, oxidative stress, disturbed metal homeostasis or familial AD mutations affect the dimer stability of β -CTF and thus influences A β production. Compounds targeting the dimerization of the APP TMS and interfering with the interaction motif of two γ -secretase substrate molecules may be useful as future therapeutics to prevent generation of A β 42.

Pharmacological Intervention

The current treatments cannot cure the disease but are suspected to offer patients modest improvement in some symptoms. For treating the cognitive symptoms of AD, a class of drugs known as cholinesterase inhibitors, such as Galantamin, Rivastigmin, Donepezil and Tacrin, act in delaying the breakdown of acetylcholine that facilitates normal functioning of nerve cells. Another approved agent, Memantine, is an uncompetitive NMDA antagonist which prevents the excessive binding of glutamate to the receptor. Other examples used to treat behavioral and psychiatric symptoms of AD include antidepressant medications for low mood and irritability as well as anxiolytics and antipsychotic medications.

Drugs in clinical development that directly target the A β pathway are at an early stage. Inhibitors of β - and γ -secretases that can lower the A β production have entered clinical phase trials with β -secretase inhibitors being years behind the development of γ -secretase inhibitors. Functional γ -secretase inhibitors have been shown to reduce the rate of A β formation *in vitro* and *in vivo*. The reduction of A β monomer levels could prevent oligomer formation and subsequent synaptotoxicity. Numerous anti-amyloid approaches to

Alzheimer's Disease. Figure 2 A β is derived from the APP by the sequential action of proteolytic activities exerted by β - and γ -secretases. APP-CTF is (C99) produced after cleavage of the APP by β -secretase and represents the substrate of the γ -secretase. The yellow box marks membrane embedded amino acid residues of A β peptide. Scissors represent the main cleavage sites of β - and γ -secretase, e.g. the ζ -, ϵ -, and γ -cleavages at positions 49, 46, 42, 40 and 38.

disassemble, neutralize or degrade A β oligomers are under development. For the latter, an up-regulation of enzymes involved in A β degradation, such as over-expression of neprilysin (NEP) or the insulin degrading enzyme (IDE) led to the desired effects. A β levels in APP transgenic animals were found decreased and plaque burden was reduced. Alternatively, inhibitors of A β aggregation have been tested *in vitro* for two different purposes: first, to stabilize the monomer and then to shift these molecules into the normal degradation pathway and second, to bind to A β oligomers and to disrupt these structures. The compound tramiprosate is a sulfated glycosaminoglycan mimetic, which is suggested to preferentially bind to soluble A β and can inhibit plaque formation in APP transgenic mice. Other compounds such as AZD-103 (scyllo-cyclohexane-hexol) were shown to disassemble large A β oligomers and to neutralize A β dimers and trimers. Similarly, it has been shown that anti-A β antibodies hold a great promise for elucidating the A β clearance by redistributing A β from the brain to the systemic circulation. New therapeutic approaches based on the assumption that the APP pathway underlies the cause of the disease will have more and more to consider structural and functional information on the biological roles of APP and APLPs that may prove useful for novel strategies against this devastating disorder. Thus, compounds targeting the oligomerization mediated by the APP TMS and interfering with the interaction of two γ -secretase substrate molecules may be useful as therapeutics to prevent generation of A β 42.

Synonyms

AMP-activated protein kinase, AMPK; SNF1 complex (fungi); SNF1-related kinase-1 (higher plants)

Definition

The AMP-activated protein kinase (AMPK) is the downstream component of a protein kinase cascade that acts as a sensor of cellular energy status [1, 2, 3]. It is activated, via mechanisms described below, by an increase in the cellular AMP:ATP ratio. Because all eukaryotic cells express a very active adenylate kinase, which maintains the reaction $2\text{ADP} \leftrightarrow \text{ATP} + \text{AMP}$ close to equilibrium at all times, any increase in the ADP:ATP is amplified into a much larger increase in the AMP:ATP ratio. This can happen due to a metabolic stress that interferes with ATP production (e.g. hypoxia, glucose deprivation), or that increases ATP consumption (e.g. muscle contraction). Once activated by a fall in cellular energy status or other stimulus, AMPK switches on ATP-generating catabolic pathways, while switching off ATP-consuming processes to restore energy status. The system is the primary target of the ►biguanide drugs (e.g. ►metformin), and is both a direct and indirect target of the ►thiazolidinediones (e.g. ►rosiglitazone, ►pioglitazone), all of which are used as insulin-sensitizing drugs in the treatment of type 2 diabetes.

Basic Characteristics

AMP-activated protein kinases are heterotrimeric complexes comprised of catalytic α subunits and regulatory β and γ subunits (Table 1). Each subunit is encoded by at least two genes, some of which can also be subject to alternate splicing, leading to a diverse array of possible heterotrimeric combinations.

The α subunits, for which two isoforms exist in mammals ($\alpha 1$, $\alpha 2$), contain conventional protein serine/threonine kinase domains at the N-terminus, with a threonine residue in the activation loop (Thr-172) that must be phosphorylated by upstream kinases (see below) before the kinase is active. The kinase domain is followed by an autoinhibitory domain, whose effect is somehow relieved by interaction with the other subunits. The C-terminal domain of the α subunit is required for the formation of a complex with the C-terminal domain of the β subunit, which in turn mediates binding to the γ subunit. The $\alpha 1$ and $\alpha 2$ catalytic subunit isoforms are widely distributed, although $\alpha 2$ is most abundant in muscle and may be absent in cells of the endothelial/hemopoietic lineage.

The β subunits, for which two isoforms exist in mammals ($\beta 1$, $\beta 2$), contain a central glycogen-binding domain. This domain, related to noncatalytic domains found in enzymes that metabolize the $\alpha 1 \rightarrow 6$ branch points in $\alpha 1 \rightarrow 4$ -linked glucans, such as starch and glycogen, causes the AMPK complex to bind to glycogen, although the physiological role of this remains unclear. The β subunits also contain a C-terminal domain that is responsible for the association with the α and γ subunits. The two β subunit isoforms ($\beta 1$ and $\beta 2$) are widely distributed, although $\beta 2$ is most abundant in muscle and may be low or absent in some cell types.

The γ subunits, for which three isoforms exist in mammals ($\gamma 1$, $\gamma 2$, $\gamma 3$), contain variable N-terminal regions followed by four tandem repeats of a 60 residue sequence known as a CBS motif. CBS motifs, named after the enzyme cystathionine β -synthase in which they are also found, occur in around 20 proteins in the human genome and always occur in tandem pairs. A pair of CBS motifs form a stable domain known as a Bateman domain, the function of which appears to be the binding of regulatory adenosine-containing ligands such as AMP, ATP, or S-adenosylmethionine (the latter being an activating ligand for cystathionine β -synthase). Bateman domains have central clefts formed by two hydrophobic β -sheets, with the adenosine moiety of the ligand binding within this cleft. The three AMPK γ subunits are unusual, in that they contain two Bateman domains (i.e. four CBS motifs), each of which binds one molecule of the activating nucleotide, AMP, or the inhibitory nucleotide, ATP. Thus, two molecules of nucleotide bind to each γ subunit, with binding being highly cooperative. The γ subunits also contain a short

AMP-activated Protein Kinase. Table 1 Information about subunit isoforms of AMP-activated protein kinase. Data refer to the full-length forms of the human isoforms. The $\gamma 2$ and $\gamma 3$ isoforms also exist as splice variants that are N-terminal truncations, with lower molecular mass and number of amino acids (38 kDa and 328 amino acids for the short form of $\gamma 2$, 52 kDa and 464 amino acids for the short form of $\gamma 3$). Other splice variants may also exist

conserved sequence of about 25 residues immediately N-terminal to the first CBS motif, which appears to be involved in the interaction with the β subunit. The function of the variable N-terminal domains present in the $\gamma 2$ and $\gamma 3$ isoforms (some or all of which can be

removed by RNA splicing) are not known, although one possibility is that they are involved in subcellular targeting of the complex. The $\gamma 1$ isoform is the major isoform in most cell types and appears to be universally distributed. The $\gamma 2$ isoform is most abundant in skeletal

and cardiac muscle but probably also occurs elsewhere. The $\gamma 3$ isoform appears to be almost restricted to skeletal muscle.

Upstream kinases can phosphorylate the AMPK α subunits at Thr-172, thus activating the kinase complex by >100-fold. The major upstream kinase in most mammalian cells is a complex between the tumor suppressor, LKB1, and two accessory subunits, STRAD and MO25. LKB1, which does not require to be phosphorylated for activity, is completely inactive unless STRAD is bound to it, while MO25, a protein containing helical repeats distantly related to armadillo proteins, appears to stabilize the LKB1:STRAD complex. STRAD is a “pseudokinase” that has a domain related to a protein kinase domain. This domain has no catalytic activity but still binds ATP, although this is not required for its ability to activate LKB1.

In humans, the LKB1 complex is now known to act as an upstream kinase for the whole subfamily of AMPK-related protein kinases, including twelve other kinases with functions distinct from AMPK, as well as the two catalytic subunit isoforms of AMPK ($\alpha 1$ and $\alpha 2$). The LKB1 complex appears to be constitutively active, thus constantly phosphorylating Thr-172 on $\alpha 1$ and $\alpha 2$. However, the phosphate is normally rapidly removed by dephosphorylation by protein phosphatases, with the physiological phosphatase probably being a form of protein phosphatase-2C. Binding of AMP to the γ subunit of the AMPK complex markedly inhibits dephosphorylation by protein phosphatase-2C, thus providing a sensitive switch mechanism that converts AMPK to the active phosphorylated form (Fig. 1). AMP binding also allosterically activates AMPK up to tenfold, so that the system will remain hyper-activated until AMP dissociates (the combined effect of phosphorylation and allosteric activation is at least 1000-fold). The second CBS motif (in the N-terminal Bateman domain) of all γ subunits contains a sequence that resembles the sequence of the target sites on downstream substrates for AMPK, except that it contains a nonphosphorylatable residue in place of serine or threonine. An attractive hypothesis is that this “pseudosubstrate” sequence binds to the substrate-binding groove on the α subunit in the absence of AMP. Some of the residues within this pseudosubstrate sequence also appear to be directly involved with AMP binding, suggesting an obvious mechanism whereby AMP binding relieves this pseudosubstrate interaction and causes allosteric activation.

Both effects of AMP (inhibition of dephosphorylation and activation) are antagonized by high concentrations of ATP, which compete with AMP for binding at the Bateman domains. Thus, the AMPK system can monitor changes in the cellular AMP:ATP ratio.

As well as the activation of AMPK by increases in cellular AMP:ATP, due to phosphorylation by LKB1,

AMP-activated Protein Kinase. Figure 1 Mechanism of activation of AMPK by AMP and Ca^{2+} . In resting cells, the catalytic α subunit of the AMPK complex is continually phosphorylated at Thr-172 by the LKB1:STRAD:MO25 complex, but the phosphate is at the same time rapidly removed by protein phosphatases (probably a form of protein phosphatase-2C, PP2C). Binding of AMP due to the AMPK γ subunit, due to elevation of AMP in response to metabolic stress, inhibits dephosphorylation and thus tends to switch the AMPK complex to the active, phosphorylated form, where it is further activated allosterically by AMP. High concentrations of ATP antagonize both effects of AMP, by competing with AMP for binding at the γ subunit. In some cell types that express CaMKK β , elevation of cytosolic Ca^{2+} due to an external stimulus can cause increased phosphorylation of AMPK. This is not dependent on an increase in AMP, although it may be further accentuated by it.

AMPK can also be activated by a Ca^{2+} -mediated pathway involving phosphorylation at Thr-172 by the Ca^{2+} /calmodulin-dependent protein kinase, CaMKK β . CaMKK α and CaMKK β were discovered as the upstream kinase for the calmodulin-dependent protein kinases-1 and -IV; they both activate AMPK in a Ca^{2+} /calmodulin-dependent manner in cell-free assays, although CaMKK β appears to much more active against AMPK in intact cells. Expression of CaMKK α and CaMKK β primarily occurs in neural tissues, but CaMKK β is also expressed in some other cell types. Thus, the Ca^{2+} -mediated pathway for AMPK activation has now been shown to occur in response to depolarization in rat neuronal tissue, in response to thrombin (acting via a Gq-coupled receptor) in endothelial cells, and in response to activation of the T cell receptor in T cells.

AMPK is also regulated by a number of cytokines, including ►adipokines secreted from adipocytes that

are thought to play a key role in the regulation of whole body energy balance. Thus, it is activated by the adipokine ▶leptin in skeletal muscle, where it stimulates energy expenditure by activating fatty acid oxidation whereas, conversely, it is inhibited by leptin in the hypothalamus. The latter appears to be involved in the ability of leptin to inhibit food intake, because other agents that stimulate AMPK in the hypothalamus, such as the gut hormone ghrelin, cannabinoids, and hypoglycemia, all stimulate food intake in rodents. AMPK is also activated in muscle and liver by the ▶adipokine ▶adiponectin, with activation of AMPK by ▶adiponectin in the liver being required for its hypoglycemic effects, and by the proposed “▶myokine” interleukin-6. The molecular mechanism(s) by which these cytokines regulate AMPK remain unclear at present.

Once activated, the AMPK system switches on catabolic pathways that generate ATP (upper entries in Table 2), such as the uptake and oxidation of fatty

acids and glucose, while at the same time inhibiting ATP-consuming processes (lower entries in Table 2) such as biosynthetic pathways involved in energy storage, and in cell growth and proliferation. AMPK achieves this both by direct phosphorylation of metabolic enzymes, and by phosphorylation of transcription factors or coactivators that regulate gene expression.

Drugs

The first pharmacological agent shown to activate AMPK was 5-aminoimidazole-4-carboxamide (AICA) riboside, also known as ▶acadesine. This adenosine analogue is taken up into cells by adenosine transporters and phosphorylated by adenosine kinase to the monophosphorylated form, AICA ribotide or ZMP. ZMP accumulates inside cells to higher concentrations than the concentration of AICA riboside present in the medium, and it mimics both effects of AMP on AMPK system (allosteric activation and inhibition of

AMP-activated Protein Kinase. Table 2 Metabolic effects of AMPK activation. In cases marked with an *asterisk, there is evidence that AMPK mediates its effects by modulating the target named, although it is not yet clear whether the protein is directly phosphorylated by AMPK

Metabolic process	Effect	Immediate target	Immediate effects	Tissue
Glucose uptake	↑	AS160?	↑ GLUT4 translocation	Muscle

Glucose uptake	↓	?	↓ Insulin stimulation	Adipocytes
Lipolysis	↓	Hormone sensitive lipase (HSL)	↓ Adrenergic stimulation of lipolysis	Adipocytes

dephosphorylation), although it is less potent than AMP itself. Thus, AICA riboside can be used to activate AMPK in intact cells and in vivo. It has been used in animal models of obesity and insulin resistance such as the ob/ob mouse, the fa/fa rat and the fat-fed rat, where it improves glucose tolerance, increases insulin sensitivity and lowers blood pressure. Acadesine has also undergone clinical trials in humans, particularly as an acute treatment during coronary artery bypass graft surgery. These studies were initiated before it was realized that the drug was a potential AMPK activator, and the rationale was that it could be used to replenish adenine nucleotides lost from the cardiac muscle during periods of ischemia. These trials appear to have yielded inconclusive results regarding the efficacy of acadesine in such circumstances.

In 2001 it was reported that AMPK was activated by the ►biguanide metformin, and the following year it was reported that it was activated by the ►thiazolidinediones, ►rosiglitazone, and ►pioglitazone. ►Metformin is currently the most widely prescribed drug used to treat type 2 diabetes (current estimates are that it is used to treat 120 million worldwide), while the ►thiazolidinediones are another major drug class used to treat insulin resistance and type 2 diabetes. ►Metformin (and its sister drug ►phenformin) have no known target other than AMPK, and recent evidence involving mice in which the LKB1 gene was knocked down in liver (thus preventing activation of AMPK by the ►biguanides) supports the idea that the primary target of the drug is liver AMPK. Activation of liver AMPK decreases hepatic glucose production by downregulating expression of enzymes of gluconeogenesis, e.g. phosphoenolpyruvate carboxykinase and glucose-6-phosphatase. ►Metformin and ►phenformin do not activate AMPK directly in cell-free assays but, surprisingly, appear to work indirectly by inhibiting complex I of the respiratory chain, thus increasing the cellular AMP:ATP ratio. This mechanism of action explains the main side effect of ►phenformin, i.e. lactic acidosis, which led to the withdrawal of the drug. There appears to be a much lower risk of lactic acidosis in the case of ►metformin, where gastrointestinal disturbance is the major side effect. However, there is evidence from animal studies that the major source of lactic acid produced in response to ►biguanides is the gut, and it is possible that inhibition of the respiratory chain in intestinal epithelial cells may explain the gastrointestinal side effects commonly reported during metformin use.

The thiazolidinediones have also been reported to act as inhibitors of the respiratory chain at high concentrations, and this appears to account for their ability to activate AMPK in cultured cells. However, the primary target of the thiazolidinediones appears to be the peroxisome proliferator-activated receptor- γ (►PPAR- γ), a member of the nuclear receptor superfamily expressed in adipocytes. One of the major effects of stimulation of ►PPAR- γ in adipocytes is the release of the

►adipokine adiponectin, and studies in ►adiponectin-deficient mice suggest that this accounts for many, although not all, of the effects of ►thiazolidinediones. AMPK is in any case a major target for ►adiponectin action, with knockdown of liver AMPK by expression of a dominant negative mutant preventing the hypoglycemic effects of ►adiponectin.

AMPA Receptors

The ionotropic glutamate receptors have been classified based upon their pharmacology and form three distinct subgroups. These are the α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, N-methyl-D-aspartate (NMDA) receptors, and kainate (KA) receptors. AMPA receptors are responsible for the majority of fast excitatory synaptic transmission, and their over-activation is potentially excitotoxic. AMPA receptors conduct Na^+ , K^+ and sometimes Ca^{2+} in response to ligand binding. The specific conducting and kinetic properties depend on the receptor subunit composition as each mature AMPA receptor is assembled from four individual subunits. The influx of ions causes a fast excitatory postsynaptic response, supports NMDA receptor activation, and the Ca^{2+} component can also activate second messenger pathways, including many protein kinases.

- Ionotropic Glutamate Receptors

Amphetamine

Amphetamine and related compounds are indirect acting sympathomimetic agents that are frequently abused due to their stimulant properties on the central nervous system. Amphetamines act by inducing the

biogenic amine transporters to reverse or efflux neurotransmitter into the synapse. This drug-induced nonvesicular release of dopamine, norepinephrine and serotonin is thought to be the major action associated with the amphetamines. Clinically, the amphetamines are effective in the treatment of narcolepsy and Attention Deficit Hyperactivity Disorder (ADHD).

Amyloid

This is an extracellular deposition of an “insoluble” protein, which has adopted a β -sheet structure due to an unknown event that induced misfolding of unstable proteins. The name “amyloid” has been given according to the amyloid staining properties, which are similar to carbohydrate deposits, e.g., amyloid can be identified with congo red and seen under polarized light (birefringence test).

- ▶ Alzheimer’s Disease

A β Amyloid

A β amyloid is a 4 kD peptide which is the principle constituent of the Alzheimer amyloid found extracellularly in the brains of Alzheimer patients. A β amyloid is cleaved from a larger precursor protein, amyloid

precursor protein (APP). APP is a member of a family that includes various proteins. It is present in the dendrites, cell bodies and axons of neurons. Neuronal APP is probably the source of most of the A β amyloid deposited in the central nervous system of Alzheimer patients. APP is cleaved by various proteases, α -, β - and γ -secretase. The endopeptidase α -secretase cleaves within the A β region of APP, resulting in the secretion of the extracellular domain of APP; hence, the cleavage does not produce the A β peptide. In contrast, the β -secretase and γ -secretase cleavages do result in production of the A β peptide.

- ▶ Alzheimer’s Disease

Amyloid Precursor Protein

Amyloid precursor protein (APP) is the precursor of β -amyloid, the main component of senile plaques found in the brain of Alzheimer patients. The production of β -amyloid from APP to the cells from abnormal proteolytic cleavage of the amyloid precursor protein. Enzymes involved in this cleavage may be suitable targets for the therapy of Alzheimer’s disease.

- ▶ Alzheimer’s Disease

Amyotrophic Lateral Sclerosis (ALS)

ALS is a disorder of the motor neurons and the cortical neurons that provide their input. The disorder is characterized by rapidly progressive weakness and muscle atrophy. Most affected patients die of respiratory compromise and pneumonia after 2 to 3 years. There is prominent loss of motor neurons in the spinal cord and brainstem although the oculomotor neurons are spared. Large pyramidal motor neurons in layer V of motor cortex, which are the origin of the descending corticospinal tracts, are also lost.

It has been suggested that excitotoxic neurotransmitters such as glutamate participate in the death of motor neurons in ALS. This may be a consequence of diminished uptake of synaptic glutamate by an astroglial glutamate transporter, GLT1 (EAAT2) because overexpression of GLT1 in animals can delay the onset and the natural course of the disease.

ALS can run in families (10% of the cases) and superoxide dismutase 1 (SOD1) is an enzyme that has been found mutated in affected families; the majority of ALS patients, however, have normal SOD1. The importance of the SOD1 mutation is that transgenic mice expressing mutant human SOD1 develop a progressive degeneration of motor neurons that closely mimic the human disease. Disease causing mutations of SOD1, however, do not reduce the capacity of the enzyme to perform the catabolism of superoxide radicals.

► Neurotransmitter Transporters

Anabolic Steroids

Anabolic steroids increase muscle mass and strength. They are used by some athletes to enhance performance.

► Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor

Anaesthetics

► General Anaesthetics

► Local Anaesthetics

Analeptics

The term analeptics refers to convulsants and respiratory stimulants (i.e. central nervous system stimulants). They comprise a reverse group of agents (for example amphifinazole and doxapram (respiratory stimulants) and strychnine, biculline and picrotoxin). Analeptics are mainly experimental drugs. Only amphifinazole and doxapram are occasionally used for the treatment of acute ventilatory failure.

Analgesia

Synonyms

Pain medication

Definition

Analgesics interfere with the generation and/or transmission of impulses following noxious stimulation (► nociception) in the nervous system. This can occur at peripheral and/or central levels of the ► neuraxis. The therapeutic aim is to diminish the perception of ► pain.

Mechanisms of Action

Analgesics aim at modulating the generation of noxious chemicals (e.g., prostaglandins) or the activation of neuronal receptors/ion channels transducing/transmitting noxious stimuli (e.g., peptide-, kinin-, monoamine-receptors, Na⁺ channels) [5]. Clinically used drugs include opioids, nonsteroidal antiinflammatory drugs (NSAIDs), serotonergic compounds, antiepileptics, and antidepressants (Table 1) [1]. Adrenergic agonists, excitatory amino acid (e.g., *N*-methyl-D-aspartate; NMDA) receptor antagonists, neurotrophin antagonists, peptide antagonists, kinin receptor antagonists, cannabinoids, and ion channel (e.g., ► TRP, ► P2X) blockers are currently under investigation but are not used routinely yet. ► Local anaesthetics are used for local and regional anesthetic techniques. Mixed drugs (e.g., tramadol) combine various mechanisms [3].

Opioids

Opioids act on heptahelical ► G-protein-coupled receptors. Three types of opioid receptors (μ , δ , κ) have been cloned. Additional subtypes (e.g., μ_1 , μ_2 , δ_1 , δ_2), possibly resulting from gene polymorphisms, splice variants or alternative processing have been proposed. Opioid receptors are localized and can be activated

Analgesics. Table 1 Analgesics

Drugs	Targets	Mechanisms	Functional consequences	Side effects
Opioids	G-protein coupled μ -, δ -, κ -receptors	\downarrow cAMP \downarrow Ca^{2+} currents \uparrow K^+ currents	\downarrow Excitability of peripheral and central neurons \downarrow Release of excitatory neurotransmitters	μ , δ : sedation, nausea, euphoria/reward, respiratory depression, constipation κ : dysphoria/aversion, diuresis, sedation
NSAIDs	Cyclooxygenases (COX-1, COX-2)	\downarrow Prostaglandins \downarrow Thromboxanes	\downarrow Sensitization of sensory neurons \uparrow Inhibition of spinal neurons	Nonselective: gastrointestinal ulcers, perforation, bleeding, renal impairment COX-2: thrombosis, myocardial infarction, stroke
Serotonin agonists	G-protein coupled 5-HT receptors 5-HT ₃ : ion channels	\downarrow cAMP (5-HT ₁) \uparrow cAMP (5-HT ₄₋₇) \uparrow PLC (5-HT ₂)	\downarrow Release of excitatory neuropeptides \downarrow Neurogenic inflammation \uparrow vasoconstriction	Myocardial infarction, stroke, peripheral vascular occlusion
Antiepileptics	Na^+ , Ca^{2+} channels GABA receptors	\downarrow Na^+ currents \downarrow Ca^{2+} currents \uparrow GABA receptor activity	\downarrow Excitability of peripheral and central neurons \downarrow Release of excitatory neurotransmitters	Sedation, dizziness, cognitive impairment, ataxia, hepatotoxicity, thrombocytopenia
Antidepressants	Noradrenaline/5-HT transporters Na^+ , K^+ channels	\downarrow Noradrenaline/5-HT reuptake \downarrow Na^+ currents \uparrow K^+ currents	\downarrow Excitability of peripheral and central neurons	Cardiac arrhythmia, myocardial infarction, sedation, nausea, dry mouth, constipation, dizziness, sleep disturbance, blurred vision

along all levels of the neuraxis including peripheral and central processes of primary sensory neurons (► **nociceptors**), spinal cord (interneurons, projection neurons), brainstem, midbrain, and cortex. All opioid receptors couple to G-proteins (mainly G_i/G_o) and subsequently inhibit adenylyl cyclase, decrease the conductance of voltage-gated ► **Ca^{2+} channels** and/or open rectifying ► **potassium channels**. These effects ultimately result in decreased neuronal activity. The prevention of Ca^{2+} influx inhibits the release of excitatory (pronociceptive) neurotransmitters. A prominent example is the suppression of ► **tachykinin** (substance P) release from primary sensory neurons both within the spinal cord and from their peripheral terminals within injured tissue. At the postsynaptic membrane, opioids produce hyperpolarization by opening K^+ channels, thereby preventing excitation or propagation of action potentials in second order projection neurons. In addition, opioids inhibit sensory neuron-specific tetrodotoxin-resistant ► **Na^+ -channels**, ► **TRPV1 channels** and excitatory postsynaptic currents evoked by ► **glutamate receptors** (e.g., NMDA) in the spinal cord. The result is decreased transmission of nociceptive stimuli at all levels of the neuraxis and profoundly reduced perception of pain

[2, 3]. Endogenous opioid receptor ligands are derived from the precursors proopiomelanocortin (encoding β -endorphin), proenkephalin (encoding Met-enkephalin and Leu-enkephalin) and prodynorphin (encoding dynorphins). These peptides contain the common Tyr-Gly-Gly-Phe-[Met/Leu] sequence at their amino terminals, known as the opioid motif. β -Endorphin and the enkephalins are potent antinociceptive agents acting at μ and δ receptors. Dynorphins can elicit both pro- and antinociceptive effects via κ -opioid and/or NMDA receptors. A fourth group of tetrapeptides (endomorphins) with yet unknown precursors do not contain the pan-opioid motif but bind to μ -receptors with high selectivity. Opioid peptides and receptors are expressed throughout the central and peripheral nervous system, in neuroendocrine tissues and in immune cells [3, 4].

Nonsteroidal Antiinflammatory Drugs

NSAIDs inhibit ► **cyclooxygenases** (COX), the enzymes that catalyze the transformation of arachidonic acid (a ubiquitous cell component generated from phospholipids) to prostaglandins and thromboxanes. Two isoforms, COX-1 and COX-2, are constitutively expressed in peripheral tissues and in the central nervous

system. In response to injury and inflammatory mediators, (e.g., ►**cytokines**, growth factors) both isoforms can be upregulated, resulting in increased concentrations of prostaglandins. In the periphery, prostaglandins (mainly PGE₂) sensitize nociceptors by phosphorylation of ion channels (e.g., Na⁺, TRPV1) via ►**EP receptor** activation. As a result, nociceptors become more responsive to noxious mechanical (e.g., pressure, hollow organ distension), chemical (e.g., acidosis, ►**bradykinin**, ►**neurotrophic factors**) or thermal stimuli. In the spinal cord PGE₂ blocks glycinergic neuronal inhibition, enhances excitatory amino acid release, and depolarizes ascending neurons. These mechanisms facilitate the generation of impulses within nociceptors and their transmission through the spinal cord to higher brain areas [5]. By blocking one (selective COX-2 inhibitors) or both enzymes (nonselective NSAIDs) prostaglandin formation diminishes. Subsequently nociceptors become less responsive to noxious stimuli and spinal neurotransmission is attenuated [3].

Serotonergic Drugs

►**Serotonin** (5-hydroxytryptamine; 5-HT) is a monoamine neurotransmitter found in the sympathetic nervous system, in the gastrointestinal tract, and in platelets. It acts on 5-HT receptors expressed at all levels of the neuraxis and on blood vessels. Within the dorsal horn of the spinal cord serotonergic neurons contribute to endogenous pain inhibition. With the exception of 5-HT₃ (a ligand-gated ion channel), 5-HT receptors are G-protein coupled receptors. 5-HT_{1B/1D} agonists (triptans) have been studied extensively and are effective against neurovascular (migraine, cluster) headaches. Migraine is thought to be related to the release of neuropeptides (e.g., ►**calcitonin gene related peptide**) from trigeminal sensory neurons innervating meningeal and intracranial blood vessels. This leads to vasodilation, an inflammatory reaction, and subsequent pain. Triptans inhibit neurogenic inflammation via 5-HT_{1D} receptors on trigeminal afferents, with possible additional sites of action on thalamic neurons and in the periaqueductal grey. The activation of vascular 5-HT_{1B} receptors constricts meningeal (and coronary) vessels. The latter effects have stimulated a search for nonvasoconstrictor approaches such as highly selective 5HT_{1D} and 5HT_{1F} agonists. However, none of them demonstrated clinical antimigraine effects so far [3].

Antiepileptic Drugs

Antiepileptics are used in ►**neuropathic pain** resulting from lesions to the peripheral (e.g., diabetes, herpes) or central nervous system (e.g., stroke). Such syndromes have been attributed to ectopic activity in sensitized nociceptors from regenerating nerve sprouts, recruitment of previously “silent” nociceptors, and/or spontaneous neuronal activity. This may result in sensitization

of primary afferents and subsequent sensitization of second- and third order ascending neurons. Among the best studied mechanisms are the increased expression and trafficking of ion channels (e.g., Na⁺, Ca²⁺, TRP) and increased activity at ►**glutamate (NMDA) receptor** sites. The mechanisms of action of antiepileptics include neuronal membrane stabilization by blockage of pathologically active voltage-sensitive Na⁺ channels (carbamazepine, phenytoin, lamotrigine, topiramate), blockage of voltage-dependent Ca²⁺ channels (gabapentin, pregabalin), inhibition of presynaptic release of excitatory neurotransmitters (gabapentin, lamotrigine) and enhancing the activity of γ-aminobutyric acid ►**(GABA) receptors** (topiramate) [3].

Antidepressants

Antidepressants are used in the treatment of neuropathic pain and headache. They include the classic tricyclic compounds and are divided into nonselective noradrenaline/5-HT reuptake inhibitors (e.g., amitriptyline, imipramine, clomipramine, venlafaxine), preferential noradrenaline reuptake inhibitors (e.g., desipramine, nortriptyline) and selective 5-HT reuptake inhibitors (e.g., citalopram, paroxetine, fluoxetine). The reuptake block leads to a stimulation of endogenous monoaminergic pain inhibition in the spinal cord and brain. In addition, tricyclics have NMDA receptor antagonist, endogenous opioid enhancing, Na⁺ channel blocking, and K⁺ channel opening effects which can suppress peripheral and central sensitization. Block of cardiac ion channels by tricyclics can lead to life-threatening arrhythmias. The selective 5-HT transporter inhibitors have a different side effect profile and are safer in cases of overdose [3].

Clinical Use and Side Effects

Analgesics are used in both acute and chronic pain. Whereas acute (e.g., postoperative, posttraumatic) pain is generally amenable to drug therapy, chronic pain is a complex disease in its own right and needs to be differentiated into malignant (cancer-related) and nonmalignant (e.g., musculoskeletal, ►**neuropathic**, inflammatory) pain. Acute and cancer-related pain is commonly treatable with opioids, NSAIDs, and/or local anesthetic blocks. Chronic nonmalignant pain requires a multidisciplinary approach encompassing various pharmacological and nonpharmacological (e.g., psychological, physiotherapeutic) treatment strategies. Various routes of drug administration (e.g., oral, intravenous, subcutaneous, intrathecal, ►**epidural**, topical, intraarticular, transnasal) are used, depending on the clinical circumstances. Local anesthetics are used topically and in regional (e.g., epidural) anesthetic techniques for the treatment of acute (e.g., associated with surgery, child birth) and some selected chronic pain syndromes.

Opioids

Opioids are the most effective drugs for severe acute and cancer-related chronic pain. They do not improve quality of life in chronic noncancer pain. The commonly available agents (e.g., morphine, codeine, methadone, fentanyl and its derivatives) are μ -agonists. Naloxone is a nonselective antagonist at all three receptors. Partial agonists must occupy a greater fraction of the available pool of functional receptors than full agonists to induce a response (e.g., analgesia) of equivalent magnitude. Mixed agonist/antagonists (e.g., buprenorphine, butorphanol, nalbuphine, pentazocine) may act as agonists at low doses and as antagonists (at the same or a different receptor) at higher doses. Such compounds typically exhibit ceiling effects for analgesia and they may elicit an acute ►**withdrawal** syndrome when administered together with a pure agonist. All three receptors (μ , δ , κ) mediate analgesia but differing side effects. μ -Receptors mediate respiratory depression, sedation, reward/euphoria, nausea, urinary retention, biliary spasm, and constipation. κ -Receptors mediate dysphoric, aversive, sedative, and diuretic effects, but do not mediate constipation. δ -Receptors mediate reward/euphoria and, to a lesser degree, respiratory depression and constipation. ►**Tolerance** and physical ►**dependence** occur with prolonged administration of pure agonists, and abrupt discontinuation or antagonist administration can result in a withdrawal syndrome [3]. Opioids are effective in the periphery (e.g., topical or intraarticular administration, particularly in inflamed tissue), at the spinal cord (intrathecal or epidural administration), and systemically (e.g., intravenous or oral administration). The clinical choice of a particular compound is based on pharmacokinetic considerations (route of administration, desired onset or duration, lipophilicity) and on side effects associated with the respective route of drug delivery. Dosages are dependent on patient characteristics, type of pain and route of administration. Systemically and spinally administered μ -opioids can produce similar side effects, depending on dosage and rostral/systemic redistribution. For intrathecal application lipophilic drugs are preferred because they are trapped in the spinal cord and less likely to migrate to the brain within the cerebrospinal fluid. Adverse side effects can be minimized by careful dose titration and close patient monitoring, or can be treated by comedication (e.g., laxatives) or naloxone. The peripheral application of small, systemically inactive doses is devoid of side effects. Current research aims at the development of opioids with restricted access to the brain [2, 4].

Nonsteroidal Antiinflammatory Drugs

Less severe pain states (e.g., arthritis, menstruation, headache, minor surgery) are commonly treated with nonselective NSAIDs (e.g., aspirin, ibuprofen, indomethacin, diclofenac). NSAIDs are mostly used orally.

Some agents are available for parenteral, rectal, or topical application. Over-the-counter availability and self medication have led to frequent abuse and toxicity. Side effects have been attributed to COX-1 induced blockade of thromboxane production and impairment of platelet function (gastrointestinal and other bleeding disorders), decrease of tissue-protective prostaglandins (gastrointestinal ulcers, perforation), and decrease of renal vasodilatory prostaglandins (nephrotoxicity). The development of selective COX-2 inhibitors was driven by the assumption that COX-2 expression is selectively induced in inflamed tissue and that the constitutive tissue-protective COX-1 would be spared. It has now become clear that COX-2 expression is constitutive in many tissues (e.g., gastrointestinal epithelium, vascular endothelium, spinal cord) and COX-2 inhibition may exacerbate inflammation, impair ulcer healing, and decrease formation of vasoprotective prostacyclin. Selective COX-2 inhibitors confer an increased risk of thrombosis, myocardial infarction, hypertension, and stroke. Both classes of COX inhibitors can cause rare anaphylactic reactions. Acetaminophen (paracetamol) has relatively weak anti-inflammatory and antiplatelet activity. It is used for osteoarthritis, headache, and fever [1].

Serotonergic Drugs

Triptans can be applied orally, subcutaneously, or transnasally and have been used in the treatment of migraine. All triptans narrow coronary arteries via 5-HT_{1B} receptors by up to 20% at clinical doses and should not be administered to patients with risk factors or manifest coronary, cerebrovascular, or peripheral vascular disease. Some triptans have the potential for significant drug–drug interactions (e.g., with monoamine oxidase inhibitors, propranolol, cimetidine, hepatic P450-metabolized medications, P-glycoprotein pump inhibitors). Rational use of triptans should be restricted to patients with disability associated with migraine [1].

Antiepileptic Drugs

Antiepileptics have been used for neuropathic pain and for migraine prophylaxis. They are frequently coadministered with antidepressants. The most common adverse effects are impaired mental (somnolence, dizziness, cognitive impairment, fatigue) and motor function (ataxia) which limits clinical use, particularly in elderly patients. Serious side effects have been reported, including hepatotoxicity, thrombocytopenia and life-threatening dermatologic and hematologic reactions. Plasma drug concentrations should be monitored [1].

Antidepressants

Antidepressants are used in neuropathic pain and migraine prophylaxis. Tricyclics require monitoring of plasma drug concentrations to achieve optimal effect

and avoid toxicity, unless sufficient pain relief is obtained with low doses (up to 75 mg/day of imipramine or amitriptyline). In patients with ischemic heart disease there may be increased mortality from sudden arrhythmia, and in patients with recent myocardial infarction, arrhythmia, or cardiac decompensation tricyclics should not be used at all. Tricyclics also block histamine, cholinergic and adrenergic receptor sites. Adverse events include sedation, nausea, dry mouth, constipation, dizziness, sleep disturbance, and blurred vision [1].

Anaphase Promoting Complex (APC)

The APC is a complex, which is activated during mitosis and initiates anaphase by targeting key cell cycle regulators for proteasomal degradation. As proteolysis is irreversible cell cycle progression cannot be reverted. Targets are mitotic cyclins and securin. Proteolysis of securin activates separase, which cleaves cohesins thereby allowing detachment of sister chromatids.

- ▶ Selective Sex Steroid Receptor Modulators

Androgen Receptor

- ▶ Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor

Anemia, Macrocytic Hyperchromic

Macrocytic or magaloblastic anemia is caused by disturbances of DNA synthesis. It occurs, for example, in both folic acid and vitamin B12 deficiencies. Hematopoiesis is slowed down due to reduced DNA synthesis and a reduced number of abnormally large (macrocytic) and hemaglobin-rich (hyperchromic) erythrocytes is released.

Angiogenesis and Vascular Morphogenesis

MÉLANIE HÉROULT, YVONNE REISS,
HELLMUT G. AUGUSTIN

Joint Research Division Vascular Biology of the Medical Faculty Mannheim, University of Heidelberg, and the German Cancer Research Center (DKFZ), Mannheim and Heidelberg, Germany

Definition

Angiogenesis and vascular morphogenesis comprise all mechanisms and processes that lead to the development of new blood vessels. These include vasculogenesis, sprouting and non-sprouting angiogenesis, vessel assembly and maturation, and vascular remodeling. The formation of new blood and lymphatic vessels takes place primarily during embryonic development and blood neo-vessel formation is physiologically limited to few organs in the healthy adult such as the female reproductive system. Pathologic angiogenesis is widespread and is associated with diseases as diverse as tumors, wound healing, inflammatory diseases, skin diseases, eye diseases, and joint diseases.

Basic Mechanisms

Vasculogenesis and Angiogenesis

Blood vessels arise during embryogenesis by vasculogenesis and angiogenesis (Fig. 1a). These two processes are tightly regulated and display common stimulatory and inhibitory pathways [1]. During vasculogenesis, endothelial cells differentiate from mesodermal origin while during angiogenesis endothelial cells are formed from preexistent ones. Establishment of the vascular system involves formation of the vitelline (yolk sac) vasculature, the allantois (precursor of the umbilical vasculature of the placenta) and the cardiovascular system that ultimately merge to form a continuous vascular system. Differentiation of vascular lineages is synchronized and organized in parallel to other embryonic lineages. Contribution from the other germ layers (ectoderm and endoderm) to vasculogenesis has not been reported even though recent evidence has demonstrated the contribution of ectodermal tissue as a source of vascular differentiating factors as well as a support to form vascular tubes. For instance, the contribution of the peripheral neural system to vascular development has recently been demonstrated. Nerve-derived ▶vascular endothelial growth factor (VEGF) is necessary for arteriogenesis from a primitive capillary plexus. In a similar but inverse manner, the endothelium also appears to exert an active organ differentiation-inducing function, e.g., endothelial precursor cells have

Angiogenesis and Vascular Morphogenesis. Figure 1 Molecular mechanisms of vasculogenesis and angiogenesis (a) and the corresponding targets for therapeutic intervention. The primary formation of blood vessels occurs through mechanisms of vasculogenesis. Vasculogenesis refers to the formation of a vascular network from precursor cells (angioblasts) as it occurs developmentally by *in situ* differentiation or in the adult by distal recruitment of angioblastic stem cells from the bone marrow. The secondary level of vascular morphogenesis describes the angiogenic formation of blood vessels. Angiogenesis refers to the formation of vessels and vascular networks from preexisting vascular structures. This can occur through classical sprouting angiogenesis or through mechanisms of non-sprouting angiogenesis. The growing vascular network assembles and matures, eventually allowing directional blood flow. Pharmacological intervention of angiogenesis is based on different strategies interfering directly or indirectly with the endothelium as indicated in (b).

been shown to have an inducing effect on organ development in the pancreas and the liver.

The first stages of blood vessel formation involve the differentiation of mesodermal precursor cells into a plexus of angioblasts followed by their organization into angioblast cords taking the appearance of a hollow tube [2]. This first primitive vascular plexus expands by angiogenesis, the sprouting of new capillaries from preexisting vessels, and intussusception, a process during which interstitial tissue columns are inserted into the lumen of preexisting vessels (also termed non-sprouting angiogenesis; Fig. 1a). Sprouting and non-sprouting angiogenesis contribute to an increasing complexity of the growing vascular network. The network assembles and matures by the recruitment of pericytes and smooth muscle cells, eventually allowing the directional flow of blood. The morphogenic events leading to a mature vascular network involve several additional steps including vessel assembly, maturation, and acquisition of vessel identity and organotypic differentiation.

Vessel identity represents one of the major differentiation processes during blood vessel formation. Arteries and veins are structurally and functionally

distinct. It was long assumed that arteries and veins differentiate in response to differing blood flow rates and pressure gradients. Yet, the recent identification of molecules with an arteriovenous asymmetric expression pattern (arterial markers: **e**phrinB2, Notch 1, Delta-like 4 [Dll4], Connexin-40, Neuropilin-1, Bmx; venous markers: EphB4, Neuropilin-2) has paved the way for the genetic understanding of arteriovenous differentiation. Emerging is a concept of distinct transcriptional programs driving the differentiation of different endothelial lineages (arterial differentiation: sonic hedgehog \rightarrow VEGF \rightarrow VEGFR \rightarrow FoxC1/FoxC2 \rightarrow Notch \rightarrow Notch downstream transcription factors [Hey1/Hey2 {mammals}; Gridlock {zebrafish}]; venous differentiation: transcription factor COUP-TFII [maintains venous differentiation by inhibiting Notch pathway; lymphatic differentiation: transcription factor Prox1).

Molecular Regulators of the Angiogenic Cascade

The supply of oxygen and nutrients is a critical determinant for mammalian cell survival. Therefore, cells are located within a distance of 100 μm to maximally 150 μm of blood vessels. Multicellular

organisms growing beyond this size must recruit new blood vessels in order to achieve growth by mechanisms of vasculogenesis and angiogenesis. The regulation of this process is tightly controlled by a balance of pro- and antiangiogenic molecules. To date, more than

20 stimulators and 20 inhibitors have been identified (Table 1) and the composition of the “angiogenic cocktail” has not been well defined for most situations involving angiogenesis. Of the many angioregulatory molecules, well-defined families of molecules, i.e., the

Angiogenesis and Vascular Morphogenesis. Table 1 Positive and negative endogenous regulators of angiogenesis (noncomprehensive list)

Stimulators	Inhibitors
Peptide growth factors	Proteolytic peptides
VEGF-A, -B, -C, -D, -E	Angiostatin (plasminogen fragment)
PIGF	Vasostatin (calreticulin fragment)
Ang-1, Ang-2, ANGPTL4	α 6 IV NC1 domain (collagen α 1 IV fragment)
FGF-1, -2	Endostatin (collagen α 1 XVIII fragment)
PDGF-BB	Tumstatin (collagen α 3 IV fragment)
EGF	Canstatin (collagen α 2 IV fragment)
TGF- α , TGF- β	Arresten (collagen α 1 IV fragment)
HGF	Restin (α 1 Collagen IV NC1 fragment)
IGF-1, -2	Endorepellin (Perlecan fragment)
	Anastallin (fibronectin fragment)
	Antithrombin III fragment
Platelet-derived regulators	Inhibitors of enzymatic activity
PD-ECGF, TP	TIMP-1, -2, -3, -4
NPY	PAI-1, -2
Multifunctional cytokines/immune mediators	Multifunctional cytokines/immune mediators
TNF- α (low dose)	TNF- α (high dose)
Chemokines	Chemokines
MCP-1 (CCL2)	PF-4
IL-8 (CXCL8)	IP-10
Gro- α , - β , - γ , (CXCL1, 2, 3)	Gro- β
ENA-78 (CXCL5)	
NAP-2 (CXCL7)	
GCP-2 (CXCL2)	
Enzymes	Extracellular matrix molecules
Angiogenin (ribonuclease A homolog)	Thrombospondins
Hormones	Fibulin-5
Estrogens	Hormones/metabolites
Prostaglandin-E ₁ , -E ₂	2-ME
Follistatin	Proliferin-related protein
Hyaluronan oligosaccharides	
Gangliosides	Oligosaccharides
Hematopoietic growth factors	Hyaluronan, HMW species
Erythropoietin	
G-CSF	
GM-CSF	

Abbreviations: VEGF, vascular endothelial growth factor; -A, -B, -C, -D, -E; PIGF, placenta growth factor; Ang, angiopoietin, ANGPTL, angiopoietin like FGF, fibroblast growth factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor; HGF, hepatocyte growth factor; IGF, insulin-like growth factor; TNF, tumor necrosis factor; MCP, monocyte chemoattractant protein; IL, interleukin; PD-ECGF, platelet-derived endothelial cell growth factor; G-CSF, granulocyte-colony stimulating factor; GM-CSF, granulocyte-macrophage colony stimulating factor; TIMP, tissue metalloproteinase inhibitor; PAI, plasminogen activator inhibitor; PF, platelet factor; IP-10, interferon- γ -inducible protein-10; 2-ME, 2-Methoxyestradiol; HMW, high molecular weight, TP, Thymidine Phosphorylase, NPY, neuropeptide Y.

VEGFs, the ►angiopoietins, the Ephrins and Notch molecules stand out as they act specifically or preferentially on the vascular system and have, thus, to be considered as key regulatory molecules of the angiogenic cascade [3].

The best characterized angiogenic signaling pathway is VEGF. This has been unambiguously demonstrated through gene targeting experiments in mice which have shown that disruption of just one VEGF allele is not compatible with life and leads to early embryonic lethality. VEGF, now designated VEGF-A, is a member of a family of growth factors comprising VEGF-A, VEGF-B, VEGF-C, VEGF-D, and VEGF-E [4]. VEGF molecules exert their vascular specificity through the limited expression of their corresponding receptors, VEGFR-1, VEGFR-2, and VEGFR-3 which are differentially expressed by blood and lymphatic endothelial cells, respectively. Additionally, ►placenta growth factor (PlGF) is a VEGF related molecule (PlGF-1 and PlGF-2) which exclusively binds to VEGFR-1. PlGF is dispensable for embryonic and reproductive angiogenesis but plays important roles in pathological angiogenesis as it relates to tumor growth or cardiac ischemia. Despite its requisite role in angiogenesis, VEGF must act in concert with other growth factors. The angiopoietins (Ang-1 and Ang-2) have been identified as ligands for the endothelial cell receptor tyrosine kinase Tie-2. Gene ablation experiments in mice suggested a role of the Ang/Tie-2 system in vessel remodeling and stabilization of the growing neo-blood and -lymphatic vasculature. There are now four members of the angiopoietin (Ang) family, although Ang-3 and Ang-4 may represent widely diverged counterparts of the same gene locus in mouse and man. All of the known angiopoietins bind to Tie-2 and no ligand has yet been solidly established for the second Tie receptor, Tie-1.

More recently, the role of axon-guidance receptors and ligands during developmental angiogenesis has emerged as a focus in the field of angiogenesis research. These families of molecules involve Semaphorin/Neuropilin/Plexin, ephrin/Eph, Slit/robo, and Netrin/UNC. The ►Eph receptor tyrosine kinases comprise the largest known family of receptor tyrosine kinase receptors and interact in a specific, yet somewhat promiscuous manner with their corresponding ephrin ligands. Although initially characterized as regulators of axonal outgrowth in the nervous system, gene inactivation experiments in mice have revealed key roles for ephrinB2 and its EphB2, EphB3, and EphB4 receptors during vascular development. Mouse embryos lacking ephrinB2 or EphB4 (or the combination of EphB2 and EphB3) suffer dramatic defects in early angiogenic remodeling that are similar to those seen in mice lacking Ang-1 or Tie-2. Moreover, ephrinB2 and EphB4 display remarkable asymmetric

arterio-venous expression patterns, with ephrinB2 selectively marking arterial vessels and EphB4 preferentially being expressed by venous endothelial cells. More recently, several reports have associated class A Eph receptor signaling with tumor-associated angiogenesis. Another family of molecules, Notch receptors and their ligands Delta-like and Jagged, have been associated to venous and arterial specification during development and to also play critical roles during tumor angiogenesis. Dll4-deficient mice display the same vascular haploinsufficiency as VEGF with embryonic lethality of heterozygously targeted mice. Dll4 binds to Notch 1 and 4 receptors inducing a cascade of events leading to the up-regulation of the transcriptional repressors, Hey1 and Hey2. Dll4 expression is strongly up-regulated during angiogenesis. Its expression is induced by VEGF and it acts as a negative feedback regulator that restrains vascular sprouting and branching. Consistent with this role, the genetic deletion or manipulatory inhibition of Dll4 results in excessive, nonproductive angiogenesis and is therefore considered and explored as an attractive tumor angiogenesis target.

Angiogenic activation induces a specific gene expression program in endothelial cells enabling the cells to execute the complex molecular tasks required to grow new blood vessels. The invasive ingrowth of angiogenic endothelial cells involves a set of adhesion molecules including the integrin heterodimers $\alpha_v\beta_3$ and $\alpha_v\beta_5$ as well as the homotypic endothelial cell-specific adhesion molecule VE-cadherin. Likewise, sprouting endothelial cells display a shift of their proteolytic balance toward a proinvasive phenotype, involving the plasminogen activator (tPA and uPA) and plasminogen activator inhibitor system (PAI). Angiogenic endothelial cells deposit their own extracellular matrix, rearrange their cytoskeleton, and activate their proliferative machinery. All of these molecular systems are extensively being explored to therapeutically interfere with the angiogenic process.

Angiogenesis in Pathological Conditions

Abnormal vessel growth is involved in numerous pathological conditions. Pioneering work more than 35 years ago showed that the growth of solid tumors is critically dependent on the supply with new blood vessels. While some of this supply may be provided by mechanisms of vessel cooption, the process whereby a growing tumor is preying on the preexistent vasculature, the primary mechanism of tumor vascularization appears to be the angiogenic growth of blood vessels from the tumor neighboring blood vessels. Tumor cells release proangiogenic growth factors, such as VEGF, which diffuse into nearby tissues and bind and activate receptors on endothelial cells of preexisting blood vessels. Secretion of proteolytic enzymes, such as matrix metalloproteinases (MMPs) results in the

degradation of basement membrane and extracellular matrix components, allowing endothelial cells to invade and proliferate, and form new lumen containing vessels. Tumor angiogenesis involves the specific molecular regulators of the angiogenic cascade as they have been identified during developmental or reproductive angiogenesis. However, tumor angiogenesis also involves additional mechanisms that include the pleiotrophic angiogenic growth factors, for example as a consequence of the inflammatory response usually associated with tumor growth.

In addition to tumor angiogenesis, an increasing list of diseases is now recognized to critically depend on either increased or reduced angiogenesis. For example, increased angiogenesis occurs during diabetic retinopathy, macula degeneration, arthritic joint diseases, and hyperproliferative skin diseases. In turn, reduced angiogenesis may have a negative impact on wound healing and the regenerative processes associated with ischemic diseases as they occur in the heart or during peripheral limb ischemia.

Pharmacological Intervention

Both angio-inhibitory as well as angio-stimulatory therapies are presently being explored extensively for a number of indications [5]. Angio-inhibitory therapies are being developed most intensely to therapeutically interfere with tumor angiogenesis and tumor growth (Fig. 1b). Other major antiangiogenic therapies that are currently in clinical development target retinal diseases (diabetic retinopathy, macular degeneration), joint diseases (arthritis), as well as hyperproliferative skin diseases (psoriasis). In February 2004, the US Food and Drug Administration approved Bevacizumab, a humanized anti-VEGF-A monoclonal antibody for the treatment of metastatic colorectal cancer in combination with 5-fluorouracil-based chemotherapy. In December 2004, the FDA approved pegaptinib, an aptamer that blocks VEGF-A₁₆₅, for the treatment of the neovascular form of age-related macular degeneration. In turn, angio-stimulatory therapies are being developed to stimulate wound healing angiogenesis, peripheral limb ischemia, and arteriogenic growth of collateral vessels during cardiac ischemia.

Antiangiogenic Tumor Targeting

Antiangiogenic tumor targeting is conceptually a particularly attractive therapeutic avenue for a number of reasons: (i) As an oncofetal mechanism that is mostly downregulated in the healthy adult, targeting of angiogenesis should lead to minimal side effects even after prolonged treatment, (ii) tumor-associated angiogenesis is a physiological host mechanism and its pharmacological inhibition should, consequently, not lead to the development of resistance, (iii) each tumor

capillary potentially supplies hundreds of tumor cells and the targeting of the tumor vasculature should, thus, lead to a potentiation of the antitumor effect, and (iv) in contrast to the interstitial location of tumor cells, direct contact of the vasculature to the circulation allows efficient access of therapeutic agents.

A number of approaches have been taken to inhibit tumor angiogenesis and other diseases involving angiogenesis (Table 2). Pharmacological inhibition of angiogenesis is aimed at interfering with the angiogenic cascade or the immature neovasculature. Pharmacological agents may be synthetic or semisynthetic substances, endogenous inhibitors of angiogenesis, or biological antagonists of the angiogenic cascade. In contrast, vascular targeting is aimed at utilizing specific molecular determinants of the neovasculature for the delivery of a biological, chemical, or physical activity that will then locally act angiocidal or tumoricidal. Moreover, in addition to their role on tumor cells, chemotherapeutic agents contribute may exert an antiangiogenic effect by targeting bone-marrow-derived proangiogenic cells, dividing endothelial cells from sprouting vessels, and endothelial cell progenitor incorporation to the lumen of growing vessels.

A comprehensive website summarizing the status of tumor antiangiogenic compounds in various stages of clinical trial is maintained by the National Cancer Institute at: ► www.cancer.gov/clinicaltrials/developments/anti-angio-table. Following is a survey of the most important substances currently in clinical development.

Specific Synthetic and Biological Antagonists of the Angiogenic Cascade

Specific inhibition of any of the key regulators of the angiogenic cascade is one of the most specific and selective ways to interfere with angiogenesis. A number of experimental strategies have been taken to interfere with the interaction of VEGF with its receptors. These include antisenses, ribozymes (i.e., Angiozyme in clinical trial Phase I) and antibody approaches to inhibit VEGF, the development of small molecular weight antagonists to the VEGF receptors, as well as the use of soluble VEGF receptors. A number of new generation small molecular weight VEGF receptor antagonists are rapidly proceeding in various stages of clinical trials (Table 3).

One of the most important steps to block angiogenesis has been made in targeting VEGF-A using the humanized antibody, Bevacizumab (Avastin) or a chimeric, soluble VEGF receptor (“VEGF-trap”) which is also undergoing clinical development as an anti-cancer agent. Bevacizumab is a nonimmunogenic, 93% humanized murine monoclonal antibody that binds all VEGF-A isoforms. Bevacizumab has been clinically approved in 2004 in combination with chemotherapy

Angiogenesis and Vascular Morphogenesis. Table 2 Antiangiogenic therapeutic strategies (noncomprehensive list)

Substance	Mechanism
<i>Biological antagonists</i>	
VEGF inhibitors	Humanized neutralizing antibodies, antisense oligonucleotides, siRNA, aptamers
VEGF receptor blockers	Small receptor tyrosine kinase antagonists
VEGF-trap	Inhibition with soluble forms of VEGF-R1, VEGF-R2
$\alpha_v\beta_3$ integrin antagonists	Induce angiogenic endothelial cell apoptosis
<i>Endogenous inhibitors</i>	
Angiostatin	Inhibits EC proliferation, migration, and induces EC apoptosis
Endostatin	Inhibits EC proliferation, migration, and induces EC apoptosis
Vasostatin	Inhibits EC proliferation, adhesion to laminin and induces EC apoptosis
Tumstatin	Inhibits EC proliferation, migration, and induces EC apoptosis
Canstatin	Inhibits EC proliferation, migration, and induces EC apoptosis
Arresten	Inhibits EC proliferation, migration, and induces EC apoptosis
Restin ($\alpha 1$ Collagen IV NC1 fragment)	Inhibits EC proliferation and induces EC apoptosis
Maspin (Mammary serine protease inhibitor)	Induces EC apoptosis
Vascular Endothelial Growth Inhibitor (Protein sharing homology with TNF- α)	Inhibits EC proliferation
Derivative of prolactin	Inhibits EC proliferation and induces EC apoptosis
Proliferin-related protein (PRP) (16 kDa fragment of the prolactin)	Inhibits EC proliferation and induces EC apoptosis
Pigment epithelial-derived factor	Induces EC apoptosis
2-methoxyestradiol (2ME2)	Induces EC apoptosis
IL-12	Modulates angiogenic factors
IL-18	Modulates angiogenic factors
IL-24	Inhibits EC differentiation and migration induced by VEGF and bFGF
Interferons	Inhibits EC proliferation and induces EC apoptosis
NK4 (4-kringle domains of HGF)	Inhibits EC differentiation and migration induced by VEGF
Thrombospondins	Inhibits EC proliferation, migration and induces EC apoptosis by binding to endothelial CD36
<i>Synthetic/semisynthetic inhibitors</i>	
Carboxyamidotriazole	Calcium channel blocker
CM101	Analog of group B streptococcus toxin, binds to tumor endothelium, induces inflammation
Marimastat	Metalloproteinase inhibitor, inhibits endothelial cell invasion
Pentosan polysulfate	Inhibits heparin-binding growth factors
TNP470	Analog of fumagillin, inhibits cell migration and proliferation
Thalidomide	Polycyclic teratogen, antiangiogenic mechanism unknown
<i>Vascular targeting</i>	
Regional TNF- α therapy	Isolated limb perfusion to target in transit metastases
Antibody targeting	Use of mono- and bispecific antibodies to target components of angiogenic blood vessels (e.g., VEGF receptors, endoglin, L19 antigen) to deliver specific angio- and/or tumoricidal activity
Vascular gene therapy	Transfer of dominant-negative receptors or suicide genes under the control of angiogenic endothelial cell specific promoters

for the first line treatment of advanced colorectal tumors. Phase III clinical trials have since been successfully completed for other tumors, including mammary tumors and lung tumors.

VEGF-Trap is a protein-based product candidate designed to bind all forms of VEGF and the related PlGF, and prevents their interaction with cell surface receptors. VEGF Trap is being pursued in phase II

Angiogenesis and Vascular Morphogenesis. Table 3 Antiangiogenic drugs (noncomprehensive list)

Target	Drug
Extracellular matrix	Dalteparin
Endothelial cells	ABT-510
	CNGRC peptide TNF alpha conjugate (NGR-TNF)
	Combretastatin A4 Phosphate
	Dimethylxanthenone Acetic Acide
	Lenalidomide
	LY317615 (Enzastaurin)
	PPI-2458
	soy isoflavone (Genistein; soy protein isolate)
Tamoxifen Citrate	
Activators of angiogenesis	ADH-1 (Exherin™)
	Cetuximab (Erbix™)
	AG-013736
	AMG-706
	Neovastat (AE-941)
	Anti-VEGF Antibody (Bevacizumab; Avastin™; Lucentis™)
	VEGF-Trap
	AZD2171
	Bay 43-9006 (Sorafenib tosylate; Nexavar™)
	BMS-582664
	CHIR-265
	GW786034 (Pazopanib)
	PI-88
	PTK787/ZK 222584 (Vatalanib)
	RAD001 (Everolimus)
	Suramin
	SU11248 (Sunitinib malate; Sutent™)
	SU6668
XL184	
ZD6474	
ZD1839 (Gefitinib; Iressa)	
Endothelial-specific integrin/survival signaling	ATN-161
	EMD 121974 (Cilengitide)
Nonspecific mechanism of action	Celecoxib
	Thalidomide

The table lists drugs with antiangiogenic activity that are in clinical development. Some of the compounds are already clinically approved as specific antiangiogenic drugs (e.g., Bevacizumab [Avastin] or Sunitinib [Sutent]). Others are approved as antiangiogenic as well as antitumorigenic drugs (e.g., Sorafenib [Nexavar]). A third group of drugs is approved as tumorigenic drugs, but is also well established to have antiangiogenic activity (e.g., Cetuximab [Erbix] or Tamoxifen). Most of the listed compounds are in various phases of clinical trials. Given the rapid pace of clinical development, the reader is encouraged to confirm the actual status of a listed compound through an internet search.

studies including advanced ovarian cancer and non-small cell lung adenocarcinoma. In addition, five phase II single-agent studies have been started for relapsed/refractory multiple myeloma, metastatic colorectal cancer, recurrent or metastatic cancer of the urothelium, locally advanced or metastatic gynecological soft tissue sarcomas and recurrent malignant gliomas.

Paralleling the clinical implementation of large molecular weight VEGF inhibitors (antibodies, ligand traps), the first small molecular weight VEGF receptor antagonists have received clinical approval. Sunitinib (Sutent) is a combined VEGF receptor and PDGF receptor inhibitor and thereby blocks angiogenesis and vessel maturation. Sorafenib (Nexavar) targets the VEGF receptors as well as the tumor target c-raf

and acts thereby as a combined antiangiogenic and antitumorogenic drug.

The different VEGF/VEGFR targeting drugs have somewhat varying clinical efficacy. Yet, hitherto approved antiangiogenic drugs in combination with chemotherapy lead on average to an approximately 25% extension of mean life expectancy compared with chemotherapy alone. Depending on the tumor type, this translates in absolute figures to “only” 4.5 to only 9 months. Yet, it needs to be considered that the clinical data are not parametrically distributed, i.e., while some patients respond very beneficially to antiangiogenic treatments, many show little or no clinical response. This reflects the lack of stratifying diagnostic and prognostic procedures that would be necessary to identify those patients that would benefit most from an antiangiogenic intervention (note: “*a targeted therapy requires targeted diagnostic and prognostic procedures!*”)

VEGF and VEGFR blockers specifically interfere with VEGF/VEGFR signaling. Yet, their functional mechanism of action is not well understood. VEGF/VEGFR inhibition blocks angiogenesis and is thereby supposed to starve tumors to death. Yet, more recent work rather suggests that VEGF/VEGFR blockade prunes the immature tumor neovasculature leaving a network of more mature vessels that actually facilitates a more regular blood flow. This “normalization” effect supposedly facilitates better access of chemotherapeutic drugs to the tumor which would explain the empirically determined good synergy of antiangiogenic and chemotherapeutic treatments and the lack of efficacy of antiangiogenic monotherapies. However, the mechanistic dissociation of antiangiogenic tumor starvation versus tumor vessel normalization is subject of intense controversy in the field and focus of much ongoing experimental work.

Inhibitors of the Angiopoietin/Tie-2 and Ephrin/Eph systems are in preclinical development which parallels the biological target validation of these molecules. As vascular assembly, maturation, and homeostasis regulating molecules, therapeutic interference with these molecular systems may hold promise for a number of vascular indications.

Interference with specific cell–cell and cell–matrix adhesion mechanisms is another rapidly advancing approach to therapeutically interfere with angiogenesis. Antagonistic antibodies (Vitaxin) to the integrin heterodimer $\alpha_v\beta_3$ have been shown to act on the blood vessels of tumors but not on the resting organ vasculature. Vitaxin demonstrated some promise in ►Phase II clinical trials.

The growing list of endogenous inhibitors of angiogenesis holds great promise for therapeutic applications (Table 2). Substances most advanced in clinical development include Endostatin, Angiostatin, Interleukin-12, Thrombospondin, and Tumstatin. As

endogenous substances, these molecules have a long half life in the plasma and are, thus, particularly attractive for long-term treatments. Some of them, like Endostatin and Angiostatin, are the proteolytically generated fragments of larger molecules. Endostatin is a 20 kDa C-terminal fragment of collagen XVIII and specifically inhibits endothelial cell proliferation, angiogenesis, and tumor growth. Primary tumors may regress to dormant microscopic lesions. Furthermore, the concept of a dormancy therapy is being extended to Endostatin using cycles of therapy. Angiostatin, a 38 kDa internal domain of plasminogen, is a circulating endogenous protein that supposedly binds ATP synthase on the surface of endothelial cells. It thereby induces endothelial and tumor cell apoptosis, and inhibits endothelial cell migration and tubule formation. Yet, it does not appear to affect growth-factor-induced signal transduction. Angiostatin inhibits matrix-enhanced plasminogen activation, which, in part accounts for its angio-suppressive and anti-invasive properties. Of great interest, Angiostatin is generated by free sulfhydryl donors (e.g., d-penicillamine and captopril) that may partially explain their angio-suppressive properties. Taken together, the clinical development of endogenous angiogenesis inhibitors is proceeding slowly and the results of hitherto pursued clinical trials were not particularly encouraging. It may well emerge that endogenous inhibitors of angiogenesis have little short term interventional therapeutic potential. Yet, they may be very effective preventive drugs which may conceptually actually reflect much better their physiological roles.

Nonspecific Synthetic and Biological Angiogenesis Inhibitors

Systematic screening experiments have identified more than 100 synthetic compounds with potent antiangiogenic activity. The mode of action for most of these molecules is not well understood, but some of the 40 compounds are well advanced in clinical trials (Table 3). The first substance to have entered clinical trials was the Fumagillin-derivative AGM 1470. Fumagillin is an antibiotic which inhibits bFGF- and PDGF-induced endothelial cell proliferation. The mechanism of action of AGM 1470 is poorly understood, but it was shown that it binds and inhibits the metalloprotease methionine aminopeptidase (MetAp-2).

Other antibiotics with antiangiogenic activity are minocycline and herbimycin A. Carboxyamidotriazole (CAI) inhibits the calcium influx into cells and suppresses the proliferation of endothelial cells. It inhibits angiogenesis and metastasis, but it is not an endothelial cell-specific substance. Similarly, the metalloproteinase have long been considered as promising antiangiogenic drugs. Yet, the field is moving slowly following the failure of some MMP inhibitors in advanced clinical trials.

Some natural compounds have also demonstrated antiangiogenic activities. Neovastat (\AE-941) is a naturally occurring (shark cartilage extract), oral agent that shows angio-suppressive and anti-MMP activities in vitro and in the chorioallantoic membrane (CAM) assay. Squalamine (MSI 1256 F), originally derived from the liver of a dogfish shark, is a novel noncytotoxic aminosterol with potent antiangiogenic properties in vivo and in vitro. Squalamine prevents the neovascularization of tumors by suppressing endothelial cell migration and proliferation. Combretastatins are small organic molecules found in the bark of the African bush willow, the *Combretum caffrum*. Combretastatins not only suppress proliferating endothelium, but also specifically target tumor endothelium. The combretastatin A-4 prodrug is a derivative of combretastatin, which is activated by a phosphatase selectively amplified in proliferating endothelial cells. Combretastatin A-4 induces apoptosis in human endothelial cells. In tumor-bearing mice, combretastatin A-4 significantly enhanced the antitumor effects of radiation therapy.

Vascular Targeting

The goal of vascular targeting is to utilize specific molecular determinants of angiogenic endothelium to deliver substances or activities that destroy the vasculature. Unlike antiangiogenic drugs that inhibit the formation of neo-vessels, vascular targeting agents (VTAs) occlude the preexisting blood vessels of tumors to cause tumor cell death from ischemia and extensive hemorrhagic necrosis. VTAs can indirectly kill tumor cells that are resistant to conventional antiproliferative cancer therapies, i.e., cells in areas distant from blood vessels where drug penetration is poor, and hypoxia can lead to radiation and drug resistance. There are broadly two types of VTAs, small molecules and ligand-based, which are grouped together, because they both cause acute vascular shutdown in tumors leading to massive necrosis. The small molecules include tubulin-destabilizing drugs, combretastatin A-4 disodium-phosphate, ZD6126, AVE8062, and Oxi 4503, and the flavonoid, DMXAA. Ligand-based VTAs use antibodies, peptides, or growth factors that bind selectively to tumor versus normal vessels to target tumors with agents that occlude blood vessels. The ligand-based VTAs include fusion proteins (e.g., vascular endothelial growth factor linked to the plant toxin gelonin), immunotoxins (e.g., monoclonal antibodies to endoglin conjugated to ricin A), antibodies linked to cytokines, liposomally encapsulated drugs, and gene therapy approaches.

Proangiogenic Therapies

Antiangiogenesis research has driven the field. Yet, there are a number of indications which may benefit from an induction of angiogenesis, including wound

healing, cardiac ischemia, and peripheral limb ischemia. Various approaches have been taken to therapeutically deliver angiogenic cytokines such as VEGF and FGF-2. These include the local administration of recombinant proteins and gene therapeutic delivery of angiogenic cytokines. Individual cytokine therapy may have limitations as it may be capable of inducing a neovascular response, but it may not induce the growth of a patent neovascular network that is stable for prolonged periods of time. This notion has led to alternative strategies aimed at inducing the complex endogenous angiogenic program and not just a single cytokine. For example, experiments are underway to locally induce hypoxia-inducible factor-1 (HIF-1), a key regulator of the hypoxia response program which is able to control the complex endogenous program of angiogenesis induction. Several angiogenic factors (VEGF-A, VEGF-C, FGF-1, FGF-2 and FGF-4) have been tested in patients with myocardial or limb ischemia.

Direct laser-assisted myocardial revascularization (DMR) is an approved technique in the US, Europe, and parts of Asia to create numerous myocardial channels. This results in the induction of a massive inflammatory reaction, which in turn induces angiogenesis. The other FDA-approved pro-angiogenic therapy is the use of recombinant human platelet-derived growth factor (Regranex) for use in the treatment of diabetic neuropathic foot ulcers.

Angiotensin Converting Enzyme

Synonyms

ACE

Definition

Angiotensin converting enzyme (ACE) is identical to kininase II. It is an essential component of both the renin–angiotensin system and the kallikrein–kinin system. Three different forms of ACE are known. It exists as a membrane bound protein with a molecular weight of 150–180 kD, anchored to the cytoplasmic membrane of endothelial cells and as a circulating protein of similar size. The enzyme consists of two highly homologous lobes with an active site in each lobe. Interestingly, although still of uncertain consequence, the active sites exhibit different catalytic profiles and different affinities for ACE inhibitors. A third, smaller form of ACE (90 kD) with only one active site is expressed in mature germ cells.

The substrate specificity of ACE is low. ACE cleaves a variety of pairs of amino acids from the carboxy-terminal part of several peptide substrates. The conversion of ANG I to ANG II and the degradation of bradykinin to inactive fragments are considered the most important functions of ACE. Both peptides have profound impact on the cardiovascular system and beyond. ACE is thus an important target for ACE inhibitors. These compounds are frequently and efficiently used in the treatment of hypertension and cardiac failure.

Angiotensin Receptors

Angiotensin receptors mediate the effects of angiotensin (ANG) II, the effector peptide of the renin–angiotensin system. Two receptors termed AT1 and AT2 have been characterized in detail. Both receptors belong to the super family of G-protein coupled receptors. Most of the cardiovascular functions of ANG II are mediated through the AT1 receptor. This receptor is usually Gq/11-coupled and its activation leads to intracellular calcium surges and protein kinase C activation. Downstream of the G-protein activation, small GTP-binding proteins such as RAS and RHOA and tyrosine kinase cascades are activated. These include members of the MAP-Kinase and JAK/STAT pathways. Finally transcription factors, such as AP-1, NF- κ -B, and the STATs (signal transducer and activators of transcription) are activated, which initiates the expression of growth-related genes and/or is involved in inflammatory processes. This explains the effects of ANG II on growth, proliferation, and its assumed role in inflammation. The functions of the AT2 receptor are still a matter of debate. The AT2 receptor is probably involved in differentiation processes, inhibits proliferation, and induces apoptosis, and thus may partially counteract some effects of AT1 receptor activation. It is expressed during embryonic development in a tightly controlled manner. In adults it is expressed in adrenal gland and ovary and its expression is induced during inflammatory processes and tissue damage. At present, there are no drugs available, which specifically inhibit or stimulate the AT2 receptor.

Anion Exchange Resin

Anion exchange resins are basic polymers with a high affinity for anions. Because different anions compete for binding to them, they can be used to sequester anions. Clinically used anion exchange resins such as cholestyramine are used to sequester bile acids in the intestine, thereby preventing their reabsorption. As a consequence, the absorption of exogenous cholesterol is decreased. The accompanying increase in low density lipoprotein (LDL)-receptors leads to the removal of LDL from the blood and, thereby, to a reduction of LDL cholesterol. This effect underlies the use of cholestyramine in the treatment of hyperlipidaemia.

Antacids

Antacids are neutralizing agents. Examples are magnesium hydroxide, magnesium trisylcate and aluminium hydroxide. Prior to the introduction of histamine- H_2 receptor antagonists and proton pump inhibitors, they were the standard drugs for the treatment of duodenal/peptic ulcers. Today their clinical use is limited to the treatment of dyspepsia and the symptomatic relieve for patients with peptic ulcers.

- ▶ Histaminergic System
- ▶ Proton Pump Inhibitors and Acid Pump Antagonists

Antagonist

Antagonists are natural or synthetic ligands that bind to a receptor but do not cause a downstream signal transduction process. Antagonists that bind to the same ligand-binding site than the respective agonist act as competitive antagonists. Antagonists (or blockers) that bind to another binding site and exert their pathway-disrupting activity by allosteric effects are termed

noncompetitive antagonists. Antagonists are commonly synthetic or semisynthetic compounds and can be used as drugs in clinical or experimental settings.

Anthelmintic Drugs

Anthelmintic drugs are used for the treatment of worm infections. They represent a small but diverse group of drugs with regard to both their chemical structure and their mechanism of action. Like antimicrobial agents they are effective against certain types of worm and ineffective against others. The benzimidazoles (mebendazole, thiabendazole and albendazole) are broad-spectrum agents and the main group of anthelmintics used in the clinic. They induce multiple biochemical changes. However, their main mechanism of action appears to be inhibition of microtubule formation by binding to free parasitic β -tubulin. The spectrum of worms includes nematodes (e.g. the common round worm and the worm causing trichiniasis, *Trichinella spiralis*) and some cestodes. The drug of choice for the treatment of river blindness (caused by *Onchocerca volvulus*) is ivermectin. Trematodes (e.g. *Schistosoma* species causing bilharzia) are sensitive to praziquantel.

Anthracyclins

Anthraquinones; Antibiotics; Cytotoxics

Definition

The ▶anthracyclines represent a broad family of antibiotics that exhibit activity in numerous tumors. The first anthracyclines, doxorubicin (DOX) and daunorubicin (DNR), were isolated from *Streptomyces* var *peucetius*; they were shown to be composed of a tetracyclic ring system with adjacent quinone–hydroquinone moieties, a short side chain with a carbonyl group, and an aminosugar bound to the C-7 of the four-ring system. DOX and DNR only differed in the side chain terminus ($-\text{CH}_2\text{OH}$ in DOX vs. $-\text{CH}_3$ in DNR). Second generation anthracyclines, like epirubicin (EPI) and idarubicin (IDA), were obtained after minor chemical modifications of DOX or DNR, respectively (Fig. 1).

Mechanisms of Action

DOX and other approved anthracyclines have long been known to inhibit ▶topoisomerase II (topo II). This enzyme promotes the formation of double-strand DNA breaks, which are resealed after changing the twisting status of the double helix of DNA. Topo II is highly important to proliferating cells, as the supercoiling of the DNA double helix is modulated according to the cell cycle phase and transcriptional activity. Anthracyclines stabilize a reaction intermediate in which DNA strands are cut and covalently linked to topo II, eventually impeding DNA resealing. Rings B, C, and D are important determinants of anthracycline intercalation into DNA, while ring A and the aminosugar residue play a major role in the formation and stabilization of the ternary complex. Anthracycline- and topo II-mediated DNA damage is followed by growth arrest in G1 and G2 and apoptosis. This is usually, but not always, relayed by p53 and the consequent induction of the WAF1/CIP1 p21 gene product, a strong inhibitor of cyclin-dependent kinases that favor cell cycle progression through the G1 to S transition.

Topo II inhibition remains the most persuasive mechanism to explain the antitumor activity of anthracyclines; accordingly, limited clinical studies showed that tumor

Anthracyclins. Figure 1 Structure of the four main anthracyclins approved for clinical use. The anthracyclins are composed of a tetracyclic ring with adjacent quinone–hydroquinone moieties and a short side chain with a carbonyl group at C-13; an aminosugar is attached by a glycosidic bond to the C-7 of the tetracyclic ring. Doxorubicin (DOX) and daunorubicin (DNR) differ in the side chain terminus ($-\text{CH}_2\text{OH}$ or $-\text{CH}_3$, respectively). Epirubicin (EPI) is obtained after an axial-to-equatorial epimerization of the hydroxyl group at C-4' in the aminosugar. Idarubicin (IDA) is characterized by the absence of the methoxy group at C-4 in ring D.

response and patient's outcome correlated with apoptosis induced by topo II inhibition. Nonetheless, clinically relevant concentrations of anthracyclins were shown to induce apoptosis also through corollary mechanisms that were not bound to topo II or p53; these mechanisms include, among others: (i) the activation of neutral sphingomyelinases, followed by ceramide formation and converse activation of cell death effectors (c-Jun N-terminal kinase) or downregulation of survival pathways (Akt/protein kinase B), (ii) mitochondrial dysfunction, followed by cytochrome *c* (cyt *c*) release and apoptosome formation, (iii) induction of lipid peroxidation and formation of malondialdehyde-DNA adducts, followed by the reduced activity of cyclin E- and cyclin B- associated kinase activities and growth arrest in both p53-proficient and p53-deficient cells, and (iv) inhibition of the ►proteasome, followed by an accumulation of undegraded ubiquitinated proteins that signal apoptosis [1]. The mechanisms (i–iii) are triggered by ►reactive oxygen species (ROS), which are major byproducts of anthracycline metabolism. ROS may also enable anthracyclins to damage and shorten telomeres, long sequences of base repeats that otherwise would delay cell senescence and apoptosis by preventing the degradation and ligation of the end of chromosomes; however, anthracycline-induced telomere damage and dysfunction would be relayed to apoptosis through p53 (Fig. 2).

Anthracycline treatment may be accompanied by the acquisition of a resistance phenotype through a combination of pharmacokinetic and pharmacodynamic mechanisms. On pharmacokinetic grounds, tumor resistance is caused by the reduced accumulation and/or an altered distribution of anthracyclins in tumor cells. A major mechanism of such a kind of resistance rests on the overexpression of drug transporters that belong to the ATP-binding cassette family of proteins and are collectively referred to as ABC proteins (P-glycoprotein/Pgp, ►multidrug resistance protein 1/MRP1, breast cancer resistance protein/BCRP). For many years, it was thought that ABC proteins could confer resistance to anthracyclins by localizing to the plasma membrane of tumor cells and by mediating drug efflux through a canonical ATP-dependent antiporter mechanism. More recently, ►ABC proteins were shown to localize also to the membrane of cytoplasmic acidic organelles like lysosomes, recycling endosomes, and vesicles of the *trans*-Golgi network. Vesicular ABC proteins mediate an [out]→[in] transport of the anthracyclins, which subsequently undergo protonation of their amino residue and remain entrapped in the lumen of the vesicles. The ABC proteins therefore divert anthracyclins away from the nucleus or mitochondria toward pharmacologically unproductive cell sanctuaries like cytoplasmic organelles. Anthracycline-naïve tumor cells do not exhibit such a mechanism of anthracycline

Anthracyclins. Figure 2 Mechanisms of anthracycline-induced apoptosis of tumor cells. ROS, reactive oxygen species; topo II, topoisomerase II; cyt c, cytochrome c.

sequestration, as they usually lack the vesicular expression of ABC proteins or fail to generate a proton gradient across the envelope of cytoplasmic organelles.

On pharmacodynamic grounds, tumor resistance may be caused by such diverse mechanisms as the mutation or redundancy of topo II, the overexpression and preferred nuclear localization of proteasome α -type subunits (leading to a anomalous degradation of topo II), genetic deletion or loss-of-function mutations of p53, overexpression of ROS-detoxifying enzymes, overexpression of Bcl-2 (leading to a diminished cyt *c* release), etc. However, none of these factors would universally predict the development of anthracycline-resistance in a given tumor or another.

Clinical Use

In spite of their longer than 40 years record of longevity the anthracyclines still rank among the most effective cytotoxics available to the oncologists. DOX and its second generation analogue EPI are essential components of the treatment of breast cancer, childhood solid tumors, soft tissue sarcomas, and aggressive lymphomas. DNR is used to treat acute lymphoblastic or myeloblastic leukemias, while its second generation analogue IDA shows activity also in multiple myeloma, non-Hodgkin's lymphomas, and breast cancer. The broader spectrum of activity of IDA versus DNR is attributed to pharmacokinetic and pharmacodynamic factors such as an increased lipophilicity and cellular uptake, and a stronger stabilization of a ternary anthracycline-topoisomerase II-DNA complex. An additional point of consideration is that DOX, EPI, and DNR must be administered by i.v. boluses, while IDA shows a

nonnegligible bioavailability (~ 10 – 30%) also when administered orally.

Many other anthracyclines were extracted or synthesized over the last two decades, but only few of them eventually progressed toward a robust program of clinical development. A rather benign conclusion is that the novel anthracyclines or related anthraquinones offered only modest advantages over DOX-EPI or DNR-IDA, with the possible exceptions being nemorubicin (for the locoregional treatment of hepatocellular carcinoma), pixantrone (for the second-line treatment of non-Hodgkin's lymphomas), sabarubicin (for the treatment of non-small cell lung cancer, hormone refractory metastatic prostate cancer, platinum- or taxane-resistant ovarian cancer), valrubicin (for the topical treatment of bladder cancer).

As with any other anticancer agent, the clinical use of anthracyclines is limited by hematologic and nonhematologic toxicities. The main nonhematologic toxicity is represented by a life-threatening dilative cardiomyopathy; in the long-term survivors of childhood cancer, cardiomyopathy may surface in a hypertrophic-restrictive form. The precise mechanisms of anthracycline cardiotoxicity remain a matter of debate. The current thinking is that DOX and other anthracyclines may become cardiotoxic after their conversion to ROS or secondary alcohol metabolites. ROS are formed after a one-electron reduction of the quinone moiety and the consequent formation of a semiquinone that reduces oxygen to superoxide anion $O_2^{\cdot -}$, hydrogen peroxide (H_2O_2), hydroxyl radical $\cdot OH$. Due to the lower levels of ROS-detoxifying enzymes in cardiomyocytes as compared with other cell types (and many tumors

as well), anthracyclins may gradually overrule the cardiac defenses and cause oxidative stress, suppression of cardiac-specific genes, apoptosis. Secondary alcohol metabolites are formed after a two-electron reduction of the side chain carbonyl group; they do not only downregulate cardiac-specific genes, but also inactivate calcium- and iron-handling proteins. The two pathways of toxicity, induced by ROS or secondary alcohol metabolites, share multiple links and feedbacks (Fig. 3).

Anthracycline-induced cardiomyopathy exhibits a well-defined dose-dependence, and may progress toward congestive heart failure (CHF) in the face of medication with β -blockers, calcium antagonists, converting enzyme inhibitors, diuretics. In the case of DOX, the threshold to cardiomyopathy and CHF is currently set at ~ 500 mg/m², but there have been concerns about whether cumulative doses < 500 mg/m² caused nonsymptomatic cardiac dysfunction that could surface at a later time in the form of symptomatic CHF. These concerns are less than speculative if one considers that very many women receive ~ 300 mg of DOX/m² for the neoadjuvant (presurgery) or adjuvant (postsurgery) treatment of early breast cancer. The available evidence suggests that these women do develop nonsymptomatic cardiac dysfunction,

usually detected as pathologic or borderline decreases of the \blacktriangleright left ventricular ejection fraction; however, there is no compelling demonstration that such a dysfunction would eventually progress to symptomatic CHF. Clinically, CHF may occur anytime after the completion of a cumulative anthracycline regimen; children tend to develop cardiomyopathy and CHF at longer times, sometime as late as 15 years after the last of several doses of an anthracycline. This latter observation suggests that changes in the lifestyle, environmental factors, and growth-related hemodynamic challenges may trigger the progression of noncardiotoxic injuries toward symptomatic cardiac dysfunction [2].

Cardiotoxicity may develop at lower than expected cumulative doses of anthracyclins in patients with risk factors like hypertension, preexisting arrhythmias or valvular disease, advanced age, prior irradiation of the mediastinum.

A higher than expected incidence of CHF is also observed in patients treated with DOX and other cytotoxics (e.g., the \blacktriangleright taxane paclitaxel) or new generation targeted agents (e.g., the humanized anti-ErbB-2/neu monoclonal antibody trastuzumab) [3]. The cardiotoxic synergism of DOX with taxanes or

Anthracyclins. Figure 3 Mechanisms of anthracycline cardiotoxicity. One-electron ($1 e^-$) reduction of the quinone moiety generates a semiquinone that recycles to the parent quinone by redox coupling with oxygen. The consequent cascade of superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radical ($\cdot OH$), induces apoptosis through oxidative stress and gene suppression. Two-electron ($2 e^-$) reduction of the side chain carbonyl group generates a secondary alcohol metabolite that also suppresses cardiac-specific genes and inactivates proteins of calcium and iron homeostasis. These mechanisms share multiple links and feedbacks.

Anthracyclins. Table 1 Strategies for reducing anthracycline cardiotoxicity

Strategy	Rationale	Indications
Substituting EPI for DOX	Lower formation of ROS or secondary alcohol metabolite	Same as those of DOX; combination with drugs that stimulate anthracycline conversion to secondary alcohol metabolite or diminish the cardiac defenses against ROS
Liposomal encapsulation of DOX or DNR	Preferred anthracycline delivery to the tumor	Breast cancer, ovarian cancer, AIDS-related Kaposi's sarcoma, multiple myeloma (pegylated liposomal DOX). Breast cancer (uncoated liposomal DOX). AIDS-related Kaposi's sarcoma, acute myeloblastic leukemia, multiple myeloma, non-Hodgkin's lymphomas (uncoated liposomal DNR)
Conjugation of DOX with copolymers or peptides	Recognition of DOX by tumor-specific receptors or proteases	Investigational
Coadministration of dexrazoxane	Chelation of iron in the heart, correction of iron dysregulation or mitigation of free radical formation	Approved for use in patients who continue DOX above 300 mg/m ² or require another anthracycline after a prior exposure to 300 mg of DOX/m ²
Substituting slow infusions for 5–10 min boluses	Diminished anthracycline C _{max} and cardiac uptake	At the investigator's discretion (doubtful usefulness in pediatric settings)

EPI, epirubicin; DOX, doxorubicin; ROS, reactive oxygen species; DNR, daunorubicin

trastuzumab has been attributed to anomalous increases of the formation of secondary alcohol metabolites or an interruption of salvage pathways against ROS, respectively. While providing a validation of the mechanistic hypotheses of anthracycline cardiotoxicity, these concepts anticipate that a higher than expected incidence of CHF might well occur, if DOX were combined with other biologic agents that blocked proliferation-survival pathways. Recent studies show that bevacizumab, a humanized antibody against the Vascular Endothelial Growth Factor, synergizes with DOX and causes moderate to severe cardiotoxicity at cumulative doses of 300–420 mg of DOX/m². Other agents that could cause excess cardiotoxicity upon combination with DOX might include sunitinib (inhibitor of the Vascular Endothelial Growth Factor receptor) and lapatinib (inhibitor of the tyrosine kinase domain of both ErbB-1 and ErbB-2 receptors).

The unabated need for anthracyclines in many clinical settings has formed the basis to develop strategies that optimize their activity and/or tolerability. The reversion of the resistance phenotype has been pursued – with a limited success – through the use of first and second generation Pgp inhibitors like verapamil, dexverapamil, cyclosporine A, valspodar, quinidine. Third generation revertants are now available (biricodar, zosuquidar, laniquidar), but the benefits of this strategy remain uncertain [4]. The attenuation of cardiotoxicity is obtained – with a somewhat higher success – through the combination of one or more of the following strategies: (i) substitution of EPI for

DOX, as EPI seems to form fewer amounts of ROS and secondary alcohol metabolite, (ii) encapsulation of anthracyclines in uncoated or pegylated ►liposomes that ensure a good drug delivery to the tumor but not to the heart, (iii) conjugation of anthracyclines with chemical moieties that are selectively recognized by the tumor cells, (iv) coadministration of dexrazoxane, an ►iron chelator that diminishes the disturbances of iron metabolism and free radical formation in the heart, and (v) administration of anthracyclines by slow infusion rather than 5–10 min bolus (Table 1). Pharmacological interventions with antioxidants have also been considered, but the available clinical studies do not attest to an efficacy of this strategy.

Antiarrhythmic Drugs

STEFAN DHEIN

Universität Leipzig, Herzzentrum Leipzig,
Klinik für Herzchirurgie, Leipzig, Germany

Synonyms

Antiarrhythmics

Definition

Antiarrhythmic drugs are substances that affect cardiac ionic channels or receptors, thereby altering the cardiac action potential or its generation or propagation. This results in changes of the spread of activation or the pattern of repolarization. Thereby, these drugs suppress cardiac arrhythmia.

These drugs are traditionally classified according to Vaughan-Williams (**Table 1**): (i) sodium channel blockers; slowing the spread of activation (► **antiarrhythmic drugs, class I**) with prolongation of the action potential (class IA), with shortening of the action potential (class IB) or without effect on action potential duration (class IC), (ii) β -adrenoceptor antagonists; slowing sinus rhythm and atrioventricular conduction (► **antiarrhythmic drugs, class II**), (iii) potassium channel blockers; prolonging the action potential (► **antiarrhythmic drugs, class III**), (iv) calcium channel

blockers; mainly slowing atrioventricular conduction (► **antiarrhythmic drugs, class IV**), and (not included in this classification) (v) digitalis glycosides, (vi) adenosine, (vii) atropine and (viii) sympathomimetic drugs like orciprenaline.

Mechanism of Action

Basic Considerations

Normal rhythmic activity is the result of the activity of the sinus node generating action potentials that are conducted via the atria to the atrioventricular node, which delays further conduction to the His-Tawara-Purkinje system. From the Purkinje fibres, action potentials propagate to the ventricular myocardium. Arrhythmia means a disturbance of the normal rhythm either resulting in a faster rhythm (tachycardia, still rhythmic) or faster arrhythmia (tachyarrhythmia) or slowed rhythm (bradycardia, bradyarrhythmia).

Arrhythmia is either the result of impaired conduction or altered electrical activity. However, in all arrhythmias, conduction and intercellular communication are important since arrhythmia only occurs if the altered electrical activity in one region is transduced to the whole organ.

Antiarrhythmic drugs can either influence electrical activity of the single cell or can interfere with the spread of activation.

In the following, the cardiac action potential is explained (**Fig. 1**): An action potential is initiated by depolarization of the plasma membrane due to the pacemaker current (I_f) (carried by K^+ and Na^+ , which can be modulated by acetylcholine and by adenosine) modulated by effects of sympathetic innervation and β -adrenergic activation of Ca^{2+} -influx as well as by acetylcholine- or adenosine-dependent K^+ -channels [in sinus nodal and atrioventricular nodal cells] or to depolarization of the neighbouring cell. Depolarization opens the fast Na^+ channel resulting in a fast depolarization (phase 0 of the action potential). These channels then inactivate and can only be activated if the membrane is hyperpolarized

Antiarrhythmic Drugs. Table 1 Classification of antiarrhythmic drugs according to Vaughan-Williams

Class	Effects	Drugs
I	Block of sodium channel	
I a	With prolongation of action potential	Quinidine, Procainamide, Disopyramide, Ajmaline, Prajmaline
I b	With shortening of action potential	Lidocaine, Mexiletine, Tocainide, Phenytoin, Aprindine
I c	With only little effect on action potential duration	Lorcainide, Flecainide, Propafenone
II	β -adrenoceptor antagonists	Propranolol, Metoprolol and others
III	Block of repolarizing potassium channels, prolongation of action potential	Amiodarone, Dronedarone, Sotalol, Dofetilide, Ibutilide
IV	Block of calcium channels	Verapamil, Diltiazem

Antiarrhythmic Drugs. Figure 1 Transmembrane ionic currents of the cardiac action potential. In the middle of the figure, a typical cardiac action potential is shown as can be obtained from the ventricular myocardium (upper trace). Below, the contribution of the various transmembrane currents is indicated. Currents below the zero line are inward; currents above the zero line are outward fluxes. In the left column the name of the current is given and in the right column the possible clone; redrawn and modified after [5].

again. This fast upstroke is followed by a short incomplete repolarization (activation of the transient outward rectifier $I_{t.o.}$ carried by K^+ , phase 1). Next, the action potential remains quiet constant for about 50–350 ms (plateau phase, phase 2), which is the result of inward Ca^{2+} current (via L-type Ca^{2+} channels) and simultaneous activation of the repolarizing potassium current, the delayed rectifier I_K (which has three components: rapid, $I_{K,r}$, ultrarapid, $I_{K,ur}$, slow component, $I_{K,s}$). This is followed by complete repolarization of the membrane to about -80 mV via activation of the delayed rectifier (phase 3), while the Ca^{2+} channels close during this phase. During an action potential it is not possible to elicit a second action potential since the fast Na^+ channel is inactivated. This period is called refractory period [4].

Not all cells in the heart express the fast sodium channel. Thus, sinus nodal and atrioventricular nodal cells lack the fast Na^+ channel and instead generate their action potentials via opening of Ca^{2+} channels. This is the basis for their sensitivity to Ca^{2+} antagonists.

Action potential propagation along the fibre is mainly dependent on the Na^+ channel availability, which is a function of the resting membrane potential. Propagation from cell to cell is realized via intercellular gap junction channels. These channels can be regulated by a number of stimuli. Thus, e.g. low pH, high $[Ca^{2+}]_i$ or low $[ATP]_i$ result in a closure of these channels leading to conduction disturbances and arrhythmias in myocardial infarction. Moreover, the density of these channels can be regulated by e.g. chronic adrenergic stimulation, angiotensin-II or endothelin and has been

found to be altered in arrhythmias such as atrial fibrillation or arrhythmogenic conditions like cardiac hypertrophy.

There are several basic mechanisms of arrhythmia:

1. A single cell or group of cells capable of a pacemaker potential may generate extrastimuli (enhanced automaticity).
2. A cell may generate oscillating afterpotentials which reach the threshold for activation of the Na^+ channel (triggered activity).
3. A cell generates late afterdepolarizations (typically induced by catecholamines or digitalis) following a complete repolarization that may elicit an action potential.
4. A cell may produce early afterdepolarizations that are depolarization during incomplete repolarization. This is possible if the action potential is considerably prolonged. This is the typical mechanism for elicitation of Torsade de Pointes arrhythmia, a typical complication of class III antiarrhythmics and many other drugs.
5. Furthermore, under certain conditions (e.g. local unidirectional block) it is possible that the activation wavefront is delayed and encounters areas already repolarized. This may result in a circulating wavefront (= reentrant circuit ▶reentrant arrhythmia), from which centrifugal activation waves originate and elicit life-threatening ventricular fibrillation.
6. Block of propagation may occur in the specific conduction system leading to bradyarrhythmia

(sinusatrial block, atrioventricular block, intraventricular bundle block).

Antiarrhythmic treatment is based upon modulation of the ionic currents mentioned above. A principal problem with this therapy is that the electrophysiology of all cells is targeted and not specifically the arrhythmogenic focus. As a consequence, all antiarrhythmics acting at transmembrane ionic channels possess a risk for elicitation of arrhythmia (= proarrhythmic risk).

Molecular Mechanism of Action

Class I, III and IV antiarrhythmics bind to and block transmembrane ionic channels (Fig. 2). Class I antiarrhythmics block the fast Na^+ channel. This channel switches from a resting state to an open state, and then time- and voltage-dependently inactivates (inactivated state) (Fig. 3). The block of this channel by an antiarrhythmic drug is a **state-dependent block**: a class I compound like lidocaine enters the channel in its open state and binds to the inactivated state, altering the kinetics of recovery from inactivation. If the channel switches to its resting state, the affinity for lidocaine is less and the drug dissociates from the channel. This is the basis for the use-dependence of block: the kinetics of dissociation determines the interval after which a subsequent action potential is not influenced. That means that an action potential early after the foregoing action potential will be suppressed while another after a long interval will not be altered.

Drugs with fast dissociation will only suppress high frequency arrhythmia (high use-dependence). Drugs with a long dissociation time constant will suppress action potentials at normal frequency as well. Class IB drugs exhibit the shortest time constant (0.2–0.4 s; highest use-dependence), while class IC drugs have the longest dissociation time constant (2–250 s; no use-dependence). Class IA antiarrhythmics show an intermediate dissociation time constant (5–50 s).

Class I drugs (Na^+ channel blockers) suppress action potential amplitude, reduce fast depolarization (upstroke) velocity and propagation velocity, prolong total refractory period and reduce automaticity. These drugs have no or little influence on slow Ca^{2+} carried action potentials (AV- or sinus nodal cells). All these drugs prolong the ventricular QRS complex, exert negative inotropic effects and a strong proarrhythmic effect especially in patients with structural heart disease and, thus, cannot be used in patients after myocardial infarction.

Besides the class I-typical proarrhythmic risk class IA antiarrhythmics possess a marked proarrhythmic risk for the induction of **torsade de pointes arrhythmia** (life-threatening polymorphic ventricular tachycardia observed with most action potential prolonging drugs).

Quinidine, the classical class IA drug, binds to the open state of the Na^+ channel, and prolongs the action potential by block of the delayed rectifier. In higher concentrations, L-type Ca^{2+} channels are inhibited. Quinidine exerts antimuscarinic effects, thereby accelerating AV-nodal

Antiarrhythmic Drugs. Figure 2 Targets of the various antiarrhythmic drugs. The K^+ channel, regulated by acetylcholine (via M_2 receptors) or adenosine (via A_1 receptors), plays a role only in supraventricular tissues. The action potential which is generated in one cell propagates to the neighbouring cell via the gap junction channel.

Antiarrhythmic Drugs. Figure 3 Binding of class I antiarrhythmic drugs to the cardiac sodium channel. Summary of the modulated receptor hypothesis as an explanation of state-dependent block of Na^+ channels by local anaesthetics such as lidocaine. The Na^+ channel switches between resting and open and inactivated state. On the extracellular side, a selectivity filter controls the ions passing through the channel. On the intracellular side, the inactivation gate can close the channel. A class I antiarrhythmic drug (lidocaine) enters the channel during its open state and binds with its lipophilic moiety to the inactivated state, the hydrophilic part of the molecule extending into the water-filled channel pore blocking it.

conduction and antagonising α -adrenergic effects, which may lead to accelerated AV-conduction and faster ventricular rhythms in situations as atrial fibrillation or atrial flutter. Typical untoward effects include vomiting, diarrhoea, allergies, immunological and haematological effects and hepatitis.

Ajmaline (intravenously only) and its orally applicable propyl-substituted prodrug prajmaline are classified as class IA drugs, but due to their long dissociation time constant can also be considered as class IC compounds.

Further class IA drugs include the open state blockers procainamide and disopyramide with electrophysiological effects similar to those of quinidine; procainamide lacks the antimuscarinic and antiadrenergic effects. Characteristic side effects of procainamide are hypotension and immunological disorders.

Class IB drugs like lidocaine, phenytoin or mexiletine preferentially bind to the inactivated state. Lidocaine, a local anaesthetic, can be used intravenously for antiarrhythmic treatment. It is one of the classical drugs used in emergency medicine for the

treatment of ventricular fibrillation. The side effects of lidocaine are typical for local anaesthetics including dizziness, tremor, nystagmus, seizures or nausea.

The antiepileptic drug phenytoin, an orally available class IB antiarrhythmic, is mainly effective in digitalis-induced arrhythmias. This drug exhibits non-linear pharmacokinetics and a number of side effects including neuropathy, gingival hyperplasia, hepatitis, immunological disorders and suppression of white blood cells.

Class IC antiarrhythmic drugs such as flecainide or propafenone block the Na^+ channel (open state; propafenone: open and inactivated state) with a very long dissociation time constant so that they alter normal action potential propagation. Flecainide increased mortality of patients recovering from myocardial infarction due to its proarrhythmic effects (CAST study). Action potential is shortened in Purkinje fibres but is prolonged in the ventricles.

Propafenone possesses β -adrenoceptor antagonistic effects due to its structural similarity to propranolol.

In high concentrations it blocks calcium channels and, thus, exerts prominent negative inotropic effects. Its adverse effects include proarrhythmic effects, worsening of heart failure and (due to β -adrenoceptor blockade) bradycardia and bronchospasm.

Class II drugs are classical β -adrenoceptor antagonists such as propranolol, atenolol, metoprolol or the short-acting substance esmolol. These drugs reduce sinus rate, exert negative inotropic effects and slow atrioventricular conduction. Automaticity, membrane responsiveness and effective refractory period of Purkinje fibres are also reduced. The typical extracardiac side effects are due to β -adrenoceptor blockade in other organs and include bronchospasm, hypoglycemia, increase in peripheral vascular resistance, depressions, nausea and impotence.

Class III antiarrhythmic drugs block the repolarizing K^+ channel thereby prolonging the action potential duration and lengthen the refractory period. The classical class III antiarrhythmic compounds like sotalol block the rapid component of the delayed rectifier, I_{Kr} . However, at higher heart rates the repolarization is mainly carried by the slow component I_{Ks} and, thus, the action potential prolonging effect of these agents is progressively reduced with increasing heart rate (inverse use-dependence). Class III antiarrhythmics can induce early afterdepolarizations and torsade de pointes, a polymorphic ventricular tachycardia associated with excessive QT prolongation, which can degenerate into ventricular fibrillation.

d,l-Sotalol is a racemate of l-sotalol, a β -adrenoceptor antagonist, and d-sotalol, an inhibitor of both I_{Kr} and I_{Ks} . This substance exhibits a strong inverse use-dependence. Regarding the beneficial antiarrhythmic effects, studies with only l-sotalol showed that the racemate is superior. However, due to β -adrenoceptor blockade d,l-sotalol can induce bronchoconstriction, increase in peripheral vascular resistance, negative inotropy, depressions, hypoglycemia and bronchospasm. A serious side effect is the induction of torsade de pointes arrhythmia (ca. 3%).

Amiodarone blocks several ionic channels; besides predominant blockade of I_{Kr} and I_{Ks} , as well as I_{K1} , $I_{K.ACh}$, I_{sus} , I_f , I_{Na} , $I_{Ca.L}$, $I_{Ca.T}$ is inhibited. Moreover, amiodarone acts as an antagonist at both α - and β -adrenoceptors. Inverse use-dependence is less than with sotalol. The action potential prolonging effect is slowly developing (steady state after 2–5 months). From today's understanding the molecular mechanism includes the generation of an inactive triiodothyronine isomere thus acting as a functional T3-antagonist affecting the T3-dependent gene activation, which seems to explain the slowly developing prolongation of the action potential. A small acute prolongation of the action potential is probably dependent on the formation of the metabolite desethylamiodarone. Side effects

include defects of vision, corneal depositions, neurological disorders, pigmentation, photosensibilization, torsade de pointes arrhythmia (but less than 1%) and AV-block. Moreover, alterations of thyroid function with both hypo- (due to the inactive T3-isomere) and hyperthyroidism (due to the iodine content of the drug) and lung fibrosis are observed.

Since alterations of thyroid function by amiodarone are related to the iodine substitution of the drug, the iodine-free derivative dronedarone has been developed with similar electrophysiological effects as amiodarone. It seems to act also as a T3-antagonist, but does not provoke hyperthyroidism [1].

Newly developed class III drugs comprise dofetilide, a specific I_{Kr} blocker, and ibutilide, which blocks I_{Kr} and activates the slow I_{Na} . Both drugs lack hemodynamic side effects. These drugs are scheduled for the treatment of atrial fibrillation and atrial flutter. As with class III drugs, they can induce torsade de pointes arrhythmia.

Class IV antiarrhythmic drugs (Ca^{2+} entry blockers) inhibit L-type Ca^{2+} channel. For antiarrhythmic purposes, only those Ca^{2+} channel antagonists are used with higher affinity to the heart (i.e. phenylalkylamines like verapamil, gallopamil and D600, or benzothiazepine derivatives like diltiazem) than to the vasculature (as nifedipine or other 1,4-dihydropyridines, which therefore do not belong to the class IV antiarrhythmics). Class IV antiarrhythmic drugs like verapamil or diltiazem exert the strongest electrophysiological effects on sinus and atrioventricular node, since in sinus and AV-nodal cells I_{Na} is not expressed but action potentials are carried by Ca^{2+} . They reduce sinus rate, slow atrioventricular conduction, prolong refractory period of the AV node and exert a strong negative inotropic and vasodilator effect. Ventricular electrophysiology is only slightly affected, but force of contraction is markedly reduced.

Verapamil is a phenylalkylamine which blocks L-type Ca^{2+} channels in a use-dependent manner. The drug binds to the inactivated state of the channel. Diltiazem is a benzothiazepine derivative with a profile of action most similar to that of verapamil.

Other Antiarrhythmic Compounds

► **Cardiac glycosides** exert parasympathomimetic effects by activation of vagal nerves leading to slowing of sinus rate and predominantly to prolongation of atrioventricular conduction time. This latter action is used for the control of the ventricular response frequency in the treatment of atrial fibrillation with digitalis (frequency control therapy of atrial fibrillation). In that indication it can be combined with verapamil or β -adrenoceptor antagonists.

Adenosine activates the atrial A_1 -adenosine receptor, which opens the $I_{K.Ado}$ channel leading to

hyperpolarization, slowing of spontaneous depolarization, reduces sinus rate and atrioventricular conduction [3]. The drug has to be administered intravenously. It produces a short cardiac arrest and is used for termination of atrioventricular reentrant tachycardia. Due to its extremely short half-life time (0.6–1.5 s) the effects are only transient. Since adenosine is also a potent vasorelaxant, it may produce pronounced hypotension, and in patients suffering from asthma bronchospasm. The latter effects are transduced via other adenosine receptors. This is the basis for the development of a new A_1 -selective agonist, tecadenoson.

The antimuscarinic drug atropine, and its derivative ipratropiumbromide, can also be used for antiarrhythmic treatment. Muscarinic receptors (M_2 subtype) are mainly present in supraventricular tissue and in the AV node. They inhibit adenylylcyclase via G_i proteins and thereby reduce intracellular cAMP. On the other hand, activation of the M_2 receptor leads to opening of hyperpolarizing $I_{K,ACH}$ and inhibits the pacemaker current I_f probably via the $\beta\gamma$ -subunit of the G_i protein associated with this receptor. The results are hyperpolarization and slower spontaneous depolarization. Muscarinic receptor antagonists like atropine lead to increased heart rate and accelerated atrioventricular conduction. There are no or only slight effects on the ventricular electrophysiology.

Intravenous administration of magnesium sulfate (1–5 g) is used for the termination of torsade de pointes arrhythmia. The underlying electrophysiological mechanism is not well understood. It includes changes of the current–voltage relationship of I_{K1} and Ca^{2+} channel blockade.

Clinical Use

Clinical uses of antiarrhythmics have been restricted after CAST [2] due to their proarrhythmic risk, and preference is given to electrophysiological methods.

Supraventricular bradycardia is treated by implantation of a pacemaker device or has been treated pharmacologically with atropine. Supraventricular paroxysmal tachycardia is treated with ajmaline or prajmaline. Supraventricular tachyarrhythmias or AV reentrant arrhythmia typically can be terminated using adenosine.

The risk of atrial flutter is a 2:1 transmission to the ventricles generating a high ventricular rate. The therapeutic goal is to reduce transmission to 3:1 or 4:1 by administration of either β -adrenoceptor antagonists, Ca^{2+} channel blockers or amiodarone. Quinidine must not be used in this arrhythmia, since it accelerates AV-conduction due to its vagolytic effect.

The most common arrhythmia in humans is atrial fibrillation. Because of the lack of rhythmic atrial activation, irregular ventricular rhythms and thromboembolism result. There are two possible therapeutic goals:

control of heart rate or return to sinus rhythm. For frequency (heart rate) control, β -adrenoceptor antagonists, Ca^{2+} channel blockers and digitalis can be used. For conversion to sinus rhythm, electrophysiological ablation is the therapy of choice. Alternatively, a pharmacological attempt with class IA drugs or class IC drugs can be made. Thereafter, relapse to atrial fibrillation has to be prevented by amiodarone or β -adrenoceptor antagonists. A recent concept is the pill-in-the-pocket concept which means that the patient takes just one dose of oral flecainide (or similarly acting drugs) when experiencing a relapse to atrial fibrillation. It is necessary to include oral anticoagulant therapy with phenprocoumon or warfarin in the treatment strategy of chronic atrial fibrillation to prevent from stroke, which is the main risk of a patient suffering from atrial fibrillation.

Atrioventricular block in general is treated by implantation of an electrical pacemaker. A pharmacological alternative (although no longer used today) was atropine. However, atropine can be used for bridging the time between the onset of symptoms and the definitive implantation of a pacemaker.

Ventricular extrasystoles are treated only if they may degenerate into life-threatening arrhythmia. In milder forms the proarrhythmic risk of the drugs overshadows their benefits. In such cases β -adrenoceptor antagonists may be attempted. For the treatment of ventricular extrasystoles, such as series or runs of extrasystoles, amiodarone or sotalol are used. In the absence of structural heart disease, class I antiarrhythmic drugs can be considered an alternative. However, they may not be administered during the post-infarction period.

Ventricular fibrillation should be terminated by electrical defibrillation. Alternatively, lidocaine can be injected intravenously. In cases with lower frequency, ventricular tachyarrhythmia class I drugs such as ajmaline, flecainide or propafenone are more effective as a result of the use-dependence of lidocaine. For prophylaxis treatment, amiodarone or sotalol may be helpful or the implantation of a cardioverter-defibrillator system. Acute amiodarone (i.v.; in higher doses) can also terminate ventricular tachyarrhythmias. This action, however, seems to be mediated by its I_{Na} -blocking side effects and not (or less) by its class III like effects.

Torsade de pointes arrhythmia can be terminated by intravenous (not oral) administration of large doses of magnesium.

Antiarrhythmic Drugs Class I

Antiarrhythmic drugs are antagonists of the fast Na^+ channel, which slow the propagation of the cardiac action potential. Class I drugs suppress the fast upstroke of the action potential.

► [Antiarrhythmic Drugs](#)

Antiarrhythmic Drugs Class II

Class II antiarrhythmic drugs are β -adrenoceptor antagonists such as propranolol, metoprolol or atenolol. β -adrenoceptor antagonists slow sinus rate and atrioventricular conduction and exert negative inotropic effects.

► [Antiarrhythmic Drugs](#)

Antiarrhythmic Drugs Class III

Class III antiarrhythmic drugs are drugs which act as K^+ channel antagonists and result in action potential prolongation without effect on the upstroke of the action potential.

► [Antiarrhythmic Drugs](#)

Antiarrhythmic Drugs Class IV

Class IV antiarrhythmic drugs are Ca^{2+} channel blockers, which predominantly slow sinus rate and atrioventricular conduction and thus are used in the treatment of supraventricular tachyarrhythmias. These drugs exert a pronounced negative inotropic effect.

Antibiotic Resistance

PETER HEISIG

Pharmaceutical Biology and Microbiology, University of Hamburg, Hamburg, Germany

Definition

From the mechanistic point of view three basic principles of microbial resistance to drugs are known: inactivation of the drug, alteration of the target, and reduced drug accumulation at the target site. However, several variations on these themes are known.

Basic Mechanisms

The phenomenon of bacterial resistance to antibiotics was already known by the pioneers of the era of antibiotics, like Paul Ehrlich, who coined the term "selective toxicity" as the basic principle of antimicrobial therapeutics, as well as Gerhard Domagk, the inventor of the sulfonamide drugs, and Sir Alexander Fleming, the discoverer of the penicillins. When penicillin G was introduced into clinical practice in 1944, as many as 5% of the isolates of *Staphylococcus aureus* were resistant to penicillin, while 5 years later the percentage was 50%.

That bacterial resistance predates the era of clinical use of antibiotics by several hundred millions of years is the recent result of genomic sequence data mining from antibiotic-producing microorganisms. These are supposed to be the "inventors" of antibiotic resistance genes which they had "developed" to protect themselves from the lethal action of their own antibiotics [4].

Sharing these resistance genes with other bacteria, including human pathogens, by ► [gene transfer mechanisms](#) has resulted in a wide spread and in the adaption of these foreign gene sequences to the genetic codon usage of the respective pathogen. This is the preferred

strategy to provide bacteria with resistance determinants to naturally occurring antibiotics [1].

In addition, due to their the short generation times resulting in high cell densities within a short time, bacteria can easily acquire mutations in genes encoding antibiotic targets. The usually haploid bacterial genome assures that resistant variants of these targets are phenotypically expressed and, thus, mediate resistance. With this strategy bacteria are able to respond to novel chemical structures of synthetic antibacterials.

Over 4 decades, between 1960 and 2000, the development of new antibiotics used well characterized basic structures for partial synthetic modifications, primarily to overcome resistance by increasing the pharmacodynamic properties and, secondarily, to improve the pharmacokinetic profile of older compounds. However, bacteria rapidly responded by acquiring additional genetic alterations either as mutations or by accumulating resistance genes as part of mobile genetic elements (► **integrons**) on transferable ► **resistance plasmids**.

Inactivation of the Drug

The inactivation of a drug is an enzymatic process which results either in the cleavage of a chemical bond, e.g. by proteases or esterases, or the formation of a new chemical bond, e.g. by transferring phosphate (phosphotransferase), acetate (acetyltransferase), or nucleotidylate (nucleotidyltransferase) moieties to a functional group of the antibiotic. The cleavage causes the loss of function of the antibiotic. Chemical modification can eliminate a specific molecular interaction between drug and target or can alter the physico-chemical properties of a drug, e.g. electrical charge, that has an impact on the ability of a drug to penetrate the bacterial membrane(s).

Proteases

An example for proteases are the β -lactamases that hydrolyse a peptide bond in the essential β -lactam ring of penicillins, cephalosporins, carbapenems and monobactams and, thereby, irreversibly inactivate the drug. β -lactamases share this mechanism with the ► **penicillin binding proteins (PBPs)**, which are essential enzymes catalyzing the biosynthesis of the bacterial cell wall. In contrast to the PBPs which irreversibly bind β -lactams to the active site serine, the analogous complex of the drug with β -lactamases is rapidly hydrolyzed regenerating the enzyme for inactivation of additional β -lactam molecules.

According to their genetic relationship and their biochemical mechanism of action β -lactamases are divided into enzymes of the serine-protease type containing an active-site serine (molecular class A, C, and D enzymes) and those of the metallo-protease type (molecular class B enzymes), which contain a complex bound zinc ion.

The further classification of the over 400 different enzymes described so far into different subclasses is based upon different parameters, like substrate profile, molecular mass, isoelectric point, stability against β -lactamase inhibitors, localization of the encoding gene on a plasmid or on the chromosome (Fig. 1). According to this classification the group 1 enzymes are cephalosporinases of Gram-negative pathogens (most enterobacteria and ► *Pseudomonas aeruginosa*) which usually are chromosomally encoded. In many bacteria, like several enterobacteria (Citrobacter, Enterobacter, Serratia, Providencia, Morganella) their expression can transiently be induced in the presence of β -lactams, however, this induction is not of clinical relevance. Instead, the constitutive overexpression of the genes due to a mutation inactivating a genetic repressor of the β -lactamase will result in a high level of resistance to cephalosporins and penicillins, but not carbapenems. Enzyme inhibitors, like clavulanic acid are not active against these enzymes.

The group 2 contains the greatest number of enzymes showing the broadest spectrum of substrates. The majority of these enzymes belongs to the plasmid-encoded families TEM, SHV, CTX-M and OXA. Each family consists of one or a few progenitor enzymes with narrow substrate profile, e.g. TEM-1, TEM-2, and TEM-13, and several descendents which have acquired mutations resulting in the extension of the substrate profile (► **extended spectrum β -lactamases, ESBL**). This is accomplished either by widening the binding pocket or by introducing amino acids with side chains allowing for the stabilization of the drug-enzyme interaction. These group 2 enzymes are usually inhibited by clavulanic acid, however, some variants exist, which are resistant to the action of β -lactamase inhibitors (IR- β -lactamase), but have lost their broad substrate spectrum.

For the CTX-M family which has been rapidly growing during the last three years genomic data have identified the genome of *Kluyvera* species as the genetic source of progenitor enzymes (e.g. encoding CTX-M1, CTX-M2 or CTX-M9).

► **Metallo-enzymes** belonging to group 3 naturally show a very broad substrate spectrum including all β -lactams except monobactams and are not inhibited by clavulanic acid, but by complexing agents, like EDTA. This can only be exploited for diagnostic purposes.

Esterases

Hydrolysis of macrolides by products of the *ere* genes detected in enterobacteria is only of scientific interest, while esterases VGB-A and VGB-B encoded by the *vgb* type genes mediate clinically relevant resistance in staphylococci to the B compound (quinupristin) of the streptogramin combination quinupristin-dalfopristin.

Classification of β -lactamases - by
molecular and functional features

Mole- cular class	Ambler group	Enzymatic aktivty	Localisation and way of distribution of gene	Examples
1	C	Cephalosporinase	Chromosome, Gram- negatives	AmpC
2a	A,D	Penicillinase	<i>S.aureus</i> , <i>P. aeruginosa</i>	BlaZ
2b	A	"broad spectrum" TEM-1,-2; SHV-1	Plasmid, Gram-negatives	TEM-1 SHV-1
2be	A	"extended spectrum"	Plasmid, Gram-negatives Chromosome, <i>K. oxytoca</i>	TEM-3 to 161 SHV-2 to 104 CTX-M1 to n
2br	A	"inhibitor resistant"	Plasmid, Gram-negatives	TEM-30 to 41 SHV-10
2c	A	Carbenicillinase PSE; CARB	Plasmid, Gram-negatives	CARB-1
2d	D	Cloxacillinase	Plasmid, Gram-negatives	OXA type
2e		Cephalosporinase	Chromosome, <i>P. vulgaris</i>	CepA
2f	A	Carbapenemase, ceph-, pen-ase	Chromosome, <i>E. cloacae</i> , <i>S.marcescens</i>	SME-1, MNC-A, KPC-1
3	B	Metalloenzym	Chromosome, <i>B. cereus</i>	L1, CfiA, IMP-1, VIM-1
4	?	Penicillinase	Chromosome, <i>P. cepacia</i>	

Antibiotic Resistance. Figure 1 According to Bush, Jacoby and Medeiros [2] four molecular classes of β -lactamases can be discriminated based upon biochemical and molecular features. Classes 1, 2, and 4 included serine-proteases, while metallo enzymes are included in class 3. The substrate spectrum varies between different subclasses and the corresponding genes can be part of an R-plasmid leading to a wider distribution or are encoded chromosomally in cells of specific species.

Acetyltransferases

The preferred substrates of acetyltransferases are amino-groups of antibiotics, like chloramphenicol, streptogramin derivatives, and the various aminoglycosides. The modification is believed to block a functional group involved in the drug-target-interaction. All acetyltransferases use acetyl-coenzyme A as cofactor.

The major mechanism of resistance to chloramphenicol is mediated by the chloramphenicol acetyltransferases (CAT enzymes) which transfer one or two acetyl groups to one molecule of chloramphenicol. While the CAT enzymes share a common mechanism, different molecular classes can be discriminated. The corresponding genes are frequently located on integron-like structures and are widely distributed among Gram-negative and – positive bacteria.

Resistance to the A compound of streptogramins is mediated by products of the *vat* genes (virginiamycin acetyltransferase), of which at least five molecular classes are known (*vatA-E*). These genes are located on plasmids of *Enterococcus faecium* and frequently in combination with a gene encoding a streptogramin hydrolase (*vga/vgb*) in staphylococci.

Enzymes transferring an acetyl moiety to one specific of several amino-groups of the aminocyclitol-aminoglycoside antibiotics (e.g. gentamicin, amikacin, kanamycin) are called aminoglycoside acetyltransferases

(AAC). These enzymes are also widely distributed among Gram-positive and Gram-negative pathogens and are classified according to the position of the amino group modified (e.g. AAC3, AAC6'). They are further subdivided into different molecular classes based upon substrate profile (e.g. AAC6'-I, AAC6'-II) and amino acid sequence homology (e.g. AAC6'-IIa, AAC6'-IIb). A summary of relevant aminoglycoside modifying enzymes (AMEs) mediating resistance to clinically used aminoglycosides is given by Shaw et al [3].

Nucleotidyltransferases, Phosphotransferases

Beside AAC enzymes two different enzyme classes, nucleotidyltransferases (ANT enzymes), and phosphotransferases (APH enzymes) modify the hydroxyl groups of aminocyclitol-aminoglycoside antibiotics.

Alteration of the Target

Target alterations usually result in the reduction of the affinity for a drug. This strategy enables the bacteria to respond to alterations in the selective pressure due to, e.g. novel antibiotics within a short period of time. Genetic basis for a target alteration are either point mutations in the respective target gene or acquisition of a DNA fragment containing information for an altered less susceptible target. Alternatively, targets can be modified enzymatically.

Target Alteration by Point Mutations

The major mechanism of resistance to fluoroquinolones is the acquisition of point mutations in the genes *gyrA* and *parC* encoding the respective A subunits of both targets, ►topoisomerases II and IV. Only a few codons are affected which are located in the so-called quinolone resistance-determining region (QRDR) between ala-67 and gln-106 (*E. coli* numbering of *gyrA*). To achieve a high level of resistance, at least two *gyrA* and one *parC* mutations are required.

Other examples include rifampin resistance due to mutations in the *rpoB* gene encoding the β -subunit of RNA polymerase, or oxazolidinone resistance due to a G2576T mutation in the gene for the 23S rRNA as central part of the 50S large ribosomal subunit. Macrolide resistance is based upon the alteration of nucleotide A2058 by a point mutation.

Target Alteration by Enzymatic Modification

An alternative strategy to modify nucleotide A2058 of the 23S rRNA is used by the majority of pathogens: the production of a specific methyltransferase which couples one or two methyl groups to the N6 amino group thereby reducing the affinity of macrolides to their target. Since this residue is also involved in the binding of other antibiotics, like streptogramin B and lincosamine, this mechanism is termed MLS_B type [4].

Another more sophisticated mechanism of enzymatic alteration of the target is the transfer of the complete regulon encoding a D-alanyl-D-lactate-ligase, like VanA, as basis for transferable resistance to glycopeptide resistance. In cooperation with some accessory factors the structure of the basic units of the bacterial cell wall, the disaccharide-pentapeptide with a C-terminal D-alanine, is transformed into a variant carrying a C-terminal D-lactate which prevents the binding of glycopeptide antibiotics at physiological concentrations and, thus, causes glycopeptide resistance. Such regulons reside on transposons allowing for the rapid exchange of the genetic information between different enterococcal species and even to staphylococci.

Target Modification by Acquisition of Genes Encoding Resistant Target

In contrast to macrolides, the targets of β -lactams, the penicillin binding proteins (PBPs) require several mutations in order to become resistant while simultaneously maintaining their viable function as cell wall transpeptidases/transglycosidases. Thus, in order to achieve clinically relevant resistance *Streptococcus pneumoniae* uses a unique strategy to rapidly accumulate several point mutations. Due to its natural competence for transformation during respiratory tract

infections *S. pneumoniae* cells can acquire and insert into their chromosomes genetic material from closely related species, like viridans group streptococci. Since these cells carry genes for PBPs with reduced sensitivity to β -lactams due to the presence of several genetic variations, transformation/recombination generate so-called ►mosaic genes encoding a β -lactam-resistant variant protein, PBPX.

Staphylococcus aureus cells can acquire large DNA fragments containing the *mecA* gene which encodes a complete new penicillin binding protein 2A (PBP 2A), as part of a transposon. PBP2A can substitute the natural set of penicillin-sensitive PBPs thereby mediating a complete cross resistance to all β -lactam antibiotics.

Reduced Drug Accumulation at Target Site

Uptake of nutrients from the environment, release of cell signalling molecules and virulence factors as well as disposal of toxic compounds are essential for metabolic active microorganisms. In contrast to Gram-positive bacteria having a cytoplasmic membrane only, Gram-negative bacteria are surrounded by an additional outer membrane, which forms a strict barrier between the intracellular space and the environment. While lipophilic compounds can directly penetrate the membranes' lipid bilayers, hydrophilic molecules require transmembrane proteins forming water-filled pores for passive diffusion into the cell or energy-driven transmembrane pumps for active efflux.

Two mechanisms are operating alone or in concert to minimize the antibiotic concentration at the intracellular target site: Downregulation of the expression of the pore proteins, also called porins, and upregulation of one or a set of several unspecific efflux pumps. However, the impact of these mechanisms on the resistance is low, since due to the essential function of porins for uptake of nutrients their reduction is limited and to avoid disturbances of membrane integrity due to extensive overproduction of mdr efflux pumps these are subjected a strict regulation.

Resistance Due to Multiple-Drug Resistance (mdr) Efflux

Currently, five different molecular classes of mdr efflux pumps are known [5]. While pumps of the the ATP-binding cassette (ABC) transporter superfamily are driven by ATP hydrolysis, the other four superfamilies called resistance-nodulation-division (RND), major facilitator superfamily (MFS), multidrug and toxic compound extrusion (MATE), and small multidrug resistance transporter (SMR) are driven by the proton-motive force across the cytoplasmic membrane. Usually a single pump protein is located within the cytoplasmic membrane. However, the RND-type pumps which are restricted to Gram-negative bacteria consist of two additional components, a periplasmic membrane fusion protein (MFP) which connects the efflux pump to an outer

Antibiotic Resistance. Figure 2 The major *mdr* efflux pump of *Escherichia coli* belongs to the RND superfamily and consists of the pump AcrB, the membrane fusion protein AcrA, and the porin TolC. The expression of the genes *acrAB* is under control of the local repressor AcrR, while *tolC* and *acrAB* are additionally regulated by several global transcriptional activators, like MarA induced by salicylate, SoxS derepressed by oxidants, and by Rob directly activated by bile salts.

membrane porin. This architecture allows the disposition of the antibiotics outside the cell (Fig. 2). Efflux is due to an enzymatic activity and therefore saturable.

The combined intrinsic activities of different efflux pumps play a major role for the intrinsic resistance of Gram-negative bacteria to macrolides and oxazolidinones as well as to the intrinsic resistance of *Pseudomonas aeruginosa* against a broad range of disinfectants and antibiotics.

Acquired resistance has been observed by constitutive upregulation of *mdr* efflux pump expression due to a mutation inactivating a respective repressor or inducibly, caused by molecules transiently inactivating repressor molecules upon binding. Depending upon the substrate spectra of the respective subset of efflux pumps upregulated, a multiple drug resistance (*mdr*) phenotype is expressed, which in combination with a specific resistance mechanism can contribute to a clinically relevant level of resistance.

Resistance to Tetracyclines Due to Specific Efflux Pumps

For some naturally occurring antibiotics, like chlormaphenicol and tetracyclines, specific drug efflux pumps have been detected in antibiotic-producing bacteria. The tetracycline specific efflux pumps have been detected in many bacterial pathogens and are the major mechanism of resistance to these drugs. Several of the corresponding structural genes are inducibly expressed: In the presence of tetracyclines in the growth medium a few drug molecules enter the cell by diffusion, bind to the pump repressor and, thus, induce tet efflux pump expression.

Antibodies

Antibodies are involved in the humoral immune response. They recognize foreign substances (antigens) and trigger immune responses by the host. For the former, they possess interaction sites for a specific antigen. These interaction sites (Fab portions) are highly variable between antibodies produced by different clones of B cells. For the latter, they possess a constant region (Fc portion). Engineered antibodies are increasingly used for the treatment of human diseases.

- ▶ Humanized Monoclonal Antibodies

Antibodies to Cyclic-citrullinated Peptides (Anti-CCPs)

It has long been known that antiperinuclear factor and antikeratin antibodies have high specificity for rheumatoid arthritis. Both these antibodies recognize epidermal fillagrin, a protein involved in the cornification of the epidermis. The amino acid target of these antibodies is citrulline, which is derived from the amino acid arginine after peptide translation under the influence of the enzyme peptidyl arginine deiminase. Antibodies directed at cyclic citrullinated peptides have a similar sensitivity to rheumatoid factor, but higher specificity.

- ▶ Rheumatoid Arthritis

Antibody-dependent Cellular Cytotoxicity (ADCC)

A mechanism of cell-mediated immunity whereby an effector cell of the immune system actively lyses a target cell that has been bound by specific antibodies. The typical ADCC involves activation of natural killer (NK) cells and is dependent on the recognition of

antibody-coated cells by Fc receptors on the surface of the NK cell. The Fc receptors recognize the Fc (constant) portion of antibodies such as IgG, which bind to the surface of a target cells. Following binding NK cells release cytokines such as IFN- γ and cytotoxic granules containing perforin and granzymes that enter the target cell and promote cell death by triggering apoptosis.

Anticoagulants

THEODORE E. WARKENTIN

Hamilton Regional Laboratory Medicine Program, Hamilton Health Sciences, and Department of Pathology and Molecular Medicine, Michael G. DeGroote School of Medicine, McMaster University, Hamilton, Ontario, Canada

Synonyms

Oral anticoagulants, usually coumarin derivatives (e.g., warfarin, phenprocoumon); heparin, either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH); danaparoid (heparinoid); fondaparinux (indirect factor Xa-inhibiting pentasaccharide); drotrecogin α (recombinant human activated protein C [APC]); direct thrombin inhibitors (DTIs), including hirudin derivatives (e.g., lepirudin, desirudin) or analogues (e.g., bivalirudin) and small molecule active site inhibitors (e.g., argatroban, ximelagatran)

Definition

Anticoagulants inhibit ▶ **coagulation** by preventing ▶ **thrombin** generation and, ultimately, fibrin formation [1]. They represent one of the two major classes of antithrombotic drugs, the other being antiplatelet agents. Anticoagulants are widely used to treat and prevent thrombosis involving arteries, veins, and intracardiac chambers.

In general, arterial thrombi are platelet-rich (“white clots”) and form at ruptured atherosclerotic plaques, leading to intraluminal occlusion of arteries that can result in end-organ injury (e.g., myocardial infarction, stroke). In contrast, venous thrombi consist mainly of fibrin and red blood cells (“red clots”), and usually form in low-flow veins of the limbs, producing deep vein thrombosis (DVT); the major threat to life results when lower extremity (and, occasionally, upper extremity) venous thrombi embolize via the right heart chambers into the pulmonary arteries, i.e., pulmonary embolism (PE).

Mechanism of Action Overview of Coagulation

Figure 1 shows a simplified scheme of the coagulation cascade. Coagulation is usually triggered physiologically when ►tissue factor (TF), usually found in extravascular sites, binds to circulating factor VII(a) following vessel injury. TF/VII(a) complexes activate factor X, generating factor Xa. Factor Xa, together with a cofactor (factor Va), forms “prothrombinase” on phospholipid surfaces on activated platelets. Prothrombinase generates the key procoagulant enzyme, thrombin (factor IIa), from prothrombin (factor II). Various positive feedback loops help to convert a small procoagulant stimulus into a thrombin burst. For example, TF/VII(a) complexes also activate factor IX to IXa, which acts with a cofactor (VIIIa) to form the

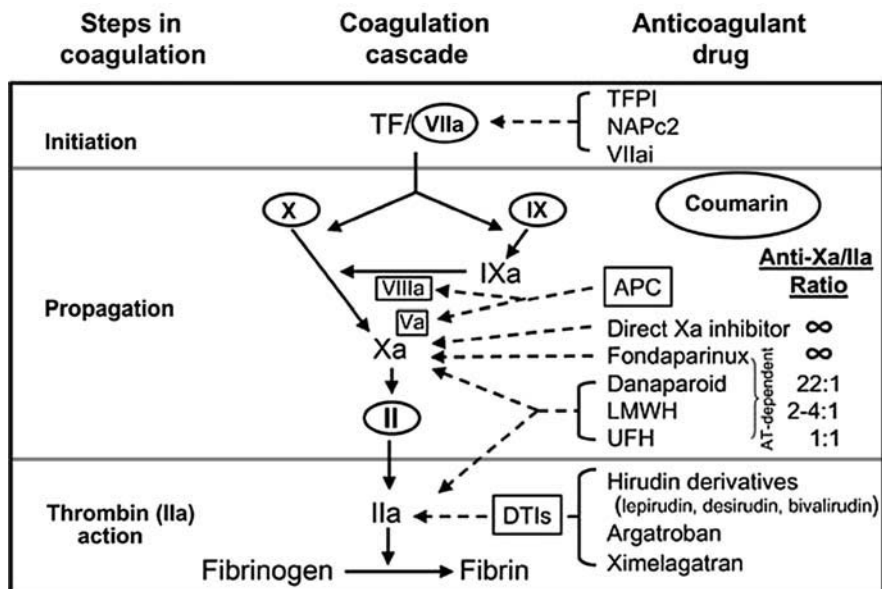

“tenase” complex that activates factor X to Xa. Other positive feedback loops initiated by thrombin include activation of factors V to Va, VIII to VIIIa and XI to XIa (not shown in Fig. 1).

Coagulation is regulated by three major inhibitory systems. (i) Antithrombin (AT, formerly, antithrombin III) inhibits circulating thrombin, Xa, IXa, XIa and TF/VII(a). However, AT does not inhibit thrombin bound to fibrin (“clot-bound thrombin”) or surface-bound Xa. (ii) The protein C natural anticoagulant pathway is triggered when thrombin binds to a receptor (thrombomodulin, TM) on endothelial cell surfaces: TM-bound thrombin activates protein C to APC, which together with a cofactor (protein S) degrades factors Va and VIIIa, thus downregulating thrombin generation in the TM-rich microcirculation. (iii) Tissue factor pathway inhibitor (TFPI) binds to and inhibits factor Xa; subsequently, TFPI/Xa complexes inhibit VII(a) within VII(a)/TF.

The most commonly used anticoagulants – coumarins and heparins – interfere with various steps, involving “propagation” of the coagulation cascade. Several newer agents inhibit thrombin directly. Drugs that inhibit initiation of coagulation are under investigation.

Oral Anticoagulants (Coumarins)

Most oral anticoagulants are coumarin derivatives that act via ►vitamin K antagonism ([2]; Fig. 2). Vitamin K

Anticoagulants. Figure 1 Effects of anticoagulants on the coagulation cascade. Coumarin agents alter the synthesis of four procoagulant zymogens (VII, X, IX, II), shown within circles. The other anticoagulants affect various coagulation factors (dotted arrows). Abbreviations: APC, activated protein C; AT, antithrombin; DTIs, direct thrombin inhibitors; LMWH, low-molecular-weight heparin; NAPc2, nematode anticoagulant protein; TF, tissue factor, TFPI, tissue factor pathway inhibitor; UFH, unfractionated heparin; VIIai, active site-blocked VIIa. (Modified from [1], with permission from Chest.)

Anticoagulants. Figure 2 Coumarin (Warfarin) and the vitamin K cycle. Abbreviations: glu, glutamate; gla, γ -carboxyglutamate. (Modified from [2], with permission from Chest.)

is required for posttranslational modification of certain glutamate (glu) residues in four procoagulant factors (II, VII, IX, X). Addition of a carboxyl group (COO⁻) to each glu residue (to form γ -carboxyglutamate, or gla, residues) causes these vitamin K-dependent factors to become functional **zymogens** (proenzymes), as they now can bind to phospholipid surfaces via Ca²⁺-recognizing gla regions. Protein C and protein S are vitamin K-dependent anticoagulant factors.

The two most widely used coumarins are warfarin (US, Canada, and UK) and phenprocoumon (continental Europe). The long half-life (60 h) of prothrombin means that coumarin cannot achieve therapeutic anticoagulation for at least 5 days following initiation. Thus, for patients with acute thrombosis, oral anticoagulants are usually started only when the patient is receiving a rapidly active agent, usually UFH or LMWH.

Disadvantages of oral anticoagulants include a narrow therapeutic index (bleeding risk), their highly variable dose-response relation (ongoing need for monitoring), embryopathy (if administered during the first trimester of pregnancy), and potential to induce microvascular thrombosis (coumarin necrosis syndromes).

Maintenance doses widely vary among patients (e.g., from 1 to 20 mg/day for warfarin), and are influenced by diet (variable vitamin K intake) and medications that affect coumarin metabolism (decreased drug clearance: e.g., cotrimoxazole, amiodarone, erythromycin; increased clearance: e.g., barbiturates, carbamazepine, rifampin). Thus, regular monitoring is needed

even during long-term maintenance therapy. This is performed using the **prothrombin time (PT)**, which is usually expressed as the **international normalized ratio (INR)**.

AT-dependent Anticoagulants: Heparins, Danaparoid, and Fondaparinux

Heparin is a highly sulfated **glycosaminoglycan** [3]. Usually obtained from pig intestine or beef lung, UFH contains polymer varying from 3,000 to 30,000 Da (mean, 15,000 Da; range, 10–90 monosaccharide units). Chemical or enzymatic methods can be used to make LMWH preparations that vary from 1,000 to 10,000 Da (mean, 4,500 Da; range, 3–30 monosaccharide units). A specific five saccharide sequence (“AT-binding pentasaccharide”) present within up to one third of UFH chains binds to AT, greatly increasing the efficiency of AT to inactivate thrombin, Xa, IXa, XIa, and TF/VII(a). AT is most efficient at inactivating thrombin and Xa, as shown by higher second-order rate constants (8,900 and 2,500 M⁻¹s⁻¹, respectively) compared with values of 300–450 for VII(a)/TF, IXa and XIa, respectively). Catalysis by UFH increases AT-mediated inhibition 1,000-fold.

Besides containing the specific AT-binding pentasaccharide sequence, heparin molecules must be at least 18 monosaccharide units long to bind to both AT and thrombin; in contrast, AT bound to any pentasaccharide-containing heparin – even with a chain length <18 monosaccharide units – will inhibit factor Xa. Thus, whereas UFH catalyzes inhibition of thrombin and Xa equally well, LMWH preferentially inhibits factor Xa (usual anti-Xa/anti-IIa ratio, 2–4:1) (Fig. 3). LMWH preparations (e.g., ardeparin [Normiflo], dalteparin [Fragmin], enoxaparin [Lovenox], reviparin [Clivarin], tinzaparin [Innohep]) differ in both jurisdictional availability and composition, and cannot be assumed to be interchangeable.

The **activated partial thromboplastin time (aPTT)** is usually used to monitor the anticoagulant effect of UFH, with the target aPTT level corresponding to an anti-factor Xa level of 0.35–0.70 U/mL (i.e., a ratio of patient/control aPTT of 1.5–2.5 for many aPTT reagents). However, prolongation of the aPTT is not sufficiently great to permit monitoring of LMWH therapy by this test. Nevertheless, since the shorter LMWH polymers have less nonspecific binding to plasma proteins, LMWH anticoagulation is quite predictable. Thus, weight-adjusted LMWH dosing without monitoring is standard practice. Particularly during inflammation (high levels of UFH-binding proteins), high doses of UFH may be needed to prolong the aPTT and anti-factor Xa levels into the therapeutic range (heparin “resistance”). Anticoagulant monitoring of LMWH using anti-factor Xa levels may be needed in renal failure as LMWH accumulates.

Anticoagulants. Figure 3 Relative effects of UFH, LMWH, and fondaparinux on AT-mediated inhibition of factor Xa and thrombin (IIa). Whereas UFH catalyzes inhibition of Xa and thrombin equally well, only LMWH chains of 18 saccharide units or longer catalyze thrombin inhibition; thus, the anti-Xa/anti-IIa ratio of LMWH preparations ranges from 2:1 to 4:1. In contrast, fondaparinux exclusively inhibits Xa. (Modified from [3], with permission from Chest.)

Danaparoid (Orgaran; mean MW, 6,000 Da) is a mixture of nonheparin glycosaminoglycans derived from pig gut (dermatan sulfate, heparan sulfate, chondroitin sulfate). The anti-Xa/anti-IIa ratio (22:1) is even greater than seen with LMWH. The anti-IIa effect may be mediated in part by dermatan sulfate, which catalyzes thrombin inhibition by heparin cofactor II.

Fondaparinux, the factor Xa-binding pentasaccharide (Arixtra, MW 1,728 Da), is prepared synthetically, unlike UFH, LMWH and danaparoid, which are obtained from animal sources. Despite only inactivating free factor Xa, clinical trials indicate that fondaparinux is an effective antithrombotic agent, both for venous thromboembolism prophylaxis and treatment, as well as for acute coronary syndrome and ST elevation myocardial infarction [4].

In addition to the AT-dependent agents discussed above, various direct Xa inhibitors (e.g., tick anticoagulant peptide, antistatin, DX-9065a) are undergoing clinical testing. Unlike fondaparinux, these drugs also inhibit surface-bound Xa within prothrombinase.

Activated Protein C

Protein C is a vitamin K-dependent natural anticoagulant activated by thrombin to form APC in the presence of the endothelial receptor, TM. APC proteolyzes factors Va and VIIIa, thus downregulating thrombin generation. APC may also have anti-inflammatory

properties, as recombinant human APC (drotrecogin α , Xigris) reduces mortality in \blacktriangleright septicemia. Nonactivated protein C concentrates, prepared from pooled plasma, are also available for use in patients with congenital or acquired protein C deficiency.

Direct Thrombin Inhibitors

There are two major classes of DTIs: hirudin derivatives and small molecule active site inhibitors. Hirudin is a 65-amino acid polypeptide produced by the medicinal leech, which binds irreversibly and with high affinity to both the active site and exosite I (fibrinogen binding site) regions of thrombin, resulting in stable non-covalent hirudin–thrombin complexes (dissociation constant, $\sim 10^{-14}$ M). Hirudin binds to both circulating and clot-bound thrombin. Lepirudin (Refludan, MW $\sim 7,000$ Da) and desirudin (Revasc) closely resemble hirudin. In contrast, bivalirudin (Angiomax, MW $\sim 2,180$ Da) is a 20-amino acid oligopeptide consisting of the active site and exosite I regions of hirudin connected by a short “spacer.” All three agents are obtained by recombinant technology.

Two small molecule DTIs are argatroban (Novastan, MW 527 Da) and the oral thrombin inhibitor, ximelagatran (Exanta, MW 474 Da). Ximelagatran is an inactive pro-drug: after absorption, it is metabolized to the active DTI, melagatran [MW 430 Da]. Concerns regarding hepatotoxicity have prevented (xi)melagatran

from successful regulatory and marketplace adoption. In general, levels of DTIs are monitored indirectly using the ▶aPTT (usual target therapeutic range, about 1.5–2.5-times baseline aPTT). The DTIs prolong the INR in the order: argatroban > bivalirudin > lepirudin.

Factor VII(a)/Tissue Factor Pathway Inhibitors

Recombinant TFPI (tifacogin) directly inhibits VII(a)/TF complexes. Unlike recombinant APC, TFPI did not reduce mortality in clinical trials of septicemia. Recombinant nematode anticoagulant protein (NAPc2) is a small hookworm protein that binds to a noncatalytic site on both X and Xa, thus inhibiting VII(a)/TF. The half-life of NAPc2 is long (48 h), resembling that of factor X. Active site-blocked VIIa (factor VIIai) achieves an anticoagulant effect by competing with VII(a) for binding to TF.

Clinical Use (Including Side Effects)

Both UFH and LMWH are used when rapid anticoagulation is needed, such as acute venous thromboembolism (DVT and/or PE), acute coronary insufficiency (acute myocardial infarction or unstable angina), or for ▶percutaneous coronary intervention (PCI). UFH is also used for intraoperative anticoagulation during cardiac surgery employing cardiopulmonary bypass (CPB) as well as during vascular surgery. ▶Protamine sulfate is used to reverse UFH anticoagulation after heart surgery.

Treatment of DVT or PE consists of therapeutic-dose heparin, given as intravenous UFH or subcutaneous LMWH or fondaparinux with overlapping oral anticoagulation. Until the early 1990s, UFH was usually given alone for 5 days, followed by at least 5 days of UFH/coumarin overlap, then several months of coumarin anticoagulation. Now, coumarin is often started within 24 h of initiating UFH or LMWH. Duration of coumarin typically ranges from as low as 6 to 8 weeks (small calf-vein DVT in a transient prothrombotic situation, such as postsurgery) to indefinite (multiple prior DVTs complicating a chronic hypercoagulability state). Often, treatment of DVT or PE employing LMWH followed by oral anticoagulants occurs exclusively in an outpatient setting.

Prevention of DVT and PE (antithrombotic prophylaxis) is another common indication for UFH, LMWH or coumarin, especially following surgery or immobilizing trauma. Fondaparinux is approved for prevention of DVT and PE after hip and knee surgery, and following abdominal surgery.

Coumarin is also widely used for long-term anticoagulation in chronic atrial fibrillation (particularly to avoid cardioembolic strokes), to prevent DVT or PE in patients with chronic hypercoagulability (e.g., congenital AT or protein C deficiency), or to prevent

atherothrombosis in patients with atherosclerosis. Coumarin is often unsuccessful in patients with hypercoagulability states, such as immune heparin-induced thrombocytopenia or cancer-associated disseminated intravascular coagulation. In contrast, LMWH therapy is often appropriate for patients with cancer-associated hypercoagulability or to prevent or treat thrombosis during pregnancy.

Danaparoid, lepirudin, and argatroban are important options for rapid anticoagulation when UFH or LMWH are contraindicated (e.g., heparin-induced thrombocytopenia). Desirudin is approved in some jurisdictions for antithrombotic prophylaxis after hip replacement surgery. Bivalirudin is an alternative to heparin for anticoagulation during ▶PCI; both bivalirudin and argatroban are approved for anticoagulation during PCI in patients in whom heparin is contraindicated because of acute or previous heparin-induced thrombocytopenia.

Side Effects

Bleeding is the most common adverse effect of anticoagulants [1–3] and is often associated with overdosing. When bleeding occurs during anticoagulation within the target therapeutic range, factors such as recent surgery or gastrointestinal lesions often coexist. For bleeding caused by coumarin overdosing, vitamin K will reverse anticoagulation beginning at least 4 h after administration. More urgent reversal can be achieved by coagulation factor replacement, using plasma or prothrombin complex concentrates. Rapid reversal of UFH is achieved by ▶protamine sulfate (1 mg protamine for 100 U heparin). However, only about 60% of the anticoagulant effect of LMWH is neutralized by protamine. Specific antidotes are not available for danaparoid, fondaparinux, DTIs, or inhibitors of the VII(a)/TF pathway. Thus, careful patient selection and anticoagulant monitoring are usually needed to reduce bleeding risk with these newer agents.

Unusual adverse effects sometimes occur with coumarin [2] or heparin [5]. For example, coumarin-induced skin necrosis is a rare complication of oral anticoagulants characterized by (sub)dermal microvascular thrombosis that usually begins 3–6 days after commencing coumarin. Typically, central tissue sites such as the breast, abdomen, and thigh are affected. Congenital abnormalities of the protein C natural anticoagulant pathway are implicated in some patients. A related syndrome of microvascular thrombosis can lead to limb gangrene in some patients treated with oral anticoagulants during heparin-induced ▶thrombocytopenia and hypercoagulability. This syndrome of coumarin-induced venous limb gangrene has been linked to severe protein C depletion during use of warfarin to treat DVT, complicated by metastatic cancer or heparin-induced thrombocytopenia.

As many as 3–5% of postoperative patients who receive UFH for 2 weeks develop heparin-induced thrombocytopenia, also known as HIT. This hypercoagulable state is caused by IgG antibodies that recognize complexes between heparin and platelet factor 4 (a platelet α -granule protein). Paradoxically, patients with HIT remain at high risk for thrombosis, even when heparin is discontinued or heparin is replaced with coumarin. To avoid coumarin-induced venous gangrene, alternative anticoagulants such as danaparoid, lepirudin, or argatroban should be given, and coumarin delayed until thrombocytopenia has resolved. Vitamin K should be given to reverse coumarin if HIT is diagnosed after warfarin or another vitamin K antagonist has been given. Long-term UFH treatment can cause ►osteoporosis, likely because heparin both decreases bone formation by osteoblasts and increases bone resorption by osteoclasts. Both HIT and osteoporosis are less likely to occur with LMWH.

Coumarins are generally contraindicated for use during pregnancy, particularly the first trimester. This is because γ -carboxyglutamate (gla), containing proteins are found in bone. Thus, pharmacologic vitamin K antagonism can cause embryopathy (chondrodysplasia punctata). LMWH is an attractive option for many pregnant women who require anticoagulation.

Antidepressant Drugs

ION ANGHELESCU, ISABELLA HEUSER

Department of Psychiatry and Psychotherapy, Charité, CBF, Berlin, Germany

Synonyms

Antidepressants; Mood elevators; Psycho energizers

Definition

Antidepressants are small heterocyclic molecules entering the circulation after oral administration and passing the blood–brain barrier to bind at numerous specific sites in the brain. They are used for treatment of depression, panic disorders, generalized anxiety disorder, social phobia, obsessive compulsive disorder, and other psychiatric disorders and nonpsychiatric states.

Mechanism of Action

Most available antidepressants enhance neurotransmission of ►biogenic amines, mainly ►norepinephrine and ►serotonin, to a lesser extent dopamine. Once released from specialized vesicles at the presynaptic nerve terminal ►neurotransmitters enter the synaptic cleft and bind to respective receptors at the postsynaptic cell membrane, thus modulating the associated signaling cascades (Fig. 1). Additionally, some of them bind to presynaptically localized receptors that regulate the amount of transmitter released. The cell membrane of presynaptic nerve terminals also contains ►reuptake transporters that clear the synaptic cleft from biogenic amines. Once reshuffled into the presynaptic compartment the neurotransmitter is degraded by ►monoamine oxidase (MAO). These two molecular processes, reuptake through specific transporters and enzymatic degradation by MAO, are targeted by most of the antidepressant drugs. For example, the ►selective serotonin reuptake inhibitors (SSRI; citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline) and the so called “dual acting drugs” (the selective serotonin/noradrenaline reuptake inhibitors venlafaxine and duloxetine and the noradrenergic/selective serotonergic drug mirtazapine), which became the mainstay for the treatment of the majority of depressed patients either prevent clearance of serotonin and/or noradrenaline from the synaptic cleft by blocking the presynaptic transporter and thus amplify receptor-mediated events postsynaptically or antagonize specific pre- and postsynaptic receptors. Analogous effects are those by norepinephrine reuptake inhibitors, while MAO-inhibitors act by reducing norepinephrine or serotonin degradation and thus increase the releasable amount of

Antidepressant Drugs. Figure 1 Effects of stress as a model for depression and the reversal by the use of antidepressants. Multiple intracellular targets might be involved in the regulation of plasticity and resilience by antidepressants, which block extracellular transporters. Adapted from [1].

neurotransmitter from the respective vesicles. These drugs do not exert prompt antidepressant effects as it takes weeks or months until clinical amelioration occurs. The exact mode of action by which antidepressants work is still not resolved but there is consensus that their primary action, i.e., binding to cell membrane transporters, triggers a manifold of events, which we are only beginning to decipher (Fig 1; [1]). Ingredients of St. John's wort have serotonin-/noradrenaline-/GABA- and glutamate reuptake inhibiting properties. The older tricyclic antidepressants like amitriptyline are also noradrenaline and/or serotonin reuptake inhibitors but also show antagonistic effects on different cerebral receptors like α 1-adrenergic, cholinergic, histaminergic receptors.

One such hypotheses submits that most antidepressants enhance the expression of cyclic-AMP response element binding protein (CREB), which is a transcription factor that after phosphorylation binds to cyclic-AMP response elements localized in the promoter region of many genes including that coding for brain

derived neurotrophic factor (BDNF) [2]. The latter neurotrophin was found to be decreased in the hippocampus of chronically stressed rats, serving as an animal model of depression. When treated with antidepressants, BDNF expression increases, possibly through enhanced phospho-CREB driven transactivation of the *BDNF* gene. This hypothesis is in keeping with the frequently observed reduction of depressed patients hippocampus volume (estimated by magnetic resonance imaging), a limbic brain structure pertinent for cognitive function, and expressing BDNF at high levels. Some preliminary studies support that antidepressants increase adult neurogenesis in this brain area, a phenomenon also associated with increased levels of phospho-CREB. The hypothesis that phospho-CREB is involved in adult neurogenesis is also strengthened by experiments with transgenic mice overexpressing a dominant negative isoform of CREB where the Ser¹³³ is mutated preventing phosphorylation-induced transactivation of CREB. Overexpression of mutant CREB prevented decreased neurogenesis in adult

hippocampus. While many pieces of this hypothesis are in line with an antidepressant-induced enhancement of neurogenesis, evidence is lacking that this effect is the same through which antidepressants regulate emotional states. Morphological studies on brains of depressives failed to detect evidence for neuronal deterioration in the hippocampus. Moreover the increase of *BDNF* gene transcription as induced by antidepressants is possibly an unspecific response to a xenobiotic molecule. Whether increased transcription of *BDNF* conveys antidepressant effects is yet not proven, as mouse mutants where *BDNF* production is lowered by heterozygous gene deletion failed to show behavioral abnormalities. Also, data on drug-induced changes in *BDNF* peptide concentrations are not giving a clear picture.

Another hypothesis derives from the clinical observation that impaired stress hormone regulation is a cardinal symptom among patients with an acute major depressive episode. If stress hormones (primarily cortisol secreted by adrenocortical glands and corticotropin released from the pituitary) are monitored longitudinally in these patients, those who respond to drug treatment show a trend towards neuroendocrine normalization while those where stress hormone regulation continues to be altered have a much worse outcome, i.e., they fail to respond or they relapse. Studies using transgenic mice with glucocorticoid receptor impairment show some behavioral and functional features reminiscent of depression. Some of these abnormalities disappear under antidepressants, which is in line with a drug-induced improvement of corticosteroid receptor function. When ligand-activated, these gluco- and mineralocorticosteroid receptors form homo- and heterodimers that interact with ▶**corticotropin releasing hormone** (CRH) in many ways (Fig. 2). This is of relevance in this context because clinical and basic studies have shown that overexpression of CRH in many brain areas is causally related to development and course of depression. The effect of antidepressants has therefore consequences upon CRH secretion and it is believed that these antidepressants may work through this corticosteroid receptor driven signaling pathway, suppressing the depressogenic and anxiogenic effects of CRH acting through CRH type 1 receptors (CRHR1). Thus, the antidepressant-induced behavioral and neuroendocrine changes in patients together with their observed molecular actions upon stress hormone signaling pathways have triggered the search for new pharmacological approaches to understand how antidepressants might work and ultimately to discover better drugs.

In the absence of a robust pathogenetic model for depression, hypotheses-driven research has limitations that hopefully can be overcome by unbiased approaches. The availability of cDNA microarrays allowing

one to study a huge amount of genes, which are simultaneously regulated in the brains of mice under long-term treatment with antidepressants will shift the emphasis from the “usual suspects” (such as serotonin and its receptors) to yet unheard candidate genes [3].

Clinical Use and Side Effects

Antidepressants were serendipitously discovered in the 1950s and the first generation of these drugs was constituted by tricyclic molecules. The refinement among the second and third generation of these drugs resulted in molecules that have less side effects, are better tolerated and consequently enjoy much better acceptance. In fact, the percentage of Americans treated for depression tripled nationwide. Simultaneously patient visits to doctors for depression fell by a third through the last 5 years. Such figures do not yet apply for Europe, where alternative treatments, especially herbals (St. Johns Wort is the best selling antidepressant in Germany), continue to play a major role. Given the personal and socioeconomic burden of depression the under-treatment of this disabling clinical condition seems neither ethical nor prudent.

While antidepressants have proven to be effective drugs, several drawbacks and caveats need to be resolved. This can be most likely achieved by enforced ▶**pharmacogenetic approaches** (▶**pharmacogenetics**) in combination with refined clinical research: Matching patients to the antidepressant that is most likely to be effective and less likely to harm through adverse reactions is the main goal of all modern therapies. Patient characteristics including sex, age, anxiety level, premedication, and family history (genetic load) do not predict better or worse response to a particular antidepressant drug or drug class. However, the fact that all drugs are equally effective between comparison groups does not mean that they are equally effective for individual patients. It is now hoped that combination of clinical data, including functional assessments, e.g., neuroendocrine, neuroimaging, neuropsychology together with information from genotyping, i.e., identification of a collection of single nucleotide polymorphisms (SNPs) will ultimately lead to choosing a first-line antidepressant based upon individual data. The most frequently examined candidate gene codes for the serotonin transporter. A 44-bp insertion or deletion results in a long and a short variant of this gene; the s-variant is associated with a twofold decreased expression and transport activity in vitro. Individuals in an epidemiological sample with one or two copies of the short allele of the serotonin transporter promoter polymorphism showed more depressive symptoms, diagnosable depression, and tendency to commit suicide in relation to stressful life events than individual homozygous for the long allele.

Antidepressant Drugs. Figure 2 The corticotropin-releasing factor system in depression. Corticotropin releasing factor (CRF) from the paraventricular nucleus (PVN) of the hypothalamus is released into the hypophyseal portal system and triggers the release of corticotrophin (ACTH) from the anterior pituitary via stimulation of CRF1 receptors. ACTH, in turn, stimulates the secretion of glucocorticoid hormones (cortisol in humans or corticosterone in rodents) from the adrenal cortex. Increased glucocorticoid levels suppress hypothalamic CRF expression via negative feedback through hippocampal and hypothalamic glucocorticoid receptors. The neurotransmitter action of CRF on CRF1 receptors throughout the limbic system mediates anxiogenic effects of stress. By contrast, its neurotransmitter action on CRF2 receptors in more discrete regions of the brain might reduce anxiety-like behavior in a delayed fashion (adapted from [2]).

Unfortunately, twin studies were not concordant in lending support to this result [4].

In practice, a genotype-guided medication selection is yet not in reach, but several minor innovations emerging from hypothesis-driven research are. The current antidepressive pipeline contains three promising candidates: ► **Substance P**, a peptide from the tachykinin family, which binds preferentially at the NK_1 -receptor, was suspected to play a role in causality of depression. Several clinical studies testing NK_1 -receptor antagonists showed promising results and a number of pharmaceutical companies are developing

drugs antagonizing NK - receptors. NK_2 -receptor antagonists might also be effective in the treatment of depression. Another neuropeptide is CRH that seems to be causally related to symptoms of depression through activation of CRHR1, which led to the development of CRHR1 antagonists as potential antidepressants. A first clinical study supported such a possibility. Finally, glutamate antagonists like ketamine might have some use in treatment-resistant depression.

Another new development of immediate clinical usefulness is the analysis of genetic variability in the cytochrome P450 enzyme system in patients, which

may elucidate clinically relevant changes in drug metabolism and adverse reactions. For example, if a patient receives an SSRI such as Prozac, which blocks the P4502D6 enzyme, and an antiarrhythmic, which is metabolized by the same enzyme, a fatal increase of the cardiotoxic drug may occur. Other possible candidates involved in pharmacokinetics are P-glycoproteins, which are important regulators of a drug's blood-brain barrier passage. It was recently shown that antidepressants are substrates of P-glycoprotein, which, if over-expressed, can extrude the antidepressant out of the brain cells into the circulation thus preventing central effects that may lead to therapy resistance.

Side effects of antidepressants usually occur during the first days of treatment and tend to diminish over time. The side-effect profile can be easily derived from the transporter-binding profile. Serotonergic drugs might cause headaches, appetite loss, nervousness, sweating and sexual dysfunction and noradrenergic drugs palpitations, sweating, anxiety, and drowsiness. Anticholinergic antidepressants show side effects like constipation, blurred vision, memory dysfunction, dry mouth, while antihistaminergic drugs exhibit side effects like sedation, hypotension, and weight gain. Antiadrenergic properties are associated with postural hypotension and reflex tachycardia.

Antidiabetic Drugs

Antidiabetic drugs is the general term for drugs that lower blood glucose concentrations and are used in the treatment of diabetes mellitus. Antidiabetic drugs are

typically categorized as either oral (sulphonylureas, prandial insulin releasers, metformin, thiazolidinediones, alpha-glucosidase inhibitors) which are used to treat most type 2 (non-insulin-dependent) diabetic patients, or insulin (given parenterally) which is used to treat all type 1 and some type 2 diabetic patients.

Antidiabetic Drugs other than Insulin

CLIFFORD J BAILEY

School of Life and Health Sciences, Aston University, Birmingham, UK

Synonyms

Oral hypoglycaemic agents; Oral blood glucose-lowering drugs; Insulin secretagogues; Antihyperglycaemics

Definition

Antidiabetic drugs are used to treat hyperglycaemia in type 1 (insulin-dependent) and type 2 (non-insulin-dependent) diabetes mellitus. They are used in conjunction with non-pharmacological interventions involving diet, exercise and health education. Insulin therapy is essential for all type 1 patients and is often used to treat more advanced stages of type 2 diabetes. Other antidiabetic drugs are mostly used to treat type 2 diabetes, which accounts for more than 85% of all cases of diabetes. The classes of antidiabetic drugs other than insulin are sulphonylureas, prandial insulin releasers (also termed meglitinides), the biguanide metformin, thiazolidinediones (TZDs), α -glucosidase inhibitors, incretin mimetics, gliptins (also termed dipeptidyl peptidase-4 inhibitors or incretin enhancers) and the amylin analogue pramlintide (Table 1) [1].

Mechanism of Action

Type 2 diabetes is a heterogeneous and progressive endocrine disorder associated with insulin resistance (impaired insulin action) and defective function of the insulin-secreting β -cells in the pancreatic islets of Langerhans. These endocrine disorders give rise to widespread metabolic disturbances epitomised by hyperglycaemia. The present classes of antidiabetic agents other than insulin act to either increase insulin secretion, improve insulin action, slow the rate of intestinal

Antidiabetic Drugs other than Insulin. Table 1 Classes of antidiabetic drugs other than insulin and their main mechanisms of action

Class	Examples ^a	Main mechanism of action	Route
Sulphonylureas	Chlorpropamide, glibenclamide ^b , gliclazide, glimepiride, glipizide, gliquidone, tolazamide, tolbutamide	Stimulate insulin secretion (typically 6–24 h)	Oral
Prandial insulin releasers (meglitinides)	Repaglinide, nateglinide	Stimulate insulin secretion (rapid and short-acting < 6 h)	Oral
Biguanide	Metformin	Improve insulin action	Oral
Thiazolidinediones	Pioglitazone, rosiglitazone	Improve insulin action (PPAR γ agonists)	Oral
α -Glucosidase inhibitors	Acarbose, miglitol, voglibose	Slow rate of carbohydrate digestion	Oral
Incretin mimetic	Exenatide	Mimic GLP-1 ^c : enhance prandial insulin secretion	SC injection ^d
Gliptins (DPP-4 inhibitors)	Sitagliptin	Inhibit DPP-4 ^e : enhance prandial insulin secretion	Oral
Amylin analogue	Pramlintide	Suppress glucagon secretion and slow gastric emptying	SC injection ^c

^aAvailability of agents and prescribing instructions vary between countries.

^bGlibenclamide is called glyburide in some countries.

^cGlucagon-like peptide-1.

^dSubcutaneous injection.

^eDipeptidyl peptidase-4.

carbohydrate digestion, enhance the incretin effect, suppress glucagon secretion or slow gastric emptying.

Sulphonylureas

The first sulphonylureas were introduced in the 1950s. They stimulate insulin secretion by a direct effect on pancreatic β -cells. Sulphonylureas enter the β -cell and bind to a site at the cytosolic face of the sulphonylurea receptor (SUR). The SUR-1 isoform is expressed by the β -cell. It forms part of a transmembranal complex that includes ATP-sensitive Kir6.2 potassium efflux channels (K-ATP channels). The binding of a sulphonylurea to SUR-1 produces a conformational change that closes K-ATP channels, favouring local depolarisation of the plasma membrane. This opens voltage-dependent L-type calcium channels, increasing calcium influx and raising the cytosolic free calcium concentration. In turn, this activates calcium-dependent signalling proteins controlling the contractile activities of microtubules and microfilaments that mediate exocytosis of insulin granules. Preformed insulin granules adjacent to the plasma membrane are released first (first-phase insulin release). Newly formed granules contribute to the secretory pool within 1 h of continued stimulation. Increased insulin release is sustained as long as drug stimulation is maintained, provided the β -cells are functionally competent (Fig. 1).

The SUR–Kir6.2 complex is a non-covalently bonded octamer (4 \times SUR/4 \times Kir6.2), with the pore-forming Kir6.2 channels located at the centre (Fig. 2).

SUR molecules are members of the ATP binding cassette proteins (ABC proteins). Each SUR-1 molecule comprises 17 transmembrane domains, 2 cytosolic nucleotide binding domains and cytosolic binding domains for sulphonylurea, benzamido and other ligands. The Kir6.2 channel also has cytosolic binding regions, including one for ADP/ATP. Sulphonylureas bind to the sulphonylurea site with high affinity (e.g. K_i for glibenclamide in low nanomolar range), being dependent on a ‘U’ shape to the ligand with 5.5 Å between the hydrophobic rings.

By closing K-ATP channels, sulphonylureas induce insulin release by activating a step along the normal pathway of glucose-induced insulin secretion. Activation of insulin secretion is therefore independent of glucose, provided there is sufficient glucose metabolism to stimulate proinsulin biosynthesis and service the energy requirements for the cellular processing and exocytosis of insulin. Hence sulphonylureas can stimulate insulin secretion at low glucose concentrations, creating the risk of hypoglycaemia. Sulphonylureas will also increase the amount of insulin secreted at any level of stimulation by glucose, subject to adequate β -cell function. Additionally, sulphonylureas may potentiate insulin release that is stimulated by glucose and other nutrients. This may involve SUR molecules located within the membranes of insulin granules and activation of certain isoforms of protein kinase C.

Although the main therapeutic effect of sulphonylureas is increased insulin secretion, there is evidence that

Antidiabetic Drugs other than Insulin. Figure 1 Sulphonylureas stimulate insulin release by pancreatic β-cells. They bind to the sulphonylurea receptor (SUR-1), which closes Kir6.2 (ATP-sensitive) potassium channels. This promotes depolarisation, voltage-dependent calcium influx, and activation of calcium-sensitive proteins that control exocytotic release of insulin.

Antidiabetic Drugs other than Insulin. Figure 2 Octameric structure (4 × SUR/4 × Kir6.2) of the SUR–Kir6.2 complex.

these drugs exert weak extra-pancreatic effects. The latter effects include suppression of hepatic gluconeogenesis, possibly by suppression of a kinase which leads to increased formation of fructose-2, 6-bisphosphate. This stimulates phosphofruktokinase and suppresses fructose-1, 6-bisphosphatase, thereby increasing glycolytic flux and suppressing gluconeogenic flux. Sulphonylureas might also enhance insulin-stimulated glucose transport by increasing translocation of GLUT-4 glucose transporters to the plasma membrane in adipocytes and muscle. However, these effects appear to require

supra-therapeutic concentrations of sulphonylureas and are probably not therapeutically relevant. Sulphonylureas have been reported to reduce the hepatic extraction of insulin and to act on pancreatic α-cells to transiently stimulate and then suppress glucagon secretion.

The increase in insulin concentrations produced by sulphonylureas lowers blood glucose concentrations through decreased hepatic glucose output and increased glucose utilisation, mostly by muscle (► [insulin](#), ► [insulin receptor](#)).

Prandial Insulin Releasers (Meglitinides)

This class comprises the meglitinide analogue repaglinide (introduced in 1998) and the structurally related D-phenylalanine analogue nateglinide (introduced in 2001). These agents have a benzamido group that binds to a site on SUR-1 that is distinct from the sulphonylurea site, but probably in close proximity and capable of binding interference. Some sulphonylureas also have a benzamido moiety (e.g. glibenclamide, glimepiride, glipizide) but the binding affinity for the sulphonylurea site has a higher affinity. Binding of repaglinide or nateglinide to the benzamido site closes the K-ATP channels and induces insulin secretion via the same pathway described for sulphonylureas.

Repaglinide and nateglinide are rapidly absorbed; their binding durations to SUR-1 are much shorter than sulphonylurea binding, and their hepatic metabolism

and subsequent elimination are faster. Consequently, repaglinide and nateglinide are faster-acting and shorter-acting insulin releasers than sulphonylureas. They can be taken immediately before a meal, and quickly stimulate insulin secretion to coincide approximately with the period of meal digestion, hence the categorisation of ‘prandial insulin releasers’.

Biguanide

Metformin is the main compound in this class, introduced in the late 1950s. Other biguanides, namely phenformin and buformin have been widely discontinued. The antihyperglycaemic effect of metformin results partly from a direct improvement of insulin action and partly from actions that are not directly insulin dependent. A presence of insulin is required for the therapeutic efficacy of metformin, but the drug does not stimulate insulin release and is often associated with a small decrease in basal insulin concentrations in hyperinsulinaemic patients. Metformin has a variety of metabolic effects: The main antihyperglycaemic actions involve a reduction of excess hepatic glucose production, increased insulin-mediated glucose utilisation predominantly by muscle, decreased fatty acid oxidation and increased splanchnic glucose turnover.

Metformin restrains hepatic glucose production principally by suppression of gluconeogenesis. The mechanisms involve potentiation of insulin action and decreased hepatic extraction of certain gluconeogenic substrates such as lactate. In addition, metformin reduces the rate of hepatic glycogenolysis and decreases the activity of hepatic glucose-6-phosphatase. Insulin-stimulated glucose uptake and glycogenesis by skeletal muscle is increased by metformin mainly by increased

movement of insulin-sensitive glucose transporters (GLUT-4) into the plasma membrane. Metformin also appears to increase the transport function of glucose transporters and increases the activity of glycogen synthase. Further actions of metformin include insulin-independent suppression of fatty acid oxidation in liver and muscle, and insulin-independent increase in anaerobic glucose metabolism by the intestine. Lactate produced in this way is recycled to glucose by the liver. Thus metformin acts to a modest extent via several different effects to lower blood glucose concentrations (Fig. 3).

Metformin enters some cell types (e.g. liver) at least in part via the organic cation transporter 1. The drug improves insulin sensitivity by increasing insulin-stimulated tyrosine kinase activity of the β -subunit of the insulin receptor, possibly by reducing phosphatase-mediated receptor dephosphorylation. Metformin also increases insulin signalling at more distal steps in the postreceptor cascades. Although metformin can increase insulin receptor binding when insulin receptor numbers are depleted, this does not appear to have a significant impact on insulin action. The mediating steps that enable metformin to interface with insulin-signalling pathways are not resolved. Metformin has been shown to alter membrane fluidity in hyperglycaemic states and to alter the activities of several metabolic enzymes (listed above), apparently independently of insulin. Emerging evidence suggests that metformin can activate adenosine monophosphate-activated protein kinase (AMPK) via an LKB1-dependent mechanism. Very high concentrations of metformin that occur in the intestine could increase anaerobic glucose metabolism by suppression of the respiratory chain at complex I.

Antidiabetic Drugs other than Insulin. Figure 3 The antihyperglycaemic effect of metformin involves enhanced insulin-mediated suppression of hepatic glucose production and muscle glucose uptake. Metformin also exerts non-insulin-dependent effects on these tissues, including reduced fatty acid oxidation and increased anaerobic glucose metabolism by the intestine. FA, fatty acid; \uparrow , increase; \downarrow , decrease.

Thiazolidinediones

Two TZDs introduced in 1999 are presently available, pioglitazone and rosiglitazone. Another TZD, troglitazone has been withdrawn. TZDs improve insulin sensitivity and their principal mechanism of action is stimulation of the nuclear receptor peroxisome proliferator-activated receptor- γ (PPAR γ). PPAR γ (▶PPARs) is a member of the nuclear receptor superfamily for retinoid, steroid and thyroid hormones. PPAR γ exists as a heterodimer with the retinoid X receptor (RXR). Binding of a TZD to PPAR γ together with binding of *cis*-retinoic acid to the RXR moiety produces a conformational change that prompts dissociation of co-repressors. The activated heterodimer then binds to the peroxisome proliferator response element (PPRE), which is a sequence (AGGTCAAGGTCA) located in the promoter region of the responsive genes. Recruitment of co-activators including PGC-1 and assembly of the RNA polymerase complex follows, initiating transcription (Fig. 4). Many of the responsive genes are also activated by insulin, hence the ability of TZDs to improve insulin sensitivity [2].

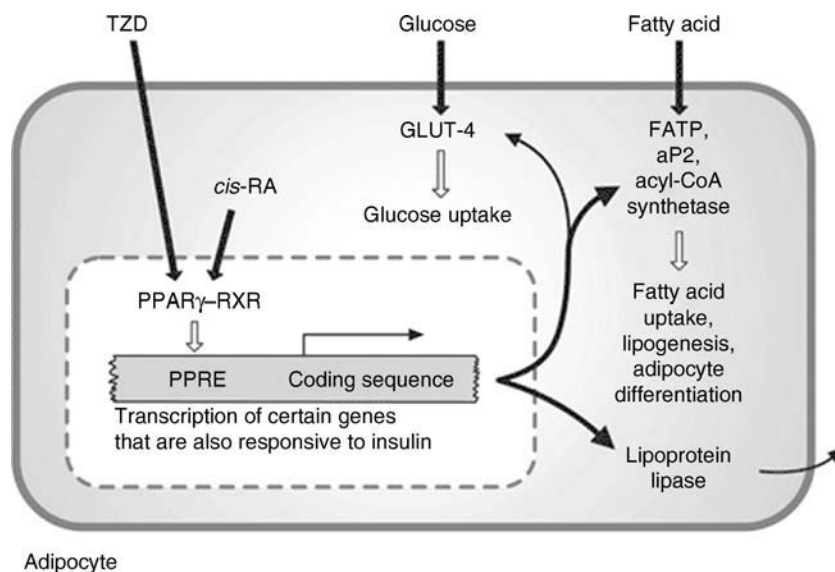

PPAR γ is strongly expressed in adipocytes, and stimulation by TZDs promotes adipogenesis, predominantly in preadipocytes from subcutaneous depots. Increased transcription of transporters and enzymes involved in fatty acid uptake and lipogenesis increases the deposition of lipid in these adipocytes (Table 2). This appears to facilitate a reduction in hyperglycaemia by reducing circulating concentrations of non-esterified

(free) fatty acids and triglycerides. The consequent effect on the glucose-fatty acid (Randle) cycle is to reduce the availability of fatty acids as an energy source, thereby favouring the utilisation of glucose. Additionally, TZDs increase transcription of GLUT-4 glucose transporters that directly facilitates glucose uptake. Reducing free fatty acid concentrations also reduces the production of lipid metabolites, which suppress early postreceptor steps in the insulin-signalling pathway. TZDs may further improve insulin signalling by increasing production of the adipocyte hormone adiponectin, decreasing production of the adipocyte cytokine tumour necrosis factor- α (TNF α), and decreasing production of the adipocyte hormone resistin (and possibly leptin), which have been implicated in the pathogenesis of insulin resistance.

There is weak expression of PPAR γ in muscle, liver and other tissues, enabling TZDs to support the effects of insulin in these tissues, notably increased glucose uptake in muscle and reduced glucose production in liver. TZDs may also affect nutrient metabolism by skeletal muscle through a direct mitochondrial action that is independent of PPAR γ .

α -Glucosidase Inhibitors

The first member of this class, acarbose, was introduced in the early 1990s. α -Glucosidase inhibitors slow the intestinal process of carbohydrate digestion by competitive inhibition of the activity of α -glucosidase enzymes located in the brush border of the enterocytes

Antidiabetic Drugs other than Insulin. Figure 4 Thiazolidinediones stimulate the PPAR γ moiety of the PPAR γ RXR nuclear receptor complex, which then binds to a response element, leading to transcription of certain genes that are also responsive to insulin. These facilitate increased uptake of fatty acids, lipogenesis and adipogenesis. PPAR γ , peroxisome proliferator-activated receptor- γ ; RXR, retinoid X receptor; PPRE, peroxisome proliferator response element; TZD, thiazolidinedione; *cis*-RA, *cis*-retinoic acid; GLUT-4, glucose transporter isoform-4; FATP, fatty acid transporter protein; aP2, adipocyte fatty acid binding protein.

(Fig. 5). Acarbose also causes a modest inhibition of pancreatic α -amylase activity. The principal α -glucosidase enzymes are glucoamylase, sucrase, maltase and dextrinase. The inhibitors bind to these enzymes with much higher affinity than their natural disaccharide and oligosaccharide substrates. Hence, when bound to the inhibitor, the enzyme fails to cleave the disaccharides and oligosaccharides into their absorbable monosaccharides. The available α -glucosidase inhibitors, acarbose, miglitol and voglibose, show different binding affinities for the enzymes, giving them different activity profiles. For example, the affinity profile of acarbose is glucoamylase > sucrase > maltase > dextrinase. Miglitol is a more potent inhibitor of sucrase, and voglibose of other α -glucosidases [3].

When α -glucosidase activity is inhibited, carbohydrate digestion is prolonged and takes place further along the intestinal tract. This in turn delays and spreads the period of glucose absorption, which reduces the extent of the postprandial rise in blood glucose concentrations. The effectiveness of α -glucosidase inhibitors is dependent on the consumption of a meal rich in complex carbohydrate.

Incretin Mimetics

The first incretin mimetic 'exenatide' was introduced in 2005. It is an analogue of the gut hormone glucagon-like peptide-1 (GLP-1). This therapy is based on the so-called 'incretin' effect, which is the enhanced insulin response to nutrients that occurs after a meal (compared with the insulin response to similar plasma nutrient levels created by intravenous administration). The incretin effect is due to hormonal and neural stimuli produced by the gut during meal digestion which increase glucose-induced insulin secretion, and thereby reduce prandial glucose excursions. The main incretin hormones are GIP (glucose-dependent insulinotropic polypeptide), produced by K-cells in the mucosa of the duodenum and jejunum, and GLP-1 from L-cells located mostly in the mucosa of the ileum. Both GIP and GLP-1 increase glucose-stimulated insulin secretion. Additionally, GLP-1 reduces glucagon secretion from pancreatic α -cells in a glucose-dependent manner, slows gastric emptying and exerts a satiety effect (Table 3). Animal and in vitro studies have suggested that GIP and GLP-1 might increase neogenesis and proliferation of β -cells and reduce β -cell apoptosis, but

Antidiabetic Drugs other than Insulin. Table 2 Tissue expression, ligands, genes activated, and biological actions of the peroxisome proliferator-activated receptor- γ (PPAR γ)

Tissue expression	Mainly white and brown adipose tissue; weak expression in liver, muscle, gut, macrophages, pancreatic β -cells and haemopoietic tissues
Natural ligands	Certain unsaturated fatty acids and prostaglandin metabolites
Synthetic ligands	Thiazolidinediones and some non-steroidal antiinflammatory drugs
Gene activated	Lipoprotein lipase; fatty acid transporter protein; adipocyte fatty acid binding protein; acyl-CoA synthetase; malic enzyme; GLUT-4 glucose transporter; phosphoenolpyruvate carboxykinase
Biological actions	Adipocyte differentiation; fatty acid uptake; lipogenesis; glucose uptake; other effects on nutrient metabolism which lower hepatic glucose production

Antidiabetic Drugs other than Insulin. Figure 5 α -Glucosidase inhibitors slow the rate of intestinal carbohydrate digestion by competitive inhibition of α -glucosidase enzymes in the brush border of enterocytes. The α -glucosidase inhibitors have a higher affinity for the α -glucosidase enzymes than the natural disaccharide and oligosaccharide substrates.

it is uncertain whether these hormones can preserve β -cell mass in human type 2 diabetes [4].

The incretin effect is reduced in type 2 diabetes, and this is attributed, at least in part, to reduced secretion of GLP-1. The biological actions of GLP-1 remain essentially intact in type 2 diabetes, but administration of extra GLP-1 is not a practical therapeutic option because the peptide is degraded rapidly ($t_{1/2} < 2$ min) by the enzyme dipeptidyl peptidase IV (DPP-4). DPP-4 cleaves the N-terminal dipeptide from many of the peptides that have either an alanine or a proline residue penultimate to the N-terminus (Fig. 6).

Exenatide (exendin-4) is a GLP-1 analogue with a 52% sequence homology in which the penultimate N-terminal alanine residue of GLP-1 is replaced by glycine. This confers resistance to degradation by DPP-4, giving exenatide protracted biological activity of about 5–7 h after subcutaneous injection. Since exenatide interacts with the same receptor as GLP-1 and retains the same profile of biological effects as GLP-1, exenatide enables the incretin effect to be enhanced. It is noteworthy that DPP-4 exists free in the circulation and tethered to the external surface of endothelia and other epithelial cells in most tissues: it is also the CD26

Antidiabetic Drugs other than Insulin. Table 3 Actions of the incretin hormones GIP (glucose-dependent insulinotropic polypeptide, gastric inhibitory peptide) and GLP-1 (glucagon-like peptide-1)

Antidiabetic Drugs other than Insulin. Figure 6 The incretin mimetic, exenatide is a long-acting analogue of the gut hormone GLP-1. Arrow indicates the site of action of dipeptidyl peptidase-IV (DPP-4). Exenatide is resistant to degradation by DPP-4, allowing protracted GLP-1 mimetic activity that enhances the 'incretin' effect.

T-cell activating antigen although the aminopeptidase and immunological functions do not appear to interfere with each other.

Exenatide was discovered in the saliva of a lizard from Arizona – the Gila monster (*Heloderma suspectum*). For therapeutic purposes exenatide is usually administered by twice daily subcutaneous injection before the main meals. Because the insulin-releasing and glucagon-suppressing effects of exenatide (like GLP-1) are glucose dependent, there is low risk of severe hypoglycaemia. The satiety effect is often associated with some weight loss, and the slowing of gastric emptying can cause nausea, at least during initial therapy. About one third of patients develop antibodies to exenatide, but biological activity of the molecule is rarely affected.

Gliptins

Gliptins (also termed dipeptidyl peptidase-IV inhibitors, DPP-4 inhibitors or incretin enhancers) are selective inhibitors of DPP-4 (described above). They enhance endogenous incretin activity by preventing the rapid degradation of GLP-1 and GIP (Fig. 6). The first gliptin ‘sitagliptin’ became available in the USA and UK in 2007. Since there are many other natural substrates for DPP-4 including neuropeptide Y (NPY), peptide YY (PYY), gastrin releasing polypeptide (GRP), substance P, insulin-like growth factor-1 (IGF-1), vasostatin-1 and several chemokines, gliptins have the potential to influence the hunger–satiety system, gastrointestinal motility, growth, vascular reactivity and immune mechanisms. However neither CD26 knockout mice nor the DPP-4-specific inhibitors used in animals or humans have yet shown any substantive untoward effects.

In clinical studies, selective DPP-4 inhibition increased active circulating concentrations of GLP-1 and GIP by two- to threefold. This was associated with increased glucose-induced insulin secretion and suppression of glucagon secretion, although changes in satiety and gastric emptying have not been reported.

Pramlintide

Pramlintide was introduced in the USA in 2005 as an adjunct to insulin therapy. It is a soluble analogue of the islet hormone amylin (islet amyloid polypeptide, IAPP) that is normally co-secreted from the pancreatic β -cells with insulin and C-peptide in response to nutrient stimuli. Paradoxically, amylin has been a suspect in the demise of β -cells in type 2 diabetes due to its accumulation and polymerisation to form insoluble fibrils in the islets. However normal amylin secretion appears to contribute to glucose homeostasis. Amylin acts centrally, probably via receptors in the area postrema (where there is no blood–brain barrier), dorsal raphe and nucleus accumbens. The central effects induce satiety and initiate a vagally-mediated suppression of prandial glucagon secretion and a slowing of gastric emptying (Fig. 7). In type 1 diabetes and advanced stages of type 2 diabetes there is a lack or substantial reduction of amylin. Thus replacement therapy with a non-aggregating analogue of amylin can be used to complement insulin therapy in type 1 and advanced type 2 diabetic patients.

The structure of pramlintide (Fig. 8) differs from human amylin by the substitution of three residues with proline residues, retaining biological potency but preventing self aggregation. Pramlintide is not used alone: it is administered by subcutaneous injection as an adjunct to insulin therapy. Since pramlintide requires a more acidic pH than insulin it has to be given as a separate injection to insulin, usually just before the main meals. The suppression of glucagon secretion and to a lesser extent the slowing of gastric emptying are the main immediate actions of pramlintide that reduce blood glucose. The satiety effect is typically associated with a long-term reduction of food intake and body weight: reduced adiposity in obese type 2 diabetes generally improves metabolic control. It is advised to reduce the mealtime insulin dose during initiation of pramlintide therapy to reduce the risk of interprandial hypoglycaemia. Antibodies to pramlintide have been

Antidiabetic Drugs other than Insulin. Figure 7 Mechanisms of action of the amylin analogue pramlintide.

identified in some patients although these do not appear to affect biological activity.

Clinical Use

Type 2 (non-insulin-dependent) diabetes typically emerges in middle or later life. Unlike type 1 diabetes in which there is total loss of pancreatic β -cells and a critical need for exogenous insulin administration, type 2 diabetes is associated with a continued presence of β -cells and continued insulin production. However insulin resistance usually develops as a prelude to type 2 diabetes and creates a demand for a compensatory increase in insulin secretion. Eventually, the β -cells are unable to produce sufficient extra insulin to overcome the insulin resistance. This results in impaired insulin-mediated glucose uptake by muscle, failure of insulin to suppress hepatic glucose production and consequently hyperglycaemia. Pancreatic β -cells of type 2 diabetic patients become increasingly sluggish in their responsiveness to raised glucose concentrations, and eventually β -cell function becomes severely impaired, leading to a state of hypoinsulinaemia and greater hyperglycaemia. The toxic effects of hyperglycaemia on the permeability of small blood vessels and

nerve function result in the long-term microvascular and neuropathic complications of diabetes (retinopathy, nephropathy and neuropathy). The additional effects of other metabolic disturbances associated with insulin resistance (the so-called 'metabolic syndrome') are largely responsible for the long-term cardiovascular complications of type 2 diabetes [5].

Achieving and maintaining blood glucose concentrations as close to normal as possible reduces the morbidity and premature mortality of the long-term complications of type 2 diabetes. All treatments begin with non-pharmacological measures (diet, exercise and healthy living), but compliance is limited, and lasting glycaemic control occurs in only a small minority of patients. Patients are usually started on one oral antidiabetic drug. Recent studies suggest that metformin offers additional advantages beyond glycaemic control to reduce long-term cardiovascular complications. Thus, this is often the first oral agent to be used. The mechanisms of action of metformin also prevent weight gain and avoid overswings into hypoglycaemia. Alternatively, a sulphonylurea or a prandial insulin releaser may be favoured as the first oral antidiabetic agent if substantial β -cell failure is suspected. The

Hb, haemoglobin; Vit B12, vitamin B12; LFT, liver function test.

^aThe dosage of each antidiabetic drug should be increased until either the target level of glycaemia is achieved or the last dosage increment produces no additional effect.

^bAppropriate monitoring of glycaemic control using fasting or random blood glucose, glycated haemoglobin (HbA1c) or fructosamine (glycated albumin) should be undertaken for all patients receiving antidiabetic drugs.

^cDepending upon pathways of metabolism and elimination of individual members of the class.

^dPrandial insulin releasers are less likely to produce severe or prolonged episodes of hypoglycaemia than sulphonylureas.

^eLiver function should be checked in patients on high dose acarbose.

prandial insulin releaser would be preferred for individuals with either mainly postprandial hyperglycaemia or irregular meal patterns which predispose to interprandial hypoglycaemia when taking a sulphonylurea. An α -glucosidase inhibitor can be used if the hyperglycaemia is modest and predominantly restricted to postprandial periods. The TZDs are slower to take effect than other agents, presumably due to their largely genomic mode of action. In Europe TZDs are used mainly as an alternative to metformin if metformin is not tolerated, or as add-on (combination) therapy with metformin. Nateglinide, or a gliptin (DPP-4 inhibitor) or a GLP-1 analogue (incretin mimetic) are presently recommended as second-line agents to be used in combination with another differently acting agent, when that agent alone does not achieve glycaemic control. The amylin analogue pramlintide is not available in Europe: it is used as add-on therapy to insulin to improve glycaemic control without increasing the insulin dose and without weight gain.

Type 2 diabetes is a progressive disease with continued insulin resistance and gradually declining β -cell function. Thus, hyperglycaemia increases with disease duration and glycaemic control becomes ever more difficult to maintain. If two or possibly three *differently acting* antidiabetic agents listed above do not achieve glycaemic control then it is apposite to switch to insulin therapy (► [insulin](#), [insulin receptor](#)).

The main limitations and precautions for the use of oral antidiabetic drugs are listed in [Table 4](#).

Antidiarrhoeal Agents

Antidiarrhoeal drugs are used for the symptomatic treatment of diarrhoea (the frequent passage of liquid

faeces). Commonly used antidiarrhoeal drugs are opioids including codeine, diphenoxylate and loperamide. They reduce the motility of the intestine. Other antidiarrhoeal agents (chalk, charcoal, methyl cellulose) probably act by adsorbing toxins or microorganisms causing diarrhoea. Bismuth subsalicylate is used for the treatment of traveller's diarrhoea. It mainly reduces fluid secretion in the bowel.

Definition

► [Epilepsy](#) is a chronic neurological disorder that affects about 0.6–0.8% of the general population worldwide. The clinical hallmark of epilepsy is

recurrent seizures (▶seizure), which disrupt normal brain function. A large number of different types of epilepsies and epileptic syndromes have been distinguished. Many specific syndromes start in infancy and are accompanied by further developmental, neuropsychological and metabolic alterations, mostly of unknown origin. Generally, epilepsies with a focal origin (focal epilepsies) are discriminated from epilepsies with a generalized beginning (primary generalized epilepsies).

At the cellular level, focal and general convulsions correspond to synchronized high-frequency ▶discharges (▶discharge of neurons) of large groups of neurons, which disrupt normal information processing. Depending on the areas of the CNS recruited into the abnormal discharge, clinical symptoms observed during focal seizures may vary considerably. Thus, discharges within limited areas of the motor cortex may lead only to mild motor seizures, while seizure activity in the ▶temporal lobe may cause complex semiologies that include behavioral automatisms and loss of consciousness. Focal seizures without loss of consciousness are termed simple partial seizures, whereas focal seizures with loss of consciousness are named complex partial seizures. In some epilepsies, initially focal seizures spread to involve most of the cerebral cortex (secondary generalized seizures).

Primary generalized seizures are also heterogeneous with respect to their clinical features. Such seizures can impose as ▶absence epilepsy, which is characterized by a brief interruption of consciousness due to highly synchronized neuronal activity involving thalamocortical networks without increases in neuronal firing rate. On the other hand, ▶tonic-clonic convulsions with loss of consciousness are often also primarily generalized.

Basic Mechanisms

Both focal and generalized epilepsies are heterogeneous with respect to their etiology and the principles of therapy.

Basic Mechanisms Underlying Focal Epilepsies

A large group of focal epilepsies arises as a consequence of developmental lesions, CNS tumors, trauma or inflammatory processes, which may be located in neocortical areas as well as the mesial temporal lobe. In a second group of patients, no such causal factor can be identified. Very frequently, such epilepsies arise from a focus within the ▶hippocampus, which shows characteristic neuropathological and molecular changes. Only few focal epilepsies seem to be due to a mutation in ion channel ▶(ion channels) genes. In contrast, a large number of generalized epilepsies is thought to have a genetic basis, and the chromosomal localization or the

gene mutation has been identified in some of these disorders.

Many patients with focal epilepsies respond well to antiepileptic drugs, but a sizeable portion continues to have seizures even in the presence of optimal therapeutic drug concentrations. For unknown reasons, patients with an epileptic focus residing in the temporal lobe (Temporal Lobe Epilepsy, TLE) often develop pharmacoresistant epilepsy. Therefore, considerable attention has been focused on unraveling the cellular changes underlying hyperexcitability in this form of epilepsy. Identifying such changes is of obvious importance in determining promising novel therapeutic strategies.

In focal epilepsies a number of functional and morphological changes are observed which may act in concert to support enhanced excitability. Such changes have been intensively investigated in order to develop targets for drug design.

- Altered density of voltage-dependent ion currents in neurons: Such changes may considerably affect the firing properties of neurons. They may also affect how neurons integrate a given synaptic input.
- Altered synaptic properties: Numerous changes in the properties of inhibitory (GABAergic) and excitatory (glutamatergic) synapses have been reported. While the simple adage of an imbalance between inhibitory and excitatory neurotransmission in epilepsy is not generally applicable, some forms of inhibition are lost or impaired in epilepsy. Likewise, an increased function of glutamate receptors has been demonstrated in some brain areas.
- Formation of novel aberrant synapses, axonal sprouting: In addition to altered properties of inhibitory and excitatory synapses, numerous synapses are newly formed in chronically epileptic tissue. In some regions, as in the dentate gyrus, the subiculum and area CA1 of the hippocampus, excitatory neurons form recurrent synapses terminating within the same region. This and other forms of recurrent sprouting are thought to constitute a positive feedback pathway facilitating seizure generation in this area. Very little is known about the elementary properties of newly formed synapses.
- Altered properties of glial cells: Glial cells are centrally involved in regulating the size of the extracellular space and the composition of the extracellular milieu, amongst other important tasks. In particular, glial cells normally take up K^+ released by neurons during repetitive neuronal activity. Preventing excessive increases in the extracellular K^+ concentration is important because they may enhance excitability of surrounding neurons. In chronic epilepsy, one of the numerous changes occurring in glial cells is the loss of the capacity to take up K^+ .

Clearly, the largest difficulty in chronic focal epilepsy is to identify amongst the numerous changes that might plausibly affect excitability those that are most important in mediating hyperexcitability. Because of the lack of molecular targets with a proven causal role in mediating seizures, design of anticonvulsant drugs has been driven mainly by considering which drugs potentially limit excitability in normal brain tissue or normal animals. It must be also stressed that, in focal epilepsies, our knowledge extends mainly to the cellular changes that underlie hyperexcitability in the chronic stage of the disease. The factors governing the development of the epileptic condition in humans are much less clear, and the design of substances aimed at inhibiting the progression of epilepsy is in its first stages.

Primary Generalized Epilepsies

Primary generalized epilepsies are a heterogeneous group of diseases. Some of the generalized epilepsies are hereditary, and several genetic mutations of ion channels or membrane receptors linked to this disorder have been identified. In others, the pathogenesis is less clear. Absence epilepsies present with a characteristic 3/s discharge in the electroencephalogram, and the mechanism for similar aberrant discharges have been well studied in animal models. It is thought that thalamic projection neurons that have the capacity to generate burst discharges mediated by low-threshold Ca^{2+} channels provide a phasic excitation of interneurons. These interneurons in turn inhibit thalamic projection neurons via GABA receptors, resulting in a pronounced hyperpolarization. This hyperpolarization removes inactivation of low-threshold Ca^{2+} channels, subsequently enabling these neurons to generate a new, Ca^{2+} channel-dependent burst discharge. Thus, rhythmogenesis seems to rely on the interplay between low-threshold Ca^{2+} channel-dependent bursting and GABA-mediated inhibition. Accordingly, absence epilepsies respond well to substances blocking low-threshold Ca^{2+} channels (ethosuximide, trimethadione), as well as to some GABA-antagonists (which are still in an experimental stage for this indication).

Substances Acting on Voltage-dependent Ion Channels

With few exceptions, information on the anticonvulsant pharmacology of specific ion channel subunits analyzed in expression systems is scarce. Hitherto, a first understanding of the mechanism of action of most antiepileptic drugs has evolved from analyses of somatic ion channel pharmacology either in isolated neurons from human or rodent neurons, or cell culture models.

Voltage-dependent Na^+ Channels

A large number of anticonvulsant drugs commonly in use for focal epilepsies act on fast voltage-dependent

Na^+ channels at clinically relevant concentrations (carbamazepine, phenytoin, lamotrigine). Most of these anticonvulsant drugs display three distinct effects on Na^+ channels:

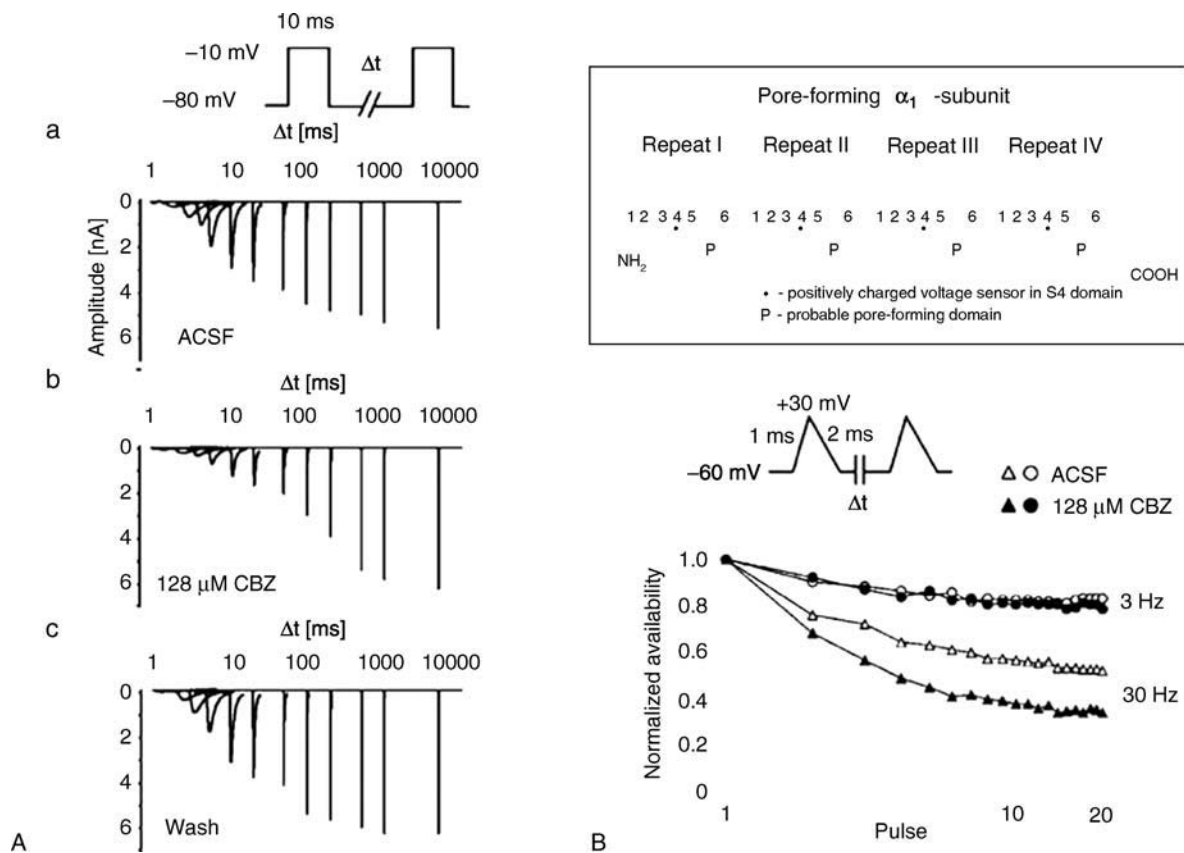

- A shift of the voltage-dependence of inactivation to a hyperpolarizing direction, resulting in a lower fraction of channels available for activation at action potential threshold.
- A reduction of the peak Na^+ channel conductance.
- A pronounced slowing of Na^+ channel recovery from the inactivated state.

The latter effect results in a prolongation of the time required after an action potential for inactivated Na^+ channels to become available again. This prolongation would be expected to inhibit repetitive firing only if the time between action potentials is not long enough to permit recovery of Na^+ channels, i.e. at high discharge frequencies. Indeed, phenytoin, carbamazepine and lamotrigine have been shown to preferentially inhibit high frequency but not low frequency firing (see Fig. 1). It has to be noted that this mechanism is most probably invoked not only at somatodendritic Na^+ channels, but also at presynaptic Na^+ channels. In the latter case, application of one of the antiepileptic drugs mentioned above would be expected to preferentially inhibit transmitter release induced by high frequency presynaptic action potentials.

In addition to inhibiting fast voltage-dependent Na^+ currents, many anticonvulsants also suppress persistent Na^+ currents, in some cases even more efficiently. This mechanism may also be important in the anticonvulsant action of these substances because persistent Na^+ currents are thought to give rise to high frequency burst discharges in some neurons.

Voltage-dependent Ca^{2+} Channels

A number of anticonvulsant drugs also display effects on Ca^{2+} channels. In most cases, effects on Ca^{2+} channels with a depolarized threshold of activation are small at clinically relevant concentrations. In the case of gabapentin, binding to a Ca^{2+} channel accessory subunit has been demonstrated, but whether this binding affects channel function is unknown. In contrast, Ca^{2+} channels with a hyperpolarized threshold of activation (low-threshold channels) are sensitive to a number of drugs (i.e. ethosuximide, trimethadione through its metabolite dimethadione, phenytoin, lamotrigine). As stated above, the activity of ethosuximide and trimethadione against absence epilepsy is thought to be due to their inhibition of low-threshold Ca^{2+} channels. The differing anticonvulsant profile of lamotrigine and phenytoin may be due to the fact that the three pore-forming subunits underlying low-threshold Ca^{2+} channels are differentially sensitive to anticonvulsant drugs.

Antiepileptic Drugs. Figure 1 Effects of carbamazepine on voltage-dependent Na⁺ channels. (a) Fast recovery from inactivation can be analyzed in double pulse experiments using the whole-cell patch clamp technique. Recordings shown are from rat hippocampal dentate granule neurons. Inactivation is induced with a conditioning pulse (10 ms, -10 mV), after which recovery of Na⁺ channels from inactivation is monitored by a test pulse applied at various intervals following the conditioning pulse (inset, a). Representative traces after various recovery intervals are displayed on an exponential time scale. Application of 128 μM CBZ causes a marked slowing of the time course of recovery. (b) Use-dependent block of Na⁺ channels by CBZ. Trains of mock action potentials were applied as voltage commands at different frequencies. Application of CBZ reduces Na⁺ channel availability preferentially during high-frequency stimulation. Inset: General molecular structure of pore-forming α subunits of voltage-dependent Na⁺ channels.

Voltage-dependent K⁺ Channels

Up-modulation of voltage-dependent K⁺ channels may be a plausible mechanism to reduce cellular excitability and action potential-dependent neurotransmitter release. However, the number of novel antiepileptic drugs developed that target potassium channels is small. Interestingly, it has recently been discovered that a mutation resulting in a moderate loss of function of KCNQ2/3 K⁺ channels causes a focal form of epilepsy. The novel anticonvulsant retigabine, which enhances the activity of this very channel type, displays a high clinical efficacy in these patients.

Substances Acting on Neurotransmitter Receptors

A large fraction of anticonvulsants are based on the attempt to boost inhibitory synaptic transmission in

order to restore the balance between inhibition and excitation in epileptic tissue. The first drug using this mechanism of action was phenobarbitone, which was introduced into clinical practice in 1912. Today, there are at least three different targets of anticonvulsant drugs at the synaptic level, all centered on the main inhibitory transmitter GABA (γ -aminobutyric acid).

GABAergic Synapses

Based on the key elements in synaptic inhibitory transmission, three classes of drugs can be distinguished:

- GABA receptor modulators. These substances yield a potentiation of synaptic responses to GABA by changing the affinity of the GABA receptor

(benzodiazepines) or enhancing the open probability of this ligand-gated ion channel (barbiturates). Benzodiazepines are especially useful against status epilepticus but are also used as an adjunctive therapy in partial and generalized seizures. Clinically used substances are clobazepam, clonazepam, clorazepate, diazepam, lorazepam, midazolam and nitrazepam. Barbiturates (esp. phenobarbitone) are used in tonic-clonic and partial seizures, in status epilepticus and in neonatal seizures. Chronic treatment with benzodiazepines and barbiturates is complicated due to the sedative side effects and, most importantly, development of tolerance.

- GABA-uptake blockers. Block of GABA-uptake prolongs the presence of the transmitter in the synaptic cleft and thereby strengthens the postsynaptic effects of synaptically released GABA. Tiagabine, a derivative of nipecotic acid, is in clinical use as an add-on therapy against simple and complex partial seizures. Like all substances that generally increase

GABAergic transmission, tiagabine has sedative side effects.

- Blockers of GABA catabolism. Blocking the GABA-degrading enzyme GABA-transaminase increases the concentration of GABA in synaptic terminals and enhances or stabilizes the inhibitory transmission. A “new” anticonvulsant designed for this purpose is γ -vinyl-GABA (Vigabatrin), but it should be noted that valproate has the same effect. Vigabatrin is used as an adjunctive therapy in partial and secondary generalized seizures. It is very efficient against infantile spasms and is being used in Lennox-Gastout (together with sodium valproate and benzodiazepines). Side effects of vigabatrin include neuropsychiatric (especially mood) disturbances as well as retinopathic changes. Novel experimental approaches are aimed at increasing GABA synthesis, rather than blocking its degradation, by potentiating the action of the GABA-synthesizing enzyme glutamate decarboxylase.

Antiepileptic Drugs. Table 1 Summary of the known spectrum of actions of a selection of antiepileptic drugs

	Voltage-dependent ion channels			Neurotransmitter receptors			NT release	Other mechanisms
	Na ⁺	Ca ²⁺	K ⁺	GABA	NMDA	AMPA		
Phenytoin	+++	++ (T)	+ (DR)	?	?	?	++	Calmodulin and cyclic nucleotide-dependent second messenger systems
Carbamazepine	+++	–	?	–	+	?	?	Adenosine receptors
Lamotrigine	+++	++	–	–	–	–	?	
Valproic acid	+++	+	+	?	?	?	++	Increase in brain GABA, decrease in brain aspartate
Ethosuximide	+ (I _{Na,p})	+++ (T)	+	?	?	?	–	Inhibition of Na ⁺ /K ⁺ ATPase
Trimethadione	?	+++ (T,L)	?	?	?	?	?	
Phenobarbital	–	+	?	+++	?	?	++	
Diazepam	+	–	–	+++	–	–	–	
Felbamate	++	?	?	?	+++	?	?	
Gabapentin	–	+ (HVA)	+	–	–	–	+	Increased GABA synthesis, GDH, GAD, GABA-aminotransferase
Vigabatrin	?	?	?	?	?	?	+++	GABA-transaminase inhibition
Tiagabine	?	?	?	?	?	?	+++	
Losigamone	?	++	?	++	?	?	?	
Ramecemide	?	?	?	?	?	?	?	
Topiramate	++	?	?	++	–	?	?	
Levetiracetam	–	–(T), + (HVA)	?	?	?	?	?	GABA-T, GAD
Retigabine	?	?	+++ (KCNQ)	?	?	?	?	

This synopsis refers only to actions demonstrated within or close to the therapeutic concentrations of drugs. Abbreviations: (+) to (+++) weak to strong efficacy, (–) no efficacy, (?) not investigated. HVA: high threshold Ca²⁺ channels, T: T-type Ca²⁺ channels, L: L-type Ca²⁺ channels, I_{Na,p}: persistent sodium current, DR: delayed rectifier K⁺ channels, KCNQ: KCNQ subtypes of K⁺ channels.

One of the oldest antiepileptic drugs, bromide, has been reported to boost inhibition by an unknown mechanism. Bromide is still in use in certain cases of tonic-clonic seizures and in pediatric patients with recurrent febrile convulsions and others. The mechanism of action may include a potentiation of GABAergic synaptic transmission, although the precise target is not known.

Excitatory Amino Acid Antagonists

The complementary approach to boosting inhibition, i.e. antagonizing the effects of the excitatory neurotransmitter ►glutamate (►GABAergic System), has been less fruitful so far. Antagonists of the NMDA-subtype of glutamate receptors show anticonvulsant activity in animal experiments but have not been introduced into clinical use due to severe neuropsychological side effects. An exception may be felbamate, which seems to exert at least part of its effect by a block on NMDA receptors. Antagonists of two other glutamate receptor subclasses (AMPA- and Kainate-receptors) are under development. Topiramate, a new anticonvulsant drug, partially blocks kainate-receptors and thus may provide the first example of an AED with effects against excitatory neurotransmission.

Substances with Unknown or Mixed Mechanism of Action

It should be pointed out that most anticonvulsants have more than one effect on neuronal excitability or

Antiepileptic Drugs. Figure 2 The GABAergic synapse as a target of anticonvulsant drugs. GABA is synthesized from glutamate in the presynaptic terminal and is packed into small synaptic vesicles. After release, GABA activates postsynaptic ion channels (GABA_AR, marked "1") which mediate the chloride influx and thereby the inhibition of the postsynaptic cell. From the synaptic cleft, GABA is removed into the presynaptic terminal and into a adjacent glia cells by GABA-uptake ("2"). A fraction of the transmitter is degraded into succinyl-semialdehyde by GABA-transaminase ("3"), which is present in glia cells as well as in neurons. Pre- and postsynaptic metabotropic GABA_BR are indicated by ellipsoid bodies in the cell membrane but are no major target for anticonvulsants presently in use. GABAergic drugs against epilepsy act as positive modulators of the GABA_AR ("1"), blockers of GABA-uptake ("2") or inhibitors of GABA degradation ("3").

synaptic transmission. A prominent example is valproic acid, which affects GABAergic transmission (probably by enhancing cellular GABA-content), glutamatergic synaptic transmission by reducing synthesis of excitatory amino acids as well as voltage-dependent ion channels (see Table 1).

Drugs with unknown mechanism of action are gabapentin, bromides (but see above effects on GABAergic transmission) and adrenocorticotrophic hormone (ACTH), which is used in infantile spasms.

Antimycotic drugs; Antimycotics; Fungicides

Definition

►Fungi cause diseases in plants, animals and humans. Antifungal drugs (fungicides) are therefore used in agriculture, animal and human medicine. In this article, only antifungal drugs used for human chemotherapy are described.

Antifungal drugs inhibit the growth of fungi in tissue (►fungistatic activity) by a number of different mechanisms; some of the agents even kill the fungal cell (►fungicidal effect). Antifungal drugs are used for the treatment of established fungal diseases; however, in immunosuppressed patients at high risk they are also used as prevention or empiric therapy.

Antifungal drugs are classified according to their mode of action and/or their chemical class. Four chemical classes have mainly contributed to the actual armamentary of antifungal drugs: the broadest class is the one of ►azoles (imidazoles and triazoles), followed by ►polyenes, ►allylamines and ►morpholines. Some individual compounds are used in dermatology.

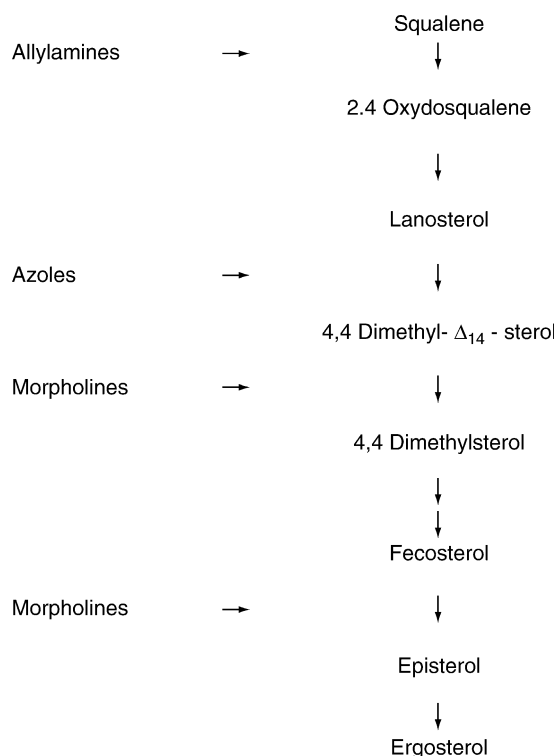

Mechanism of Action

The difficulty of killing the eukaryotic fungal cell without damaging the host is perhaps more akin to the problems of cancer chemotherapy than those of antibacterial treatment. Biochemical studies have identified a number of potential targets for antifungal chemotherapy, including cell wall synthesis, membrane sterol biosynthesis, nucleic acid synthesis, metabolic inhibition and macronuclear biosynthesis. The cell wall synthesis is the only fungal-specific target, since the fungal cell wall has a unique molecular structure; all other pathways (enzymatic steps) in the fungal cell are closely related to the ones used in human cells. (Fig. 1)

Sterol Biosynthesis Inhibitors

Most antifungals on the market (►azoles, ►allylamines, ►morpholines, Tolnaftate, Tolciclate) interfere with the various enzymatic steps involved in the cascade of ergosterol synthesis from squalene to ergosterol; this pathway being the Achilles' heel of the fungal cell. Ergosterol is the essential component of the fungal membrane and exerts two functions: it is the bulk membrane component and it regulates cell growth and proliferation. All sterol biosynthesis inhibitors induce depletion of the essential ergosterol and accumulation of a wrong sterol moiety, consequently disturbing the function of the cell membrane. The morphological changes seen in all cells treated with a sterol biosynthesis inhibitor are similar, all including thickening of the cell wall by chitin deposits.

The imidazoles and triazole (►azoles) (for example, ketoconazole, itraconazole (ITRA), fluconazole (FLU), voriconazole) interfere with cytochrome P₄₅₀-dependent lanosterol C₁₄ demethylase, leading to depletion of ergosterol and accumulation of lanosterol in the

Antiepileptic Drugs. Figure 1 Antifungal drugs.

membrane. At the molecular level, one of the nitrogen atoms of the azole ring binds to the haem moiety of cytochrome P₄₅₀. Only compounds with higher specific binding to the fungal cytochrome than to the human one can be used as systemic antifungal drugs. Compared to the imidazoles, the triazoles have a much higher affinity for fungal cytochrome than for human cytochrome P₄₅₀ enzyme steps. In addition to the main interactions with the P₄₅₀ cytochrome, azoles may inhibit cytochrome C oxidase and peroxidative enzymes; they may also interfere with phospholipids. The fact that miconazole and ITRA are fungicidal is thought to be the result of a direct membrane interaction, leading to the loss of cytoplasmic constituents.

Allylamines

Allylamines (terbinafine, naftifine) interfere with the ergosterol pathway at the level of squalene epoxidase leading to the depletion of ergosterol and the accumulation of squalene. Again, only compounds with a higher specificity for the fungal enzyme than for the human enzyme can be used for systemic use. A clear correlation exists between growth inhibition and degrees of sterol biosynthesis inhibition; the fungicidal effect is more correlated to the intracellular accumulation of squalene. (Fig. 2).

Morpholines

Morpholines (amorolfine) interfere at two levels of the ergosterol pathway, the Δ₁₄-reductase and the Δ₇-

Antiepileptic Drugs. Figure 2 Antifungal drugs – targets of antifungal activity.

Δ_8 -isomerase leading to depletion of ergosterol and accumulation of an unplanar sterol ignosterol. With the inhibition of two steps in the same pathway, a natural synergistic effect is built into the molecule so that the risk of appearance of resistant mutants is low and efficacy high.

Drugs Binding Directly to Ergosterol (amphotericin B, nystatin, candicidin).

The current model for the mechanism of the \blacktriangleright polyene amphotericin B (Amph B) is based on the formation of a 1:1 Amph B/Ergosterol aggregate, which associates into a transmembrane channel with a large $-OH$ lined aqueous pore down the middle. The result of the interaction between Amph B and the sterols is the disturbance of the ergosterol function leading to increased permeability, disruption of the proton gradient and leakage of potassium. The fungicidal effect, however, has been linked to irreversible inhibition of the membrane ATPase.

5-Fluorocytosine

5-Fluorocytosine (5FC), a mock pyrimidine, is the only antifungal drug that acts as true antimetabolite. 5FC is taken up into the fungal cell, deaminated to 5-fluorouracil (5FU) which is the active principle responsible for the killing of the fungal cell. Fungi lacking the cytosine deaminase are resistant to 5FC. Intracellularly, 5FU acts along two different pathways: it is incorporated as 5-fluorouridine monophosphate into the RNA and it inhibits after conversion to 5-fluorodeoxyuridine monophosphate, the thymidylate synthetase, leading to inhibition of DNA synthesis. 5FU itself cannot be used for antifungal therapy due to its toxicity for mammalian cells.

Glucan Synthase Inhibitors

Echinocandins (i.e. caspofungin), semisynthetic lipopeptides, inhibits the synthesis of β -(1,3)-D-glucan, an

integral component of the fungal cell wall not present in mammalian cells.

Griseofulvin

Griseofulvin is the first antimycotic drug detected that is only active against \blacktriangleright dermatophytes. Its activity manifests as nuclear and mitotic abnormalities followed by distortions in the hyphal morphology.

Hydroxypyridones (Ciclopirox, Rilopirox)

The primary mode of action of this class of antimycotics is interference with uptake and accumulation of products required for cell membrane synthesis. In higher concentrations it causes a disturbance of the cellular permeability. Some investigations show an interaction with $Fe(III)$ - ions; the compounds acting as chelators. Very high concentrations interfere with the function of fungal mitochondria.

Clinical Use (including Side Effects)

Fungal diseases divide themselves into three classes: superficial (topical, local) mycoses (\blacktriangleright dermatomycoses and gynaecological infections), subcutaneous and organ mycoses. This division is important not especially for microbiological reasons, but in the view of the different problems arising during treatment. Superficial mycoses are not life threatening, but they are irritating. Subcutaneous mycoses are also not life threatening but are associated with a high morbidity, and deep mycoses, especially in immunosuppressed patients, are life threatening showing a high mortality rate in patients, if untreated. The treatment schedules (dose, duration of treatment, galenical formulation) are strongly dependent on the localisation of the fungal disease, on the pathogenicity of the fungi, and on the conditions of the host. Additionally, the diagnosis of the disease is not always guaranteed; therefore, a clear-cut, simple description of clinical usage for antifungal drugs is not possible.

Due to the divergence of fungal diseases, there is neither single best treatment nor a superior drug for all diseases. However, a superior drug does exist for dermatomycoses caused by dermatophytes, namely the allylamine terbinafine (TER). For the treatment of deep mycoses in immunosuppressed patients the most efficacious drug is the polyene Amph B.

The therapy of ▶**dermatomycoses** and acute vaginal infections is unproblematic. A large choice of various drugs (all chemical classes and compounds discussed above) in different galenical formulations (crèmes, tinctures, sprays, ovula, powder, shampoo, nail lacquer and tablets) exists. All drugs topically applied – used in various treatment schedules – show high efficacy and a low incidence of adverse reactions. For the treatment of onychomycoses without matrix involvement two nail lacquers (a morpholine and hydroxypyron) are on the market showing high efficacy with low (<1%) adverse reactions after topical therapy for several months. A combination therapy with a topical and a systemically applied antifungal drug is the most efficacious and the most economic therapy for onychomycosis with matrix involvement. Systemic therapy is indicated if the dermatomycosis is widespread. The highest cure rate is achieved with TER. TER is well tolerated in adults and children. In ca. 5% of the patients, mild and reversible side effects have been observed: gastrointestinal, skin, central nervous system, respiratory events and loss of taste. For acute vaginal candidosis the treatment of choice with the highest compliance and best efficacy is one daily dose of FLU.

Three fungal infections – Madura feet (mycetoma), chromomycosis and ▶**sporotrichosis** – fall into the category of subcutaneous mycoses, their distribution is mainly in tropical and subtropical areas. The ideal treatment for madura feet caused by fungi is not yet established; the azoles are of some benefit, however, neither the optimal drug, dose, nor the treatment schedules are known. Chromomycosis responds well to ITRA monotherapy or the combination of 5FC plus ITRA. ITRA has been set up as standard therapy for cutaneous and lymphatic sporotrichosis.

Systemic Mycoses

Systemic mycoses are caused either by true pathogenic fungi (endemic in distinct areas of USA/South America) or by opportunistic fungi that induce severe infections in immunosuppressed patients. The arsenal for the treatment of deep organ mycoses is relatively small: Amph B, 5FC, azoles (FLU, ITRA, voriconazole (NDA filing)) and CAS.

The polyene Amph B (intravenous formulation) has the broadest spectrum, is fungicidal and shows its superiority in immunosuppressed patients. Its only drawback is its infusion-related toxicity and its negative influence on renal function. Acute reactions to Amph B – usually fever chills, rigor and nausea – can be

ameliorated by concomitant administration of meperidine, acetomiophen or hydrocortisone. Additionally, there is the possibility of tailoring time and duration of infusion. Prevention of the chronic tubular injury is feasible by salt loading. Encapsulation of Amph B into liposomes or complexing of the drug with other lipid carriers brings a major reduction of nephrotoxicity. Three lipid-associated forms are now available (Ambisome, Amph B lipid complex and Amph B colloidal dispersion). Due to its toxic side effects, Amph B is not widely used for prevention; it is, however, often used as empiric therapy with high success rates.

Due to the rapid appearance of resistance, 5FC is only used as a combination partner for the intensive therapy of established severe fungal infections caused by *Candida spp.*, *Cryptococcus neoformans* and *Aspergillus sp.* Anorexia, nausea, vomiting, diarrhoea and abdominal pain occur in 6% of the patients. Of greater concern is the potential for bone marrow depression (seen in 5% of the patients, all with elevated 5FC levels).

Azoles

Generally the azoles are well tolerated in children and adults; mild side effects like nausea and vomiting are seen in <5% of the patients treated with FLU.

Attention has to be given to the problem of interaction between azoles and other drugs; these are based on two mechanisms:

- inhibition of absorption of the azoles leading to lower bioavailability or
- interference with the activity of hepatic microsomal enzymes, which alters the metabolism and plasma levels of azole, the interacting drug or both. This latter induces often increased toxicity of the concomitant drug.

With FLU, only few drug interactions are seen, namely with rifampicin (reduction of FLU), phenytoin, cyclosporin, tolbutamide and warfarin (increasing levels of concomitant drug). The interactions with ITRA are more significant than with FLU: H₂ antagonists and all drugs increasing intragastric pH decrease the absorption of ITRA. Interactions due to hepatic enzymes are seen with rifampicin (reducing the levels of ITRA to undetectable levels), phenytoin, isoniazid, carbamazepine, phenobarbital, midazolam, triazolam, digoxin, lovastatin terfenadine, warfarin and cyclosporin. The list of interacting drugs is still increasing.

Oral FLU is well established as first line therapy for oropharyngeal candidosis and *Candida* oesophagitis and for maintenance therapy in AIDS patients with meningeal cryptococcosis. FLU (oral or intravenous) is also efficacious in candidemia without neutropenia. It shows efficacy in prevention (attention: *Aspergillus sp.* are not in the spectrum) and empiric therapy. ITRA, being fungicidal against *Aspergillus sp.*, shows

promising results in aspergillosis, especially under intravenous therapy, and is used as maintenance therapy in AIDS patients with histoplasmosis. ITRA is the first line therapy for histoplasmosis and blastomycosis in HIV-negative patients. A combination of ITRA plus 5FC may be the optimal therapy of phaeohyphomycoses.

The glucan synthase inhibitor caspofungin (intravenous formulation) is new on the market for the treatment of invasive aspergillosis in patients whose disease is refractory to, or who are intolerant of, other therapies. During the clinical trials fever, infused vein complications, nausea, vomiting and in combination with cyclosporin mild transient hepatic side effects were observed. Interaction with tacrolimus and with potential inducer or mixed inducer/inhibitors of drug clearance was also seen.

Antigen

An antigen is a molecule recognised by specific receptors on cells of the immune system such as B lymphocytes.

- ▶ Immune Defense
- ▶ Humanized Monoclonal Antibodies

Antigen Presentation

Antigen presentation is the key mechanism allowing T-lymphocytes to survey whether intracellular pathogens exist in the cells of the body. As T-lymphocytes can only recognize antigen in the form of peptides presented on specific molecules termed major histocompatibility complex (MHC), antigen-presenting cells instruct T-cell reaction and thus the development of adaptive immunity. Professional antigen-presenting

cells (MHC class II positive) are dendritic cells, monocytes/macrophages, and B-lymphocytes.

- ▶ Immune Defense

Antigen-presenting Cells

Antigen-presenting cells (APCs) are cells of the immune system that are able to process and present foreign antigens to effector cells. The antigen is presented in the context of an MHC-I or MHC-II molecule on APCs in the presence of so-called co-stimulatory molecules to activate the effector cells.

- ▶ Immune Defense
- ▶ DNA Vaccination and Genetic Vaccination

Antigen Receptors

Each T- and B-lymphocyte carries one type of receptor, which recognizes one specific antigen. T-cells carry the heterodimeric T-cell antigen receptor consisting of an alpha and beta chain. This receptor recognizes a peptide presented by a MHC (major histocompatibility complex) molecule. B-cells express an immunoglobulin on their surface, which can recognize epitopes on antigens of different sizes and qualities without the need for presentation. Both forms of antigen receptors are created by random genetic rearrangement during the ontogeny of each individual lymphocyte. Both types of antigen receptors require additional transmembrane molecules for signal transduction.

Definition

Pathophysiology and Clinical Manifestations of Gout

►Uric acid is the end product of purine catabolism in man. Purines originate from food and the degradation of nucleic acids and nucleotides. ►Xanthine oxidase (XOD) is the key enzyme in purine degradation. XOD converts hypoxanthine to xanthine, and xanthine to uric acid, respectively (Fig. 1). Uric acid is filtered in the glomerulus of the kidney, is almost completely absorbed in the proximal tubules and secreted more distally (Fig. 2). At physiological pH (<7.4), uric acid exists predominantly in its ionic form (urate). At lower pH, the fraction of uric acid molecules (protonated form) increases. This is important because uric acid possesses a lower solubility than urate. Thus, a decrease in pH, as it occurs in inflamed tissue and in the tubules, facilitates the formation of uric acid crystals, which are the initial cause of gout. In most mammals, the enzyme uricase converts uric acid to the more soluble allantoin, but humans do not express uricase. Of importance for therapeutic intervention is the fact that xanthine and hypoxanthine are more soluble than uric acid. Specifically, by preventing uric acid formation through XOD inhibition, the excretion of xanthine and hypoxanthine increases, and the risk of uric acid crystal formation decreases. An increase of the serum uric acid concentration above 416 $\mu\text{mol/L}$ is referred to as hyperuricemia and is associated with an increased risk of uric acid crystal formation and acute attacks of gouty arthritis. With a serum uric acid level of 535 $\mu\text{mol/L}$, the annual incidence of gouty arthritis is 4.9–5.7%.

Hyperuricemia can have genetic causes or acquired causes. A defect of hypoxanthine-guanine phosphoribosyl transferase is the cause of Lesch–Nyhan syndrome, resulting in increased uric acid production. Among the genetically caused defects, impaired renal uric acid secretion is a very common cause of gout. Myeloproliferative diseases, a purine-rich diet (e.g. meat, beer, beans, peas, oatmeal, or spinach), obesity, and alcoholism are common causes of acquired hyperuricemia and result from increased uric acid production. Renal diseases and the application of certain drugs such as the tuberculostatic drug pyrazinamide, thiazide diuretics, loop diuretics, or acetylsalicylic acid at doses of up to 1–2 g/day, and the immunosuppressant cyclosporin A are acquired causes of impaired uric acid secretion.

Gout is the consequence of hyperuricemia and is caused by uric acid deposits in joints, tendons, bursae, kidney and urinary tract. In the USA, the prevalence of gout is ~1% for all ages and both sexes. The prevalence of gout is higher in men than in women and exceeds 5% in men ≥ 65 years. These epidemiologic data are important for drug therapy since older patients are more sensitive to side effects of anti-gout drugs than younger patients. In the initial stage, gout is characterized by asymptomatic hyperuricemia. In the second stage, the disease manifests itself by acute gouty arthritis. The third (intercritical) stage is asymptomatic, and the fourth stage is characterized by progressive uric acid deposits in joints, tendons, bursae, kidney, and urinary tract (tophus formation). Uric acid deposits result in the deformation and loss of function of joints

Anti-gout Drugs. Figure 1 Xanthine oxidase-catalyzed reactions. Xanthine oxidase converts hypoxanthine to xanthine and xanthine to uric acid, respectively. Hypoxanthine and xanthine are more soluble than uric acid. Xanthine oxidase also converts the uricostatic drug allopurinol to alloxanthine. Allopurinol and hypoxanthine are isomers that differ from each other in the substitution of positions 7 and 8 of the purine ring system. Although allopurinol is converted to alloxanthine by xanthine oxidase, allopurinol is also a xanthine oxidase inhibitor. Specifically, at low concentrations, allopurinol acts as a competitive inhibitor, and at high concentrations it acts as a noncompetitive inhibitor. Alloxanthine is a noncompetitive xanthine oxidase inhibitor. XOD: xanthine oxidase.

Anti-gout Drugs. **Figure 2** Reabsorption and secretion of uric acid in the proximal renal tubulus. (a) Normal situation. Uric acid is completely reabsorbed in the proximal segment of the renal tubulus and secreted more distally. (b) Situation in untreated hyperuricemia. In most genetically caused cases of gout, uric acid secretion is defective (1). (c) Situation in hyperuricemia under treatment with uricosuric drugs (2); Inhibition of uric acid secretion by uricosuric drugs at low doses (3). Inhibition of uric acid secretion and reabsorption by uricosuric drugs in therapeutic doses. The inhibition of uric acid secretion with low doses of uricosuric drugs can further increase blood levels of uric acid and induce attacks of acute gouty arthritis.

and recurrent episodes of urate lithiasis. Uric acid deposits in the kidney and urate lithiasis can ultimately result in renal failure.

Figure 3 illustrates important pathophysiologic events leading to acute gouty arthritis. Once the concentration of uric acid exceeds its solubility, uric acid crystals form in the synovial fluid of joints. Subsequently, the uric acid crystals are phagocytosed by synoviocytes that form the inner cell layer of joints. Next, synoviocytes release numerous mediators of inflammation including leukotriene B₄ (LTB₄), prostaglandin E₂ (PGE₂), platelet-activating factor (PAF), histamine, interleukins (ILs) 1, 6, and 8, and tumor necrosis factor- α that in conjunction with products of the complement cascade (C5a and C3a) and kinins (bradykinin) induce an inflammatory response. Moreover, LTB₄, PAF, C5a, and IL-8 attract polymorphonuclear leukocytes (neutrophils). Neutrophils migrate into affected joints along a concentration gradient of these inflammatory mediators (chemotaxis). Accordingly, LTB₄, PAF, C5a, and IL-8 are also referred to as chemoattractants. Once present in joints, neutrophils phagocytose uric acid crystals. Uric acid crystals and chemoattractants trigger the release of cytotoxic lysosomal enzymes, NADPH oxidase-catalyzed formation of reactive oxygen species, LTB₄ formation and the release of other proinflammatory molecules from neutrophils. The latter molecules attract additional neutrophils and mononuclear phagocytes. Moreover, neutrophils generate lactate that decreases the pH within the joint and further accelerates uric acid crystal formation. Oxygen radicals and lysosomal enzymes cause damage to tissues.

Thus, the presence of uric acid crystals in joints triggers a vicious cycle, resulting in an extremely painful inflammation. A typical localization of acute gouty arthritis is the first metatarsal joint of the foot (podagra). The diagnosis of acute gouty arthritis is confirmed by the detection of urate crystals in the joint or tophus.

Anti-gout Drugs

Figure 4 shows the structures of commonly employed anti-gout drugs. The treatment of acute gouty arthritis aims at rapidly reducing the pain and inflammatory reaction. This aim can be achieved by treatment with colchicine. In addition, **nonsteroidal anti-inflammatory drugs** (NSAIDs), **glucocorticoids**, and adrenocorticotropic hormone (ACTH) can be used to treat acute gouty arthritis. However, since NSAIDs and glucocorticoids are used in numerous other commonly occurring inflammatory conditions, they are not *per se* considered specific anti-gout drugs. Glucocorticoids can be given systemically (orally, intramuscularly, or intravenously) or locally into afflicted joints. The long-term goals of gout treatment are the prevention of acute gouty arthritis, the prevention of urate lithiasis and renal failure and the resorption of existing uric acid deposits in the joints and urinary tract. The long-term therapy aims at reducing the serum concentration of uric acid below 357 $\mu\text{mol/L}$. Therapy with the **uricostatic drug** allopurinol and the **uricosuric drugs** benzbromarone, sulfapyrazone, or probenecid can accomplish the long-term goals. These drugs are well tolerated in most patients. Uricostatic and uricosuric drugs can be combined. Additionally, low doses of colchicine can be used to prevent the occurrence of acute gouty arthritis. However, as is unfortunately often the case with classic diseases, there are only few well conducted clinical studies assessing the clinical efficacy and safety of anti-gout drugs.

Mechanism of Action

Colchicine

Colchicine is an alkaloid from the autumn crocus *Colchicum autumnale*. Colchicine binds to the cytoskeletal protein **tubulin** and, thereby, prevents microtubule formation. As a result, colchicine inhibits neutrophil chemotaxis and the influx of these cells into areas containing uric acid crystals (**Fig. 3**). Colchicine also inhibits neutrophil phagocytosis. As a result, colchicine interrupts the vicious cycle of inflammation in gouty arthritis. However, because of its mechanism of action, colchicine is most effective only when given in the early stages of gouty arthritis, i.e. within 24 h. Otherwise, the inflammatory reaction may be too advanced. Specifically, colchicine is effective in >90% of patients when given within the first few hours after the start of the attack, but after 24 h, the responsiveness decreases to 75%. Given the very significant side effects of colchicine, it is absolutely crucial to initiate colchicine therapy as early as possible.

Anti-gout Drugs. Figure 3 Important pathophysiologic events in acute gouty arthritis. Uric acid crystals activate the complement cascade, the formation of kinins and the release of various mediators of inflammation from synoviocytes that phagocytose uric acid crystals. The combined action of the released mediators induces a strong inflammatory reaction that is further enhanced by neutrophils. Neutrophils migrate along a concentration gradient to loci in which C5a, LTB₄, PAF and IL-8 are produced (chemotaxis). Accordingly, C5a, LTB₄, PAF and IL-8 are also referred to as chemoattractants. Neutrophils phagocytose uric acid crystals. Upon exposure to uric acid crystals and chemoattractants, neutrophils release various mediators of inflammation, reactive oxygen species and lysosomal enzymes. The concerted effects of all these compounds amplify the inflammatory reaction even further. Colchicine interrupts the vicious cycle of inflammation predominantly by inhibiting neutrophil chemotaxis. IL-1, interleukin 1; IL-6, interleukin 6; IL-8, interleukin 8; LTB₄, leukotriene B₄; MCP, monocyte chemoattractant protein; PAF, platelet-activating factor; PGE₂, prostaglandin E₂; TNF-α, tumor necrosis factor-α.

Allopurinol

Allopurinol is an analog of hypoxanthine and is converted to alloxanthine by XOD. Both allopurinol and hypoxanthine inhibit XOD (Fig. 1). Alloxanthine is a noncompetitive inhibitor of XOD as is allopurinol at high concentrations. At low concentrations, allopurinol is a competitive inhibitor of XOD. As a result of XOD inhibition, the formation of the poorly soluble

uric acid is reduced, whereas the formation of the more soluble metabolites hypoxanthine and xanthine is increased. Because of the good solubility of hypoxanthine and xanthine, formation of hypoxanthine/xanthine crystals is a rare complication of allopurinol treatment. Another consequence of XOD inhibition is the accumulation of the precursor of xanthine, inosine. Inosine inhibits the key enzyme of *de novo* purine synthesis,

phosphoribosyl-pyrophosphate amidotransferase. The allopurinol metabolite allopurinol ribonucleotide also inhibits phosphoribosyl-pyrophosphate amidotransferase. Inhibition of purine biosynthesis contributes to the anti-hyperuricemic effects of allopurinol.

Uricosuric Drugs

Depending on the dose applied, uricosuric drugs inhibit tubular reabsorption and tubular secretion of uric acid in the kidney differentially (Fig. 2). At low (subtherapeutic) doses, uricosuric drugs inhibit uric acid secretion without inhibiting reabsorption. Therefore, low doses of uricosuric drugs can actually increase serum levels of uric acid and trigger acute attacks of gouty arthritis. At higher, i.e. therapeutic doses, uricosuric drugs inhibit both tubular secretion and tubular reabsorption. Since inhibition of tubular reabsorption is quantitatively more important than inhibition of tubular secretion, the net effect is an increased renal elimination of uric acid. In order to avoid formation of uric acid crystals in the kidney and urinary tract, it is important that the pH of the urine is kept >6.0 . This goal can be achieved by the oral administration of potassium sodium hydrogen citrate, sodium bicarbonate or acetazolamide. In addition, it is mandatory that the patient drinks at least 3L per day to avoid formation of uric acid crystals.

New Drugs

Rasburicase is a recombinant urate oxidase that catalyzes the conversion of uric acid to allantoin which possesses a greater water-solubility than uric acid. In contrast to allopurinol, rasburicase has also an inhibitory effect on

existing uric acid pools, and therapy with the enzyme does not require urine alkalinization. Rasburicase is used in the treatment of pediatric patients with leukemias, lymphomas, and solid tumors who are at high risk for chemotherapy-induced hyperuricemia. Hyperuricemia is part of the so-called tumor lysis syndrome. Further studies are required to compare the clinical efficiency of rasburicase in adult patients and its efficiency in comparison to standard treatment with allopurinol. The use of rasburicase can be associated with severe side effects including hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, methemoglobinemia, kidney failure, and anaphylactic reactions.

Febuxostat (TEI-6720, TMX-67) is a highly potent mixed-type inhibitor of XOD with K_i values in the 0.5–3 nM-range. Febuxostat displays high selectivity relative to a large number of other purine- and pyrimidine-metabolizing enzymes. Febuxostat can be administered orally and is well tolerated, and there is no need for dose-adjustment in patients with kidney failure and mild-to-moderate liver failure. Therapeutic doses are 80–120 mg daily. Clinical trials indicate that febuxostat may be superior to allopurinol at reducing serum urate concentrations but not at reducing the incidence of gouty arthritis and tophus formation.

Clinical Use (including side effects)

Colchicine

Daily doses of 3–8 mg (6–8 times 0.5–1.0 mg) are used for the treatment of acute gouty arthritis. For prophylaxis, daily doses of 0.5–1.5 mg are used, but the use of colchicine for prophylaxis is controversial.

Anti-gout Drugs. Figure 4 Structures of commonly used anti-gout drugs. Colchicine is an alkaloid from the autumn crocus *Colchicum autumnale* and inhibits tubulin polymerization. Allopurinol is an isomer of xanthine and inhibits uric acid formation (uricostatic drug). Benzbromarone, sulfipyrazone and probenecid are uricosuric drugs and inhibit uric acid reabsorption in the proximal tubulus of the kidney.

The side effects of colchicine are very significant. About 80% of the patients experience gastrointestinal problems including nausea, vomiting, and diarrhea. The anti-mitotic effects of colchicine can result in thrombocytopenia, agranulocytosis, hair loss, and azoospermia. In the central nervous system, confusion, ascending paralysis, respiratory failure, and seizures have been reported. These side effects can be explained by the fact that intact microtubules are essential for proper transport functions in neuronal axons. Moreover, colchicine can cause myopathy. Because of the significant side effects, many physicians prefer to treat acute gouty arthritis with NSAIDs or glucocorticoids. Although colchicine is a classic anti-gout drug, colchicine can also be used to treat other inflammatory diseases including amyloidosis, Dupuytren's contracture, Behcet's syndrome, vasculitis, various forms of hepatic cirrhosis, pulmonary fibrosis, pericarditis, and various inflammatory diseases of the skin. Colchicine is extensively metabolized through the hepatic cytochrome CYP 3A4. Accordingly, inhibitors of CYP 3A4 such as diltiazem, gestodene, grapefruit juice, ketoconazole, and macrolide antibiotics prolong and enhance the pharmacological (and toxic) effects of colchicine. Drugs that are inactivated via CYP 3A4 such as steroid hormones, lidocaine, midazolam, quinidine, terfenadine, nifedipine, and verapamil can also prolong colchicine action. Because of its anti-mitotic effects, colchicine should not be used in pregnant women.

Allopurinol

The daily dose of allopurinol is 300–600 mg. In combination with benzbromarone, the daily allopurinol dose is reduced to 100 mg. In general, allopurinol is well tolerated. The incidence of side effects is 2–3%. Exanthems, pruritus, gastrointestinal problems, and dry mouth have been observed. In rare cases, hair loss, fever, leukopenia, toxic epidermolysis (Lyell syndrome), and hepatic dysfunction have been reported. Allopurinol inhibits the metabolic inactivation of the cytostatic drugs azathioprine and 6-mercaptopurine. Accordingly, the administered doses of azathioprine and 6-mercaptopurine must be reduced if allopurinol is given simultaneously.

Uricosuric drugs

Benzbromarone

The daily dose of benzbromarone is 50–200 mg. In combination with allopurinol, the benzbromarone dose is reduced to 20 mg. Benzbromarone is well tolerated. Rare side effects are headaches, gastrointestinal problems, and exanthems.

Probenecid

The daily dose of probenecid is 0.5–3.0 g. Probenecid is well tolerated, and there are few serious side effects. In

less than 10% of the treated patients, gastrointestinal disturbances, hypersensitivity, and skin reactions occur.

Sulfinpyrazone

The daily dose of sulfinpyrazone is 200–400 mg. The side effects of sulfinpyrazone are comparable with those of probenecid. A potential therapeutic advantage of sulfinpyrazone in patients with coronary heart disease and thromboembolic diseases is its inhibitory effect on platelet aggregation.

Antihypertensive Drugs

REINHOLD KREUTZ

Freie Universität Berlin, Berlin, Germany

Synonyms

Antihypertensives; Blood pressure lowering drugs

Definition

Reducing blood pressure by pharmacological means reduces cardiovascular morbidity and mortality rates. Benefits include protection from stroke, coronary events, heart failure, progression of renal disease, progression to more severe hypertension, and, most importantly mortality from all causes. Owing to the complexity of the pathogenesis of hypertension, antihypertensive drugs are directed against a variety of pharmacological targets in various cell types in different organs involved in blood pressure control.

Mechanism of Action

The fundamental mechanisms involved in blood pressure control have been outlined in chapter “Blood pressure control.” In addition to direct neuronal modulation of arterial pressure two neurohumoral systems, i.e., the sympathetic nervous system and the renin–angiotensin–aldosterone system (RAS) play a pivotal role in blood pressure control. Both systems are always either directly or indirectly affected by treatment with any antihypertensive drug. Antihypertensive agents can be categorized into seven different drug classes (Fig. 1) [1]. Centrally-acting antihypertensive drugs can be classified according to their relative affinities to α_2 - and imidazoline (I_1) receptors. Clonidine is considered as a mixed α_2 - and I_1 -agonist, whereas moxindine acts as a relative selective I_1 -agonist. Methyldopa is a selective α_2 -agonist. Administration of clonidine results in decreased cardiac output, a preservation of baroreflexes with a relative reduction in tendency of heart rate to rise, and little change in peripheral resistance. Methyldopa decreases sympathetic outflow predominantly to the α_1 -receptors of the arterioles, thereby reducing peripheral resistance with little (but some) effect on the heart. The baroreceptor arc is impaired because of the effect on arterioles [2]. Direct vasodilators such as minoxidil and hydralazine work by opening potassium channels in vascular smooth muscle cells in arterioles, which leads to K^+ efflux and hyperpolarization. Since the heart is not directly affected, direct vasodilators lead when used alone to reflex increases in heart rate and force of contraction; a significant neurohumoral activation of both the sympathetic nervous system and RAS occurs. Because of the activation of counterregulatory systems, the simultaneous use of β -blockers and diuretics is generally required [3]. Selective α_1 -blockers inhibit the action of norepinephrine (noradrenaline) at arteriolar receptors, thereby leading also to activation of counterregulatory systems [4]. Calcium channel blockers act primarily as inhibitors of vasoconstriction by blocking L-type calcium channels in vascular smooth muscle cells. However, there are two different main classes (dihydropyridines and nondihydropyridines), which work on different sites within the L-channel and hence produce different effects in the kidney, heart and vasculature. The nondihydropyridines

verapamil and diltiazem blunt increases in heart rate in response to exercise and have both negative inotropic and negative chronotropic (verapamil > diltiazem) effects; most dihydropyridines do not have major cardiodepressant effects because the long-acting agents slightly increase sympathetic nervous system tone, while this negative effect is even more pronounced with short-acting agents. In general, dihydropyridines lead to increases in heart rate and do not blunt the increase in heart rate response to exercise. Calcium channel blockers have a slight (transient) natriuretic effect [5]. The competitive inhibition of β -blockers on β -receptors results in numerous effects on functions that regulate blood pressure, including a reduction in cardiac output, a decrease in renin release, perhaps a decrease in both central sympathetic nervous outflow and peripheral resistance. The view that the primary effect is a reduction in cardiac output as a result from the blockade of cardiac β_1 -receptors with a subsequent reduction of heart rate and myocardial contractility has been questioned. Indeed, it seems that although cardiac output usually falls acutely and remains lower chronically, peripheral resistance on the other hand rises acutely but falls towards, if not to, normal with time. Thus, the hemodynamic hallmark of chronic established hypertension, which is an increased peripheral resistance, is also normalized by β -blockers. All currently available β -blockers antagonize cardiac β_1 -receptors competitively, but they vary in their degree of β_2 -receptor blockade in extra cardiac tissues. However, there seems to be little difference in antihypertensive efficacy among those that are more or less cardio- or β_1 -selective. Although the presence of intrinsic sympathomimetic activity (ISA) in some compounds such as pindolol and acebutolol could in theory translate into some beneficial effects, there is little convincing evidence that partial agonism confers significant clinical benefits. The newer compounds carvedilol and nebivolol produce additional vasodilator features that are attributable either to the additional blockade of α -receptors (carvedilol) or endothelial nitric oxide release (nebivolol). The mode of action of diuretics depends on their major site of action within the nephron (Fig. 1). These differences determine their relative efficacy as expressed in the maximal percentage of filtered sodium excreted. Sixty percent of the filtered sodium is reabsorbed in the proximal tubule of the nephron. Thirty percent is reabsorbed in the thick ascending limb of Henle by $\blacktriangleright Na^+/K^+/2Cl^-$ cotransport ($\blacktriangleright Na^+/K^+/2Cl^-$ cotransporter), which is inhibited by loop diuretics. Seven percent is reclaimed by Na^+/Cl^- cotransport in the distal convoluted tubule, which is inhibited by thiazide diuretics. The last 2% is reabsorbed via the \blacktriangleright epithelial Na^+ channel (ENaC) in the cortical collecting duct, which is a target either directly (amiloride, triamterene) or indirectly via the mineralocorticoid receptor (spironolactone) for potassium-sparing agents (Fig. 1).

Antihypertensive Drugs. Figure 1 Site of action of different classes of antihypertensive drugs. Antihypertensive drugs are directed against a variety of pharmacological targets in various cell types in different organs involved in blood pressure control. The most important targets in the brain, heart, vasculature (vascular smooth muscle cells), and the kidney (nephron) are shown. *Some diuretics produce some direct vasodilation; # non-ACE, conversion of angiotensin I (Ang I) to angiotensin II (Ang II) may occur independent from ACE due to the activity of other enzymes in different tissues such as chymase in the heart; DCT, distal convoluted tubule; CCT, cortical collecting duct; TAL, thick ascending limb of the loop of Henle; (-), indicates inhibition. Modified according to reference 3.

Agents acting in the proximal tubule are seldom used to treat hypertension. Treatment is usually initiated with a thiazide-type diuretic. Chlorthalidone and indapamide are structurally different from thiazides but are functionally related. If renal function is severely impaired (i.e., serum creatinine above 2.5 mg/dl), a loop diuretic is needed. A potassium-sparing agent may be given with the diuretic to reduce the likelihood of hypokalemia.

By themselves, potassium-sparing agents are relatively weak antihypertensives. In general, there are four ways to reduce the activity of the RAS. The first way is the use of β -blockers to reduce renin release from the juxtaglomerular (JG). The second way, the direct inhibition of the activity of renin, although being actively investigated has not been successful in the clinical arena thus far. The third way is to inhibit the activity of the

► **angiotensin converting enzyme (ACE)**, which converts the inactive decapeptide angiotensin I to the potent octapeptide angiotensin II (Ang II), by agents referred to as ACE inhibitors. Thus, these agents inhibit the biosynthesis of Ang II and thereby decrease the availability of Ang II at both angiotensin type 1 (AT₁) and angiotensin type 2 (AT₂) receptors. The fourth way is to use a competitive and selective antagonist at the AT₁ receptor (i.e., AT₁ antagonists) and thereby to inhibit the classical effects mediated by Ang II such as vasoconstriction and aldosterone release. ACE inhibitors exhibit additional effects that are independent from RAS such as on kinins, since ACE is also a kininase. Although the clinical relevance is not fully understood, blood pressure effects mediated via inhibition of breakdown of bradykinin may contribute to the vasodilatory effects of ACE inhibitors. Some of the latter effects could be mediated via kinin stimulation of prostaglandin production. In addition to these effects on vascular tone, multiple other effects may contribute to the antihypertensive effects of ACE inhibitors. The blunting of the expected increase in sympathetic nervous activity typically seen after vasodilation is potentially of greater importance for the documented clinical benefits of ACE inhibitors. As a result, heart rate is not increased as is seen with direct vasodilators, α -blockers and less pronounced with dihydropyridine calcium channel blockers. The presence of the complete RAS within various tissues including the vasculature, kidney, heart and brain has been demonstrated and the activation of the RAS at the tissue level seems to play - beyond its role on blood pressure regulation - an important role for the manifestation and progression of hypertensive target organ damage in these organs. Our understanding of the molecular mechanisms by which Ang II contributes to both structural and functional changes, e.g., due to its growth factor capacity,

at the tissue level continues to expand. Consequently, the inhibition of tissue ACE may play an important role for the prevention and regression of hypertensive target organ damage that has been documented for these agents in experimental and clinical studies.

The major obvious difference between AT₁ antagonists and ACE inhibitors is the absence of an increase in kinins that may be responsible for some of the beneficial effects of ACE inhibitors and probably their side effects. Direct comparison between the two types of drugs show little differences in antihypertensive efficacy but cough, a common side effect seen with ACE inhibitors, is not provoked by AT₁ antagonists, although angioedema and aguesia have also been reported for these newer agents.

Clinical Use (Including Side Effects)

Recent consensus committees, including the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI) and the World Health Organization-International Society of Hypertension (WHO-ISH) Guidelines Subcommittee, have modified traditional treatment recommendations in several important ways.

Criteria for initiation of drug treatment now take into consideration total cardiovascular risk rather than blood pressure alone, such that treatment is now recommended for persons whose blood pressure is in the normal range but still bear a heavy burden of cardiovascular risk factors. Thus, the role of simultaneous reduction of multiple cardiovascular risk factors in improving prognosis in hypertensive patients is stressed. In addition, more aggressive blood pressure goals are recommended for hypertensive patients with comorbid conditions such as diabetes mellitus or renal insufficiency.

Antihypertensive Drugs. Table 1 Common side effects of antihypertensive drugs

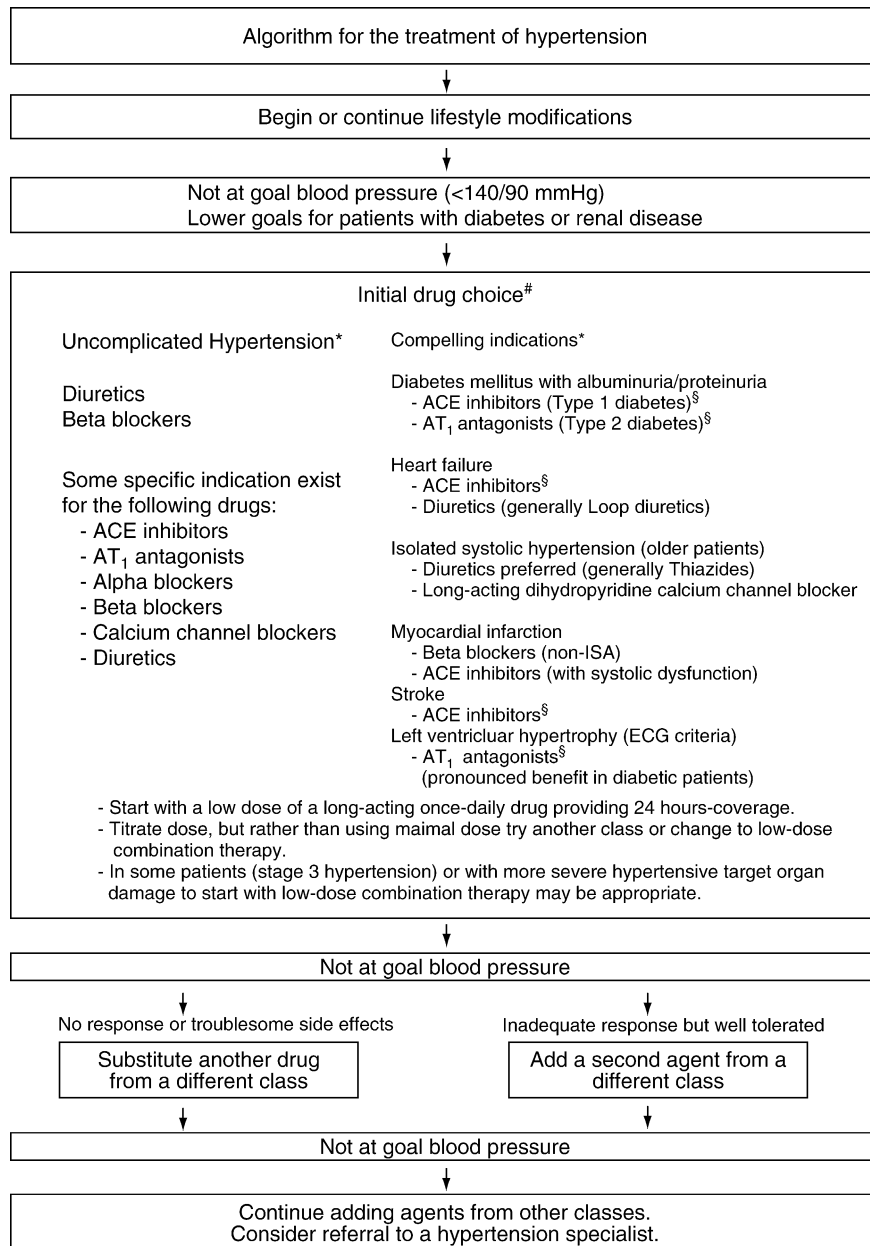

Class of drug		Side effects
ACE inhibitors		Cough, hyperkalemia, skin reactions
AT ₁ -antagonists		Hyperkalemia (less frequent compared with ACE inhibitors)
Calcium channel blockers	Dihydropyridine	Pedal edema, headache
	Nondihydropyridine	Constipation (verapamil); headache (diltiazem)
Diuretics		Frequent urination, hyperuricemia, hyperglycemia, hyperlipidemia
Centrally acting drugs	α 2-Receptor agonists	Sedation, dry mouth, rebound hypertension
	Imidazoline-receptor agonists	
Central neuronal blockers (reserpine)		Depression, sedation, nasal congestion
α -Blockers		Orthostatic hypotension, rapid drop of blood pressure after first dose, pedal edema, dizziness
β -Blockers		Fatigue, hyperglycemia, bronchospasm
Potassium channel openers		Hypertrichosis (minoxidil); lupus-like reactions and pedal edema (hydralazine)

Modified according to reference 3.

Finally, drug treatment in the elderly is of great importance and warrants special attention with regard to safety and tolerability, since systolic blood pressure is recognized as an important target for treatment, particularly in older persons. The benefits of antihypertensive treatment in the elderly and in patients with isolated systolic hypertension are greater than in younger persons.

As a consequence for drug treatment, an increasing number of patients will be treated with antihypertensive

compounds and the importance of tailoring the choice of antihypertensive drug treatment to the patient's individual profile of concomitant cardiovascular risk factors/comorbid conditions has to be emphasized. Moreover, it is reasonable to individualize antihypertensive treatment on the basis of each patient's personal needs with respect to tolerability, convenience and quality of life. Initiation of treatment with a drug that is expected to be well tolerated and therefore likely to be effective in lowering blood pressure over time is

Antihypertensive Drugs. Figure 2 Algorithm for the treatment of hypertension. # Unless contraindicated; *based on randomized controlled trials; § Evidence suggests that the beneficial effects of ACE inhibitors can be duplicated with AT₁ antagonists (and probably vice versa). Thus, ACE inhibitors could be substituted by AT₁ antagonists in the case of troublesome side effects, such as cough under treatment with ACE inhibitors. Modified according to reference 5.

prudent (common side effects are listed in Table 1). Long-acting agents are preferable because adherence to therapy and consistency of blood pressure control are superior when the drug is taken once a day. Low-dose, fixed-dose combination therapy can be used in place of monotherapy as initial treatment or as an alternative to adding a second agent of a different therapeutic class to unsuccessful monotherapy. The advantage of this approach is that low doses of drugs that act by different mechanisms may have additive or synergistic effects on blood pressure with minimal dose-dependent adverse effects. Giving the patient a single tablet provides an additional benefit. A case in point represents the well-established combination of an ACE inhibitor or AT1-antagonist with low-dose hydrochlorothiazide, which does not produce more side effects than placebo.

Many of the concepts of antihypertensive treatment put forward are adopted from the algorithms recommended by the JNC VI (Fig. 2). Treatment should always include lifestyle modifications. For the minority of hypertensive patients without comorbid conditions, target organ damage, or concomitant cardiovascular disease, the JNC VI recommends starting drug therapy with a diuretic (i.e., thiazides) or β -blocker because these agents had been proven to lower morbidity and mortality compared with placebo in randomized controlled trials. Secondly, they are less costly than newer classes of drugs. Therefore, the era of placebo-controlled trials is past and any new agents can only be compared against the gold standard of diuretics and β -blockers. Overall, these early trials with diuretics and β -blockers established a greater reduction of risk related to stroke (−40%) than the risk related to coronary heart disease (−14%). While diuretics are more effective in preventing stroke than β -blockers the opposite holds true for cardiac risk. A reduction in cardiovascular risk has also been documented for the ACE-inhibitor captopril and in elderly patients with isolated systolic hypertension for the dihydropyridine calcium channel blocker (nitrendipine). However, outcome trials comparing two anti-hypertensives require large groups of patients, because the risk in patients with mild-to-moderate essential hypertension is low, and intervention trials are usually limited to duration of 5 years. Therefore, differences between drug classes have been documented when patients with higher absolute cardiovascular risk and/or comorbid conditions were studied. Compelling indications that have been established in randomized controlled trials are summarized in Fig. 2.

Anti-integrins

SHAKER A. MOUSA

Albany College of Pharmacy, Albany, NY, USA

Definition

Integrins are a widely expressed family of cell adhesion receptors via which cells attach to extracellular matrices either to each other or to different cells. All integrins are composed of $\alpha\beta$ heterodimeric units (Fig. 1), expressed on a wide variety of cells, and most cells express several integrins. The interaction of integrins with the cytoskeleton and extracellular matrix appears to require the presence of both subunits. The binding of integrins to their ligands is cation-dependent. Integrins appear to recognize specific amino acid sequences in their ligands. The best studied is the RGD sequence found within a number of ▶matrix proteins including fibrinogen, vitronectin, fibronectin, thrombospondin, osteopontin and VWF (Fig. 1). However, other integrins bind to ligands via non-RGD binding domain such as the $\alpha4\beta1$ integrin receptors that bind and recognize the LDV sequence within the CS-1 region of fibronectin. There are at least 8 known β subunits and 14 α subunits [1]. Although the association of the different β and α subunits

Anti-integrins. Figure 1

could in theory result in more than 100 integrins, the actual diversity is restricted.

Basic Characteristics

Integrin adhesion receptors contain an extracellular face that engages adhesive ligands and a cytoplasmic face that engages with intracellular proteins. The interactions between the cell adhesion molecules and extracellular matrix proteins are critical for cell adhesion and for anchorage-dependent signaling reactions in normal and pathological states. For example, platelet activation induces a conformational change in integrin α IIb/ β 3, thereby converting it into a high affinity fibrinogen receptor. Fibrinogen binding then triggers a cascade of protein tyrosine kinases, phosphatases and recruitment of numerous other signaling molecules into F-actin-rich cytoskeletal assemblies in proximity to the cytoplasmic tails of α IIb and β 3 [2]. These dynamics appear to influence platelet functions by coordinating signals emanating from integrins and G protein-linked receptors. Studies of integrin mutations confirm that the cytoplasmic tails of α IIb/ β 3 are involved in integrin signaling presumably through direct interactions with cytoskeletal and signaling molecules [2]. Blockade of fibrinogen binding to the extracellular face of α IIb/ β 3 has been shown to be an effective way to prevent arterial **thrombosis** after coronary angioplasty in myocardial infarction and unstable angina patients [2].

Mechanism of Action and Clinical Use Pathophysiology and Therapeutic Potential

The role of integrins has been found in various pathological processes, including **angiogenesis**,

thrombosis, apoptosis, cell migration and proliferation. These processes lead to both acute and chronic diseases such as ocular diseases, metastasis, unstable angina, myocardial infarction, stroke, **osteoporosis**, and a wide range of inflammatory diseases, vascular remodeling and neurodegenerative disorders. A breakthrough in this field is evident from the role of the platelet α IIb/ β 3 integrin in the prevention, treatment and diagnosis of various thromboembolic disorders. Additionally, significant progress in the development of leukocyte α 4 β 1 antagonists for various inflammatory indications and α v integrin antagonists for angiogenesis and vascular-related disorders has been achieved.

β 1 Integrins

α 4 β 1 Integrin

The largest numbers of integrins are members of the β 1 integrins, also known as the very late antigen (VLA) subfamily because of its late appearance after activation. There are at least seven receptors characterized from this subfamily, each with different ligand specificity. Among the most studied include the α 4 β 1 and α 5 β 1 receptors. The leukocyte integrin α 4 β 1 is a cell adhesion receptor that is predominantly expressed on lymphocytes, monocytes and eosinophils.

Potent and Selective Small Molecule Antagonists of α 4 β 1 Integrins

The α 4 β 1 integrins are heterodimeric cell surface molecules central to leukocyte-cell and leukocyte-matrix adhesive interactions. The integrin α 4 β 1, expressed on all leukocytes except neutrophil, interacts with the immunoglobulin superfamily member VCAM-1 and with an alternately spliced form of fibronectin. Additionally, the integrin α 4 β 7 is also restricted to leukocytes and can bind not only to VCAM1 and fibronectin, but also to MAdCAM the mucosal addressin or homing receptor, which contains Ig-like domains related to VCAM-1. *In vivo* studies with α 4 β 1 monoclonal antibodies in several species demonstrate that the interactions between these integrins and their ligands play a key role in immune and **inflammatory disorders** [3] and selected ones are in clinical trials.

α 5 β 1 Integrin in Angiogenesis

In contrast to collagen, expression of the extracellular matrix protein fibronectin in provisional vascular matrices precedes permanent collagen expression and provides signals to vascular cells and fibroblasts during blood clotting and wound healing, atherosclerosis and hypertension. Fibronectin expression is also upregulated on blood vessels in granulation tissues during wound healing. These observations suggest a possible role for this isoform of fibronectin in angiogenesis. Evidence was recently provided that both fibronectin and its receptor integrin α 5 β 1 directly

regulate angiogenesis [4]. Thus, integrin antagonist for $\alpha 5\beta 1$ integrin might be a useful target for the inhibition of angiogenesis associated with human tumor growth; neovascular related ocular and inflammatory diseases.

$\alpha 5\beta 1$ Integrin and Bacterial Invasion

Recent studies suggested a key role for $\alpha 5\beta 1$ integrin in certain bacterial invasion of human host cells leading to antibiotic resistance [5].

$\beta 3$ Integrins

Intravenous and Oral Platelet IIb/ $\beta 3$ Receptor

Antagonists: Potential Clinical Utilities

There is an urgent need for more efficacious antithrombotic drugs superior to aspirin or ticlopidine for the prevention and treatment of various cardiovascular and cerebrovascular thromboembolic disorders. The realization that the platelet integrin $\alpha IIb\beta 3$ is the final common pathway for platelet aggregation regardless of the mechanism of action prompted the development of several small molecule $\alpha IIb/\beta 3$ receptor antagonists for intravenous and/or oral antithrombotic utilities. Platelet $\alpha IIb/\beta 3$ receptor blockade represents a very promising therapeutic and diagnostic strategy of thromboembolic disorders. Clinical experiences (efficacy/safety) gained with injectable but not oral $\alpha IIb\beta 3$ antagonists (Abciximab, Eptifibatide, Aggrastat) elucidate the safety and efficacy of this mechanism in combination with other antiplatelet and anticoagulant therapies.

Orally Active GPIIb/IIIa Antagonists

A high level of platelet antagonism has been required when GPIIb/IIIa antagonists have been employed for acute therapy of coronary arterial diseases using intravenous GPIIb/IIIa antagonists with heparin and aspirin. Interaction with aspirin and other antiplatelet and anticoagulant drugs lead to shifts in the dose-response curves for both efficacy and unwanted side effects, such as increased bleeding time. More recently, all oral GPIIb/IIIa antagonists with or without aspirin but not with anticoagulant were withdrawn because of a disappointing outcome (no clinical benefit or increased thrombotic events). This raises a lot of serious questions with regard to the potential of oral GPIIb/IIIa antagonists as compared to the well-documented success of intravenous GPIIb/IIIa antagonists.

GPIIb/IIIa Integrin Receptor Antagonists in the Rapid Diagnosis of Thromboembolic Events

The role of the platelet integrin GPIIb/IIIa receptor and its potential utility as a radio-diagnostic agent in the rapid detection of thromboembolic events has been demonstrated [6]. This approach may be useful for the noninvasive diagnosis of various thromboembolic disorders.

Integrin $\alpha v\beta 3$ Antagonists Promote Tumor Regression by Inducing Apoptosis of Angiogenic Blood Vessels

Antagonists of integrin $\alpha v\beta 3$ inhibit the growth of new blood vessels into tumors cultured on the chick chorioallantoic membrane without affecting adjacent blood vessels, and also induce tumor regression [7]. Antagonists of $\alpha v\beta 3$ also inhibit angiogenesis in various ocular models of retinal neovascularization [7].

Integrin $\alpha v\beta 3$ in Restenosis

The calcification of atherosclerotic plaques may be induced by osteopontin expression, since osteopontin is a protein with a well-characterized role in bone formation and calcification. Vascular smooth muscle cell migration on osteopontin is dependent on the integrin $\alpha v\beta 3$ and antagonists of $\alpha v\beta 3$ prevent both smooth muscle cell migration and restenosis in some animal model [8].

Integrin $\alpha v\beta 3$ Antagonists Versus Anti- $\alpha v\beta 3$ and $\alpha v\beta 5$

Since the recognition of at least two αv integrin pathways for cytokine-mediated angiogenesis, $\alpha v\beta 3$ and $\alpha v\beta 5$ antagonists may be more effective in certain indications as compared to a specific anti- $\alpha v\beta 3$. However, further work is needed to document this notion.

Potential Role of $\alpha v\beta 3$ Antagonists in Osteoporosis

RGD analogs have been shown to inhibit the attachment of osteoclasts to bone matrix and to reduce bone resorptive activity *in vitro*. The cell surface integrin, $\alpha v\beta 3$, appears to play a role in this process. RGD analogs may represent a new approach to modulating osteoclast-mediated bone resorption and may be useful in the treatment of osteoporosis [9].

Integrins $\alpha v\beta 3$ Ligands

Therapeutics: A number of potent small molecule antagonists for $\alpha v\beta 3$ integrin are under preclinical investigations for various angiogenesis or vascular-mediated disorders [10].

Site directed delivery: This approach of conjugating $\alpha v\beta 3$ integrin ligand with a chemotherapeutic agent for optimal efficacy and safety in cancer is under investigation. Earlier work demonstrated the validity of this concept [10].

Diagnostics: Imaging metastatic cancer using technetium-99m labeled RGD-containing synthetic peptide has been demonstrated. Additionally, detection of tumor angiogenesis *in vivo* by $\alpha v\beta 3$ -targeted magnetic resonance imaging (MRI) was demonstrated [10].

Synonyms

Anticancer antimetabolites; Antimetabolic agents; Antineoplastic antimetabolites

Definition

Antimetabolites compete with and possibly oust naturally occurring metabolites required for normal biochemical reactions and lead either to the synthesis of malfunctioning macromolecules and/or blockade of necessary intermediate or final metabolic products that are vital to cell survival. Both processes interfere with DNA synthesis and therefore antimetabolites can be used in cancer treatment, as they inhibit cell division and the growth of tumors.

Mechanism of Action

A broad description of antimetabolites would include compounds with structural similarity to precursors of purines or pyrimidines or agents that interfere with purine and pyrimidine synthesis. Antimetabolites can cause either DNA damage indirectly through misincorporation into DNA followed by abnormal timing or progression through DNA synthesis, or altered function of enzymes involved in pyrimidine and purine synthesis. All antimetabolites tend to exert greatest cytotoxicity in the S-phase of cells and the duration of exposure is of great importance. The antimetabolite activity is rather unselective and affects all fast proliferating cells. In contrast to alkylating agents, second malignancies are not associated with their use. The following is a list of commonly used antimetabolites [1].

1. Folate antagonists
 - Methotrexate
 - Ralitrexed
 - Pemetrexed (alimta)
2. Purine antagonists
 - Mercaptopurine (6-MP)
 - Thioguanine (6-TG)
 - Pentostatine
 - Fludarabine phosphate (fludara, F-ara-A)
3. Pyrimidine antagonists
 - Fluorouracil (5-FU)
 - Cytosine arabinoside (cytarabine, Ara C)
 - Gemcitabine (gemzar)

Some newly introduced pyrimidine analogs (e.g., azacitidine and decitabine) differ in their mechanism of action to such a degree from the other antimetabolites that they are subgrouped under the heading DNA de- or ► **hypomethylating agents** (see below).

Methotrexate (MTX, chemical structure shown in Fig. 1.) competitively inhibits the dehydrofolate reductase, an enzyme that plays an essential role in purine synthesis. The dehydrofolate reductase regenerates reduced folates when thymidine monophosphate is formed from deoxyuridine monophosphate. Without reduced folates cells are unable to synthesize thymine. Administration of *N*-5 tetrahydrofolate or *N*-5 formyl-tetrahydrofolate (folinic acid) can bypass this block and rescue cells from methotrexate activity by serving as antidote.

Antimetabolites. Figure 1 Chemical structure of methotrexate.

MTX and naturally occurring reduced folates are transported into cells by the folate carrier which has a higher affinity to MTX than to the natural folates. Inside of cells, MTX will be polyglutamated and thus enter a deep compartment from which it can be released again only slowly. High extracellular concentrations can bypass this carrier by passive diffusion. MTX is well absorbed orally and at usual dosages half of its level is bound to plasma proteins. After intravenous application the decay is triphasic: distribution phase; initial elimination and a prolonged elimination, the latter corresponding to the slow release from the intracellular polyglutamate compartment.

Clinical Use (including Side-Effects)

This scenario is the background for designing high dose methotrexate regimens with leucovorin rescue of normal hematopoietic and mucosa cells as part of curative therapy schedules for osteosarcoma and hematological neoplasias of children and adults. Methotrexate is cleared from the plasma by the kidney by both glomerular filtration and tubular secretion. Therefore the toxicity of this drug is augmented by renal dysfunction.

MTX is part of curative therapeutic schedules for acute lymphoblastic leukemias (ALL), Burkitt's lymphoma, and choriocarcinoma. It was also used in adjuvant therapy of breast cancer. High dose MTX with leucovorin rescue can induce about 30% remissions in patients with metastatic osteogenic sarcoma. MTX is one of the few antineoplastic drugs that can be safely administered intrathecally for the treatment of meningeal metastases and leukemic infiltrations (routine prophylaxis in ALL). In addition, MTX can be used as an immunosuppressive agent for the treatment of severe rheumatoid arthritis and psoriasis.

Myelosuppression is the major dose-limiting side effect. Gastrointestinal toxicity may appear as ulcerative mucositis and diarrhea. Nausea and vomiting, alopecia, and skin inflammation are common following high-dose MTX treatment. Renal toxicity has major impact for high-dose regimens with MTX and the drug should not be used in patients with renal injury. ▶**Intrathecal application** may be associated with mild arachnoiditis or severe and progressive myeloencephalopathy. Chronic low dose MTX may cause cirrhosis of the liver. MTX is a potent ▶**teratogen** and abortifacient.

Ralitrexed is a folate analog with greater selectivity. It easily crosses the cell membrane and undergoes polyglutamation. Within tissues, ralitrexed may be stored up to 29 days. It directly inhibits thymidylate synthase, the key enzyme for synthesizing thymidine triphosphate (TTP). The drug has been described to induce apoptosis in tumor cells. Ralitrexed is used for the treatment of colon carcinomas.

Pemetrexed is an antifolate ▶**antineoplastic agent** that exerts its action by disrupting folate-dependent metabolic processes essential for cell replication. Pemetrexed disodium heptahydrate has the chemical name L-Glutamic acid, *N*-[4-[2-(2-amino-4,7-dihydro-4-oxo-1*H*-pyrrolo[2,3-*d*]pyrimidin-5-yl)ethyl]benzoyl]-, disodium salt, heptahydrate. Pemetrexed is an antifolate containing the pyrrolopyrimidine-based nucleus that exerts its antineoplastic activity by disrupting folate-dependent metabolic processes essential for cell replication. In vitro studies have shown that pemetrexed also inhibits thymidylate synthase (TS), dihydrofolate reductase (DHFR), and glycinamide ribonucleotide formyltransferase (GARFT), which are all folate-dependent enzymes involved in the de novo biosynthesis of thymidine and purine nucleotides. Pemetrexed is transported into cells by both the reduced ▶**folate** carrier and the membrane folate binding protein transport systems. Once in the cell, pemetrexed is converted to polyglutamate forms by the enzyme folylpolyglutamate synthetase. The polyglutamate forms are retained intracellular and are inhibitors of TS and GARFT. Polyglutamation is a time- and concentration-dependent process that occurs in tumor cells and, to a lesser extent, in normal tissues. Polyglutamated metabolites have an increased intracellular half-life resulting in prolonged drug action in malignant cells. Preclinical studies have shown that pemetrexed inhibits the in vitro growth of mesothelioma cell lines, an effect which was synergistically increased in combination with cisplatin.

The recommended dose of pemetrexed is 500 mg/m² administered as an intravenous infusion over 10 min on Day 1 of each 21-day cycle. Pemetrexed is not metabolized to an appreciable extent and is primarily eliminated in the urine, with 70-90% of the dose recovered unchanged within the first 24 h following administration. Pemetrexed has a steady-state volume of distribution of 16.1 L. Pemetrexed is highly bound (approximately 81%) to plasma proteins. Binding is not affected by the degree of renal impairment. Plasma

clearance of pemetrexed in the presence of cisplatin decreases as renal function decreases, with increase in systemic exposure. Patients with creatinine clearances of 45, 50, and 80 mL/min had 65%, 54%, and 13% increases, respectively in pemetrexed total systemic exposure (AUC) compared to patients with creatinine clearance of 100 mL/min. Pemetrexed in combination with cisplatin is used for the treatment of patients with malignant pleural mesothelioma. As a single agent it is used for treating patients with locally advanced or metastatic non-small cell lung cancer after prior ►chemotherapy. The main dose-limiting side effect is myelosuppression. Skin rashes and neurotoxic reactions have been recorded, too.

Mercaptopurine (6-MP, Fig. 2) is an analog of hypoxanthine and was one of the first agents shown to be active against acute leukemias. It is part of maintenance therapy for ALL. Mercaptopurine has to be activated by hypoxanthine guanine-phosphoribosyl-transferase (HGPRTase) to 6-MP monophosphate. This metabolite inhibits the synthesis of adenine and guanine at the initial aminotransferase step and suppresses the conversion of inosinic acid to adenylylate and guanylate. Some part of the drug is also incorporated into DNA in the form of thioguanine. Resistance to 6-MP may be associated with decreased drug activation by HGPRTase or increased inactivation by the alkaline phosphatase. The drug is slightly bound (20%) to plasma proteins and does not cross the blood-brain barrier. Xanthine oxidase is the primary enzyme responsible for its metabolic inactivation.

The plasma half-life of 6-MP after intravenous bolus injection is 21 min in children and is twofold greater in adults. After oral intake peak levels are attained within 2 h. 6-MP is used for the treatment of ALL and has shown certain activity in chronic myelogenous leukemia. The major side effects involve myelosuppression, nausea, vomiting, and hepatic injury.

Thioguanine (6-thioguanine, 6-TG; Fig. 3) is an analog of guanine in which a hydroxyl group has been substituted by a sulfhydryl group in position 6 of the purine ring. The mode of action involves two mechanisms: incorporation into DNA or RNA; and feedback inhibition of purine synthesis. Similarly to 6-MP, 6-TG undergoes initial activation by the enzyme HGPRTase. The corresponding monophosphate can be eventually

Antimetabolites. Figure 2 Chemical structure of mercaptopurine.

converted to deoxy-6-thioguanosine-triphosphate (dTGTP) and subsequently incorporated into DNA. Resistance to thioguanine has been correlated with decreased activity of HGPRTase and to inactivation by alkaline phosphatase. After oral intake the drug is slowly absorbed and peak levels of metabolites occur only after 6-8 h. Within the first 24 h a part (up to 46%) of the dose administered is excreted via the urine.

Thioguanine is used primarily as part of induction chemotherapy regimens for acute myelogenous leukemia (AML).

The most common adverse effects are myelosuppression, with leukopenia and thrombocytopenia appearing 7-10 days after treatment, as well as mild nausea. Liver toxicity with jaundice has been reported in rare cases.

Pentostatin (deoxycoryformycin; Fig. 4) is a purine isolated from cultures of *Streptomyces antibioticus*. Its mode of action involves inhibition of adenosine deaminase, which plays a key role in purine salvage pathways and DNA synthesis. As a consequence, deoxyadenosine triphosphate (dATP) is accumulated, which is highly toxic to lymphocytes. This is associated with augmented susceptibility to apoptosis, particularly in T cells.

Pentostatin is effective in the treatment of hairy cell leukemia, producing 80-90% remissions (with a complete remission rate of more than 50%). The common side effects of pentostatin include myelosuppression, nausea, and skin rashes. Renal failure,

Antimetabolites. Figure 3 Chemical structure of thioguanine.

Antimetabolites. Figure 4 Chemical structure of pentostatin (nipent).

immunosuppression and CNS dysfunction have also been observed.

Cladribine (2-Chlordeoxyadenosine) is a synthetic purine nucleoside that is converted to an active cytotoxic metabolite by the deoxycytidine kinase. The drug is relatively selective for both normal and malignant lymphoid cells.

Cladribine is highly active against hairy cell leukemia (complete remissions were achieved in more than 60% of patients receiving a single 7-day course). Activity has been recorded in other low-grade lymphoid malignancies. The major side effect is myelosuppression.

Fludarabine is a fluorinated purine analog of the antiviral drug vidarabine. The active metabolite, 2-fluoro-adenosine-arabinoside triphosphate (F-ara-A), inhibits various enzymes involved in DNA synthesis such as DNA-polymerase- α , ribonucleotide reductase, and DNA primase. F-ara-A is incorporated into DNA and can cause delayed cytotoxicity even in cells with low growth fraction, e.g., CLL and follicular B cell lymphoma. Unlike typical antimetabolites, it is toxic to nonproliferating cells of lymphoid origin. The drug is highly active against chronic lymphocytic leukemia (CLL) with approximately 40% of patients achieving remission after previous therapy with alkylating agents. Therapeutic responses can also be seen in low-grade lymphomas. Dose-limiting side effect is myelosuppression that contributes to fevers and infections in half of treated patients. Occasional neurotoxicity (agitation, confusion, visual disturbances) has been noted at higher doses. Recently, an oral drug formulation has been developed.

Fluorouracil (5-fluorouracil, 5-FU, Fig. 5) represents an early example of "rational" drug design in that it originated from the observation that tumor cells, especially from gut, incorporate radiolabeled uracil more efficiently into DNA than normal cells. 5-FU is a fluorinated pyrimidine analog that must be activated metabolically. In the cells 5-FU is converted to 5-fluoro-2'-deoxyuridine-monophosphate (FdUMP). This metabolite inhibits thymidilate synthase which catalyses the conversion of uridylate (dUMP) to thymidilate (dTMP) whereby methylenetetrahydrofolate plays the role of the carbon-donating cofactor. The reduced folate cofactor occupies an allosteric site of

Antimetabolites. Figure 5 Chemical structure of 5-fluorouracil.

thymidilate synthase, which allows for the covalent binding of 5-FdUMP to the active site of the enzyme. In addition, misincorporation can induce single strand breaks, and RNA can aberrantly incorporate FdUMP. Leucovorin augments the activity of 5-FU by promoting formation of the ternary covalent complex consisting of 5-FU, the reduced folate, and thymidilate synthase. The drug is selectively toxic to proliferating rather than nonproliferating cells and is active in both the G1- and S-phases of the cell cycle. 5-FU is metabolized by dihydropyrimidine dehydrogenase and therefore deficiency of this enzyme can lead to excessive toxicity from 5-FU.

Capecitabine is a special prodrug of 5-FU. It is readily absorbed from the gastrointestinal tract. In the liver, a carboxylesterase hydrolyzes much of the compound to 5'-deoxy-5-fluorocytidine (5'-DFCR). Cytidine deaminase, an enzyme found in most tissues, including tumors, subsequently converts 5'-DFCR to 5'-deoxy-5-fluorouridine (5'-DFUR). Finally, the enzyme thymidine phosphorylase (dThdPase or TP), hydrolyzes 5'-DFUR to the active drug 5-FU. Both normal and tumor cells metabolize 5-FU to 5-fluoro-2'-deoxyuridine monophosphate (FdUMP) and 5-fluorouridine triphosphate (FUTP). These metabolites cause cell injury by two different mechanisms. First, FdUMP and the folate cofactor N5-10-methylene-tetrahydrofolate bind to thymidilate synthase (TS) to form a covalently bound ternary complex. This binding inhibits the formation of thymidilate from 2'-deoxyuridylate. Thymidilate is the necessary precursor of thymidine triphosphate, which is essential for the synthesis of DNA, so that a deficiency of this compound can inhibit cell division. Second, nuclear transcriptional enzymes can mistakenly incorporate FUTP in place of uridine triphosphate (UTP) during the synthesis of RNA. This metabolic error can interfere with RNA processing and protein synthesis. The addition of leucovorin to capecitabine is not recommended since there was no apparent advantage in response rate; however, toxicity was increased.

Capecitabine is used for the treatment of colorectal and breast cancers. It is contraindicated in patients with known hypersensitivity to capecitabine or any of its components or to 5-fluorouracil and in patients with known dihydropyrimidine dehydrogenase (DPD) deficiency. The use of capecitabine is restricted in patients with severe renal impairment. The drug can induce diarrhea, sometimes severe. Other side effects include anemia, hand-foot syndrome, hyperbilirubinemia, nausea, stomatitis, pyrexia, edema, constipation, dyspnea, neutropenia, back pain, and headache. Cardiotoxicity has been observed with capecitabine. A clinically important drug interaction between capecitabine and warfarin has been demonstrated. Care should be exercised when the drug is co-administered with CYP2X9 substrates.

Cytarabine (cytosine arabinoside, ara C, Fig. 6) is an analog of the pyrimidine nucleosides. It is one of the most potent agents available for treating acute myeloid leukemia. The drug must first be activated by pyrimidine nucleoside kinase to the triphosphate nucleotide ara-cytosine triphosphate (ara-CTP). The susceptibility of tumor cells to cytarabine is thought to be a reflection of their ability to activate the drug more rapidly by kinases than to inactivate it by deaminases. Cytarabine is incorporated into DNA and kills cells during the S-phase of the cycle by competitively inhibiting the DNA polymerase.

The drug is metabolized rapidly in the liver, kidney, intestinal mucosa, and even red blood cells. Therefore it has a plasma half-life of only 10 min after bolus intravenous application. The major metabolite, uracil arabinoside (ara-U), can be detected in the blood shortly after cytarabine administration. About 80% of the dose is excreted in the urine within 24 h, with less than 10% appearing as cytarabine; the remainder is ara-U. After continuous infusion, cytarabine levels in the liquor (cerebro-spinal fluid) approach 40% of that in plasma. Continuous infusion schedules allow maximal efficiency, with uptake peaks of 5-7 μM . It can be administered intrathecally as an alternative to methotrexate.

Cytarabine is used in the chemotherapy of acute myelogenous leukemia, usually in combination with anthracyclines, thioguanine, or both. It is less useful in acute lymphoblastic leukemia and lymphomas and has marginal activity against other tumors. Myelosuppression is a major toxicity, as is severe bone marrow hypoplasia; nausea and mucositis may also occur.

Gemcitabine (Fig. 7) is a cytosine derivative that is very similar to ara C. It undergoes metabolic activation to difluorodeoxycytidine triphosphate, which interferes

with DNA synthesis and repair. Gemcitabine causes the so called masked termination of DNA elongation. After incorporation into the DNA strand a normal nucleotide is further added. Therefore, DNA repair enzymes can not recognize and reconstruct the damaged DNA. In contrast to ara C, gemcitabine appears to have useful activity in a variety of solid tumors, with limited nonmyelosuppressive toxicities. Gemcitabine is a well known inducer of apoptosis at micro- to nanomolar concentrations. It is administered by intravenous infusion and has pharmacokinetics similar to ara C.

The usual dose consists of 1000 mg/m^2 i.v. It is the most active single agent for treating pancreatic cancer, and it is used as a first-line treatment for both pancreatic and small cell lung cancers. The dose-limiting toxicity is bone marrow suppression.

Azacitidine (5-aza-cytidine, Fig. 8) is a pyrimidine nucleoside analog of cytidine. The structural formula is

Antimetabolites. Figure 7 Chemical structure of gemcitabine (gemzar).

Antimetabolites. Figure 6 Chemical structure of cytarabine (ara C).

Antimetabolites. Figure 8 Chemical structure of Azacitidine (4-amino-1- β -D-ribofuranosyl-s-triazin-2 (1H)-one).

shown in Fig. 8. Azacitidine is believed to exert its antineoplastic effects by causing hypomethylation of DNA and direct cytotoxicity on abnormal hematopoietic cells in the bone marrow. The concentration of azacitidine required for maximum inhibition of DNA methylation in vitro does not cause major suppression of DNA synthesis. Hypomethylation may restore normal function to genes that are critical for differentiation and proliferation. The cytotoxic effects of azacitidine cause the death of rapidly dividing cells, including cancer cells that are no longer responsive to normal growth control mechanisms. Nonproliferating cells are relatively insensitive to azacitidine.

The pharmacokinetics of azacitidine shows that it is rapidly absorbed after s.c. administration; with the peak plasma concentration occurring after 0.5 h. The bioavailability of s.c. azacitidine relative to i.v. azacitidine is approximately 89%. Urinary excretion is the primary route of elimination of azacitidine and its metabolites. The mean elimination half-lives are about 4 h, regardless of i.v. or s.c. administration.

In vitro studies in human liver fractions indicated that azacitidine may be metabolized by the liver. Azacitidine and its metabolites are known to be substantially excreted by the kidney, and the risk of toxic reactions to this drug may be greater in patients with impaired renal function.

Azacitidine is used for treating patients with some myelodysplastic syndrome subtypes and chronic myelomonocytic leukemia. The most commonly occurring adverse reactions include nausea, anemia, thrombocytopenia, vomiting, pyrexia, leucopenia, diarrhea, fatigue, neutropenia, and ecchymosis.

Azacitidine is contraindicated in patients with a known hypersensitivity to azacitidine or mannitol as well as in patients with advanced ▶malignant hepatic tumors.

Decitabine (5-aza-deoxycytosine) is an analog of the nucleoside 2'-deoxycytidine. It is believed to exert its antineoplastic effects after phosphorylation and direct incorporation into DNA and by inhibition of the enzyme DNA methyltransferase, causing hypomethylation of DNA and cellular differentiation or apoptosis. DNA hypomethylation is achieved at concentrations below those required to significantly inhibit DNA synthesis, which may promote restoration of function to genes associated with control of cellular differentiation and proliferation. Cytotoxicity in rapidly dividing cells may also result from covalent adducts between DNA methyltransferase and decitabine.

Decitabine is specifically indicated for the treatment of multiple types of myelodysplastic syndromes and chronic myelomonocytic leukemia. As anticipated, use of decitabine is associated with bone marrow suppression including neutropenia and thrombocytopenia which are the most frequently observed serious adverse effects.

Definition

Cancer or neoplastic disease is a genomic disorder of the body's own cells which start to proliferate and metastasize in an uncontrolled fashion that is ultimately detrimental to the individual. Antineoplastic agents are used in conjunction with surgery and radiotherapy to restrain that growth with curative or palliative intention. The domain of antineoplastic chemotherapy is cancer that is disseminated and therefore not amenable to local treatment modalities such as surgery and radiotherapy.

Development and Characteristics of Cancer Cells

The genesis of cancer cells can be modeled by the formula

$$\text{Cancer} = f\{\text{Exposure, Genetic disposition, Age}\}$$

in which "*Exposure*" denotes the impact of exogenous factors that can be of chemical (chemical carcinogens), physical (UV or γ -irradiation) or biological (viruses, bacteria) origin. "*Genetic disposition*" indicates the germline transmission of genes associated with cancer development and "*Age*" points to the fact that certain cellular injuries which cause mutations and lead to cancer development are not reversible but accumulate with time. Thus, a cancer cell is characterized by genetic abnormalities such as chromosomal alterations, changes in its DNA- methylation status as well as activation of cellular protooncogenes (mainly related to cellular growth) to oncogenes and inactivation of tumor suppressor genes. As result of these changes they show autonomous proliferation, dedifferentiation, loss of function, invasiveness, and metastasis formation. Furthermore, drug resistance (primary or acquired in response to treatment with antineoplastic drugs) is a common phenomenon.

Growth of Cancer Cells

Proliferation of cancer cells is not restricted by ►**contact inhibition** as for normal cells but rather by the supply of growth factors and nutrients. Once a cell has become malignant and its descendants got the necessary blood supply, the initial growth rate is exponential and follows approximately the pattern shown in Fig. 1. The subsequent loss of logarithmic growth is related to insufficient supply of nutrients which drives cancer cells to either die or exit the cell cycle. As result, larger tumors contain only a certain ratio of dividing cells which is termed growth fraction. The resultant steady state growth is depicted by the so called Gompertz function (Fig. 2).

Mechanism of Action

Anticancer drugs can be grouped into several classes, according to their mechanism of action and origin [1]. These are (i) alkylating agents and related compounds which act by forming covalent bonds with cellular

Antineoplastic Agents. Figure 1 Relationship of cell number, number of cell divisions, and corresponding weight.

Antineoplastic Agents. Figure 2 Growth curve of tumor cells according to Gompertz.

macromolecules such as DNA, (ii) antimetabolites which block metabolic pathways that are vital for cell survival or proliferation, (iii) cytotoxic antibiotics of microbial origin and (iv) plant derivatives which mainly interfere with mammalian cell division, (v) hormonal agents which suppress hormone secretion, block hormone synthesis or antagonize hormone action, (vi) biological response modifiers which enhance the host's response to cancer cells, (vii) antibodies which recognize antigens specific for cancer cells, (viii) tyrosine kinase inhibitors, (ix) antisense oligonucleotides, and (x) miscellaneous agents which do not fit into the classes described above [2].

General effects include cytostatic or cytotoxic effects, the latter being related to killing a constant fraction of cells. The mode of action of antineoplastic agents is not causal for it does not reverse the basal changes that have led to the development of cancer cells but symptomatic since it aims at their destruction, or more recently, on blocking/ablating the result of genetic alterations by inhibiting proteins whose malfunction contributes to the formation and maintenance of cancer cells. However, cytotoxicity is generally not restricted towards cancer cells but for the

majority of currently used, classical antineoplastic drugs (groups 1–4) affects all (quickly) dividing cells, especially those from bone marrow, gastrointestinal tract, hair follicles, gonads, and growing tissues in children (lack of selectivity).

The limited efficacy of classical anticancer drugs can be explained in part by the compartment model of dividing (growth fraction, compartment A) and nondividing (compartment B) cells. The majority of antineoplastic drugs acts upon cycling cells and will hit, therefore, compartment A only.

Alkylating Agents and Related Compounds

Alkylating agents are activated spontaneously or enzymatically to give rise to an electrophilic species that can form covalent bonds with nucleophilic cellular constituents. Reaction of monofunctional agents with DNA bases will lead to single strand breaks, that of bifunctional groups to ►crosslinks between bases of the same strand of DNA (intrastrand crosslink) or two complementary strands (interstrand crosslink). Replicating cells are more susceptible to these drugs since parts of the DNA are unpaired and not protected by proteins. Therefore, although alkylating agents are not cell cycle specific, cells are most susceptible to alkylation in late G1- and S-phases of the cell cycle resulting in block at G2 and subsequent apoptotic cell death.

Cells which survive these damages may have undergone mutations leading themselves to cancer development. This is reason for the carcinogenicity of alkylating agents.

The most important subgroup is that of nitrogen mustard derivatives. Nitrogen mustard was developed in relation to sulfur mustard, the “mustard gas” used during World War I which was found to suppress ►leukopoiesis. Nitrogen mustard was the first drug to induce a remission in a lymphoma patient at the end of World War II, but has been abandoned since then. The highly reactive R-N-bis-(2-chloroethyl) group, however, is part of many drugs in current use, such as cyclophosphamide, melphalan, and chlorambucil. The activity of cyclophosphamide is dependent on P450 mixed function oxidases mediated activation into active and/or toxic metabolites. One of the toxic metabolites is acrolein which causes hemorrhagic cystitis if not prevented by the antidote mesna. Mesna is a sulfhydryl donor and interacts specifically with acrolein, forming a nontoxic compound.

Other subgroups of alkylating agents are the nitrosoureas (examples: carmustine, BCNU; lomustine, CCNU) and the triazines (example: dacarbazine, DTIC). Platinum derivatives (cisplatin, carboplatin, oxaliplatin) have an action that is analogous to that of alkylating agents (formation of crosslinks) and therefore are appended to this class, as well.

Alkylating agents are used for treating solid tumors as well as leukemias and lymphomas. Their broad spectrum of activity is reason for their inclusion into many past and current chemotherapy schedules. Platinum derivatives are especially useful in treating testicular and ovarian cancers. All alkylating agents depress bone marrow function and cause gastrointestinal side effects. With prolonged use depression of gametogenesis will result leading to sterility and an increased risk of leukemias as well as other malignancies.

Antimetabolites

Antimetabolites interfere with normal metabolic pathways. They can be grouped into folate antagonists and analogues of purine or pyrimidine bases. Their action is limited to the S-phase of the cell cycle and therefore they target a smaller fraction of cells as compared with alkylating agents.

The main folate antagonist is methotrexate. In structure, folates are based on three elements: a heterobicyclic pteridine, *p*-aminobenzoic acid and glutamic acid. The latter moiety is polyglutamated within cells which causes a prolonged intracellular half life and, as compared with monoglutamate, an increased affinity to dihydrofolate reductase, the target enzyme of antifolates. This enzyme catalyses the reduction of dihydrofolate to tetrahydrofolate and its inhibition interferes with the transfer of monocarbon units that are needed for purine- and thymidylate synthesis and thus blocks the synthesis of DNA, RNA, and Protein. Methotrexate has a higher affinity for dihydrofolate reductase than the normal substrate (dihydrofolate) and inhibits thymidylate synthesis at a tenfold lower concentration (1 nM) than purine synthesis. Methotrexate is toxic to normal tissues (especially the bone marrow) and causes hepatotoxicity following chronic therapy. Acute toxicity following iatrogenic error or high dose therapy can be rescued by using folinic acid, a form of tetrahydrofolate, as antidote.

Purine- and pyrimidine analogs are characterized by modifications of the normal base or sugar moieties. The uridine analog 5-fluorouracil is converted intracellularly into fluorouridine-monophosphate (FUMP) and fluorodeoxyuridine-monophosphate (FdUMP). Further phosphorylation leads to the respective triphosphates FUTP and FdUTP. FdUMP inhibits the enzyme thymidylate synthase and thus blocks the generation of thymidine whereas FUTP and FdUTP are incorporated into RNA and DNA, respectively. Gemcitabine is a cytosine analog in which the pentose moiety contains two fluorine atoms at position 2 of the sugar ring. This drug is converted into the respective diphosphate, which inhibits ribonucleotide reductase, and the triphosphate, which after incorporation into DNA causes masked termination of DNA chain elongation since the altered base sequence cannot be

efficiently repaired. Cytosine arabinoside is a cytosine analog with a “wrong” pentose which after phosphorylation to the respective triphosphate inhibits the DNA polymerase. The purine analogs mercaptopurine and fludarabine are converted into fraudulent nucleotides and inhibit DNA polymerase. The main unwanted effects are gastrointestinal epithelial cell damage and myelotoxicity.

Cytotoxic Antibiotics

Cytotoxic antibiotics affect normal nucleic acid function by intercalating between DNA bases which blocks reading of the DNA template and also stimulate ►topoisomerase II dependent DNA-double strand breaks. In addition, metabolism of the drugs gives rise to free radicals which cause DNA damage and cytotoxicity, and to membrane effects that occur directly or via oxidative damage. Cytotoxic antibiotics are poorly absorbed from the gut and therefore are given intravenously. They have long half-lives (1–2 days), and are eliminated by metabolism.

Anthracyclins (e.g., doxorubicin, epirubicin, and idarubicin) are the most important subgroup. They consist of a four ringed planar quinone structure attached to an amino sugar group. In addition to the general unwanted effects, anthracyclins can cause cumulative, dose-related cardiotoxicity leading to heart failure and hair loss. Epirubicin is less cardiotoxic than doxorubicin.

Mitoxantrone has a three ringed planar quinone structure with amino containing side chains and exerts also dose-related cardiotoxicity and bone marrow depression. Mitomycin C is a nonplanar tricyclic quinone which is activated to give an alkylating metabolite. Bleomycins are metal chelating glycopeptides that degrade DNA, causing chain fragmentation and release of free bases. This subgroup causes little myelosuppression but pulmonary fibrosis, mucocutaneous reactions, and hyperpyrexia. Actinomycin D (dactinomycin) is a chromopeptide which intercalates in the minor groove of DNA between adjacent guanosine–cytosine pairs and interferes with RNA polymerase, thus preventing transcription. Unwanted effects include nausea, vomiting, and myelosuppression.

In general, the mechanisms of action are not cell cycle specific, although some members of the class show greatest activity at certain phases of the cell cycle, such as S-phase (anthracyclins, mitoxantrone), G1- and early S-phases (mitomycin C) and G2- and M-phases (bleomycins).

Plant Derivatives

Plant derivatives comprise several subgroups with diverse mechanisms of action.

Some are mitosis inhibitors which affect microtubule function and hence the formation of the mitotic spindle, others are topoisomerase I and II inhibitors.

Vinca alkaloids (vincristine, vinblastine, vindesine) are derived from the periwinkle plant (*Vinca rosea*), they bind to tubulin and inhibit its polymerization into microtubules and spindle formation, thus producing metaphase arrest. They are cell cycle specific and interfere also with other cellular activities that involve microtubules, such as leukocyte phagocytosis, chemotaxis, and axonal transport in neurons. Vincristine is mainly neurotoxic and mildly hematotoxic, vinblastine is myelosuppressive with very low neurotoxicity whereas vindesine has both, moderate myelotoxicity and neurotoxicity.

Taxanes (paclitaxel, docetaxel) are derivatives of yew tree bark (*Taxus brevifolia*). They stabilize microtubules in the polymerized state leading to nonfunctional microtubular bundles in the cell. Inhibition occurs during G2- and M-phases. Taxanes are also radiosensitizers. Unwanted effects include bone marrow suppression and cumulative neurotoxicity.

Epidodophyllotoxins (etoposide, teniposide) are derived from mandrake root (*Podophyllum peltatum*). They inhibit topoisomerase II thus causing double strand breaks. Cells in S- and G2-phases are most sensitive. Unwanted effects include nausea and vomiting, myelosuppression, and hair loss.

Camptothecins (irinotecan, topotecan) are derived from the bark of the Chinese tree Xi Shu (*Camptotheca accuminata*). They inhibit topoisomerase I thus effecting double strand breaks. Unwanted effects include diarrhea and reversible bone marrow depression.

Hormonal Agents

Tumors derived from hormone sensitive tissues may remain hormone dependent and are then amenable to therapeutic approaches with hormonal agents. These include hormones with opposing (apoptotic) action, hormone antagonists, and agents that inhibit hormone synthesis.

Glucocorticoids have inhibitory (apoptotic) effects on lymphocyte proliferation and are used to treat leukemias and lymphomas. Estrogens (fosfestrol) are used to block the effect of androgens in prostate cancer. Progestogens (megestrol, medroxyprogesteroneacetate) have been useful for treating endometrial carcinoma, renal tumors, and breast cancer.

Gonadotropin releasing hormone analogs (goserelin, buserelin, leuprorelin, triptorelin) inhibit gonadotropin release and thus lower testosterone or estrogen levels. They are used to treat breast cancer and prostate cancer.

Hormone antagonists (tamoxifen and toremifen bind to the estradiol receptor, flutamide binds to the androgen receptor) are used for treating breast and prostate cancer.

Aromatase inhibitors (aminogluthetimide, formestane, trilostane) block the formation of estrogens from precursor steroids and thus lower estrogen levels. They have been used for treating breast cancer.

Side effects are less prominent in type and extent as compared with cytostatics and include typical hormonal or lack of hormone like effects.

Biological Response Modifiers

Agents which enhance the host's response against neoplasias or force them to differentiate are termed biological response modifiers. Examples include interleukin 2 which is used to treat renal cell carcinoma, interferon α which is active against hematologic neoplasias, and tretinoin (all-trans retinoic acid) which is a powerful inducer of differentiation in certain leukemia cells by acting on retinoid receptors. Side effects include influenza like symptoms, changes in blood pressure and edema.

Antibodies

Recombinant ► **humanized monoclonal antibodies** have been used recently to target antigens that are preferentially located on cancer cells. Examples include trastuzumab and rituximab which are used to treat HER2 positive breast cancer and B-cell type lymphomas, respectively. Unwanted side effects include anaphylactic reactions.

A more recently developed IgG1 monoclonal antibody is cetuximab which targets the epidermal growth factor receptor (EGFR). This binding inhibits the activation of the receptor and the subsequent signal-transduction pathway, which results in reducing both the invasion of normal tissues by tumor cells and the spread of tumors to new sites. Cetuximab is used to treat colorectal cancer and locally advanced squamous cell carcinoma of the head and neck. The most common side effects include an acne-like skin rash that seems to be correlated with a good response to therapy and hypersensitivity reactions.

Another monoclonal antibody is bevacizumab which binds to and inhibits the activity of vascular endothelial growth factor (VEGF) thus inhibiting the interaction of VEGF with its receptor on endothelial cells. This, in turn, inhibits the proliferation of endothelial cells and the formation of new blood vessels. In essence then, it kills tumors by cutting off its own blood supply. For this activity bevacizumab belongs to a family of drugs termed antiangiogenic agents, or angiogenesis inhibitors. Bevacizumab is used to treat metastatic colorectal cancer and nonsmall cell lung cancer (NSCLC). Side effects include hemorrhage, hypertension, gastrointestinal perforation/wound healing complications, and congestive heart failure.

Tyrosine Kinase Inhibitors/Receptor Associated Tyrosine Kinase Inhibitors (RTK-I)

A number of anticancer drugs have been developed that specifically target kinases known to be oncogenic. The first drug in this area is imatinib mesylate, which targets

ABL, *KIT*, and *PDGFR*. Imatinib mesylate is the treatment of choice for patients with chronic myeloid leukemia (CML) and gastrointestinal stromal tumors (GIST). In CML, the Philadelphia chromosome (Ph) results from a translocation which codes for the chimaeric fusion protein, BCR-ABL, which is a constitutively activated tyrosine kinase. Imatinib inhibits the normal Abelson tyrosine kinase (ABL) as well as BCR-ABL. The protooncogene *c-KIT* encodes the KIT tyrosine kinase, which serves as a receptor for stem cell factor. KIT is important in cell cycle regulation and critically important in haematopoiesis. GIST tumors contain a mutated *c-kit* gene leading to increased activity of this tyrosine kinase. Imatinib mesylate blocks the activity of c-KIT and thus suppresses tumor cell proliferation. Also, two receptors for platelet-derived growth factor (PDGF) are sensitive to imatinib. PDGF is involved in cell cycle regulation, angiogenesis, and fibroblast proliferation. Side effects of imatinib mesylate are rare.

Other drugs of this class include gefitinib (iressa[®]) and erlotinib (tarceva[®]) which attach to the EGF receptor, prevent the receptor from being activated and thus stop the cells from dividing. Both agents have been used in patients with nonsmall cell ► **lung cancer**. Side effects include diarrhoea, acne-like rash, loss of appetite, nausea and vomiting, tiredness, and change in blood pressure. Sorafenib is a multitargeted kinase inhibitor, which blocks the activity of VEGF. Sorafenib is used to treat ► **kidney cancer**, side effects include hand/foot skin reaction, effects on the skin, and high blood pressure.

Antisense Oligonucleotides

Oblimersen sodium is a DNA antisense oligonucleotide designed to specifically bind to human bcl-2 mRNA, resulting in catalytic degradation of bcl-2. This results in decreased translation of the protein Bcl-2, which is a cellular antiapoptotic protein. Thus, oblimersen enhances sensitivity to chemotherapy by shifting the intracellular balance to a state in which the cells are more likely to be killed by apoptosis. Currently, it is used in combination chemotherapy for treating advanced melanoma.

Miscellaneous Agents

Antineoplastic agents that cannot be grouped under subheadings 1–9 include miltefosine which is an alkylphosphocholine that is used to treat skin metastasis of breast cancer, and crispatase which breaks down asparagine to aspartic acid and ammonia. It is active against tumor cells that lack the enzyme asparaginase, such as acute lymphoblastic leukemia cells. Side effects include irritation of the skin in the case of miltefosine and anaphylactic reactions in the case of crispatase. Another recent development is the proteasome inhibitor bortezomib which is used to treat multiple ► **myeloma**.

The ►boron atom in bortezomib binds the catalytic site of the ►26S proteasome with high affinity and specificity. In normal cells, the proteasome regulates protein expression and function by degradation of ubiquitinated proteins, and also cleanses the cell of abnormal or misfolded proteins. While multiple mechanisms are likely to be involved, cancer cells may be especially susceptible to proteasome inhibition since more abnormal or misfolded proteins are likely to be present. Also, bortezomib may prevent degradation of proapoptotic factors, permitting activation of programmed cell death in neoplastic cells dependent upon suppression of proapoptotic pathways. Main side effects include nausea and vomiting, fatigue, and diarrhea.

Clinical Use

Cancer treatment is a multimodality treatment, i.e., surgery is combined with radiotherapy and antineoplastic chemotherapy. The latter treatment mode is used mainly for cancers which have disseminated. Different forms of cancer differ in their sensitivity to chemotherapy with antineoplastic agents. The most responsive include lymphomas, leukemias, choriocarcinoma and testicular carcinoma, while solid tumors such as colorectal, pancreatic and squamous cell bronchial carcinomas generally show a poor response. The clinical use of antineoplastic agents is characterized by the following principles.

1. The therapeutic ratio of antineoplastic agents, which is defined by the dose necessary to cause a significant anticancer effect divided by the dose effecting significant side effects, is generally low (near to one).
2. The intention to treat a cancer patient can vary between curative and palliative, pending on the prognosis. Antineoplastic therapy with curative intention is based on high dosages and takes into account severe side effects that have to be tolerated by patients in order to receive the optimal treatment. Palliative therapy with cytotoxic agents aims at maximum life quality for a patient who can not be cured. This includes palliation of symptoms like pain, fractures, and compression of vital tissues that are caused by cancer growth, but tries to accomplish this aim with dosages of cytostatics that bring about as few side effects as possible.
3. Generally, combination therapy with antineoplastic agents is superior to monotherapy. The reason is that several different mechanisms of action can be combined thus lowering the risk of rapid induction of resistance, and the dosages of the single agents can be reduced. This, in turn, decreases the incidence in side effects caused by the single agents and, in addition, the side effects will not sum up if the respective toxicity profiles differ from each other.

4. To be successful, antineoplastic therapy often has to be applied for considerable periods of time. The initial therapy period is being termed “induction therapy” which is then followed by a “maintenance therapy” and possibly a “reinduction therapy.”
5. The therapeutic success is measured by its effect on tumor size and can be described as tumor remission (complete or partial), stable disease, or progression of the tumor. Also, the impact of a therapy is related to time and can be measured as disease free interval, time to progress, or overall survival time.
6. Patients receiving cytotoxic chemotherapy very often need concomitant administering of antiemetic therapy. Such protocols will start well in advance of administering the cytotoxic, and last for a reasonable time with regard to pharmacokinetics of the antineoplastic agent. In addition, side effects of antineoplastic therapy are made better tolerable by supportive care.
7. Few side effects can be alleviated by the use of antidotes. An example is the prevention of hemorrhagic cystitis caused by cyclophosphamide by the concomitant infusion of mesna.

Weight-loss therapies

Definition

►Obesity results from an energy imbalance, when energy intake exceeds energy expenditure over a prolonged period of time. The excess energy is stored in the form of triglycerides in the adipose tissue.

Leptin exerts its effects on food intake behaviour via two distinctive neuronal populations in the hypothalamus. Elevated levels of leptin inhibit neurons expressing the appetite-stimulating (►orexigenic) peptides ►neuropeptide Y (NPY) and agouti-related protein (AGRP) and stimulate neurons expressing the appetite-suppressing (►anorexigenic) peptides pro-opiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART), which are co-localized in a different neuron population. POMC is the precursor of α -melanocyte-stimulating hormone that activates the melanocortin-4 receptor to mediate anorexigenic effects. The neuron populations project further to other brain centres, which ultimately communicate with the cerebral cortex for the final coordination of feeding. Neuropeptides further downstream from leptin include ►galanin, melanin concentrating hormone (MCH) and the ►orexins (also termed hypocretins), which all exert orexigenic effects. The level of food intake will in turn affect fat depots, thus completing the feedback loop between the periphery and CNS.

The ►endocannabinoid system (ECB) system was recently shown to regulate appetite and energy homeostasis. Endocannabinoids are endogenous lipids derived from arachidonic acid that are capable of binding to and activating the two ►G-protein coupled receptors cannabinoid receptor CB1 and CB2. The regulation of food intake and peripheral effects are thought to be mediated via CB1 expressed in the CNS and in various peripheral tissues, including adipose tissue, the gastrointestinal tract, reproductive tissue, muscle and the liver. The 'first-in class' CB1 receptor antagonist rimonabant (Table 1) has recently been approved for anti-obesity treatment.

Sibutramine (Table 1) has been in the market for several years and inhibits the reuptake of serotonin, noradrenaline and, to a lesser extent, dopamine. It acts

mainly as an appetite suppressant and may also increase energy expenditure.

Feeding behaviour, defined by frequency and size of meals, is also regulated in a short-term loop. During and after a meal, various signals are generated in the periphery including taste signals from the oral cavity, gastric distension and humoral signals from secretory cells of the gastrointestinal (GI) tract. These afferent signals are transmitted to the hypothalamus and the hindbrain, which communicate with higher brain areas. Several GI hormones were shown not only to regulate appetite and satiety but also to improve the response of the pancreas to absorbed nutrients (►incretin hormones). GI hormones have gained renewed interest, with the most recent example being peptide YY (PYY). PYY₃₋₃₆ is secreted from the distal gut in response to food ingestion. It belongs to the family of peptides including NPY and pancreatic polypeptide (PP), which exert their effects via the ►G-protein-coupled Y receptor family, Y₁–Y₅. Initial studies showed that peripheral administration of PYY₃₋₃₆ reduced food intake, supposedly mediated via Y₂ receptors, however the potential as an anti-obesity drug is as yet unclear. The related peptide PP is released postprandially from the pancreas in a biphasic manner and is also being investigated for its anorexigenic effects. Glucagon-like peptide-1 (GLP-1), which results from processing of the pre-pro-glucagon precursor in the pancreas, intestinal cells and CNS, presumably regulates feeding by both peripheral and central mechanisms by delaying gastric emptying. The satiety peptide oxyntomodulin (OXM) is derived from the same precursor. Cholecystokinin (CCK) has also been proposed as satiety factor. The only gut hormone identified so far with orexigenic effects is ghrelin. This peptide was originally described as a growth hormone secretagogue. Ghrelin is mainly produced in the stomach, released into the blood, and reaches growth hormone secretagogue receptors in the hypothalamus.

Anti-obesity Drugs. Table 1 Profile of drugs approved for long-term treatment of obesity

	Orlistat	Sibutramine	Rimonabant
Site of action	Gut	CNS	CNS/periphery
Molecular target	Gastrointestinal lipases	Serotonin and noradrenaline transporter	Cannabinoid-1 receptor
Mode of action	Enzyme inhibition	Reuptake inhibition	Receptor antagonism
Effect	Reduced fat absorption	Appetite suppression	Appetite suppression, peripheral actions
Additional effects	LDL-C reduction	Increased energy expenditure?	Metabolic effects
Unwanted/side effects	GI effects	CV system	CNS?
Daily dosage	3 × 120 mg with meals	1 × 10 or 15 mg	1 × 20 mg

It was shown to decrease the production of leptin and NPY and reduced food intake when administered to humans and rodents.

Several GI peptides or derivatives are under investigation for their potential use as anti-obesity therapy.

Reduction of Energy Intake: Inhibition of Absorption

Inhibition of the absorption of fat (triglycerides) in the GI lumen represents the most efficient approach for reduction of caloric intake, as triglycerides are the most condensed energy stores. In the intestine, triglycerides are split into free fatty acids (FFAs) and monoglycerides by lipases, the targets for orlistat (Table 1). After hydrolysis, FFAs cross the membranes of the epithelial cells lining the intestinal wall. Once inside the epithelial cell, FFAs are donated to acyl-CoA synthetase in the endoplasmic reticulum by fatty acid-binding proteins (FABPs). Acyl-CoA is then transferred to 2-monoacylglycerol to resynthesize triglycerides. Acyl-CoA:diacylglycerol acyltransferase (DGAT) is a key enzyme responsible for the final step in the glycerol phosphate pathway of triglyceride synthesis. The absorption of dietary fat thus involves several steps catalysed by proteins that might represent promising drug targets.

Increase of Energy Expenditure

Total energy expenditure is the sum of basal metabolism, i.e. the constant obligatory energy expenditure required for cell and organ survival, and a variable portion needed for physical activity and adaptive thermogenesis. The stimulation of thermogenesis has raised much interest as a possible mechanism to treat obesity, especially once the mitochondrial uncoupling proteins (UCPs) were identified. UCP1 is selectively expressed in brown adipose tissue (BAT), which is rich in mitochondria and highly developed in rodents for thermogenesis. Activation of the sympathetic nervous system in response to cold stress or high-fat diet activates β 3-adrenoreceptors of the BAT, resulting in increased cAMP levels and stimulation of protein kinase A. This kinase phosphorylates and activates hormone-sensitive lipase, thereby promoting the release of FFAs. These serve both as fuel for mitochondrial respiration and as activators of UCP1. UCP1 dissipates the transmembrane proton gradient coupled to the oxidation of metabolites, releasing energy as heat. In addition, there is a chronic response, i.e. UCP1 is transcriptionally upregulated, and mitochondrial biogenesis is stimulated through mechanisms involving a transcriptional coactivator of the nuclear peroxisome proliferator-activated receptor- γ (\blacktriangleright PPAR γ), with the acronym PGC-1 (PPAR γ coactivator-1).

Despite tremendous efforts, research on energy expenditure did not yet lead to successful therapies. Much attention has been devoted to the stimulation of β 3 receptors. The stimulation of these adrenergic receptors should lead to an increased expression of the

uncoupling protein UCP1, thereby increasing thermogenesis, and inducing catecholamine-induced lipolysis. The first generation of β 3 receptors agonists failed due to species differences between human and rodent receptors. A general problem of this therapeutic approach in human may be the lack of BAT, which is prominent in rodents but disappears in human after birth, while the major thermogenic tissue in man is skeletal muscle. As UCP3 is expressed in skeletal muscle in man, it has been proposed as a promising pharmacological target, but its definite role is still uncertain.

Modulation of Fat Storage

Processes involved in the storage of fat, including adipocyte differentiation, angiogenesis or apoptosis, could also be targeted as a way to reduce fat mass. However, all of these potential approaches to reduce the ability to synthesize or store fat will be safe only if associated with an increase in fat oxidation and/or with a reduction of fat absorption. Otherwise, the inability to deliver excess calories to adipose tissue could have serious secondary consequences as lipids accumulate in the blood or various organs. A safer anti-obesity approach could be the stimulation of BAT formation in man, involving either de novo recruitment from pre-adipocytes or interconversion of white adipose tissue, which is the major site for triglyceride storage.

Clinical Use (Including Side Effects)

Obesity has reached an epidemic level not only in developed but also in developing countries. In the US, ~65% of the adult population is overweight and 20–25% of these are obese. Obesity is a complex condition frequently associated with other diseases such as type 2 \blacktriangleright diabetes and hypertension, which makes it a major health issue. The treatment of obesity aims at a sustained loss of 5–10% of body weight, which has been shown to reduce the risk of obesity-associated co-morbidities. Anti-obesity therapy should result in a reduction of the fat mass while saving lean body mass, and help to maintain the reduced weight. Furthermore, an anti-obesity drug should not induce counterregulatory mechanisms which limit its efficacy during long-term treatment, and it needs to meet high safety standards.

There are three medications approved for the long-term (>6 months) treatment of obesity: (i) Orlistat, an inhibitor of fat absorption, (ii) Sibutramine, an appetite suppressant and (iii) the recently approved Rimonabant, an appetite-suppressing agent with additional peripheral action. These medications are recommended to be used in conjunction with a reduced caloric diet (or reduced fat diet for orlistat), and increased exercise. Several other drugs are approved for short-term treatment of obesity only and are either catecholaminergic or serotonergic CNS-active (activating the sympathetic nervous system) anorectic agents (e.g. phentermine).

Orlistat (Xenical[®], Reductil[®]) – Lipase Inhibitor

Orlistat inhibits gastrointestinal lipases in the lumen of the GI tract to decrease systemic absorption of dietary fat. It is a hydrogenated derivative of lipstatin, a natural occurring lipase inhibitor of bacterial origin. The drug binds covalently to a serine residue in the active site of gastrointestinal lipases, and thus inhibits the hydrolysis of ingested triglycerides into absorbable FFAs and monoglycerides. At doses of 400–600 mg daily, ~30% of triglycerides are not absorbed by the small intestine and excreted into faeces, thereby contributing to the caloric deficit. Orlistat represents an overall safe treatment for obesity, given that the drug itself is minimally absorbed.

A clinical trial with orlistat in conjunction with a hypocaloric diet showed a weight loss of 8.7 kg in patients receiving orlistat versus 5.8 kg in patients receiving placebo after 52 weeks of treatment. The effect on body weight was sufficient to improve several metabolic parameters, including reduced LDL-C blood levels, improved oral glucose tolerance and blood pressure. The main unwanted effects of orlistat are attributable to its mode of action, as non-digested fat remains in the intestinal lumen and can cause steatorrhea (fatty stools), flatulence and faecal incontinence. These effects are associated with a high-fat meal, and therefore a low-fat diet is recommended. As absorption of fat-soluble vitamins may be hampered, supplementation of these vitamins is recommended.

Sibutramine (Meridia[®]) – Serotonin and Noradrenaline Reuptake Inhibitor

Sibutramine is a β -phenylethylamine derivative that inhibits the reuptake of noradrenaline, serotonin, and, to a lesser extent, dopamine in the CNS, resulting in reduced hunger and increased satiety. It may also increase thermogenesis, causing an increase in energy expenditure. Sibutramine treatment is indicated for weight loss and maintenance medication. A meta-analysis of randomized placebo-controlled trials with doses of 10–20 mg per day over 44–54 weeks indicated an average weight loss of 4.45 kg. Several metabolic parameters were also improved. However, there are some safety concerns as increase in systolic and diastolic blood pressure and a rise in heart rate have been observed. These cardiovascular effects of sibutramine may be explained as a consequence of the drug's peripheral effects, i.e. the inhibition of noradrenaline reuptake at sympathetic nerve terminals in the arterioles. Sibutramine should therefore be used with caution in patients with poorly controlled hypertension or with a history of cardiovascular heart disease.

Rimonabant (Acomplia[®]) – CB1 Receptor Antagonist

Rimonabant is the 'first-in class' CB1 receptor antagonist, which has recently reached the market in Europe (approval in the US is pending). The reduction of

weight observed in the clinical trials is of the same order of magnitude as that seen with the other available agents sibutramine and orlistat. In the 'Rimonabant in Obesity'-lipid trial, HDL cholesterol was increased, plasma triglycerides reduced, and glucose tolerance upon oral glucose challenge improved. Rimonabant's beneficial effects on risk factors are supposedly not only attributed to the weight loss induced by its appetite suppressant effect but also mediated through peripheral effects. Observed side effects in the trials consisted mainly of nausea, dizziness and anxiety.

Comment on the First Leptin Trials

Leptin has proved to be an efficient treatment for the rare form of obesity associated with leptin deficiency. By contrast, the results of the first clinical trial with human leptin in obese patients (without leptin deficiency) were less promising. This may be explained by leptin resistance in a high proportion of these patients. However, the mechanisms involved in the development of leptin resistance could become new drug targets.

Antioxidants

Antioxidants are substances which reduce or prevent the oxidation of other molecules. While oxidation reactions

are important for the basic metabolism of cells, they can also be damaging under certain conditions. One of the major sources for reactive oxygen is the leakage of activated oxygen like superoxide (O_2^-) which is produced via the respiratory chain in mitochondria. Also a variety of enzymes like xanthine oxidase, P450 oxidases, FADH₂ oxidase, or NADPH oxidase can produce superoxide. However, under normal conditions most cells maintain a reducing environment due to the activity of various anti-oxidant mechanisms. Several enzymes such as superoxide dismutase, glutathione peroxidase, or catalase can convert superoxide to hydrogen peroxide (H_2O_2) and finally to water. There are also various anti-oxidants such as ascorbic acid (vitamin C), glutathione, or α -tocopherol (vitamin E) which are present in cells and inactivate reactive oxygen species like superoxide or hydrogen peroxide. Under various pathological conditions, however, the balance between the formation of reactive oxygen species and their inactivation by anti-oxidant enzymes and substances can be dysregulated resulting in the increased accumulation of reactive oxygen species which have damaging effects due to the oxidation of DNA, lipids or proteins. These conditions which are described as oxidative stress are often the result of tissue injuries. A pathophysiologically relevant role for reactive oxygen species has been suggested in various neurodegenerative diseases and stroke. Oxidative stress has also been linked to the development of atherosclerosis which requires in its early stages the oxidation of LDL particles for the formation of atherosclerotic plaques. Anti-oxidants have been shown to be able to treat and prevent various diseases to some degree. There are a variety of experimental drugs which can be used as anti-oxidants. Also, several endogenous anti-oxidants can be added to the nutrition like ascorbic acid, lipoic acid, carotenes, α -tocopherol and others. Also, fruits and vegetables are rich sources of natural anti-oxidants like polyphenoles (e.g. resveratrol) and anthocyanins.

Antiparkinsonian drugs

Definition

Parkinsonism is a clinical syndrome comprising ▶bradykinesia, muscular ▶rigidity, ▶resting tremor, and impairment of postural balance. The pathological hallmark of Parkinson's disease is a loss of more than 60–70% of pigmented dopaminergic neurons of the substantia nigra pars compacta with the appearance of intracellular inclusions known as ▶Lewy bodies. Without treatment, idiopathic Parkinson's disease progresses over 5–10 years to a rigid, akinetic state, leading to complications of immobility, e.g., pneumonia and pulmonary embolism. The distinction between Parkinson's disease and other causes of parkinsonism is important because parkinsonism arising from other causes is usually more refractory to treatment with antiparkinsonian drugs.

Mechanism of Action

Pathophysiology

The primary deficit in Parkinson's disease is a loss of dopaminergic neurons in the substantia nigra pars compacta and a corresponding loss of dopaminergic innervation of the caudate nucleus and the putamen (forming the striatum). This suggests that replacement of dopamine could restore function. Physiologically, dopamine is synthesized from tyrosine in terminals of nigrostriatal neurons by the sequential action of the enzymes tyrosine hydroxylase, yielding the intermediary L-dihydroxyphenylalanine (L-DOPA), and aromatic L-amino acid decarboxylase (the corresponding prodrug L-DOPA is the most effective agent in the treatment of Parkinson's disease, see below.). The subsequent uptake and storage of synthesized dopamine in vesicles is blocked by reserpine, an earlier antipsychotic drug and admixture to antihypertensive medicines, which is known to induce parkinsonism. Release of dopamine is triggered by depolarization leading to entry of Ca^{2+} and ▶exocytosis. The pre- and postsynaptic actions of dopamine are mediated by two types of dopamine receptors, both of which are seven-transmembrane-region receptors. The D₁-receptor family (consisting of D₁ and D₅ receptors) stimulates the synthesis of intracellular cAMP and phosphatidyl inositol hydrolysis, but

the D₂-receptor family (D₂, D₃ and D₄ receptors) inhibits cAMP synthesis and modulates K⁺ and Ca²⁺ channels. D₁ and D₂ proteins are abundant in the striatum; striatal D₃ expression is rather low. Most ►antipsychotic drugs block D₂ receptors and may lead to the adverse event of parkinsonism. As the disease progresses, neuron degeneration continues, involving other systems, including mesocortical dopaminergic cells, and noradrenergic, serotonergic, cholinergic, histaminergic, and peptidergic systems.

The following model of basal ganglia function accounts for the Parkinson syndrome as a result of diminished dopaminergic neurotransmission in the striatum (Fig. 1). The basal ganglia modulate the flow of information from the neocortex to the motoneurons in the spinal cord. The striatum receives excitatory glutamatergic input from the neocortex (red solid arrows). The majority of striatal neurons are projection neurons to other basal ganglia nuclei (blue GABAergic neurons) and a small subgroup is interneurons that interconnect neurons within the striatum (yellow cholinergic neurons). Nigrostriatal dopaminergic neurons (green) innervate GABAergic neurons (blue, 2, 3) and cholinergic interneurons (yellow, 1). The cholinergic interneurons mediate the dopaminergic control of corticostriatal long-term depression in GABAergic neurons. This long-term depression is due to a reduction of the muscarinic M₁ receptor tone at dendrites of GABAergic neurons, which receive glutamatergic input from neocortical, pyramidal neurons. Physiologically, the D₂ receptor-mediated reduction of the innervation of postsynaptic M₁ receptors leads to an enhanced Ca²⁺ influx into the dendrite of GABAergic neurons, resulting in enhanced endocannabinoid production, and a retrograde activation of presynaptic cannabinoid-1 receptors that diminish glutamate release. The outflow of the striatum proceeds as the direct and the indirect pathway. The direct pathway projects directly to the output stages of the basal ganglia, the substantia nigra pars reticulata and the globus pallidus medialis, which contain GABAergic neurons (blue). These in turn relay to the thalamus, which provides excitatory input to the neocortex (red broken arrows). Since two inhibitory GABAergic neurons are arranged successively, the stimulation of the direct pathway at the level of the striatum (by glutamatergic corticostriatal afferents or via 2) results in an increased excitatory outflow from the thalamus to the neocortex. The opposite effect, i.e., a decreased excitatory outflow from the thalamus, is the result when the stimulation of the first chain link of the direct pathway, GABAergic neurons in the striatum, is abolished.

This is the case when the excitatory D₁ receptors on these striatal GABAergic projection neurons are no longer activated since the transmitter dopamine is reduced (green broken arrows at 2). The indirect pathway is

composed of striatal GABAergic neurons (blue) that project to the globus pallidus lateralis (to blue GABAergic neurons). This inhibitory structure in turn innervates glutamatergic neurons of the subthalamic nucleus (red) to diminish the excitation of subthalamic neurons. The subthalamic nucleus provides excitatory glutamatergic outflow to the output stage, i.e., to GABAergic neurons (blue) of the substantia nigra pars reticulata and the globus pallidus medialis. Thus, the net effect of stimulating the indirect pathway at the level of the striatum is to reduce the excitatory outflow from the thalamus to the neocortex. Striatal neurons forming the indirect pathway express inhibitory D₂ receptors (3 in the Fig. 1), counteracting the excitation through glutamatergic corticostriatal afferents. Thus, dopamine released in the striatum reduces the activity of the indirect pathway through D₂ receptors, but increases the activity of the direct pathway through D₁ receptors. A reduced dopaminergic neurotransmission in the striatum (depicted as green broken line) ultimately reduces the thalamic excitation of the motor cortex. Note that the view of the striatofugal system as dual (direct/indirect) projections system has been questioned; it was suggested that GABAergic projection neurons project sequentially rather than in parallel to their major target areas, compatible with the repeatedly reported colocalisation of D₁ and D₂ receptors in these neurons.

What is the reason for the rather selective degeneration of nigrostriatal dopaminergic neurons in Parkinson's disease? Apart from their oxidative metabolism, leading to the production of reactive compounds as in every cell (hydrogen peroxide, superoxide anion radical), dopaminergic neurons seem to be additionally compromised by an extra accumulation of hydrogen peroxide due to the metabolic conversion of dopamine to 3,4-dihydroxyphenylacetaldehyde (DOPAL) plus hydrogen peroxide by the enzyme monoamine oxidase (MAO). In the presence of ferrous iron, hydrogen peroxide undergoes spontaneous conversion (Fenton reaction), forming a hydroxyl free radical, one of the most risky species of all reactive compounds. Levels of iron are high in the substantia nigra; it is, however, not clear whether the excess iron exists in a form, capable of participation in redox chemistry. In addition, the increase in iron occurs only in the advanced stages of Parkinson's disease, suggesting that this increase may be a secondary, rather than a primary initiating event. Despite this objection, hydroxyl-free radicals are generated from hydrogen peroxide without the catalytic help of ferrous iron in the presence of DOPAL: Thus, the either MAO product, DOPAL, is a cofactor in the generation of the hydroxyl radical from the other MAO product, hydrogen peroxide, which is also produced enzymatically by superoxide dismutase from the superoxide anion radical. Since MAO is located on the outer mitochondrial membrane, adjacent to the free radical

sensitive permeability transition pore, its products, including the hydroxyl free radical, may function as cell death messengers, leading to ►apoptosis. Apart from this local mechanism, reactive oxygen species can lead to DNA damage, peroxydation of membrane lipids, and neuronal death. Because parkinsonian brains are free of pathological signs of necrosis, apoptosis is the likely or predominant mechanism for the death of nigrostriatal dopamine neurons.

Emerging evidence suggests that dysfunction of the ubiquitin-proteasome system may be part of the pathophysiology of sporadic Parkinson's disease, especially

the association of parkin mutations with familial forms of the disease. Disease-linked mutations in parkin may cause defects in normal ubiquitin-proteasome system function with subsequent aberrant protein accumulation, resulting in proteolytic stress [1].

Neuromelanin, a dark colored pigment and product of the oxidative metabolism of dopamine, is found in the cytoplasm of dopaminergic neurons of the human substantia nigra pars compacta. Neuromelanin deposits increase with age, matching the age distribution of Parkinson's disease. In the absence of significant quantities of iron, neuromelanin can act as an antioxidant in

that it can interact with and inactivate free radicals. Neuromelanin functions as a redox polymer and may promote the formation of reactive oxygen free radicals, especially in the presence of iron that accumulates in neuromelanin. Thus, in the early stages of the disease, the iron-chelating properties of neuromelanin may act as a powerful protective mechanism, delaying symptom appearance and/or slowing disease progression. Once these protective mechanisms have been exhausted, the pathogenic mechanisms affecting cytoplasmic organelles, other than neuromelanin, destroy neuromelanin-harboring neurons, with consequent pouring out of neuromelanin granules. These, in turn, activate microglia, causing release of nitric oxide, interleukin-6, and tumor necrosis factor- α , thus becoming an important determinant of disease aggravation [2].

A genetic defect of complex I of the mitochondrial respiratory chain has been demonstrated specifically for the substantia nigra in Parkinson's disease. This finding matches the observation that the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which causes a Parkinson-like syndrome in humans, acts via inhibition of complex I by its neurotoxic metabolite 1-methyl-4-phenylpyridine (MPP⁺), thus destroying dopaminergic neurons in the substantia nigra. Despite this obvious specificity, the question arises whether dopaminergic neurons are more vulnerable to this mitochondrial deficit per se compared with other neurons and whether there is differential vulnerability to complex I inhibition within the dopaminergic substantia nigra population. In addition, which are the death transducers of mitochondrial dysfunction? Apart from increased accumulation of reactive oxygen species and their functional consequences (see above) due to defective mitochondria, dopaminergic neurons may express differentially regulated K_{ATP} channels in the plasma membrane. These channels respond to mitochondrial complex I inhibition. There may be a differential opening of K_{ATP} channels owing to a diminished ATP/ADP ratio in dopaminergic midbrain neurons. It has recently been suggested from mice models that K_{ATP} channels are causally linked to the differential degeneration of these dopaminergic neurons: K_{ATP} channel opening due to complex I inhibition was associated with hyperpolarization, functional silencing and, finally, cell death of substantia nigra dopamine neurons; cell death of dopaminergic neurons in the ventral tegmental area was absent, however, since complex I inhibition did not induce the opening of K_{ATP} channels in these neurons [3]. How should this K_{ATP} channel-induced neuronal silencing be linked with the death of dopamine neurons? This question remains open and the possibility that the opening of K_{ATP} channels is a futile effort of cellular self-protection due to another underlying degenerative mechanism should be considered. The fact that genetic inactivation of the

K_{ATP} channels under investigation resulted in selective rescue of substantia nigra dopaminergic neurons does not prove a deleterious, neurodegeneration-promoting role of K_{ATP} channels, but may simply mean that the dopamine neurons, lacking K_{ATP} channels, have developed other, undetected self-protection mechanisms.

Symptomatic Drug Therapy and Curative Treatments of the Future

While advances in the symptomatic drug therapy (summarized below) have certainly improved the lives of many Parkinson patients, the goal of current research is to develop treatments that can prevent, retard or reverse the death of dopaminergic neurons in the substantia nigra pars compacta (and of other neurons involved in the pathogenesis of Parkinson's disease not mentioned in this essay).

A large number of molecules have provided experimental evidence of neuroprotection in *in vitro* and *in vivo* models of Parkinson's disease and many of these putative neuroprotective substances are now the objects of clinical trials. Recently, a team of experts has identified potential neuroprotective agents to be tested in pilot studies [4]. Twelve compounds have been considered for clinical trials: caffeine, coenzyme Q 10, creatine, estrogen, GPII485, GM-1 ganglioside, minocycline, nicotine, pramipexole, ropinirol, rasagiline, and selegiline (for individual discussion see [4]).

Clinical Use (Including Side Effects)

Oral L-DOPA is rapidly absorbed by the intestinal active transport system for aromatic amino acids, where dietary amino acids may act as competitors. The same is true at the corresponding aromatic amino acid carrier of the blood-brain barrier. L-DOPA is usually co-administered with a peripherally acting inhibitor of aromatic L-amino acid decarboxylase (benserazide, carbidopa) that prevents (dopamine-induced) nausea and vomiting, cardiac arrhythmias and orthostatic hypotension, and increases the fraction of L-DOPA that remains unmetabolized and available to cross the blood-brain barrier. The therapeutic and adverse effects of L-DOPA result from its intracerebral decarboxylation to dopamine. Entacapone is a selective inhibitor of catechol-O-methyltransferase, whose activity is primarily in the peripheral nervous system. Entacapone further increases the fraction of L-DOPA, crossing the blood-brain barrier, and thus prolongs its action and reduces fluctuations in response. In early Parkinson's disease, when some buffering capacity of remaining striatal dopaminergic nerve terminals is still present, the degree of motor improvement due to L-DOPA is highest (9). With time, however, the patient's motor state may fluctuate dramatically with each drug dose. Increasing the frequency of administration can

improve this situation, while increasing the L-DOPA dose may induce dyskinesias, i.e., excessive and abnormal involuntary movements. In view of the above-mentioned dopamine autotoxicity, might L-DOPA accelerate the disease progression? Although no convincing evidence for such an effect has yet been obtained, a pragmatic therapeutic approach may be appropriate, i.e., to use L-DOPA only when required by a functional impairment of the patient, not otherwise treatable.

Alternatives to L-DOPA are direct agonists of striatal dopamine receptors (e.g., pergolide, cabergoline) that are not metabolized in a manner that leads to increased free radical formation. Their use may reduce endogenous release of dopamine and the need for exogenous L-DOPA, possibly with the consequence of a delay in the progression of the disease. At present, however, there are no clinical data to support a neuroprotective effect of dopamine receptor agonists. In contrast to the prodrug L-DOPA, these agonists do not depend on the functional capacities of nigrostriatal nerve terminals, which may be advantageous in the late stages of Parkinson's disease where L-DOPA-induced fluctuations are frequent. In addition, clinically used dopamine agonists have durations of action substantially longer than L-DOPA. However, despite these pharmacokinetic advantages, the clinical efficacy of the currently available agonists that preferentially activate dopamine D₂ receptors is less than that of L-DOPA. Due to their peripheral activity, dopamine receptor agonists may cause orthostatic hypotension and nausea. Typical central adverse events in elderly patients are hallucinosis or confusion, similar to that observed with L-DOPA. In contrast to levodopa, D₂ receptor agonists impaired cognitive function in monkeys, most probably due to "tonic" activation of D₂ autoreceptors, and a similar deterioration was seen with pergolide in humans. In fact, activation of dopamine autoreceptors by drugs like pergolide and quinpirole depresses the neocortical release of dopamine in humans, i.e., phasic dopamine signaling and, thereby, learning performance. This could have deleterious effects especially in Parkinson patients, treated with D₂-receptor agonists, who in part are known to suffer in the first place from disease-related cognitive deficits.

The mode of action of selegiline, which slightly improves parkinsonian symptoms, is unclear. At clinically used doses, it inhibits the MAO-B isoenzyme whereas MAO-A prevails in dopaminergic terminals. Selegiline is metabolized to (–)-desmethyldeprenyl, which seems to be the active principle in its antiapoptotic effects in animal models, and further to (–)-amphetamine and (–)-methamphetamine. The (–)-amphetamines release biogenic amines, including dopamine from their storage sites in nerve terminals, although with less potency than their (+)-enantiomers.

This may partly explain the symptomatic relief seen with selegiline. Developmental drugs, structurally related to selegiline, which exhibit virtually no MAO-B or MAO-A inhibiting properties, and which are not further metabolized to amphetamines, show neurorescueing properties that are qualitatively similar, but obtained with about 100-fold more potency, compared to selegiline. Glyceraldehyde-3-phosphate dehydrogenase, a glycolytic enzyme with multiple other functions, including an involvement in apoptosis, seems to be the molecular target for these neuroprotective selegiline-related drugs of the future.

Adenosine A_{2A} receptors are localized to the indirect striatal output function and control motor behavior. Istradefylline is a novel adenosine A_{2A} receptor antagonist, which demonstrated a clinically meaningful reduction in motor fluctuations in L-DOPA-treated patients with established motor complications, and is safe and well tolerated.

Antagonists of muscarinic acetylcholine receptors had widely been used since 1860 for the treatment of Parkinson's disease, prior to the discovery of L-DOPA. They block receptors that mediate the response to striatal cholinergic interneurons. The antiparkinsonian effects of drugs like benztropine, trihexyphenidyl and biperiden are moderate; the resting tremor may sometimes respond in a favorable manner. The adverse effects, e.g., constipation, urinary retention, and mental confusion, may be troublesome, especially in the elderly.

Low affinity use-dependent NMDA receptor antagonists meet the criteria for safe administration into patients. Drugs like amantadine and memantine have modest effects on Parkinson's disease and are used as initial therapy or as adjunct to L-DOPA. Their adverse effects include dizziness, lethargy and sleep disturbance.

α -2 Antiplasmin

α -2 antiplasmin, a naturally occurring inhibitor of fibrinolysis, is a single chain glycoprotein that forms a stable, inactive complex within plasmin and thereby prevents plasmin's activity.

► Coagulation/Thrombosis

Antiplatelet Drugs

STEFAN OFFERMANN

Pharmakologisches Institut, Universität Heidelberg,
Heidelberg, Germany

Synonyms

Platelet inhibitors; Platelet aggregation inhibitors

Definition

Platelets play a central role in ► **primary hemostasis**. They are also important in pathological processes leading to ► **thrombosis**. Antiplatelet drugs are primarily directed against platelets and inhibit platelet activation by a number of different mechanisms. They are used for the prevention and treatment of thrombotic processes, especially in the arterial vascular system.

Mechanism of Action

Antiplatelet therapy is an important means in the prevention and treatment of thromboembolic artery occlusions in cardiovascular diseases. Platelets are discoid cell fragments, derived from megakaryocytes in the bone marrow that circulate freely in the blood. Under normal conditions they neither adhere to each other nor to other cellular surfaces. However, when blood vessels are damaged at their luminal side, platelets adhere to the exposed subendothelium. Adherent platelets release various factors (see below) that activate other nearby platelets resulting in the recruitment of more platelets at the site of vascular injury. The rapid formation of a "platelet plug" at sites of vascular injury is the main mechanism of primary hemostasis. This is followed by a strengthening of the primary thrombus due to the formation of fibrin fibrils by the coagulation cascade. Platelets also play an important role in pathological conditions since they can become activated

on ruptured ► **atherosclerotic plaques** or in regions of disturbed blood flow. This in turn leads to thromboembolic complications that underlie common diseases such as myocardial infarction or thrombotic stroke.

Mechanisms of Platelet Activation

During the first phase of platelet activation, platelets adhere to extracellular matrix proteins of the subendothelium (see Fig. 1). Platelet adhesion is initially mediated by ► **von Willebrand factor (vWf)** which after binding to subendothelial collagen changes its conformation and interacts with the platelet receptor complex glycoprotein Ib-IX-V (GPIb-IX-V). This interaction brings platelets in contact with the subendothelium but does not result in a stable interaction. A stable adhesion of platelets is induced by the extracellular matrix protein ► **collagen** which via the platelet-specific receptor glycoprotein VI (GPVI) leads to an activation of platelets. This in turn results in the activation of several ► **integrins** like integrin α 2 β 1 and α IIb β 3 which then mediate the firm adhesion of platelets to collagen, fibronectin, or laminin exposed at the subendothelial surface.

The formation of a platelet aggregate requires the recruitment of additional platelets from the blood stream to the injured vessel wall. This process is executed through a variety of diffusible mediators which act through ► **G-protein-coupled receptors**. The main mediators involved in this process are adenosine diphosphate (ADP), thromboxane A₂ (TXA₂), and thrombin (factor IIa). These mediators of the second phase of platelet activation are formed in different ways. While ADP is secreted from platelets by exocytosis, the release of TXA₂ follows its new formation in activated platelets. Thrombin can be formed on the surface of activated platelets (see Fig. 2).

Initially, activated platelets change their shape, an event immediately followed by the secretion of platelet granule contents (including ADP, ► **fibrinogen**, and serotonin) as well as by platelet aggregation. Aggregation of platelets is mediated by fibrinogen or vWf. They connect platelets by bridging complexes of glycoprotein IIb/IIIa (integrin α IIb β 3) on adjacent platelets, forming a platelet aggregate. Each platelet contains about 50,000–80,000 glycoprotein IIb/IIIa (GPIIb/IIIa) molecules on its surface. In order to bind fibrinogen and vWf, GPIIb/IIIa has to be converted from low affinity/avidity state to a high affinity/avidity state by a process described as inside-out signaling that is initiated during platelet activation (Fig. 2).

Acetylsalicylic Acid (Aspirin)

TXA₂ is produced by activated platelets via the sequential conversion of arachidonic acid by phospholipase A₂, ► **cyclooxygenase-1 (COX-1)**, and thromboxane synthase. Similar to ADP, TXA₂ acts as a

Antiplatelet Drugs. Figure 1 Platelet adhesion, activation, aggregation and thrombus formation on subendothelial surface at an injured blood vessel. After an injury of the vascular endothelium, the processes of primary hemostasis (platelet activation) as well as of secondary hemostasis (fibrin formation via the coagulation cascade) are triggered by a variety of stimuli. Shown are only the mechanisms of primary hemostasis. Platelets adhere via their receptor GPIb-IX-V and GPVI mediated by von-Willebrand factor (vWf) or binding of extracellular matrix (especially collagen) to the subendothelium. Binding of collagen to GPVI initiates platelet activation resulting in integrin activation and the formation of a variety of diffusible mediators like ADP, thromboxane A₂ (TXA₂) as well as thrombin. These mediators initiate the second phase of platelet thrombus formation by recruiting platelets from the blood stream into a growing platelet aggregate. The crosslinking of platelets primarily involves the activated integrin αIIbβ3 (GPIIb/IIIa) which can bind the bivalent ligands vWf and fibrinogen (Fb) resulting in the crosslinking of platelets.

positive feedback mediator. In vascular endothelial cells, COX-1 is involved in the generation of prostacyclin (PGL₂), which inhibits platelet activation and leads to vasodilation. Low doses of acetylsalicylic acid (aspirin) have an antiplatelet effect by inhibiting the TXA₂ production by irreversibly acetylating COX-1 at serine-530 close to the active site of the enzyme which interferes with the binding of the substrate arachidonic acid to the enzyme. This results in impaired platelet function for the rest of its lifespan (7–10 days). Anucleated platelets, in contrast to nucleated cells, are unable to *de novo* synthesize COX-1. The aspirin doses required for this antiplatelet effect are therefore considerably lower than those necessary to achieve inhibition of prostacyclin formation in endothelial cells or analgetic and antipyretic effects elsewhere in the body. Following oral administration of aspirin, platelets are exposed to a relatively high concentration of aspirin in the portal blood. This may further contribute to the relatively high sensitivity of platelets toward the action of aspirin. Most other tissues are partly protected from irreversible COX-1 inhibition by presystemic metabolism of aspirin to salicylate through esterases in the liver.

Thienopyridines

ADP is released from activated platelets by the secretion of dense granules and acts through at least three receptors. These are the ionotropic purinoceptor 2X₁ (P2X₁) and two G-protein-coupled receptors, the G_q-coupled purinoceptor 2Y₁ (P2Y₁), and the G_i-coupled P2Y₁₂ receptor. The latter has also been termed P2T_{AC} or P2_{cyc} and is targeted by a group of antiplatelet agents – the thienopyridines – such as ticlopidine and clopidogrel. To become activated, ticlopidine and clopidogrel require biotransformation by the hepatic CYP3A4 enzyme into active metabolites. The active metabolites irreversibly modify the P2Y₁₂ receptor. Due to the requirement of the formation of active metabolites, thienopyridines have a delayed onset of action. Similar to the antiplatelet effects of aspirin, the effects of thienopyridines are long-lasting due to the irreversible inhibition of the P2Y₁₂ receptor.

GPIIb/IIIa (Integrin-IIbβ3) Inhibitors

Most antiplatelet drugs only partially inhibit platelet activation. In contrast, blockers of GPIIb/IIIa interfere at the end of the pathway common to platelet aggregation. They prevent fibrinogen and vWf from

Antiplatelet Drugs. Figure 2 Mechanisms of platelet activation, together with sites of drug action. Most platelet activators function directly or indirectly through G-protein-coupled receptors and induce several intracellular signalling pathways that eventually lead to secretion of granule contents, change of shape, inside-out activation of GPIIb/IIIa (integrin α IIb β 3), the exposure of factor Va and subsequent formation of the prothrombinase complex which forms thrombin (factor IIa) as well as the activation of phospholipase A₂ (PLA₂). Activation of GPIIb/IIIa allows fibrinogen (Fb) or vWf to cross bridge adjacent platelets. The main pathway that leads to platelet activation involves the G_q/phospholipase C- β (PLC- β)-mediated formation of inositol 1,4,5 trisphosphate (IP₃) and diacyl glycerol (DAG). This in turn results in the release of Ca²⁺ from intracellular stores and the activation of protein kinase C (PKC) isoforms. Major inhibitors of platelet activation are the endothelium-derived mediators nitric oxide (NO) and prostacyclin (PGI₂). While NO via activation of guanylyl cyclase increases cGMP levels, PGI₂ via activation of a G_s-coupled receptor increases the levels of cAMP. Both cyclic nucleotides inhibit via different mechanisms signaling processes involved in platelet activation. Aspirin blocks the conversion of arachidonic acid (AA) to prostaglandin G₂ and H₂ (PGG/H₂) by irreversibly inhibiting cyclo-oxygenase-1 (COX-1). Active metabolites of thienopyridines block ADP (P2Y₁₂)-receptors on platelets and GPIIb/IIIa-blockers interfere with fibrinogen- and vWf-mediated platelet aggregation. TXA₂ stands for thromboxane A₂.

binding to activated GPIIb/IIIa and can therefore completely inhibit platelet aggregation. The first GPIIb/IIIa antagonist developed was a hybrid human/murine monoclonal antibody. Its Fab fragment, termed abciximab, is clinically used and functions in a noncompetitive manner. An alternative approach to block GPIIb/IIIa involves the use of peptides that mimic short protein sequences of fibrinogen or vWf. Several peptides (e.g. the cyclic heptapeptide eptifibatide) or nonpeptidic, low molecular weight compounds (e.g. tirofiban, lamifiban) have been developed and function as competitive antagonists (Table 1).

Others

The proteolytic enzyme thrombin is known to play a crucial role in the overall thrombotic event leading to

both, arterial and venous thrombosis by transforming fibrinogen into fibrin and by serving as a direct platelet activator. Thrombin exerts its effects on platelets via G-protein-coupled protease-activated receptors (PAR-1 and PAR-4 in human platelets). Thrombin-dependent receptor activation is achieved by cleaving an N-terminal extracellular peptide. Exposure of the newly generated N-terminal region functions as a tethered ligand for the receptor. Substances that directly bind to thrombin have been developed. The 65 amino acid long protein hirudin, originally isolated from the medical leech, *Hirudo medicinalis*, as well as related analogs have been recombinantly produced. They bind with the stoichiometry of 1:1 to thrombin and prevent its proteolytic action on fibrinogen as well as its binding to and the activation of PAR. Since they primarily act by

inhibiting thrombin-dependent fibrin formation, they are generally classified as ►**anticoagulants**.

Since platelets are the major source of TXA₂ production and action, inhibitors of thromboxane synthase and TXA₂ receptor (TP) antagonists are being developed. TXA₂ synthesis inhibitors may have some disadvantages as they lead to the accumulation of cyclic endoperoxides (e.g. PGH₂) that are themselves agonists at the TXA₂ receptor.

The major physiological inhibitors of platelet activation are endothelium-derived mediators like prostacyclin (PGI₂) which via a G_s-coupled receptor activates the formation of cAMP formation by adenylyl cyclase as well as nitric oxide (NO) which stimulates the formation of cGMP by activating guanylyl cyclase. NO-generating drugs like organic nitrates lead to platelet inhibition, however, their main effect is on the vascular smooth muscle. Dipyridamole can inhibit the degradation of cAMP by inhibition of cyclic nucleotide phosphodiesterase and has been used as an antiplatelet agent. However, its clinical usefulness is not clear.

Clinical Use

Due to the pivotal role of platelets in thrombus formation, especially in the arterial system, inhibition of platelet function has become a central pharmacological approach. Antiplatelet drugs are given in order to prevent and treat thromboembolic diseases such as coronary heart disease, peripheral and cerebrovascular disease. They have also revolutionized the procedures of invasive coronary interventions as they reduce the risk of restenosis and thrombosis.

Aspirin leads to maximal anti thrombotic effects at doses much lower than required for other actions of the drug. Clinical trials have demonstrated that aspirin is maximally effective as an antithrombotic drug at daily doses of 75–160 mg. Higher doses have no advantage but increase the frequency of side effects, especially bleeding and upper gastrointestinal symptoms. Despite the development of various other compounds, aspirin has remained the gold standard for antiplatelet drugs due to its relative safety and extremely low cost. Several studies have demonstrated a beneficial role for aspirin as an adjunctive therapy in unstable angina and acute myocardial infarction. Mortality and disease

progression were significantly reduced by low dose aspirin treatment. Patients with a history of arterial thromboembolism including myocardial infarction, stroke, transient ischemic attack, or unstable angina were shown to benefit from low dose aspirin treatment in several trials. The overall rate of mortality, as well as the occurrence of further vascular events was reduced in these patients. The results of these studies led to the recommendation to use aspirin for secondary prevention of arterial thromboembolism. However, aspirin is not generally recommended for primary prevention of arterial thromboembolism. A possible beneficial effect, such as a decreased risk of nonfatal myocardial infarction, may outweigh the risk of hemorrhagic complications only in a population already at high risk of cardiovascular diseases but not in a population of average health. Aspirin may also be beneficial as a prophylactic agent to reduce the risk of deep venous thrombosis and pulmonary embolism. However, the effectiveness compared to existing therapies remains to be determined; anticoagulants are still the mainstay of treatment in these conditions.

Thienopyridines are principally suited to treat conditions that respond to aspirin. Ticlopidin, but not clopidogrel, can lead to fatal neutropenia. Gastrointestinal problems and skin rashes can occur with both drugs but are more frequently seen when ticlopidine is used. In various trials, clopidogrel has been shown to be safe and similarly effective as aspirin. In patients at high risk from cerebrovascular events, thienopyridines seem to be somewhat more effective than aspirin in preventing serious vascular complications. Thienopyridines may be used instead of aspirin when the latter is not tolerated. However, aspirin still remains the first choice in most cases due to its low cost, relative safety and well documented efficacy. Studies are under way to test whether clopidogrel, given together with aspirin has advantages under certain clinical conditions.

GPIIb/IIIa antagonists have to be administered parenterally. They are currently used prophylactically during intracoronary interventions such as percutaneous transluminal revascularization with balloon angioplasty or intracoronary stenting, as well as to treat acute coronary syndromes like unstable angina and acute myocardial infarction. The main complications

are bleeding and thrombocytopenia. The bleeding risk appears to increase further with concomitant therapy with heparin at standard doses.

Protocidal drugs; Antiprotozoan chemotherapeutics

Definition

Protozoa are unicellular eukaryotes and a subregnum of the animal kingdom. Some protozoa exhibit a parasitic life style and are pathogenic to humans, animals and plants. An estimated 1.5 billion people suffer from protozoal infections, with malaria (*Plasmodium* spp.) alone causing an estimated 500 million clinical cases each year. Other examples of important human infectious diseases with protozoan etiology are as follows: toxoplasmosis (*Toxoplasma gondii*), African sleeping sickness (*Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*), Chagas disease (*Trypanosoma cruzi*); visceral, mucocutaneous, and cutaneous leishmaniasis (*Leishmania* spp.), amoebic colitis and liver abscess (*Entamoeba histolytica*) and lamblic enteritis (*Giardia lamblia*). Although there is a huge demand for antiprotozoal drugs, particularly drugs affordable by people living in developed countries, the incentives to develop such drugs are low. Accordingly, pharmaceutical industry has invested in other areas, such as cardiovascular, where revenues are higher (Table 1). Only recently have private–public partnerships and international institutions, such as Drugs for Neglected Disease Initiative (▶<http://www.dndi.org/>), the Medicines for Malaria Venture (▶http://www.mmv.org/papes/page_main.htm), the Institute for One World Health (▶<http://www.oneworldhealth.org/>), the WHO Tropical Disease Research Programme (▶<http://www.who.int/tdr/>), tried to fill this gap. In the following chapter, important antiprotozoal drugs (Fig. 1), including their modes of action, will be discussed (Table 1).

Antimalarial Drugs

Four different protozoa of the genus *Plasmodium* – *P. falciparum*, *P. vivax*, *P. ovale* and *P. malariae* – can cause malaria. *P. falciparum* is the most virulent, being responsible for virtually all fatal malaria cases. Humans are infected by a feeding female Anopheles mosquito (Fig. 2). The clinical symptoms of malaria are associated with the development of the parasite within human red blood cells, while the liver stages remain asymptomatic. The following drugs (in alphabetical order) are currently in use for the treatment of malaria [5].

Mechanism of Action

Amodiaquine, a Mannich base 4-aminoquinoline, eliminates blood stage parasites. Its mode of action is similar to that of chloroquine (see below) and there is some cross-resistance.

Artemisinin and its derivatives, artesunate and arthemether, kill both asexual and sexual blood stages (Fig. 2). However, artemisinins are quickly eliminated from the body, resulting in parasite recrudescence, and are therefore combined with schizontocides that have a longer biological half-life, such as amodiaquine,

Antiprotozoal Drugs. Table 1 New compounds registered between 1975 and 1999 (with permission Trouiller et al., 2003 Lancet 359: 2188–2194)

Speciality	New compounds (1975–1999)	Proportion (%) of worldwide sales

Malaria		

lumefantrine, mefloquine and sulfadoxine/pyrimethamine. The artemisinins have been shown to be potent inhibitors of a plasmodial endoplasmatic Ca^{2+} ATPase. A single-point mutation within the Ca^{2+} ATPase can abolish inhibition by artemisinin, although resistance to artemisinins has not been reported in the field. Artemisinin is a sesquiterpene lactone extracted from the leaves of *Artemisia annua*. Also known as qinghaosu, artemisinin has been used in China for the treatment of fever for more than 1,000 years.

Atovaquone, a hydroxynaphthoquinone, selectively inhibits the respiratory chain of protozoan mitochondria at the cytochrome bc1 complex (complex III) by mimicking the natural substrate, ubiquinone. Inhibition of cytochrome bc1 disrupts the mitochondrial electron transfer chain and leads to a breakdown of the mitochondrial membrane potential. Atovaquone is effective against all parasite stages in humans, including the liver stages.

Chloroquine, a 4-aminoquinoline, targets the intra-erythrocytic stages of malarial parasites (Fig. 2). Its mode of action is intricately linked with the plasmodial heme metabolism (Fig. 3). During development within erythrocytes, *Plasmodia* feed on the host cell's haemoglobin, which is digested within an acidic food vacuole. Heme released during haemoglobin proteolysis is highly cytotoxic and perforates cellular membranes. Malarial parasites detoxify heme through biomineralization within their food vacuoles to insoluble and inert ►haemozoin (malaria pigment). Chloroquine, which accumulates in the food vacuole, prevents heme biomineralization by forming complexes with heme, resulting in a build-up of toxic heme–chloroquine complexes that have an even higher affinity for membranes than heme alone and eventually destroy the parasite's cellular membranes (Fig. 3). Chloroquine resistance is linked with polymorphisms within a food vacuolar transporter that, according to current models, mediates efflux of the drug from the food vacuole.

Dapsone, an aromatic sulfone, is administered in combination with a proguanil derivative. Dapsone

inhibits the plasmodial dihydropteroate synthase (DHPS) (Fig. 4).

Tetracycline and its derivative doxycycline are antibiotics widely used in the treatment of bacterial infections. They also exert an antimalarial activity. Tetracyclines inhibit the binding of aminoacyl-tRNA to the ribosome during protein synthesis.

Piperaquine, a bisquinoline, is a rapid acting blood schizonticide. The mode of action is unknown.

Primaquine, an 8-aminoquinoline, eradicates the dormant stages (hypnozoites) of *P. vivax* and *P. ovale* from the liver. Its mode of action remains obscure.

Proguanil appears to have a dual activity. Part of it is metabolized to cycloguanil, which subsequently inhibits the protozoan dihydrofolate reductase/thymidylate synthase (DHFR/TS) (Fig. 4). In addition, the native form, proguanil itself, exerts a potent antimalarial activity, especially in combination with other antimalarial drugs. The target of proguanil is unknown.

Pyrimethamine, cycloguanil and sulfadoxine (sulfadiazine) are folate antagonists that interfere with the folic acid biosynthesis pathway in malarial parasites and other protozoa, including *T. gondii* (Fig. 4). Folate is an essential precursor of the pyrimidine deoxythymidintriphosphate (dTTP) and the amino acids serine and methionine. Both protozoa and mammalian cells require folate for DNA and protein synthesis. However, protozoa can either synthesize dihydrofolate de novo or salvage folate precursors, whereas mammalian cells have no de novo dihydrofolate synthesis and must rely on dietary sources. By acting as an analogue of *p*-aminobenzoic acid, sulfadoxine (sulfadiazine) inhibits the DHPS, which then fails to convert dihydropteroate to hydroxymethyldihydropterin, resulting in a lack of dihydrofolate in the parasite. This mechanism does not affect the mammalian cells. Pyrimethamine and cycloguanil, the active metabolite of proguanil, act further down in the folic acid pathway by inhibiting the DHFR/TS enzyme complex. In mammalian cells, the DHFR and the TS are two independent

Antileishmania drugs

Drugs against sleeping sickness

Drugs against chagas disease

Drugs against anaerobic protozoa

Antiprotozoal Drugs. Figure 1 (Continued)

enzymes. The protozoal DHFR/TS enzyme complex has a higher affinity for pyrimethamine and cycloguanil than does the human DHFR, which explains their high antiprotozoal activity. To avoid deficiency of folic acid in patients treated with antifolate antagonists, folic acid should be administered. Pyrimethamine is

a blood schizonticide and further acts against the liver stages (Fig. 2). Since resistance to pyrimethamine occurs rapidly due to single-point mutations within the DHFR/TS enzyme complex, pyrimethamine is only used in combination with sulfonamides for curative treatment.

Antimalarial drugs

Antiprotozoal Drugs. Figure 1 Chemical structure of relevant antiprotozoal drugs.

Quinine, an arylaminoalcohol, was the first antimalarial known to the Western world. It was originally produced from the bark of the cinchona tree and distributed as a powdery substance, which became

known as Jesuits powder. Several potent antimalarials are derived from quinine, including lumefantrine, mefloquine, halofantrine and quinidine, the dextrarotatory diastereoisomer of quinine. All arylaminoalcohols

Antiprotozoal Drugs. Figure 2 Life cycle of malarial parasites and site of action of different antimalarial drugs.

Malaria is caused by protozoan parasites of the genus *Plasmodium*. Infected *Anopheles* mosquitoes transmitted the parasite to humans during blood feeding. The infective stages are the sporozoites, which invade liver cells where they replicate to form merozoites. Upon rupture of the infected hepatocyte, merozoites are released into the blood stream where they infect erythrocytes. Within the erythrocyte, the parasites develop from ring stages to trophozoites, and then to schizonts. When the infected erythrocyte finally ruptures, merozoites are released, which again invade erythrocytes. Some intraerythrocytic ring stages develop to sexual stages (gametocytes). Gametocytes are taken up by feeding *Anophelines*. Within the mosquito, the parasites develop into gametes, zygotes, ookinets and finally sporozoites. Primaquine and atovaquone are effective against liver forms of all *Plasmodia* including dormant stages of *P. vivax* and *P. ovale*. Primaquine also acts against gametocytes. Artemisinin destroys intraerythrocytic ring stage parasites and schizonts. The so-called schizonticidal drugs, chloroquine, quinine, mefloquine, pyrimethamine and sulfadoxine, act against intraerythrocytic schizonts.

are believed to kill asexual blood stages by inhibiting heme detoxification in the parasite's food vacuole (Fig. 3), although the mechanism of action is not well-understood.

Clinical Use

Malaria treatment has relied on a small number of chemically related drugs of the quinoline and the

antifolate group for more than 4 decades [5]. Artemisinin derivatives have been added only recently as a third group [1]. Various degrees of resistance and geographic distributions of resistance phenotypes have developed for all classes of antimalarials, except the artemisinin derivatives, and is limiting their use [1, 5]. Chloroquine now fails in the treatment of falciparum malaria almost everywhere [5]. To prevent, or at least slow down, the

Antiprotozoal Drugs. Figure 3 The antimalarial activity of chloroquine. Chloroquine's mode of action is associated with heme detoxification. During intraerythrocytic development, *P. falciparum* degrades hemoglobin down to amino acids (AA) in its acidic food vacuole. Heme released from hemoglobin (Hb) is toxic and destroys cellular membranes unless it is converted to an inert biomineral, termed hemozoin or malaria pigment. Chloroquine (CQ) binds to heme, thereby preventing biomineralization of heme. The build-up of membrane-lytic heme/chloroquine complexes kill the parasite. Chloroquine resistant parasites have acquired an efflux system that expels the drug from the food vacuole.

emergence of resistance, compounds with different modes of action are being combined. The choice of drug, the route of drug application, and the dose regimen depend on the type of infection and the severity of the disease. The primary objective of treating uncomplicated malaria is to cure the infection, whereas in severe malaria it is to prevent death.

Severe Malaria

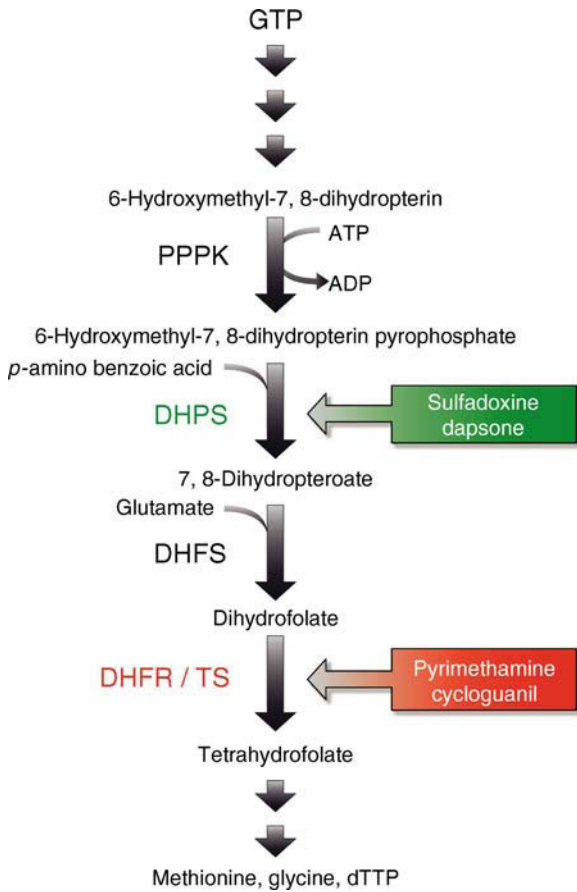

In severe malaria, rapid clearance of parasites is vital. This is achieved using an antimalarial compound that rapidly kills the parasites [5]. The compound has to be given intravenously as soon as possible with a loading dose at the start. A loading dose substantially cuts down the time by which therapeutic levels are achieved. Two classes of currently available drugs fulfill these requirements, the quinolines quinine and quinidine and the artemisinin derivatives artesunate, artemether, and artemotil. The pharmacokinetic properties of artesunate are superior to those of artemether and artemotil. It is water-soluble and can be given parenterally. Randomized trials in Southeast Asia, comparing artesunate with quinine, have clearly demonstrated the benefits of artesunate in reducing mortality rates by almost 35% as compared with quinine. Based on these results, artesunate has been suggested as the treatment of choice for severe malaria in adults. This

recommendation cannot yet be extended to children, particularly from high transmission settings. In African children, no significant difference in mortality rates were found when comparing artemether with quinine.

Uncomplicated Malaria

The treatment of uncomplicated malaria seeks to prevent recrudescence and, at the same time, tries to prevent the development of resistance. This is the rationale behind artemisinin-based combination therapies (ACT). Artemisinin and its derivatives (artesunate, artemether, artemotil, dihydroartemisinin) are clearing both parasitaemia and symptoms rapidly [1]. There is little difference in absorption and bioavailability amongst the different artemisinin derivatives. Due to the extraordinary high parasite clearance rate, artemisinin and its derivatives quickly reduce the total burden of parasites to very low levels. Thereafter, the eradication of the remaining parasites relies on the partner drug in ACTs. The partner drug needs to be effective and parasitocidal concentrations have to be sustained until all parasites have been killed. A slowly eliminated drug is ideal. The artemisinin derivatives are well tolerated with the exception of type 1 hypersensitivity reactions, which appear to be rare (1:3,000).

ACTs with amodiaquine, atovaquone-proguanil, chloroquine, clindamycin, doxycycline, lumefantrine,

Antiprotozoal Drugs. Figure 4 Mode of action of folate antagonists in protozoa. Protozoa are capable of *de novo* synthesis of dihydrofolate, a precursor of thymidine, serine and methionine. The 6-hydroxymethyl-7,8-dihydropterin pyrophosphate pyrophosphokinase (PPPK) and DHPS form one enzyme complex with two distinct active sites. The PPPK transforms GTP to 6-hydroxymethyl-7,8-dihydropterin and then to 6-hydroxymethyl-7,8-dihydropterin pyrophosphate. The product is linked to *p*-aminobenzoic acid (PABA) by DHPS, forming 7,8-dihydropterate. Sulfadoxine exerts its activity by acting as a substrate analogue of PABA in this reaction. Glutamate is added to 7,8-dihydropterate by dihydrofolate synthase (DHFS) resulting in dihydrofolate. Dihydrofolate reductase (DHFR) and thymidylate synthase (TS) form a single enzyme complex with two enzymatically active sites. The catalytic site responsible for DHFR activity converts dihydrofolate into tetrahydrofolate. Pyrimethamine and cycloguanil exert their antimalarial activity by inhibiting the protozoal DHFR. The site of DHFR/TS responsible for TS activity converts tetrahydrofolate into deoxythymidintriphosphate (dTTP).

mefloquine, piperazine, pyronaridine, proguanil-dapsone, sulfadoxine-pyrimethamine, and tetracycline have been evaluated in trials (Fig. 5) [1]. The following

Antiprotozoal Drugs. Figure 5 Artemisinin combination therapy (ACT): Adding a 3-days artesunate course to mefloquine clears the parasitaemia much more rapidly ($A_1 \rightarrow A$). The remaining parasites are exposed to higher mefloquine levels in ACT (B) compared to mefloquine monotherapy (B_1) (with permission White, 1997 *Antimicrob Agents Chemother* 41:1413–1422).

ACTs are currently recommended: artemether-lumefantrine, artesunate + amodiaquine, artesunate + mefloquine, artesunate + sulfadoxine-pyrimethamine [1, 5]. In areas with amodiaquine and sulfadoxine-pyrimethamine resistance exceeding 20%, i.e., SE Asia, artesunate + mefloquine or artemether-lumefantrine should be used [1, 5].

Malaria Treatment and Chemoprophylaxis in Nonimmune People

Travelers treated for malaria after returning to nonendemic regions are treated along the same lines as above regarding uncomplicated and severe forms of the disease. Considerations with respect to development of resistance can be neglected. Monotherapy is fully justified and the following drugs are recommended: artemether-lumefantrine, atovaquone-proguanil, mefloquine, and quinine + doxycycline or clindamycin [5]. For the millions of nonimmune travelers to malaria-endemic areas, chemoprophylaxis (high-risk areas) and stand-by treatment (low-risk areas) are the corner stones of malaria prevention [5], along with exposition prophylaxis using repellent and impregnated bed-nets.

Intermittent Preventive Therapy in Pregnant Women and Infants

In endemic areas, chemoprophylaxis has been abandoned for a variety of reasons, mainly due to sustainability problems and the risk of contributing to the development of resistance. Intermittent preventive therapy (IPT), however, appears to be an alternative to protect pregnant women (IPT_p) and children during the first year of their life (IPT_i).

Antimalarial Drugs (*P. vivax*, *P. ovale*, *P. malariae*)

Resistance of *P. vivax* to chloroquine occurs, but is geographically limited. *P. vivax* and *P. ovale* produce hypnozoites, parasite stages in the liver that can produce multiple relapses. The drug of choice for blood stage infections to date remains chloroquine for all three species. To achieve radical cure of *P. vivax* and *P. ovale* infection, this must be followed by primaquine.

Antileishmanial Drugs

Leishmania is a disease complex caused by different species of *Leishmania*. The parasite, which is transmitted to humans by the bite of phlebotomine sandflies, multiplies within human macrophages. There are an estimated 1.5 million cases in approximately 88 countries each year, with 0.5 million patients suffering from the visceral leishmaniasis.

Mechanism of Action

Amphotericin B, is a polyene antibiotic, used in the therapy of systemic fungal infections. Its mode of action exploits differences in membrane composition between the pathogen and the human host. Ergosterol, the predominant sterol of fungi, plants, and some protozoan parasites, interacts with Amphotericin B, resulting in an increased ion permeability of the membrane. Humans contain cholesterol, which has a low affinity for amphotericin B.

Miltefosine, an alkylphosphocholine derivative, is a new antileishmanial drug and the first effective oral treatment of visceral leishmaniasis. However, there are concerns regarding teratogenicity, rapid emergence of resistance, and variable cure rates, possibly due to species differences in drug sensitivity. The mechanism of action of miltefosine is not known.

The pentavalent antimonial drugs sodium stibogluconate and meglumine antimonate are prodrugs that require biological reduction to the trivalent form Sb (III) for antileishmanial activity. Sb(III) seems to inhibit the leishmanial trypanothione reductase, which, together with a depletion of thiols, results in a breakdown of the cellular thiol redox potential. *Leishmania* and other kinetoplastidae possess an unusual antioxidant termed trypanothione, which is composed of two molecules of glutathione joined by a spermidine linker. Trypanothione protects the cell from oxidative stress by reducing any disulfide bonds formed within proteins to cysteines. The trypanothione reductase regenerates oxidated trypanothione.

Clinical Use

Pentavalent antimonial drugs have been the cornerstone of antileishmanial therapy for more than 70 years, in spite of their general toxicity causing a wide range of side effects [2]. Pentavalent antimonial drugs have to be administered parenterally, which is a painful procedure. Meanwhile, resistance is widespread. In India,

pentavalent antimonial drugs have become almost obsolete because of resistance. They are still used in most other parts of the world where resistance has remained low. Alternative drugs are few and all have significant drawbacks:

1. *Amphotericin B*: This second line drug has moved into the first line in India.
2. *Liposomal Amphotericin B*: This is a highly effective drug against visceral leishmaniasis with remarkably few side effects. There is, however, only one producer and the price per treatment (US \$1,500) is beyond the reaches for most communities affected by the disease.
3. *Paromomycin*: This oral aminoglycoside was first shown to be effective as a topical treatment for cutaneous leishmaniasis, and later as a parenteral drug against visceral leishmaniasis. Phase III clinical trials were completed in 2005 in India, 15 years after the potential of this component for treating visceral leishmaniasis was discovered. It is currently not registered for this use.
4. *Miltefosin*: The antileishmanial activity of this anticancer drug was discovered in the mid-1980s. It is the first oral drug available to treat visceral and cutaneous/mucocutaneous leishmaniasis. However, the registration process is slow.

Antitoxoplasma Drugs

Infection with the obligatory intracellular parasite *T. gondii* is mainly acquired by ingestion of contaminated food or water. Approximately a third of the world's human population is infected.

Mechanism of Action

Clindamycin, a lincosamide derivative, inhibits protein biosynthesis within a unique organelle of the parasite, termed apicoplast. Its mode of action is similar to that of spiramycin.

The folate antagonists, pyrimethamine and sulfadiazine, inhibit the parasite's DHFR/TS synthase enzyme complex and the DHPS, respectively (Fig. 4) (see antimalarial drugs). To avoid deficiency of folic acid in patients treated with antifolate antagonists, folic acid supplementation is recommended to reduce bone-marrow suppression.

Spiramycin is a macrolide that inhibits protein biosynthesis by blocking transfer of the aminoacyl-rRNA along the ribosome in a unique organelle of the parasite, termed apicoplast. The apicoplast is a remnant of a secondary endosymbiosis of a red algae and is only found in the phylum sporozoa.

Clinical Use

Toxoplasmosis remains a challenge to clinicians. *T. gondii* is one of the most prevalent parasites worldwide and it persists in the body for a lifetime.

The infection passes unnoticed, or with little signs and symptoms, in immunocompetent children and adults. The parasite poses a major threat, however, when acquired during pregnancy and transmitted to the fetus, and in immunocompromised patients with or without AIDS, due to reactivation of latent disease or newly acquired infection. The major clinical conditions are congenital toxoplasmosis, ocular toxoplasmosis, and toxoplasmic encephalitis. Current treatment options are confined to the acute stage, but do not eradicate the parasite from the patient. The most commonly used treatment, and currently probably the most effective, is the combination of pyrimethamine and sulfadiazine, supplemented by folic acid to prevent bone marrow suppression [3]. In maternal infection during pregnancy, the primary goal is to prevent transmission to the fetus, the secondary goal, to treat the infected fetus at the earliest time possible to reduce damage. Due to the specific requirements during pregnancy, spiramycin is recommended for the first and early second trimester, and pyrimethamine/sulfadiazine for the late second and third trimester [3]. In most countries, treatment is continued in the newborn for various lengths of time. The efficacy of this regimen, however, has still to await confirmation by appropriately designed studies, and different drug regimens and strategies need to be tested for different clinical settings. In the immunocompromised patients, recrudescence after successful treatment of acute toxoplasmosis is a problem. If restitution of the immune response cannot be achieved or is, for therapeutic purposes, not desired, chemoprophylaxis needs to be installed.

Drugs Against African Sleeping Sickness

African sleeping sickness is a parasitic disease of increasing importance, with an estimated 300,000–500,000 cases annually. The etiological agents, *T. brucei gambiense* and *T. brucei rhodesiense*, are transmitted to humans by the bite of Tsetse flies.

Mechanism of Action

Eflornithine (difluoromethylornithine, DFMO) inhibits the ornithine decarboxylase of the polyamine pathway, in both the trypanosome and the mammalian cell, by acting as an irreversible competitor of the natural substrate ornithine. Inhibition of ornithine decarboxylase results in depletion of the polyamines, putrescine, spermidine and spermine, which are essential for cell proliferation. Eflornithine selectively harms the parasite and not the mammalian cells, despite acting as an ornithine decarboxylase inhibitor in both cell types. This selectivity is explained by the lower rate of ornithine decarboxylase production in the parasite, as compared to mammalian cells. Due to the high turnover rate, mammalian cells are capable of quickly replenishing inhibited ornithine decarboxylase by newly

synthesized enzyme. Eflornithine is only effective against *T. brucei gambiense*.

Melarsoprol, a trivalent organic melaminophenyl arsenic compound, kills intracerebral parasites of both *T. brucei gambiense* and *T. brucei rhodesiense*. Melarsoprol accumulates via an adenosine/adenine transporter in trypanosomes and is believed to inhibit glycolytic enzymes. Melarsoprol leads to a rapid lysis of trypanosomes. Melarsoprol is highly toxic to humans.

Pentamidine is an aromatic diamidine. Pentamidine uptake by the parasite is mediated by several different adenosine transporters. The mode of action is unclear.

Suramin, a symmetrical, polysulfonated naphthylamine, inhibits a number of trypanosomal enzymes; however, the importance of these effects on parasite killing is not clear.

Clinical Use

Despite great advances in the understanding of the biology of the parasite, progress in terms of drug development has been dreadfully slow.

1. Haemolympathic stage (acute stage): For the last two decades, the first line treatment for the acute stage are Pentamidine and Suramin [2]. One compound, the prodrug DB 289 (a diamidine), is currently in phase III clinical trials.
2. Central nervous system stage (late stage): Melarsoprol has remained the first line treatment for more than 20 years [2]. Melarsoprol is very toxic, and it is estimated that, of the patients treated for late-stage disease, an alarmingly high proportion suffers severe side effects or die. A cumbersome dosing schedule, used for decades, has recently been shortened to a 10-days course based on pharmacokinetic studies and controlled clinical trials. This certainly will improve patient compliance and costs. Eflornithine has joined as a second option to treat late-stage *T. gambiense* disease. Compared with melarsoprol, incidence and severity of adverse effects are much lower, however, application and manufacturing problems are the negative trade-offs. Currently, Nifurtimox, in combination with eflornithine, is in phase III clinical trials.

Drugs Against Chagas Disease

Chagas disease is a serious public health problem in Latin America, where an estimated 300,000 new cases occur each year. The causative agent is *T. cruzi*. *T. cruzi*, which is transmitted to humans by reduviid vectors. During acute disease, the parasite develops intracellularly in many tissues, including nervous and muscular tissue. Focal parasite-induced degeneration of infected organs, particularly the heart and the gastrointestinal tract, characterize the chronic form.

Mechanism of Action

Benznidazole, a nitroimidazole derivative, has a mode of action that seems to involve covalent modification of macromolecules by nitroreduction intermediates.

Nifurtimox, a nitrofuran, is a prodrug that is reduced to unstable nitroanion radicals, which react to produce highly toxic oxygen metabolites, such as superoxide and peroxide. Oxidative stress subsequently kills the parasite, which seems to lack effective enzymatic pathways to detoxify oxygen metabolites.

Clinical Use

Benznidazole and nifurtimox, which have been developed in the 1960s and 1970s, have remained the only two drugs available for the acute stage of the disease. There is no proven effect on the chronic stage, as recently reviewed by the Cochrane Collaboration. The specific treatment of the chronic stage has gained renewed interest with recent findings where persisting parasites may play a role in the development of irreversible lesions. The side effect of the two available compounds can be severe. Clinical trials have been carried out with allopurinol for the acute phase in the 1980s (phase II) and are currently in progress with benzimidazole for the indeterminate stage of the disease.

Drugs Against *E. Histolytica* and *G. Lamblia*

E. histolytica and *G. lamblia* are waterborne infectious diseases that cause colitis and liver abscess, and enteritis, respectively.

Mechanism of Action

5-Nitroimidazoles derivatives, such as metronidazole, tinidazole, ornidazole and secnidazole, are the drug of choice in the treatment of anaerobic protozoa. All 5-nitroimidazoles share the same mode of action. Anaerobic microorganisms reduce 5-nitroimidazoles to their active forms. This process only occurs under strongly reducing conditions. In some anaerobic protozoa and bacteria, such conditions are achieved when ferredoxin is reduced by the fermentation enzyme pyruvate ferredoxin oxidoreductase (POR). Ferredoxin can transfer one electron to 5-nitroimidazole, resulting in the reduction of the nitro group. POR does not occur in mammalian cells. The corresponding enzyme to POR in mammalian cells is pyruvate decarboxylase, which is not able to establish a reducing potential high enough for the reduction of 5-nitroimidazoles. The reduced products of 5-nitroimidazoles disrupt the DNA structure, thereby interfering with transcription and replication.

Clinical Use

E. histolytica colonization of the large intestine is eradicated using a luminal agent such as diloxanid furoate or paromomycin. Invasive amoebiasis (colitis,

liver abscess) is treated with one of the 5-nitroimidazole derivatives [4], followed by a luminal agent to prevent relapse from remaining cysts in the intestine.

G. lamblia is treated with 5-nitroimidazole derivatives. Paromomycin is a second choice in specific circumstances (e.g. pregnancy). In a Cochrane review, where 34 trials were included and where only one trial was without significant methodological flaws, the authors concluded that a single dose of tinidazole can provide the highest clinical cure rate with relatively few adverse effects. The high recurrence rate of disease after initial drug therapy is a problem.

Antipsychotic Drugs

DAVID C. MAMO, SHITIJ KAPUR
PET Centre - Schizophrenia Division, Centre for
Addiction and Mental Health, Toronto, ONT, Canada

Synonyms

Typical antipsychotic drugs: Neuroleptic drugs; conventional antipsychotic drugs; older antipsychotic drugs;

Atypical antipsychotic drugs: Novel antipsychotic drugs; serotonin/dopamine antagonists; 5HT_{2A}/D₂ antagonists.

Definition

Drugs that are effective in alleviating psychotic manifestations of a number of neurodegenerative and psychiatric disorders especially ►schizophrenia. Antipsychotic drugs are generally divided into two main groups based on their propensity to cause motor side effects and sustained elevation of plasma ►prolactin levels at clinically effective doses. Older or “typical” antipsychotic drugs (e.g. chlorpromazine and haloperidol) are associated with a high incidence of motor adverse effects and usually cause hyperprolactinemia. Newer antipsychotic drugs (clozapine, risperidone,

olanzapine, quetiapine, and ziprasidone) are called “atypical” antipsychotic drugs because they cause significantly lower motor side effects and usually avoid hyperprolactinemia.

Mechanism of Action

The serendipitous discovery of the antipsychotic effect of chlorpromazine in 1952 brought renewed hope in the treatment of psychotic disorders. The observation of chlorpromazine’s antagonism of dopamine receptors heralded the introduction of multiple other antipsychotic drugs based on their common ability to cause catalepsy in laboratory animals leading to the dopamine hypothesis of schizophrenia. Central to the dopamine hypothesis is that all known antipsychotic medications, including atypical antipsychotic medications, bind to dopamine-D₂ receptors (D₂-receptors). With the exception of aripiprazole, a partial agonist at D₂-receptors, ▶[positron emission tomography](#) (PET) studies have shown a direct relationship between central D₂-▶[receptor occupancy](#) and clinical effects of antipsychotic medications, with clinical response occurring only when at least 60% of central D₂-receptors are occupied while ▶[extrapyramidal side effects](#) (EPS) occur at D₂-receptor occupancy above 80% [1]. Antipsychotic doses resulting in D₂-receptor occupancy higher than 80% result in more adverse effects with no additional clinical benefit, consistent with earlier observations that increasing the antipsychotic medication beyond this ‘neuroleptic threshold’ resulted in no additional benefit other than possibly decreasing clinical measures of hostility.

The introduction of clozapine presented a major challenge to the dopamine hypothesis. Not only does it show a modest clinical superiority over older antipsychotic agents (i.e. it is effective in some patients who do not respond to older antipsychotic drugs), but it does so without causing EPS or hyperprolactinemia. Pharmacologically, clozapine has been shown to have a low affinity for dopamine D₂-receptors (resulting in 20–70% occupancy) and a high affinity for serotonin (5HT₂) receptors (>80% occupancy). This gave rise to the hypothesis that its atypical nature was related to its high 5HT₂-receptor (specifically 5HT_{2A}-receptor) affinity relative to its low D₂-receptor affinity [2]. The role of 5HT_{2A} antagonism in the uniqueness of clozapine has been challenged [1]. A number of trials using drugs known to be antagonists of the 5HT_{2A}-receptor (but not of dopamine receptors) have failed to show clozapine-like efficacy. Similarly, the 5HT_{2A}-receptors are saturated by clozapine at sub-therapeutic doses, indicating that 5HT_{2A}-receptor antagonism is not sufficient to effect an antipsychotic response. There are some case reports suggesting that augmentation of older antipsychotic medications with specific 5HT₂-receptor antagonists may potentiate the antipsychotic efficacy, but this remains to be tested in controlled clinical trials.

Recently there has been interest in modulating release of prefrontal dopamine (putative improved cognitive function) using antagonists or inverse agonists at other serotonin receptors including 5HT_{2C} and 5HT₆ receptors, though these studies remain at the preclinical stage. In summary, it has been suggested that clozapine’s low EPS and avoidance of hyperprolactinemia is attributable to 5HT₂ antagonism, but some degree of D₂-receptor antagonism may still be necessary for an antipsychotic response.

The 5HT₂/D₂ hypothesis was influential in the introduction of four new antipsychotic medications (risperidone, olanzapine, quetiapine, and ziprasidone), all having in common a high ratio of 5HT₂/D₂ receptor affinity and lower incidence of both EPS and hyperprolactinemia [2]. Paliperidone, a recently introduced antipsychotic, is the active metabolite of risperidone (5-hydroxyrisperidone), with a similar binding profile to the parent drug. At least in the case of risperidone and olanzapine (and possibly also ziprasidone), this ‘atypical’ nature appears to be lost in a dose-dependant manner resulting in the appearance of EPS and sustained hyperprolactinemia at higher doses. Indeed, the relationship between dopamine D₂-receptor occupancy and clinical effects (response and EPS) for risperidone and olanzapine in human subjects studied with PET is very similar to that found with older antipsychotic drugs (i.e. a threshold >60% D₂-receptor occupancy for clinical response and >80% D₂-receptor occupancy for EPS). On the other hand, clozapine and quetiapine are clinically effective at lower D₂-receptor occupancy without showing sustained hyperprolactinemia. Some studies evaluating the ratio of D₂-receptor occupancy in extrastriatal regions relative to the striatum suggested that atypical antipsychotic medications preferentially bind to extrastriatal (i.e. limbic) D₂-receptors when compared with typical antipsychotic drugs. However, data from a study using kinetic analysis (a technique that avoids a number of the limitations of ratio studies) in non-human primates is not consistent with this hypothesis. The dual observation that antagonism of dopamine D₂ receptors is associated with both clinical antipsychotic effects as well as adverse motor (EPS) and subjective (anhedonia) effects, partial agonists at D₂ receptors have been a focus of drug development, leading to the first drug in this category on the market (aripiprazole). The intrinsic efficacy of the partial agonist at the D₂ receptor is thought to be critical to produce adequate antagonism without deleterious stimulation of the D₂ receptors leading to worsening of psychotic symptoms. The experience with aripiprazole, with an intrinsic efficacy of circa 30%, has shown this drug to be an effective antipsychotic with minimal EPS notwithstanding very high central D₂ occupancy in excess of 90%, consistent with its partial agonist effects.

Recent studies suggest that the apparent low striatal D₂-receptor occupancy may be a result of quetiapine and clozapine's loose binding to D₂-receptors (i.e. high k_{off} resulting in low ▶affinity for D₂-receptor) [1]. Hence endogenous dopamine and low concentrations of radioligands (used in these experiments) may displace an appreciable amount of bound drug resulting in underestimation of D₂-receptor occupancy. In one study, patients treated with quetiapine at doses ranging from 300 to 600 mg/day showed normal prolactin levels and less than 20% D₂-receptor occupancy 12 h after their last dose. However, transiently elevated prolactin levels and appreciable (64%) dopamine D₂-receptor binding were noted 2 h after drug administration. Similarly clozapine (350 mg/day) resulted in 71% D₂-receptor occupancy 1–2 h after administration, declining to 55% and 26% after 12 and 24 h, respectively. While these findings await replication, they raise the possibility that different pharmacodynamic properties of dopamine receptor antagonists may be sufficient to explain their varying degrees of 'atypicality' [3]. The transient dopamine receptor occupancy may also account for clozapine's clinical superiority, since it has been shown that repeated transient dopamine receptor antagonism results in sensitization of the dopamine system, while continuous receptor antagonism results in tolerance and up-regulation of the system.

While all antipsychotic medications have a robust acute effect on delusions, auditory hallucinations, and disorganized behaviour (also known as 'positive symptoms'), and maintenance treatment has been shown to decrease both relapse and hospitalization rates, their effect on negative symptoms (apathy, avolition, alolia, and affective flattening) and related cognitive disturbance (e.g. attentional problems and disrupted working memory) is at best marginal. Newer antipsychotic medications, especially clozapine, have been shown to have some effect on negative symptoms and selected cognitive measures when compared with older antipsychotics such as haloperidol, but this topic remains controversial due to the difficulty in distinguishing primary negative symptoms from secondary (i.e. adverse) effects of the (older) medications [3]. In vivo measurements of extracellular dopamine levels using microdialysis in rodents and primates have shown that while both acute administration of clozapine and haloperidol result in an increase in dopamine levels in the striatum, clozapine results in higher dopamine levels in the prefrontal cortex compared with haloperidol. With chronic administration of clozapine in rodents, the increased dopamine release is maintained only in the prefrontal cortex but not in the striatum. It has been postulated that this modulation of prefrontal dopaminergic transmission may be involved in its effects on cognitive and negative symptoms, which are known to be associated with decreased prefrontal

activity in functional neuroimaging studies [4]. Current approaches to drug development are focused on modulation of prefrontal dopaminergic activity directly (e.g. D1 agonism), indirectly via dopaminergic mechanisms (e.g. dopamine reuptake inhibition) or serotonergic mechanisms (e.g. 5HT_{2C} and 5HT₆ antagonism) – this focus is part of a growing realization that the 'antipsychotic' effect of currently available antipsychotics is largely limited to positive symptoms, while negative and cognitive symptoms are associated with functional outcome, remain unresponsive to D₂ antagonists. Other approaches to cognitive enhancement also involves modulation of muscarinic M1 receptors (e.g. desmethylclozapine, a metabolite of clozapine with M1 agonist properties), nicotinic receptors (in particular alpha-7-nAChR), NMDA receptors (e.g. glycine and other NMDA receptor modulators), and metabotropic glutamate receptors (e.g. mGluR5 and mGluR2). These mechanisms are unlikely to be associated with effects on positive symptoms, though some downstream effects may also be related to prefrontal dopamine release (e.g. M1 agonists and medial prefrontal cortical release of dopamine) so that the effects may well be convergent mechanistically notwithstanding the targeting of different receptors.

It is thought that the mesolimbic dopaminergic projections from ventral tegmental area (VTA) are involved in the clinical response to antipsychotic drugs, and that in contrast to older antipsychotic drugs, newer antipsychotic drugs may act preferentially on these neurons. Acute administration of haloperidol in anaesthetized rodents has been shown to increase firing rate of neurons in the substantia nigra (SN) as well as the VTA. On the other hand daily administration for 3 weeks leads to a decline in the activity in these dopaminergic neurons below that at baseline, an electrophysiological phenomenon known as 'depolarization block'. All antipsychotic medications have the ability to cause depolarization block in the VTA, and their ability to cause depolarization block in the SN is related to their propensity to cause EPS in human subjects. Clozapine causes depolarization block in the VTA but not in the SN, consistent with involvement of the mesolimbic system in its antipsychotic effect [5].

In summary, the mechanism of action of antipsychotic drugs appears to be intricately linked with the normalization of a disrupted state of dopaminergic transmission. Remission of positive symptoms and the emergence of extrapyramidal side effects are associated with specific levels of striatal dopamine D₂-receptor occupancy. An increased ratio of 5HT₂/D₂-receptor antagonism and/or altered pharmacodynamic properties of atypical antipsychotic drugs resulting in loose binding to D₂-receptors may be involved in the decreased incidence of motor side effects with some newer antipsychotic drugs, while antipsychotic action may involve activity of these drugs on the mesolimbic

ascending dopaminergic neurons. Preferential activity and modulation of prefrontal dopaminergic activity by atypical antipsychotic drugs may be related to their effects on cognitive and negative symptoms of schizophrenia.

Clinical Use (Including Side Effects)

Antipsychotic medications are indicated in the treatment of acute and chronic psychotic disorders. These include schizophrenia, schizoaffective disorder, and manic states occurring as part of a bipolar disorder or schizoaffective disorder. The co-administration of antipsychotic medication with antidepressants has also been shown to increase the remission rate of severe depressive episodes that are accompanied by psychotic symptoms. Antipsychotic medications are frequently used in the management of agitation associated with delirium, dementia, and toxic effects of both prescribed medications (e.g. L-dopa used in Parkinson's disease) and illicit drugs (e.g. cocaine, amphetamines, and PCP). They are also indicated in the management of tics that result from Gilles de la Tourette's syndrome, and widely used to control the motor and behavioural manifestations of Huntington's disease.

The choice of antipsychotic medications is largely dependent on considerations related to their individual side effect profile. Older antipsychotic medications are generally divided into high, moderate, and low potency drugs, potency being related to their propensity for causing EPS. ► **Tardive dyskinesia** is the most common and potentially most disabling long-term side effect. The neuroleptic malignant syndrome is the most severe neurological side effect and consists of hyperthermia, autonomic instability, and muscle stiffness that may result in dehydration, renal failure, and death. Early diagnosis and management has resulted in decreased mortality from this condition. In addition to neurological side effects, other systems may also be affected by typical antipsychotic medications. In contrast to the neurological side effects, the incidence of these side effects are generally inversely proportional to the potency of the drug used. These include autonomic effects (e.g. tachycardia, dry mouth, urinary retention, constipation), haematologic effects (e.g. neutropenia and rarely agranulocytosis), neurological (sedation, seizures), endocrine (e.g. weight gain, galactorrhoea, obesity, hypercholesterolemia, and hyperglycemia), and dermatological effects (e.g. photosensitivity).

The atypical antipsychotic drugs were introduced with the goal of minimizing neurological adverse effects associated with older antipsychotic medications. However, these medications are not free of serious adverse effects including dose-related parkinsonism (risperidone and olanzapine), dose-related risk of seizures (clozapine), endocrinological manifestations (including diabetes, weight gain, and hypercholesterolemia), and

haematological abnormalities (neutropenia and agranulocytosis with clozapine). Nonetheless, while older antipsychotic medications remain the most widely used antipsychotic medications globally, the use of newer antipsychotic medications has largely dominated the market in Western Europe and North America. The principle clinical advantage that has led to this shift in prescribing practice is undoubtedly the decreased incidence of neurological side effects, which are associated with significant morbidity and poor outcome largely secondary to non-compliance. Indeed, they are generally recommended as first line agents in the treatment of psychotic disorders, with typical antipsychotic drugs reserved for patients having previously been successfully maintained on these medications or requiring parenteral antipsychotic drugs (e.g. short-acting intramuscular neuroleptics for agitation, and long-acting 'depot neuroleptics' for patients who are non-compliant with oral medication). While atypical antipsychotic medications are more acceptable to patients, their impact on the long-term outcome of schizophrenia remains to be established. Moreover, continued vigilance for their potentially significant long-term side effects including obesity, hypercholesterolemia, and impaired glucose tolerance is warranted. While all antipsychotic drugs may be associated with obesity and metabolic syndrome, generally the likelihood for these effects are highest for clozapine and lowest for ziprasidone and aripiprazole in the following order:

clozapine > *olanzapine* > *risperidone*, > *quetiapine*
> *ziprasidone* and *aripiprazole*.

All antipsychotic medications are effective in alleviating positive and negative symptoms of schizophrenia, while atypical antipsychotic agents have been associated with some superior efficacy in reduction of negative symptoms. Following an adequate trial of antipsychotic treatment (8–12 weeks of treatment with adequately dosed antipsychotic drug) in acute schizophrenia, 60% of patients show significant improvement or remission compared with 20% of patients treated with placebo. Of the 40% who do not respond, approximately half respond to subsequent trials with other antipsychotic medications. The acute phase of the illness is treated with an oral antipsychotic medication titrated to the appropriate clinically effective dose. This may be supplemented by short-acting intramuscular antipsychotic agents in patients in whom rapid sedation is clinically indicated (e.g. severe agitation). Patients failing to respond to an adequate trial of an antipsychotic medication should be switched to another antipsychotic drug from a different pharmacological class. Patients who fail to respond or show only partial response to two adequate trials of antipsychotic drugs (including at least one atypical antipsychotic drug) or experience severe neurological side

effects (e.g. tardive dyskinesia) should be considered for a trial of clozapine [6]. Significant inter-individual variability in dose requirements is commonly seen, and this may be influenced by sex, age, and concomitant medications. Increasing the dose beyond which causes extrapyramidal side effects results in no additional clinical advantage. The augmentation with a second antipsychotic (antipsychotic polypharmacy) has not been supported by randomized controlled trials, and while this is very common in clinical practice, the practice should be reserved after other therapeutic strategies have failed and certainly not before a trial of clozapine. Regular monitoring for weight gain, hypercholesterolemia, triglycerides, and fasting blood sugars, as well as extrapyramidal side effects is warranted especially during the first 3 months of treatment, and then every 6 months or following any medication or dose changes. Patients are maintained on the clinically effective dose for the next 3–6 months. Following the resolution of the acute phase, the dose may be decreased to address any adverse effects having significant functional or emotional impact on the patient's well-being.

The duration of treatment is generally considered to be indefinite in patients diagnosed with schizophrenia, though selected patients recovering from a first psychotic episode may be considered for gradual taper of medication after at least 1-year of treatment and with close psychiatric follow up. Patients with a history of multiple psychotic episodes should be stable for at least 5 years before considering a trial off medication. When considering discontinuation of antipsychotic treatment, an individualized approach is recommended with careful consideration of certain aspects of the disease course (e.g. severe occupational impairment when acutely ill, history of suicidal attempts and violence). Dose discontinuation is associated with a very high 2-year relapse rate up to 60% in chronically treated patients, though most relapses occur within the first 3 months of discontinuation. If drug discontinuation is to be attempted, gradual taper and very close monitoring is critical, and in some studies has not been associated with longer duration of hospitalization. Symptom-targeting strategies and drug holidays have been tried in the past, but for most patients this is no longer recommended since it is associated with very high relapse rates. Finally, with the resolution of the acute phase of the psychotic episode, psychosocial, occupational, and cognitive difficulties need to be addressed, since they usually persist with significant impact on the patients' functional status.

In summary, antipsychotic drugs have a significant impact on the acute resolution and the maintenance of remission of symptoms of schizophrenia, enabling focus on rehabilitation efforts directed at residual cognitive, social, and occupational disabilities. The

advent of atypical antipsychotic drugs brought lesser motor side effects and renewed hope to patients and families affected by this devastating illness, though these newer agents incur a variable degree of risk of weight gain and metabolic syndrome which needs to be carefully monitored. It is hoped that a better understanding of pharmacological mechanisms underlying the clinical superiority of drugs like clozapine will lead to the development of new treatment strategies with better efficacy and improved side effect profile.

Antipyretic Agents

Antipyretic agents are used for the treatment of fever. The most commonly used antipyretics are acetylsalicylic acid and paracetamol (synonym acetaminophen).

► Non-steroidal Anti-inflammatory Drugs

Antiretroviral Agents

► Antiviral Drugs

Antirheumatoid Drugs

Antirheumatoid drugs are employed in the treatment of rheumatoid disease (rheumatoid arthritis). The

characteristic feature of this autoimmune disease is a persistent inflammation of peripheral joints. The inflammatory process leads to joint damage and subsequently to marked functional impairment. Inflammatory cytokines play a major role in the pathogenesis of the disease. Drugs used in the therapy of rheumatoid arthritis are non-steroidal anti-inflammatory drugs, glucocorticoids, immunosuppressive agents and disease-modifying antirheumatoid drugs (DMARDs). DMARDs are not analgesic, but they suppress the inflammatory process. DMARDs include drugs with cytotoxic and immunosuppressant activity (azathioprine, cyclosporin, methotrexate), gold compounds (auranofin and sodium aurothiomalate), anti-malarial drugs (chloroquine and hydroxychloroquine) and sulphasalazine. The last is also used for the treatment of chronic inflammatory bowel disease.

Antisense DNA; Reverse complementary oligonucleotides; ASON

Definition

Antisense therapy means the selective, sequence-specific inhibition of gene expression by single-stranded DNA oligonucleotides. By hybridizing to the target mRNA, which results in a subsequent double-helix formation, gene expression is blocked. This process can occur at any point between the conclusion of transcription and initiation of translation or even possibly during translation.

Description

ASON are sequences of usually 17–30 bases of single-stranded DNA that hybridize to specific genes or their mRNA products by Watson–Crick base pairing and disrupt their function. In the case of AS-ODN (antisense oligodeoxyribonucleotides) cellular RNaseH is able to bind to the DNA–RNA duplex and hydrolyze the RNA, resulting in increased transcript turnover. Modifications to the deoxy moiety at the 2'-sugar position prohibits RNase H action.

In rarer cases the ODNs also prevent normal gene transcription by directly forming triplex-helix structures with target DNA. This does not destroy a gene but prevents its unwinding or its binding to a gene promoter.

The short length of a typical ASON facilitates cell internalization and increases hybridization efficiency by reducing base-mismatch errors. Once hybridization has occurred the ASON–mRNA complex becomes a substrate for intracellular ▶RNAses (e.g., RNase-H) that catalyze mRNA degradation and allow ASON to recycle for another base pairing with the next target mRNA molecule. The net result of this process is a sustained decrease of target mRNA translation and a lower intracellular level of the corresponding protein (Fig. 1).

The therapeutic utility of systemically administered ASON had been limited by their short plasma half life (sometimes even less than 3 min). This is due to their sensitivity to nuclease digestion. When the first-generation ASON were chemically modified, e.g., by replacing the oxygen in the phosphodiester bond with sulfur (phosphorothiorate) they obtained an increased stability in biological fluids while their antisense effect has been maintained. First-generation agents can be delivered via intravitreal injection, parenterally, by topical cream, enema, and inhaled aerosol. These antisense

Antisense Oligonucleotides. Figure 1 Schematic representation of the action of antisense oligonucleotides. They bind to their respective target mRNA preventing protein translation.

drugs have a sulfur chemistry modification that makes the drug more resistant to degradation, increasing stability in the blood stream and in tissues. This specific chemical modification prevents the rapid elimination of the drug from the body.

The second-generation chemistry adds 2'MOE modifications to the sulfur modification of first-generation chemistry. In turn, second-generation drugs have increased target-binding affinity and resistance to degradation. Second-generation drugs are composed of both RNA-like and DNA-like nucleotides, while first-generation drugs are entirely DNA-like. Because RNA hybridizes more tightly to RNA than to DNA, the second-generation drugs have a greater affinity for their RNA targets and, therefore, greater potency.

Another new modification is the 2'-deoxy-2'-fluoro-Darabinonucleic acid (2'F-ANA), which increases the strength of the oligonucleotide-mRNA hybrids, elicits efficient RNase H-mediated degradation of the target, is more nuclease resistant and reaches high intracellular concentrations for prolonged time. Similar results could be obtained with oxetane modified ASONs.

A problem with employment of ASON in a larger clinical setting is their poor uptake and inappropriate intracellular compartmentalization, e.g., sequestration in endosomal or lysosomal complexes. In addition, there is a need for a very careful selection of the ASON-mRNA pair sequences that would most efficiently hybridize. To date, several computer programs are used to predict the secondary and tertiary structures of the target mRNA and, in turn, which of the mRNA sequences are most accessible to the ASON. However, even with this sophisticated techniques, the choice of base-pairing partners still usually includes a component of empiricism. Despite these principal limitations, it has become clear that ASON can penetrate into cells and mediate their specific inhibitory effect of the protein synthesis in various circumstances.

The basic concept of the use of ASON can be modified in several ways:

1. Antisense RNA that is expressed intracellularly following transfection with antisense genes.
2. ► **Ribozymes** that are small RNA molecules with endoribonuclease activity and exhibit catalytic sequence-specific cleavage of the target.
3. The ribozymes were widely modified and can be further subdivided according to their structural features in group I ribozymes, hammerhead ribozymes, hairpin ribozymes, ribonuclease P (RNase P), and hepatitis delta virus ribozymes.

Pharmacological Relevance Examples of Applied ASON Therapeutics

The number of clinical trials ongoing represents a growing interest in antisense technology.

1. ASON to inhibit angioplasty restenosis. Patients suffering from coronary stenosis can successfully be treated by percutaneous transluminal coronary angioplasty (PTCA). However, in up to 50% of the patients restenoses occurs necessitating a repeated PTCA: ASON emerged as a potentially useful strategy to prevent such restenoses in animal models and fist clinical trials are currently under progress [1].
2. ASON against HIV infection. Once HIV has infected the cell, the genomic RNA of the retrovirus is used to code for a double-stranded cDNA intermediate. This cDNA is integrated into the genome of the host cell by the viral integrase. RNA identical to the genomic RNA of the virus will be transcribed from the DNA of this provirus by the infected cell. In experimental systems, ASON were used to target various parts of the viral life cycle, e.g., genomic RNA reverse transcription, viral mRNA transcription, and viral translation. With this regard, GEM 91, a 25mer ASON against the HIV-1 gag gene has extensively studied. Newer oligonucleotide analogs are now available, which act as strong steric block agents of HIV RNA function. In ongoing studies targeting the HIV-1 *trans*-activation responsive region (TAR) and the viral packaging signal (ψ) with steric block oligonucleotides of varying chemistry demonstrate their great potential for steric blocking of viral protein interactions in vitro and in cells and describe the first antiviral studies [2].
3. ASON for targeting the Bcl-2 proto-oncogene in human cancers. The Bcl-2 protein is a major-apoptosis inhibitor originally identified by its involvement of a chromosomal translocation t(14;18) found in follicular Non-Hodgkin Lymphoma. Beside lymphomas, bcl-2 is up-regulated in several other tumors, e.g., leukemia, breast cancer, melanoma, prostate cancer, small and non-small lung carcinoma. In most of these studies, an 18-mer phosphothiorate ASON targeting the first six codons of bcl-2 (ISIS G3139) was used. The bcl-2 antisense therapy was feasible and showed potential antitumor activity. However, the mean inhibition of bcl-2 expression was only moderate and the clinical significance of this small decline was uncertain. Besides bcl-2, a large variety of other ► **oncogenes** have been targeted in cancer cell models. Table 1 gives an overview of such attempts. An emerging understanding of the most effective treatment setting – to test the addition of oblimersen to other therapies – has come from recent reports of two randomized studies in melanoma and CLL. In the melanoma study, the addition of oblimersen to dacarbazine produced a survival benefit for patients with normal LDH. In the CLL study, the addition of oblimersen to fludarabine and cyclophosphamide significantly increased durable CR and nPRs,

Antisense Oligonucleotides. Table 1 Malignant disorders as potential targets for ribozyme gene therapy

Target gene	Gene product	Ribozyme-induced change of function
<i>bcr-abl</i>	Tyrosine kinase	Inhibition of cell proliferation and colony formation
<i>PML/RAR α</i>	Transcriptional regulator	Inhibition of cell proliferation; induction of apoptosis; increase in sensitivity against ATRA
AML1/MTG8	Transcription factor	Inhibition of cell proliferation; induction of apoptosis
N-ras, H-ras, K-ras	Signal transduction pathway	Inhibition of cell proliferation and colony formation; change in morphology, enhanced melanin synthesis; decrease of in vivo tumorigenicity
EGFR	Receptor tyrosine kinase	Inhibition of cell proliferation and colony formation; decrease of in vivo tumorigenicity
<i>c-erbB-2</i> (HER2/ <i>neu</i>)	Receptor tyrosine kinase	Inhibition of cell proliferation; decrease of in vivo tumorigenicity
<i>c-erbB-4</i>	Receptor tyrosine kinase	Inhibition of mitogenesis and colony formation; decrease of in vivo tumorigenicity
Estrogen receptor	Transcriptional regulator	Inhibition of cell-cycle progression
Androgen receptor	Transcriptional regulator	Inhibition of androgen receptor transcriptional activity
<i>c-fms</i>	Growth factor receptor	Inhibition of cell proliferation
RET	Receptor tyrosine kinase	Inhibition of colony formation
<i>Mdr-1</i>	Drug-efflux pump	Reduction in resistance to chemotherapeutic drugs
<i>c-fos</i>	Transcriptional regulator	Change in morphology; reduction in resistance to chemotherapeutic drugs
CD44	Cell adhesion molecule	n.d.
VLA-6	Adhesion receptor	Decrease of in vitro invasion and in vivo metastatic ability
MMP-9	Matric metalloproteinase	Decrease of in vivo metastatic ability
<i>CAPL</i> (S100A4)	Calcium-binding protein	Decrease of in vitro invasion; reduction in expression of MMP-2, MT1-MMP, and TIMP-1; decrease of in vivo metastatic ability
Pleiotrophin	Growth factor	Inhibition of colony formation; decrease of in vivo tumor growth, tumor angiogenesis, and metastatic ability
VEGF-R1/VEGF-R2	Growth factor receptors	Decrease of in vivo tumor growth; decrease of in vivo metastatic ability (VEGF-R2 only)
VEGF	Growth factor	n.d.
bFGF-BP	bFGF-binding protein	Reduction of release of biologically active bFGF; decrease of in vivo tumor growth and tumor angiogenesis
Telomerase	Ribonucleoprotein	Suppression of telomerase activity; inhibition of cell proliferation; change in morphology; induction of apoptosis
<i>Bcl-2</i>	Anti-apoptotic protein	Induction of apoptosis
PKC-α	Anti-apoptotic protein	Induction of apoptosis

with the greatest benefit occurring in patients with chemosensitive disease. Based on these considerations, a future randomized study of GO and oblimersen would be most likely to demonstrate the benefit of oblimersen in the setting of patients who had not previously been exposed to chemotherapy [2–4].

- Formivirsen to treat cytomegalovirus-induced retinitis in HIV-infected patients. The first antisense drug approved by the US Food and Drugs Administration (FDA) was formivirsen (ISIS 2922) that targets the CMVIE2 protein. Formivirsen was approved for the treatment of cytomegalovirus-induced retinitis in patients with AIDS. One or both eyes can be affected

Antisense Oligonucleotides. Table 2 Viral disorders with malignant complications as potential targets for ribozyme gene therapies

Virus	Malignant complication	Target gene for ribozymes	Ribozyme-induced change of function
Human papilloma virus (HPV)	Cervical cancer, oral cancer	E6, E7	Inhibition of cell proliferation and colony formation
Epstein–Barr virus (EBV)	Burkitt's lymphoma, nasopharyngeal carcinoma, lymphoproliferative disorders in immuno-suppressed patients (e.g., AIDS, transplant recipients)	EBNA-1	Inhibition of cell proliferation
Hepatitis B virus (HBV)	Hepatocellular carcinoma	Progenomic RNA	Inhibition of viral gene expression
Hepatitis C virus (HCV)	Hepatocellular carcinoma	5'-untranslated/cor region	Inhibition of viral gene expression

and it is not unusual for patients to suffer from severe visual impairment of even blindness as a result of untreated infections. However, the conventional treatment of CMV-retinitis also remains problematic, in particular for patients who cannot take, do not respond or become resistant to standard therapy by ganciclovir, foscarnet, and cidofovir. The main drawback of formivirsen is its need for local administration by intravitreal injection. Of note, the inhibitory effect of formivirsen for cytomegalovirus replication *in vitro* is about 30 times higher than for ganciclovir, the conventional treatment of choice for CMV infection.

- For ISIS 301012, a second-generation antisense inhibitor of apoB-100 in November 2006. Isis announced results from two Phase 2 clinical trials of ISIS 301012. In the first study reported, patients with high cholesterol on stable doses of statins were treated with ISIS 301012 for 5 weeks. Patients who received 300 mg/week of ISIS 301012 in this study achieved a 51% reduction in LDL-cholesterol (LDL), a 42% reduction in total cholesterol (TC), and a 41% reduction in triglycerides (TG) beyond the levels achieved with statins alone.
- ASON are able to regulate the sonic hedgehog pathway by down-regulating *Gli2* (glioma associated oncogene), which plays a predominant role in the proliferation of HCC (hepatocellular carcinoma) cell lines. The suppression of *Gli2* expression may provide a useful therapeutic option for the treatment of HCC [5].

Table 2 summarizes current ASON-mediated therapies against viral infections.

Non-Sequence Specific Activities of ASON

A rather unexpected stimulation of lymphocyte proliferation by ASON was frequently observed. Of note, the phosphorothiorate backbone of a given ASON

has immune stimulatory properties itself, which are independent of its DNA sequence. In contrast, the stimulatory effects of unmodified oligonucleotides are dependent of a simple unmethylated **▶CpG dinucleotide motif**. The increasing number of **▶CpG motifs** generally increases the level of activation of B-lymphocytes. In addition, ASON may have effects of cytokine or immunoglobulin secretion or may alter the DNA binding activity of transcription factors. These nonantisense immune-enhancing (or sometimes immune-suppressing) effects are generally recognized as an undesirable side-effect. However, they may have therapeutic utility by their own, even though the mechanisms are not yet fully understood.

In general, systemic treatment with ASON is well-tolerated and side effects are dose-dependent. Among those, thrombocytopenia, hypotension, fever, increasing liver enzymes, and complement activation were most frequently seen.

Antithyroid Drugs

KATJA SIBYLE MÜHLBERG, RALPH PASCHKE

Synonyms

Thionamides

Definition

Antithyroid drugs block thyroid hormone production in the thyroid gland. Based on their mechanism of action antithyroid drugs are defined as: (i) thionamides, which block thyroid hormone production by inhibition of thyroid peroxidase mediated iodination of tyrosine residues of thyroglobuline. (ii) aniones, which inhibit the transfer of iodine into the thyroid gland, e.g. perchlorate. (iii) high-dose (g range) iodine as lugol's solution or as oral radiographic contrast agents that block the release of thyroid hormones for days with subsequent escape. Other drugs utilized to treat hyperthyroidism are β -blocking agents, and seldom lithium.

Thionamides are heterocyclic compounds that contain a thiourylene group. Thiouracil was the first widely used antithyroid drug. Further studies led to the introduction of substances with fewer side effects. Three drugs of this type are currently in use: methimazole, carbimazole and propylthiouracil [1]. Thiouracil and propylthiouracil belong to the subgroup of pyrimidines, whereas methimazole and carbimazole belong to the thioglyoxalines. The goitrogenic properties of several substances were first recognized in the 1940s when thyroid enlargement was noticed in rats that had been given sulfaguanine to study the antibiotic effects of sulfaguanidine on the intestinal flora [1]. Others noted the development of goiters in rats fed with phenylthiocarbamide. Later it was concluded that the effect of thiourea and the sulfonamides was due to the inhibition of thyroid hormone synthesis. It was first suggested that the entire thiourylene grouping (NH.CS.NH) would be necessary for antithyroid activity. Further studies revealed that only the thiocarbamide group (S = C–N) is essential for antithyroid activity.

Mechanism of Action

Synthesis of thyroid hormones occurs in several steps. At first, inorganic iodide is actively concentrated by

thyroid follicular cells by the sodium iodide symporter. After oxidation to iodine (= iodination) it is bound to tyrosine residues thus forming monoiodothyronine (MIT) or diiodothyronine (DIT). MIT and DIT are coupled to form \blacktriangleright triiodothyronine (T_3) or \blacktriangleright thyroxine (T_4). Both iodination and coupling occur at the apical membrane of the thyroid follicular cell and within the \blacktriangleright thyroglobuline (Tg) molecule, and are catalyzed by the enzyme \blacktriangleright thyroid peroxidase (TPO). TPO is a haemoprotein enzyme with binding sites for both iodine and tyrosine. In model systems, TPO has no catalytic activity in the absence of H_2O_2 . Therefore, it is assumed that H_2O_2 production is important also for thyroid hormone formation in vivo. TPO degrades H_2O_2 in a catalase-like reaction releasing O_2 . Several iodination intermediates were postulated for this reaction, for instance TPO-bound iodinium (I^+) and TPO-bound hypoiodite (I^-). T_3 and T_4 are stored in the follicular lumen bound to thyroglobuline. The re-entry of Tg into the thyroid follicular cell involves a macropinocytosis process. Thyroid hormones are released after proteolysis of Tg. Type I and type II 5' deiodinase generate the active hormone T_3 by reductive deiodination of the phenolic ring of T_4 [2] (Fig. 1).

Antithyroid drugs inhibit the thyroid peroxidase-mediated iodination and coupling. Inactivation of TPO by antithyroid drugs involves a reaction between the drugs and the oxidized heme group produced by the interaction between TPO and H_2O_2 . Results of several studies suggested that antithyroid drugs bind to the enzyme either at the same site as iodide or at a nearby site, and that the binding interferes with the binding of iodide [1, 2]. The type of inhibition depends on the extent of TPO inactivation and drug oxidation. These rates depend mainly on the iodine to drug concentration ratio. At a high iodine to drug ratio the inhibition of iodination is reversible and TPO is only partially inactivated. Under these conditions extensive drug oxidation occurs. When the iodine to drug ratio is low, iodination is irreversibly inhibited. This is associated with rapid and complete inactivation of TPO [2].

Propylthiouracil (PTU), but not methyl-mercaptoimidazole (MMI), has an additional peripheral effect. It inhibits the monodeiodination of thyroxine to triiodothyronine by blocking the enzyme 5' monodeiodinase [1]. In humans the potency of MMI is at least 10 times higher than that of PTU, whereas in rats PTU is more potent than MMI. The higher potency of MMI in humans is probably due to differences in uptake into the thyroid gland and subsequent metabolism, because in vitro inhibition of thyroid peroxidase by MMI is not significantly more potent than by PTU [1, 6]. Whether antithyroid drugs have additional immunosuppressive actions is a matter of discussion [1, 2].

Antithyroid Drugs. Figure 1 Synthesis and secretion of thyroid hormones and mechanisms of action of antithyroid drugs. Iodine is actively concentrated by the thyroid gland (sodium iodide transporter). After oxidation it is bound to tyrosine residues thus forming monoiodothyronine (MIT) or diiodothyronine (DIT). MIT and DIT are coupled to triiodothyronine (T_3) or thyroxine (T_4) and are stored in thyroid follicles bound to thyroglobuline. Thyroid hormones are released by proteolysis. In the peripheral blood, T_4 is converted to T_3 . Antithyroid drugs act by inhibiting the thyroid peroxidase-mediated formation of T_3 and T_4 and compete with iodothyronine residues for oxidized iodine. Moreover, they inhibit iodine oxidation. Propylthiouracil (PTU), but not methyl-mercaptoimidazole (MMI), inhibits the monodeiodination of thyroxine to triiodothyronine.

Pharmacokinetics

Absorption of MMI from the gastrointestinal tract occurs rapidly and almost completely. Peak serum concentrations increase linearly and are in the range of 300 ng/ml 1–2 h after oral ingestion of 15 mg MMI. In vitro carbimazole is an effective inhibitor of iodination without prior hydrolysis to MMI. In contrast, carbimazole itself is inactive in vivo. During absorption and in serum it is almost completely converted to methimazole. Ten milligram carbimazole is equivalent to 6.7 mg MMI [2]. MMI is virtually not protein bound. The total volume distribution is about 40 L. The serum half life is 4–6 h and remains unchanged in hyperthyroid patients. Patients with hepatic disease have prolonged plasma disappearance, whereas in kidney disease the metabolism is unchanged. Because of its lipophilic character the transplacental passage and excretion in breast milk is high [1]. Little MMI is excreted in urine. Little is known about the products of metabolism of MMI and their way of excretion [1]. MMI can be applied parenterally.

PTU is also well absorbed from the gastrointestinal tract. Peak serum concentrations are in the range of 3 $\mu\text{g/ml}$ at 1 h after drug ingestion after an oral dose of

150 mg. PTU, 80–90%, is protein bound. The total volume distribution is around 30 L for PTU. The serum half life of PTU is 75 min. It is not altered in patients with thyrotoxicosis, renal disease and, in contrast to MMI, in liver disease. PTU is mostly excreted in the urine after hepatic conjugation with glucuronide [1]. Biotransformation of PTU primarily occurs at the S group. It results in substantial loss of antiperoxidase activity. The metabolites, 6-*n*-propyluracil, *S*-methyl-PTU, PTU disulfide and PTU glucuronide, are only weakly active or completely inactive as thyroid peroxidase inhibitors. Because of its high protein binding and ionization at a physiologic pH, PTU is excreted in breast milk to a lesser degree than MMI. PTU crosses the placenta to an equal extent as MMI.

Both drugs, MMI and PTU, are actively concentrated by the thyroid gland. Intrathyroidal concentrations of MMI are in the range of 5×10^5 M. There is no difference in intrathyroidal concentrations of MMI 3–6 and 17–20 h after ingestion of 10 mg of carbimazole. Little is known about intrathyroidal concentrations of PTU. Eight hours after a single dose of 10 mg of MMI or 100 mg of PTU inhibition of intrathyroidal organification of iodide is about 90% and 60%,

respectively. This may be one reason for the longer effect of MMI compared with PTU. MMI can be administered once daily, whereas PTU should be applied 3 times a day.

Metabolism of the drugs by TPO is largely iodine dependent. Under conditions of reversible inhibition of iodination, the drugs are rapidly metabolized to higher oxidation products such as sulfonate and sulfate, with disulfide as an intermediate. If there is irreversible inhibition of iodination (higher drug to iodide ratio), some of the drug is oxidized only to the disulfide stage, but the TPO is simultaneously inactivated and no iodination is observed [2].

Clinical Use (Including Side Effects)

In patients with a first episode of ►Graves' disease, thionamides are used for long-term treatment to achieve remission of the organ-specific autoimmune disease. The standard therapy in Europe is a 1–1.5 year course of antithyroid drug treatment. In contrast, ►radioiodine is the preferred initial treatment in North America [2, 3, 5]. The relapse rate following antithyroid drug treatment is approximately 50% within 1–2 years. Most relapses occur within the first 12 months [2, 3]. After an unsuccessful course of antithyroid drug treatment there is little chance that a second course will result in permanent remission [2, 3]. Therefore a definite treatment, i.e. surgery or radioiodine, should be performed in these cases. Various parameters have been tested for their ability to predict the outcome of the individual patient after withdrawal of antithyroid drug therapy. A prospective study showed a greater chance of remission in patients with mild hyperthyroidism, smaller goiters, a lower base-line level of antithyrotropin-receptor antibodies. However, until present no reliable markers with predictive statistical significance for the individual patient's remission or relapse has been identified [2]. In ►thyroid autonomy, which is mainly caused by somatic ►TSH receptor or Gs α mutations [3, 5], a spontaneous remission (e.g. by nodule apoplexia) is very uncommon. Therefore, antithyroid drug treatment is only used to render patients euthyroid before ablative treatment [2, 5].

Initial daily doses of 10–40 and 100–600 mg are recommended in clinical practice for MMI and PTU, respectively [1, 2]. Several studies have shown that treatment of hyperthyroidism with single daily doses of 10–40 mg of MMI is effective in the induction of euthyroidism in 80–90% of patients within 6 weeks [2]. The aim of the further antithyroid therapy is to maintain euthyroidism with the lowest necessary drug dose. Intrathyroidal drug accumulation is one cause for the efficiency of a single daily dose regimen. Moreover, a once daily dose yields better patients' compliance. Single daily doses of PTU have been shown to be less effective in achieving euthyroidism than administration of three divided doses a day. If a once daily

dose regimen is considered for the treatment of hyperthyroidism, MMI is preferred to PTU [1, 2]. In the case of antithyroid drug therapy before radioiodine therapy MMI should be preferred to PTU, because PTU increases the failure of radioiodine therapy, which may be related to its ability to neutralize iodinated free radicals produced by radiation exposure [1]. This effect can be overcome by increasing the radioiodine dose. Continuous application of MMI during and until 4 weeks after radioiodine therapy with the aim to maintain euthyroidism until the effect of the ¹³¹I therapy sets in was shown to reduce the final cure rate. It should therefore be discontinued a few days before radioiodine therapy and resumed after approximately 1 week.

The response to thionamides depends on the dose and the iodine intake. It occurs faster in subjects living in countries with moderately low iodine intake than in areas with iodine sufficiency [2]. Antithyroid drug doses should be gradually decreased to the minimal maintenance dose as the serum thyroid hormone levels fall. The aim is to restore the euthyroid state within 1–2 months. Relapses of Graves' hyperthyroidism usually occurs within the first 3–6 months after discontinuation of antithyroid drugs. A lifelong follow-up is necessary to prevent spontaneous hypothyroidism, which can develop years after thionamide therapy of Graves' disease [1]. The "block-and-replace regimen" with the simultaneous administration of an antithyroid drug and L-thyroxine is used in case of poor patients compliance or if follow-up is difficult [3]. The titration regimen with low dose therapy showed fewer adverse effects than the high dose "block-and-replace regimen" and was not less effective.

MMI and PTU can lead to methimazole embryopathy with choanal or esophageal atresia. In pregnant women the antithyroid drug dose should be minimized to prevent fetal hypothyroidism by maintaining the maternal free thyroxine serum level slightly above the upper limit of normal.

Side Effects

Antithyroid drugs have several side effects. The most frequent side effects are maculopapular rashes, pruritus, urticaria, fever, arthralgia and swelling of the joints. They occur in 1–5% of patients [1, 2]. Loss of scalp hair, gastrointestinal problems, elevations of bone isoenzyme of alkaline phosphatase and abnormalities of taste and smell are less common. The incidence of all these untoward reactions is similar with MMI and PTU. Side effects of MMI are dose-related, whereas those of PTU are less clearly related to dose [1]. PTU may cause slight transient increases of serum aminotransferase and γ -glutamyl transpeptidase concentrations but also severe hepatotoxicity whereas methimazole or carbimazole can be associated with cholestasis. The side

Antitrypanosomal Drugs. Table 1 Different treatment strategies depending on the cause of hyperthyroidism

	Graves disease	Hot nodule and toxic multinodular goiter Etiology
	Organ specific autoimmune disease TSH receptor antibody production	Constitutively activating somatic mutation in TSH receptor or in Gs α
Remission after antithyroid drug treatment	In 40–50% of patients 1 year after treatment withdrawal	No remission
Antithyroid drug treatment	1 year	Until euthyroid
Treatment with radioiodine or surgery	If relapse after 1 year of antithyroid drug treatment	After euthyroidism is achieved

effects usually appear within the first weeks or months after starting treatment. They occur more frequently with higher drug doses [1, 2]. If they are severe enough to alter treatment, it is possible to change from MMI to PTU or vice versa, although there is an estimated cross sensitivity of about 50% [2]. Most of the minor side effects are considered to be allergic reactions. Serious side effects such as bone marrow-depression, vasculitis, systemic lupus-like syndrome, cholestatic jaundice, hepatitis, hypoglycemia due to antiinsulin antibodies and hypoprothrombinemia are rare. They occur in approximately 0.2–0.5% of patients [1]. Depression of the bone marrow mostly appears as agranulocytosis, but also aplastic anemia and thrombocytopenia can be found. Symptoms of agranulocytosis like sore throat, fever and stomatitis are rare. Because of the sudden onset of agranulocytosis it can mostly not be detected in time by the routine leucocyte cell count. It occurs mostly within the first 3 months of treatment [1, 2]. Therefore, patients should be advised to stop taking the drug immediately if sore throat, pharyngitis or fever occur, and immediately seek medical attention and an urgent blood cell count. Most patients recover from agranulocytosis after discontinuation of antithyroid drugs. But deaths have been reported in 20% of patients despite treatment with intravenous broad spectrum antibiotics. Granulocyte colony-stimulating factor has been administered, but did not yield a better outcome in the treatment of antithyroid drug-induced agranulocytosis compared with antibiotic therapy only, whereas the time of recovery may be shortened by G-CSF therapy. The risk of agranulocytosis is greater in patients given larger doses and in older patients [1, 2]. Vasculitis and lupus-like syndrome occur much more frequently with PTU than with MMI. Treatment consists of discontinuation of the drug and the use of high doses of glucocorticoids. Major side effects usually occur within the first 3 months after the start of antithyroid drug treatment but can also appear during prolonged treatment and after reinstatement of the drug [1, 2, 3].

Antitrypanosomal Drugs

The etiological agents of the African sleeping sickness are *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*. Despite the enthusiasm shown by Robert Koch and Paul Ehrlich progress in the control of this disease achieved since the 19th century is sobering. Only four substances have been introduced, in total, in the therapy of African sleeping sickness, although the incidence of this disease has increased tremendously during the past decades with an estimated 50 million people at risk of infection and approximately 20 000 new cases reported each year. Suramin, the oldest of the antitrypanosomal drugs, was discovered by Paul Ehrlich and introduced in 1922. It was followed by pentamidine in 1937. Both drugs are only effective against early stages of the disease. The first and only drug effective against cerebral stages of African trypanosomiasis, of both *T. brucei gambiense* and *T. brucei rhodesiense* type, is melarsoprol, which has been in use for more than 50 years. It is still the drug of choice in most endemic areas despite its marked tendency to induce reactive encephalitis. Since then, drug and vaccine development in this field has declined to near zero. The only new antitrypanosomal substance so far has been eflornithine (difluoromethylornithine), which was introduced in 1990. It was originally developed for cancer therapy and proved later to be effective against intracerebral *T. b. gambiense*.

Nowadays, treatment of African sleeping sickness with the prevailing drugs faces three major problems:

(1) severe side effects, especially of melarsoprol; (2) wide spread drug resistance; and (3) lack of interest in drug development and production due to a low return of investment. To make matters worse, in recent years the producers of melarsoprol as well as eflornithine have tried to stop the production of these drugs entirely. A vaccine against trypanosomiasis is also not in sight, and efforts are complicated by the parasite's ability to constantly change the antigenic properties of its surface coat, a phenomenon called antigenic variation.

► Antiprotozoal Drugs

Antituberculosis Drugs

Antituberculosis drugs or antimycobacterial agents are specifically used for the treatment of tuberculosis (*Mycobacterium tuberculosis* infections). First-line drugs in tuberculosis therapy are isoniazid, rifampicin, ethambutol, pyrazinamide and streptomycin (Ribosomal Protein Synthesis Inhibitors). In order to minimize the development of drug resistance, a compound drug therapy is employed. In a first phase of two months, a combination of three drugs is employed. In a second phase of about four months, a combination of two drugs is used. A major problem is the increasing resistance of *Mycobacterium tuberculosis* strains against the first-line drugs. Infections caused by resistant strains are treated with combinations of second-line agents (e.g. capreomycin and cycloserine).

Definitions

► **Cough** is an essential protective reflex response to irritating stimuli in the respiratory tract. It involves the sudden, usually involuntary, expulsion of air from

the lungs. It can prevent foreign bodies from entering the lungs, or aid the removal of mucus and irritants from the lungs. Cough is a common symptom in upper respiratory tract infections and more chronically in asthma, chronic obstructive pulmonary disease (COPD) and lung cancer or may also indicate some other underlying disorders such as gastro-oesophageal reflux disease. It is also frequently caused by smoking. Conversely, in certain conditions such as Parkinson's disease, stroke and motorneurone disease, cough may be severely affected and the patient loses this protective function. Cough is useful if it is aiding the expulsion of foreign substances, but chronic cough is an unpleasant, difficult symptom for patients to live with and maybe debilitating.

Basic Mechanisms

Physically, cough results from a series of events starting with the patient inhaling, often to near maximum levels. Secondly, the glottis closes and the breathing muscles cause compression of the air in the lungs, leading to high pressure in the pleural space and alveoli. The expulsive phase occurs when the glottis reopens allowing the compressed air to escape. It is at this point that the cough sound is heard, and also that foreign materials which may have been deposited in the lungs, are removed. Coughing often occurs in bouts, or epochs, rather than as discrete events. *Cough* may be voluntary or involuntary – sub threshold stimuli may evoke the urge to cough, but not the reflex itself.

Airway irritation is detected by ► **sensory nerves** which are found within the walls of the airways. Various nerve endings are found in this area, but it is thought that the ► **rapidly adapting receptors (RARs)** are the predominant sensors of *cough*. RARs rapidly adapt to a maintained stimulus, and have thin myelinated A δ fibres. Slowly adapting receptors and C-fibres (C-fibres are sensory nerves with unmyelinated axons and can have a modulatory role on the cough reflex.) can have a modulatory role on the cough reflex. Several different types of sensor have been found, and more than one type of fibre is involved – it is possible that the combination of fibres and the nature of the discharge regulate *cough* as much as the quantity of action potentials.

These primary afferents project from the airway into the CNS exclusively via the vagus nerve, via the nodose or jugular ganglia. These neurons enter the brainstem and terminate in the nucleus tractus solitarius. Here they synapse with other neurons which determine the various motor components of *cough*. At these central synapses, there are many neurotransmitter receptors present (e.g. tachykinins, glutamate, 5-HT, GABA, NMDA, dopamine, opioids and nociceptin), which may be the site of action of centrally acting antitussive drugs (see below). It is also here that other sensory afferents terminate, and may modulate the synaptic signalling. If there are disorders in other organs which also have

sensory neurons carried in the vagus, it is here that these nerves may interact with airway neurons to cause *cough*. In contrast, in diseases where *cough* is reduced, it is generally due to problems in the efferent part of the reflex loop.

Previously it was thought that there was a central “cough centre” in the CNS, but current research suggests that this is an over-simplification. The ability to coordinate a combination of a variety of motor outputs is essential for *cough*. For example, outputs go to control airway structures such as the glottis and a wide range of breathing muscles such as the diaphragm and intercostal muscles. In addition, synchronisation with the respiratory rhythm is required as it is not possible to *cough* and breathe concurrently. Finally, the CNS is thought to contain a gating mechanism by which the brain determines whether the arriving stimuli are of sufficient magnitude for a cough to occur. The cortex is not necessary for cough, but it can exert descending control on the reflex. (Fig. 1)

The sensory nervous system which governs cough is subject to plasticity (►[nerve plasticity](#)) – such that there

may be an enhancement of this cough pathway, either by changes in the receptors on ►[sensory nerve](#) endings, the ganglia or within the CNS which can increase the activity of these neurons leading to a hypertussive state.

Pharmacological Interventions

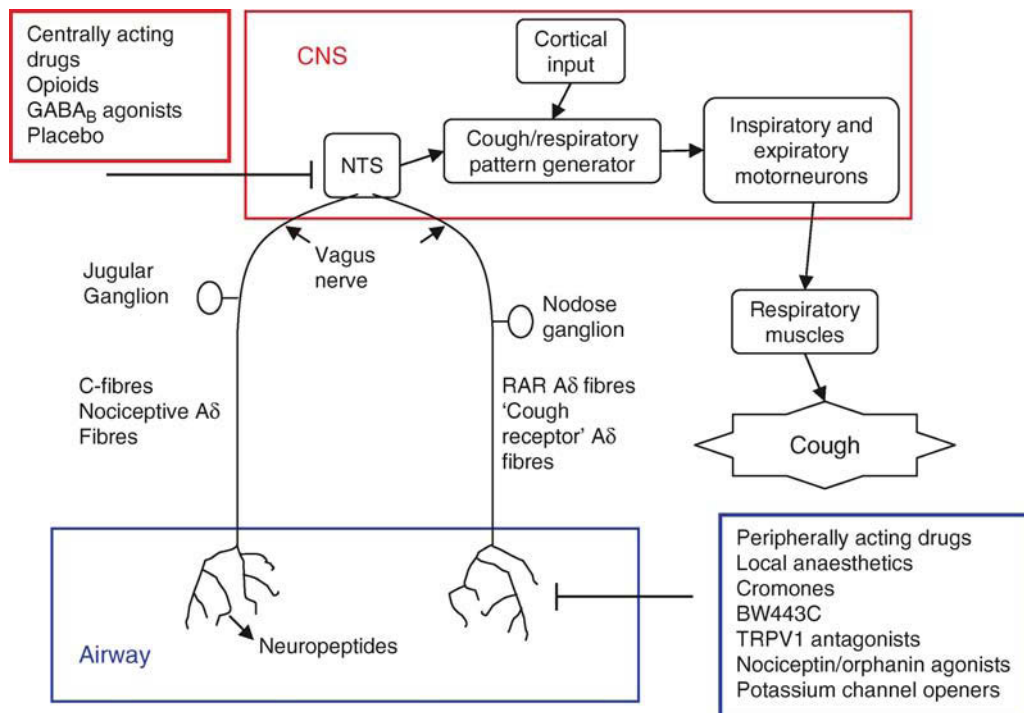

Cough is currently a huge unmet clinical need, as none of the currently available treatments are reliably effective [2]. However, there are many treatments which are currently used, with variable levels of success. In addition, if it is caused by another condition, such as gastro-oesophageal reflux disease, then treatment of that may reduce cough.

Drugs

Centrally Acting Drugs

Opioids

Opioids (►[opioid systems](#)) are thought to exert their antitussive effects by acting as agonists at μ - and κ -opioid receptors in the CNS. Activation of these receptors activates various G-proteins and leads to the inhibition of

Antitussive Drugs. Figure 1 Schematic diagram of the cough reflex and sites of action of some tussive agents. Airway sensory nerves activated in response to a tussive stimulus travel through the vagus nerve to the medulla, where they terminate in the nucleus tractus solitarius (nTS). Second order neurons relay the message to the respiratory pattern generator, which modifies the activity of the inspiratory and expiratory motoneurons and leads to cough. Tussive agents can activate a variety of airway receptors to cause cough. Many nerve types (both peripherally and centrally) undergo phenotypic changes and have increased responses to tussive stimuli following inflammation. The sites of action of antitussive drugs are shown. Abbreviations: RAR, rapidly adapting receptor; CNS, central nervous system. Figure adapted from [1].

the activity of most neurons, but the activity of a few are increased. Recent evidence suggests that morphine may also interact with ►TRPV1 receptors to explain some of its antitussive activity.

Centrally acting drugs include dextromethorphan and codeine. However the possibility that there may also be peripheral effects of these drugs has led to the development of BW443C (see below).

Opioid drugs are often more effective than other non-narcotic treatments, but they are also associated with more side effects making them less suitable for many patients. Higher doses which are more effective are also associated with undesirable effects such as sedation.

Peripherally Acting Drugs

Local Anaesthetics

Local anaesthetics are more consistently effective than other therapies, but their use is controversial. High concentrations are needed for therapeutic benefit, but this also increases the amount crossing the blood brain barrier and entering the brain producing unwanted effects. Topical administration to the airways can reduce this.

Patients who do not obtain sufficient symptomatic relief from other treatments may use lidocaine, benzonatate, bupivacaine topically or mexiletine orally.

Tachykinin Antagonists (►Tachykinins)

►C-fibre afferents from the airways contain peptide tachykinin transmitters such as substance P (SP) and neurokinins A and B (NKA and NKB). Stimulation of these nerves can also cause local release of these mediators at their peripheral terminal, allowing them to enhance the activity of the *RARs*. SP, NKA and NKB act at the tachykinin receptors (NK₁–NK₃), and so understandably, antagonists for NK₂ in particular appear promising in cough.

Cromones

Both disodium cromoglycate and nedocromil sodium have antitussive effects in humans, particularly against ACE inhibitor induced cough. This suggests an effect on bradykinin induced changes in ►sensory nerve function. Antitussive activity of these drugs is thought to occur by increasing the depolarisation of sensory nerves, which increases the threshold for an action potential and therefore inhibits the activity of these neurons.

GABA_B Receptor Agonists

►GABA is the predominant inhibitory neurotransmitter in the CNS. Baclofen acts centrally as an agonist at the GABA_B receptor, which increases inhibition of nerves. 3-Aminopropylphosphinic acid (3-APPi) has been shown experimentally to act as an antitussive at peripheral nerves and preclinical evidence suggests that baclofen indeed has antitussive actions clinically [3].

Novel Drugs

BW443C

BW443C is a novel opioid used for the treatment of cough, but which does not enter the brain and so exerts its effects only on peripheral nerves. It has not been tested as an antitussive in humans due to its rapid metabolism in the lungs but the concept of a peripheral opioid is still possible.

Nociceptin/Orphanin Receptor Agonists

Nociceptin and orphanin are synonyms for the peptide that acts at an opioid-like receptor. Nociceptin may act by inhibiting tachykinin release from sensory ►C-fibres, and a clinical trial has started to test its effects on cough.

TRPV1 Receptor Antagonists

Capsaicin, the pungent chemical from chilli peppers, induces cough. Capsaicin is an agonist at the transient receptor potential vanilloid receptor 1 (TRPV1) – a polymodal receptor which integrates several harmful stimuli such as noxious heat, low pH and various possible endogenous mediators to mediate pain and cough. TRPV1 receptors have been demonstrated to be upregulated in patients with chronic cough [4].

Capsaicin is used to cause cough experimentally and clinically and the TRPV1 antagonist capsazepine can inhibit cough elicited by both capsaicin and citric acid. This suggests that other TRPV1 antagonists could be effective treatments for cough (recently reviewed in [5]). However, capsazepine does not block hypertonic saline induced cough, suggesting that other tussive receptors are also important [5].

Potassium Channel Openers

An effect of opening ►K⁺ channels is to hyperpolarise the primary sensory neurons. Similarly to local anaesthetics, this makes the cell less likely to produce an action potential because more depolarising stimuli are needed to overcome the block. NS1619 is an example of this type of drug which has initially shown antitussive activity in a variety of experimental systems.

Quaternary Ammonium Salts

Quaternary ammonium salts such as carcamium chloride (RSD 931) have been shown to be antitussive whilst having much reduced local anaesthetic activity. Whilst the molecular mechanisms underlying this antitussive activity is not understood, RSD 931 appears to be Aδ fibre selective and may represent a novel class of antitussive drug. More recently JMF2-1 a lidocaine derivative that blocks Na⁺ channels has had beneficial effects in the airways without significant local anaesthetic activity.

Heidelberg, Germany

Synonyms

Antivirals; Virostatics

Definition

Viruses are small infectious agents composed of a nucleic acid genome (DNA or RNA) encased by structural proteins and in some cases a lipid envelope. They are the causative agents of a number of human infectious diseases, the most important for public health today being acquired immunodeficiency syndrome (AIDS), hepatitis, influenza, measles, and viruses causing diarrhoea (e.g., rotavirus). In addition, certain viruses contribute to the development of cancer. Antiviral drugs inhibit viral replication by specifically targeting viral enzymes or functions and are used to treat specific virus-associated diseases.

Mechanism of Action

Basic Principles

Viruses are obligatory intracellular parasites that can only replicate within an appropriate host cell. They rely on host cell-derived factors and mechanisms, and encode only few enzymes and other proteins of their own. Consequently, interfering with virus replication without inflicting damage to the host requires highly specific approaches and there is no general mechanism of action for virostatics. In contrast to antibacterial agents, where fundamental differences between prokaryotic and human cells (e.g., bacterial cell wall synthesis) can be exploited to inhibit a broad range of

bacteria without significant toxicity to the patient, antiviral drugs are mostly highly selective for a specific virus or a limited number of related viruses. Furthermore, many human virus infections are acute and are rapidly controlled by the immune system. In these cases, the highest viremia – i.e., the time when the patient would benefit the most from causative antiviral treatment – usually precedes the clinical manifestation of symptoms and the diagnosis by serological methods. For these reasons, the number of currently available antiviral drugs is low compared to chemotherapeutics effective against other classes of infectious agents. Most antivirals have been developed to control chronic or recurrent virus infections, and in many cases antiviral treatment does not result in elimination of the virus but rather reduction of virus replication and alleviation of symptoms. In principle, antivirals can be targeted at any of the viral replication steps outlined in Fig. 1. (A) Binding: Viruses attach to their host cells via binding of a viral surface protein to one or several receptor molecule(s) on the plasma membrane. This interaction is highly specific and presents a very attractive target for antiviral intervention. The most advanced compounds in this class are the human immunodeficiency virus (HIV) coreceptor antagonists. These substances bind to and block the cellular chemokine receptors CCR5 or CXCR4, respectively, which are required in addition to the CD4 receptor to mediate HIV entry. The most promising results so far have been obtained with CCR5 antagonists, and one of these compounds (maraviroc) has recently been approved for treatment. (B) Entry of the virus into the cell and release of the viral genome (uncoating): The drug enfuvirtide targets the HIV entry process, by preventing the fusion of the virus with the plasma membrane. Although the uncoating process is not characterized in its entirety for most viruses, random screening has identified amantadine/rimantadine, which

Antiviral Drugs. Figure 1 Basic steps of viral replication: (A) binding, (B) entry, (C) genome replication, (D) gene expression, (E) assembly, (F) release.

inhibit this step in influenza A replication. In addition, uncoating inhibitors specific for entero- and ▶**picornaviruses** are under development. (C) Replication of the viral genome: Viruses contain either single- or double-stranded DNA or RNA genomes and employ a variety of replication strategies. Thus, there is no general mechanism or replication enzyme common to viruses. However, to accommodate for various replication strategies, many viruses encode their own polymerase(s), the biochemical and structural properties of which differ in some respects from those of the host cell polymerases. This can be exploited to specifically interfere with viral genome replication, and a number of inhibitors targeting viral replicases have been developed as antiviral drugs. (D) Expression of viral genes leads to the production of virus proteins: The basic machineries for transcription of virus genes and translation of mRNA into viral proteins largely rely on cellular factors and are therefore difficult to target. Many viruses encode proteins regulating transcription or mRNA transport and modification (e.g., the HIV Tat and Rev proteins), which are potential candidates for inhibition. However, drugs specifically interfering with viral gene expression have not yet been developed. (E) Virus assembly comprises transport of the virion components to the assembly site, formation of an ordered capsid structure and in some cases morphological maturation of the particle into a fully infectious state. Capsid stability depends on multiple interactions between viral structural proteins, and interfering with only a few interactions should suffice to disturb the ordered capsid architecture essential for infectivity. The subunit interfaces, unlike viral enzymes, do not have correlates in the host cell. This should allow the design of efficient and specific inhibitors, but to date insufficient understanding of the molecular processes involved and the lack of suitable assay systems has prevented the development of assembly inhibitors for antiviral therapy. However, highly effective antiviral drugs targeting the process of virion maturation (▶**protease** inhibitors) have been developed against HIV. (F) Virus release from the producing cell is required for virus spread: It can be accomplished by cell lysis, exocytosis or, in the case of many enveloped viruses, by budding from the plasma membrane. Virus budding is a complex process involving a number of host cell-derived factors, and drugs targeting the budding process itself have not yet been developed. However, the recently introduced influenza neuraminidase inhibitors are effective by blocking the release and spread of influenza viruses.

Interferon (IFN) differs from *bona fide* antiviral drugs since it is a natural defense protein of the host organism and does not directly interfere with the viral replication steps. Interferons are small glycoproteins inducing immune modulatory and antiviral activities. They are secreted by lymphocytes, leukocytes and fibroblasts in response to foreign nucleic acids (dsRNA).

IFNs are classified into three groups α , β , and γ , and the different classes are produced from different cell types. Recombinant IFN- α is used in the treatment of chronic hepatitis B and C.

Mechanisms of Action of Currently Used Antiviral Drugs

The initial steps in viral replication are attachment to and entry into the host cell. One drug targeting the fusion event of the virus with its host cell is approved for clinical use against HIV: The peptide derivative enfuvirtide binds to a helix in the viral envelope protein gp41, which is exposed upon binding of HIV to its cellular receptor. This binding of enfuvirtide blocks a conformational rearrangement of gp41 molecules which is required to mediate the fusion of viral and cellular lipid membranes. Similar compounds with improved potency and pharmacokinetics have been generated, but are not approved for clinical use. Several drugs inhibiting the binding of HIV by inhibiting the interaction of the virus with cellular receptor or coreceptors are currently under preclinical and clinical development. One HIV-1 co-receptor antagonist (maraviroc) has recently been approved. Available drugs acting at a step in influenza virus replication are the adamantane derivatives, amantadine and rimantadine. Amantadine has been in clinical use since the early 1970s, but its mechanism of action was elucidated only 20 years later. It blocks the M2 ion channel in the envelope of influenza A virus, thereby inhibiting virus uncoating. Adamantanes are not efficient against influenza B, which lacks the M2 protein. Entry inhibitors specific for entero- and rhinoviruses are drugs based on the substance pleconaril. It binds to a hydrophobic pocket on the surface of picornavirus capsids resulting in conformational changes of the ▶**capsid** that interfere with the release of the viral RNA genome into the host cell. Pleconaril is tested in clinical trials but is currently not approved for therapy.

Polymerase inhibitors with different mechanisms of action account for the largest group of currently available antiviral drugs. The most important class are the chain terminating nucleoside analogues (Fig. 2). The prototype of this class is acyclovir (ACV) which is used against herpes simplex (HSV) and ▶**varicella zoster viruses** (VZV). ACV is an acyclic analogue of the nucleoside thymidine, with carbon atoms C2 and C3 missing from the deoxyribose ring. Phosphorylation by HSV thymidine kinase (TK) inside an infected cell yields ACV-monophosphate, which is further converted into ACV-triphosphate by cellular enzymes and then serves as a substrate for the HSV polymerase. ACV incorporation into DNA results in chain termination due to the lack of the 3'OH group required for further elongation. Since both monophosphorylation and incorporation into DNA are preferably carried out by

Antiviral Drugs. Figure 2 Mechanism of action of chain-terminating nucleoside analogues.

viral enzymes, selectivity on two levels reduces toxicity to uninfected cells. This principle is also exploited by related drugs acting against herpesviruses (brivudin, famciclovir). Efficacy of phosphorylation and incorporation into DNA are not correlated: whereas penciclovir (oral prodrug: famciclovir) is a much better substrate for TK than ACV, penciclovir triphosphate is incorporated less efficiently by the viral polymerase than ACV-triphosphate. An optimal inhibitor should be a good substrate for both viral enzymes. Human cytomegalovirus (HCMV) lacks a *tk* gene and is relatively insensitive to ACV, but a protein encoded by gene *UL97* of HCMV is able to phosphorylate the nucleoside analogue ganciclovir (GCV). This analogue also efficiently interferes with cellular DNA polymerisation, and thus has a higher toxicity than ACV. Resistance against GCV can develop through mutations in either *UL97* (90%) or the viral polymerase gene. The alternative drug cidofovir is a cytosine phosphonate analogue, which only depends on cellular enzymes for its conversion into the active form. Thus, its efficacy is not affected by mutations in *UL97*. A direct inhibitor of viral polymerase, which does not require intracellular activation, is foscarnet (phosphonoformic acid). The chain terminating mechanism is shared by another important group of antivirals, the nucleosidic and nucleotidic **reverse transcriptase (RT) inhibitors** (NRTI and NtRTI), which inhibit the RT of HIV. A number of different NRTIs are available in different

formulations, e.g., azidothymidine (AZT), ddI, ddC, and d4T. All of these are nucleoside analogues, in which the 3'OH group is missing or replaced by another functional group, e.g., an azido group in AZT. NRTI are also applied as prodrugs which have to be phosphorylated by cellular kinases into their active triphosphate form. NtRTI (Tenofovir, Adefovir) are monophosphorylated derivatives. In this case the first- and often rate-limiting step of activation is circumvented. Hepatitis B virus (HBV) (**Hepatitis**), another important human pathogen, also encodes an RT, and several nucleoside/nucleotide analogues originally developed against HIV (e.g., lamivudine) are also active against HBV. The compounds lamivudine, adefovir and the HBV polymerase selective nucleoside derivative entecavir are available as anti-HBV drugs, and several other drugs from this class are expected to be approved for this use in the future (e.g., telbivudine, clevudine, emtricitabine). As obvious from this example, chain terminators are not exclusively selective for the particular viral polymerase targeted, since nucleoside analogues bind to the relatively conserved active site of polymerases. Thus, a certain degree of inhibition of cellular polymerases also has to be taken into account. Furthermore, soon after the introduction of AZT for the treatment of AIDS patients in 1987, it became apparent that although it was possible to lower the viral load by up to 80% through AZT monotherapy, the therapeutic success was limited by the rapid emergence of drug resistant virus. The

same unfortunately holds true for other NRTI, and resistance development against nucleoside inhibitors is also observed in the case of HBV and herpesviruses. The search for alternative antiHIV drugs led to the discovery of another class of polymerase inhibitors, the so-called non-NRTI (NNRTI). NNRTI in clinical use are nevirapine, delavirdine, and efavirenz. These polycyclic compounds do not mimic nucleosides, but act as allosteric inhibitors inducing conformational changes that lock the polymerase active site in an inactive conformation. Unlike NRTI, NNRTI are highly specific for the RT of HIV-1. The RNA-dependent-RNA polymerase NS5B of Hepatitis C virus (HCV) can not efficiently be targeted by the available polymerase inhibitors. However, novel nucleosidic as well as non-nucleosidic inhibitors of NS5B have been developed and are currently in the drug pipeline against HCV infection.

Another antiviral nucleoside derivative is the guanosine analogue ribavirin, which is active against certain RNA viruses (HCV, respiratory syncytial virus, lassa-virus) and is administered in combination with IFN- α for treatment of chronic hepatitis C. Its mechanism of action is not completely elucidated. It is known that ribavirin-monophosphate inhibits cellular inosine monophosphate dehydrogenase and this leads to depletion of the cellular GTP pool, which can interfere with viral genome replication or mRNA capping. An antiviral effect of ribavirin mediated by lethal mutagenesis of the viral genome has also been proposed.

In the case of retroviruses like HIV, reverse transcription of the genome by the viral polymerase is followed by irreversible integration of the genetic information of the virus into the host cell genome. Antivirals which target this replication step are not yet approved for clinical use. However, several HIV integrase inhibitors yielded very promising results in clinical trials and the introduction of anti-HIV drugs belonging to this new class can be expected soon. Antiretroviral drugs interfering with a later replication step are ►protease (PR) inhibitors affecting HIV infectivity. Like other retroviruses, HI-virions are released from the cell as immature, noninfectious particles, in which the capsid is assembled from the structural polyprotein Gag. Concomitant with release, Gag is cleaved into its functional subdomains by the viral ►PR, leading to a structural rearrangement of the capsid essential for virion infectivity. Thus, PR inhibitors are effective anti-HIV drugs. Retroviral PR are aspartyl proteases, and inhibitors of members of this class (renin, pepsin) had been investigated prior the onset of the AIDS epidemic. These inhibitors are peptidomimetics resembling substrates in which the scissile peptide bond is replaced by a noncleavable structural analogue of the substrates ►transition state. Further modifications result in optimized selectivity,

stability, and bioavailability of the compounds. Based on this concept and detailed structural and biochemical information about HIV PR, effective inhibitors were designed, several of which are used for the treatment of AIDS patients (saquinavir, ritonavir, indinavir, nelfinavir, amprenavir, lopinavir, tipranavir, atazanavir, darunavir; more HIV protease inhibitors can be expected to be available in the future). Promising compounds inhibiting the protease of HCV are currently in clinical development. The step of HIV virion maturation is also targeted by a novel compound, bevirimat. This inhibitor does not act by binding to the viral protease, but to its substrate, the viral structural polyprotein Gag. Thereby bevirimat interferes with a specific proteolytic processing step required for maturation of the viral capsid. This compound is currently tested in clinical trials.

The influenza virus inhibitors, zanamivir, and oseltamivir, act outside the cell after virus particles have been formed. The drugs have been designed to fit into the active site of the viral envelope enzyme neuraminidase, which is required to cleave sialic acid off the surface of the producing cells. When its activity is blocked, new virus particles stay attached to the cell surface through binding of the virus protein hemagglutinin to sialic acid and are prevented from spreading to other cells.

Clinical Use (Including Side Effects)

Only a limited spectrum of viral infections can be currently treated with antiviral drugs; otherwise prevention by vaccination (if possible) and hygiene measures are the only options. Influenza can be treated with amantadine or rimantadine. Both drugs are only effective against influenza A and cause significant side effects including dizziness, lightheadedness, insomnia and nausea. Thus, the newer neuraminidase inhibitors zanamivir (aerosol) and oseltamivir (oral), active against influenza A and B and with lower risk of side effects, are preferable. Since potential side effects include bronchospasm, these drugs are not recommended for patients with chronic pulmonary disease or asthma. In any case, treatment needs to be started within 36–48 h after the manifestation of the first symptoms and only alleviates the course of disease. Amantadine is also approved for prophylactic treatment of exposed persons with particularly high risk of influenza-associated complications. Infections with the herpesviruses ►HSV and ►VZV are treated with ACV (orally available prodrug: valaciclovir), famciclovir or brivudin (indicated for herpes zoster). Intravenous treatment is indicated for herpes virus encephalitis, neonatal HSV infection, and HSV and VZV reactivation under immunosuppression. Herpes genitalis and herpes zoster are treated orally, and topical ACV treatment is used against herpes labialis. Alternative HSV and VZV

treatment is possible using idoxuridine or vidarabin. Foscarnet can be used against resistant viruses but has a higher risk of side effects (nephrotoxicity). Indications for the use of GCV or valganciclovir are ►CMV chorioretinitis in ►AIDS patients and CMV colitis. It is also used to prevent interstitial pneumonia in immunosuppressed patients. GCV is more toxic than ACV and causes neutropenia in about 40% of patients. Alternatively, CMV infection can be treated with cidofovir or foscarnet, which are also effective against GCV-resistant CMV but have an even higher toxicity. In pharmacologically immunosuppressed transplant recipients, GCV or ACV are administered to prevent CMV or HSV disease, respectively. An anti-CMV drug based on a new mechanism of action is Fomivirsen. It is an antisense RNA which inhibits the synthesis of a viral protein and is approved for intravitreal treatment of CMV retinitis.

A combination therapy of IFN- α ("pegylated", i.e., coupled to polyethylene glycol, which prevents its rapid clearance from the body) and ribavirin over 24–48 weeks is the most effective way to treat chronic hepatitis C. Therapeutic success depends on virus genotype and viral load, but overall this treatment eliminates the virus in about 60% of patients. A major side effect of this combination therapy is hemolytic anemia, attributed to ribavirin. Interferon monotherapy can be used as postexposure prophylaxis after accidental exposure to HCV to prevent chronification. Patients with chronic hepatitis B, characterized by elevated serum alanine aminotransferase levels and detectable HBe antigen for >6 months, are currently treated with pegylated IFN- α alone as the first choice. Clinical improvement can be accomplished in about 30–40% of treated patients. Fatigue, muscle aches, headache, nausea and diarrhea are common side effects of interferon. The most common serious side effect is depression. Treatment with antiviral nucleoside analogues against HBV is also efficient as monotherapy and is used mainly in cases with moderate elevation of ALT levels and when use of interferon is contraindicated (e.g., for patients with liver cirrhosis). Resistance development occurs frequently upon prolonged treatment with lamivudine; in this case, treatment can be switched to adefovir. The newest drug from this class, entecavir, appears to be superior to lamivudine with respect to both efficacy and resistance development. Combination of interferon with nucleoside analogues or combination of two nucleoside analogues has not been found to have advantageous effects. In the case of acute hepatitis B, antiviral treatment is not recommended.

The broadest spectrum of antiviral drugs is available against HIV. However, monotherapy with any of these drugs leads to rapid treatment failure due to selection and further evolution of resistant viruses. Since acquisition of resistance mutations requires virus replication,

an efficient therapy regimen and patient compliance are paramount to minimize resistance development. Currently, AIDS patients in industrial countries are treated with a combination therapy known as HAART (highly active antiretroviral therapy) involving at least three different anti-HIV drugs from the classes mentioned above (NRTI, NNRTI, PI, entry inhibitor). Treatment is currently indicated when the patient shows symptoms of AIDS or has a CD4+ cell count below 200/ μ l. Treatment decisions in other cases are complex and need to be made on an individual basis. Triple therapy is also recommended as prophylaxis following accidental exposure to the virus. In this case, it is crucial that treatment is started immediately (best within 1–2 h). The introduction of HAART led to a significant decrease in AIDS morbidity and mortality. However, severe side effects (neutropenia, neurological problems, lipodystrophy) can occur especially under prolonged therapy, and even under HAART, resistant and multi-resistant viruses emerge and are transmitted. Thus, HAART requires selection of a suitable drug combination by a physician experienced in AIDS therapy, constant monitoring of viral load and individual adjustment in case of treatment failure or intolerable side effects. Successful treatment in the case of HIV infection does not mean eradication of the virus and therapy has to be continued over many years, probably life-long. For this reason, future goals do not only include the discovery of new anti-HIV drugs, but also the improvement of existing drugs in terms of galenics, side effects and possible combination formulations that make it easier to follow the therapy scheme. Finally, it should be noted that HAART is generally not available in developing countries, where most of the millions of HIV-infected people live.

High replication rates, error-prone polymerase as well as replication strategies favoring genetic recombination result in rapid virus evolution. Thus, the emergence of drug resistant variants is a general problem for antiviral therapy. Successful antiviral strategies will probably have to be combination therapies employing different drugs. Experiences indicate that cotreatment with two or even three drugs does not prevent viral resistance development, and broadening of the antiviral arsenal is a key issue. Future additions to this arsenal will result from different approaches: First, alternative and improved drugs based on the same mechanisms of action or on the same principles (e.g., inhibition of viral enzymes by substrate analogues) will be developed. Second, as the molecular understanding of viral biology increases and suitable assay systems for *in vitro* screening can be established, other steps of viral replication that are currently not accessible (assembly, transcriptional and posttranscriptional regulation or virus release) could become targets of chemotherapeutic intervention. Third, there are attempts to include new

and experimental therapeutic approaches, such as the specific shutdown of viral gene expression by antisense RNA or siRNA (small interfering RNA) or gene therapy, into antiviral strategies. As an alternative antiviral approach, all these strategies are currently considered mainly as potential inhibitors of HIV replication, but also discussed for development of novel treatments of chronic hepatitis B and C. While some encouraging results have been obtained in experimental settings and in small-scale clinical trials, many problems and questions regarding, e.g., specificity and durability of therapeutic effects, safe and targeted delivery of the antiviral principle, and viral escape by mutation remain to be solved before these can translate into clinical applications.

Anxiety

Anxiety is a normal reaction. Pathological anxiety interferes with daily-life activities and may be accompanied by autonomic symptoms (chest pain, dyspnoea and palpitations). Severe forms include phobic anxiety and panic disorder.

- ▶ Benzodiazepines

Anxiolytics

Anxiolytics are drugs used for the treatment of anxiety disorders. Apart from benzodiazepines, a frequently used anxiolytic is the 5HT_{1A} (serotonin) receptor agonist buspiron, which has no sedative, amnesic or muscle-relaxant side effects, but whose action takes about a week to develop. Furthermore, it is less efficacious than the benzodiazepines. Buspiron's mechanism of action is not fully understood.

Apelins and the Apelin Receptor

ANTHONY P. DAVENPORT, SARAH L. PITKIN, JANET J. MAGUIRE
Clinical Pharmacology Unit, University of Cambridge, Level 6, Centre for Clinical Investigation, Addenbrooke's Hospital, Cambridge, UK

Synonyms

Apelin receptor; APJ receptor; Angiotensin II receptor-like 1

Definition

The family of apelin peptides is derived from a single gene, activate a single G-protein-coupled receptor and are substrates for the ▶ *angiotensin converting enzyme-2* (ACE2). Apelins regulate cardiovascular function and fluid homeostasis. The apelin receptor also functions as a co-receptor for infection of CD4-positive cells by human immunodeficiency virus (▶ *HIV*).

Basic Characteristics

The human gene encoding the putative APJ receptor was identified in 1993 by O'Dowd and colleagues using a degenerate PCR strategy as having a high degree of sequence similarity with the gene encoding the angiotensin AT₁ receptor (54% in the transmembrane spanning regions) [1]. However, angiotensin II did not activate APJ and it was therefore designated as an ▶ 'orphan' receptor. In 1988, apelin-36, (*APJ* endogenous ligand), a 36 amino acid peptide, was isolated from bovine stomach. Using the technique of reverse pharmacology, Tatemoto and colleagues found that the peptide bound and activated APJ receptors artificially expressed in cell lines [2]. APJ is now classified as the apelin receptor, in Family A of the superfamily of seven transmembrane spanning ▶ *G-protein-coupled receptors*.

Apelin Peptides, Synthesis and Metabolism

Cloning of corresponding human and bovine cDNA led to the identification of a gene encoding a 77 amino acid precursor peptide, preproapelin, in a number of species (human, bovine, rat and mouse). This precursor contains a number of basic amino acid pairs (Arg–Arg or Arg–Lys) thought to be proteolytic cleavage sites for endopeptidases, resulting in a family of C-terminal peptides of varying sizes that can all activate the receptor (Fig. 1). Thus far, no specific enzymatic pathway has been discovered which is responsible for cleaving preproapelin into shorter mature peptides. Apelin-36 is highly conserved between species; the last 22 residues of the C-terminus are identical in mammals (Fig. 2). The endogenous forms detected in tissues and biological fluids (usually by chromatographic separation or gel filtration followed by immunoassay) comprise predominantly apelin-36, apelin-17, apelin-13 and following ►posttranslational modification by

enzymatic conversion of the N-terminal glutamate to pyroglutamate, [Pyr¹]apelin-13 (Fig. 1) [3, 4]. This modification is common to a number of biologically active peptides, which confers resistance to degradation by peptidases. The relative abundance of these molecular forms varies according to tissue examined. For example, in the rat, peptides of a size close to apelin-36 were the major components in the lung, testis, and uterus, but both apelin-13 and apelin-36 were detected in the mammary gland. Apelin-13 predominated in plasma and brain (hypothalamus) with apelin-17 being detected. Apelin-12 also activates apelin receptors in a number of preparations being more potent than apelin-13 in reducing blood pressure in vivo in rats but apelin-12 has not been identified as an endogenous peptide. Apelin-16 has also been used in preparations. Apelin-11 and shorter sequences are devoid of binding activity to apelin receptors expressed in cells. Stepwise substitution of alanine for residues

Arg-2, Pro-3, Arg-4, Leu-5, Ser-6, Lys-8 Gly-9, Pro-10 and Met-11 into apelin-13 reduced [125 I]-(Pyr¹)apelin-13 binding to apelin receptors expressed in cell lines, suggesting they are important residues for receptor interaction. Structure activity studies using fragments of apelin-17 also identified Gln-1, Pro-12 and Phe-13 not essential for apelin binding.

Metabolism of apelin peptides *in vivo* is not yet clear. ACE2, the closest human homologue of angiotensin converting enzyme, cleaves the C-terminal Phe of apelin-13 with high catalytic efficiency *in vitro* (Fig. 1). The enzyme is expressed in ►endothelial cells particularly in the heart and kidney. ACE2 also hydrolyses apelin-36 as well as other biologically active peptides including angiotensin II to angiotensin 1–7 (a functional antagonist of angiotensin-II which acts predominantly as a vasodilator) suggesting the apelin peptides may be part of the enzymatic cascade of the ►renin–angiotensin–aldosterone system in cardiovascular regulation. ACE2 is also a receptor for severe acute respiratory syndrome coronavirus (SARS CoV) [4].

Distribution of Apelin mRNA and Peptides

Apelin mRNA (Table 1) is present in a range of peripheral rat tissues including stomach, intestine, heart, liver, kidney, testis, ovary and adipose tissues with highest levels in the lung and in particular the mammary gland (Table 1). Highest mRNA expression in the rat brain included the spinal cord, olfactory tubercle, hippocampus, hypothalamus, pineal gland, pituitary and the cerebral cortex. Apelin-like immunoreactivity was detected in rat tissues including white adipose tissue, epithelial cells of the oxyntic stomach mucosa as well as in endothelial cells of small arteries and veins in mesenterium, omentum, heart, lung, gastrointestinal tract, spleen, pancreas and liver. In rat brain, immunoreactivity is present in neurones of the pons, medulla oblongata and arcuate nucleus and also in the supraoptic and paraventricular nucleus of the hypothalamus, where apelin positive neurones also expressed vasopressin mRNA. In humans, apelin-like immunoreactivity was detected in endocardial endothelial cells lining the atria and ventricles of the heart and endothelial

cells lining large conduit vessels, small arteries and veins (<500 μm diameter) from lung, kidney and adrenal gland. Within endothelial cells, apelin-like immunoreactivity is present in secretory vesicles of the constitutive secretory pathway but not Weibel-Palade bodies of the regulated stimulated pathway, suggesting the peptide may be released from the former [4].

Apelin-like immunoreactivity has been quantified in tissues using antisera that mainly cross reacts with all apelin peptides. Levels in human atria were 650 pg/mg with lower but detectable levels in the ventricle (3 pg/mg). Apelin-like immunoreactivity in human plasma measured following extraction and radioimmunoassay ranges from 24–89 pg/ml, levels comparable to other locally acting endothelium derived peptides. This may reflect overspill from the vascular and endocardial endothelial cells, consistent with the proposed role as a locally released mediator. Whether there is any contribution from other sources such as epithelial cells of the gut, is unclear. Apelin levels rise in early heart failure and fall with severe disease although other studies reported no change in patients with dilated cardiomyopathy. Apelin is expressed and secreted by human and mouse adipocytes; with plasma apelin levels increasing with obesity and correlating with body mass index, suggesting a role as an adipokine.

In agreement with abundant mRNA in mammary gland, high levels of apelin are present in bovine colostrum; oral intake of apelin might modulate immune responses in neonates [4].

Distribution and Characterisation of Apelin Receptor

In the rat (Table 1), apelin receptor mRNA is widely distributed in almost all peripheral tissues (consistent with a vascular expression) with highest levels in lung and heart and lower levels in kidney, pituitary gland, ovary and skeletal muscle. In the rat CNS, apelin receptor is expressed in brain including the cerebral cortex, hypothalamus (particularly in neurones of the paraventricular and supraoptic nucleus), hippocampus, thalamus, striatum and pituitary gland. In humans, receptor mRNA is detectable in many peripheral tissues, also consistent with a vascular expression including spleen, thymus, prostate, testis, ovary, intestine. In human brain, mRNA is present in neurones, oligodendrocytes and astrocytes, but was not detected in macrophages or microglia. Apelin receptor-like immunoreactivity is expressed in endothelial cells lining small intramyocardial, renal, pulmonary and adrenal vessels, small coronary arteries, large conduit vessels and in endocardial endothelial cells. Lower levels of receptor are also present in cardiomyocytes and vascular smooth muscle cells of blood vessels from different vascular beds [4].

[^{125}I]-Pyr¹apelin-13 used to characterise native apelin receptors in human heart (atria and ventricles) bound with a single high affinity ($\blacktriangleright K_D = 0.4$ nM),

comparable to other vasoactive peptides. \blacktriangleright Hill slopes were close to unity, with no evidence for a biphasic curve that might indicate further receptor sub-types. Binding was time dependent with an association rate constant (K_{obs}) of 0.115 min^{-1} and dissociation rate constant of 0.01 min^{-1} . Receptor density in human heart was comparatively low, $\sim 4 \text{ fmol mg}^{-1}$ protein. In rat tissues, [^{125}I]-Pyr¹apelin-13 bound in the CNS (brain) and periphery (lung) with similar high affinities ($K_D = 0.6$ nM) [4]. Disruption of the gene encoding the apelin receptor in a *knock-out* mouse abolished, as expected, all apelin responses, supporting the concept that apelins mediate their actions via a single receptor.

Apelin receptors activate several signalling pathways including coupling through inhibitory *G-proteins* (G_i) and Ras-independent activation of extracellular-regulated kinases (ERKs) via protein kinase C (PKC). The apelin receptor is one of number of G-protein-coupled receptors that can act as an alternative co-receptor for entry into cells of HIV and simian immunodeficiency virus (SIV) strains in human U87 cells expressing CD4 in vitro. Apelin peptides blocks entry of HIV but display different potencies, with apelin-36 being more effective than shorter sequences [3].

Role in the Cardiovascular System

In the cardiovascular system, apelins act directly on smooth muscle cells of the vasculature to cause \blacktriangleright vasoconstriction, on apelin receptors on the endothelium to indirectly release \blacktriangleright vasodilators to cause relaxation and on myocyte receptors to increase cardiac contractility (Fig. 3). In animals, short apelin peptides play a role in the regulation of cardiovascular homeostasis. Apelin-13 ($\sim 3 \mu\text{g/kg}$) transiently lowered \blacktriangleright blood pressure by ~ 10 mm Hg for 3–4 min in anaesthetised rats in vivo following intravenous injection in a nitric oxide dependent manner. This action was more pronounced in spontaneously hypertensive rats, with apelin-13 ($15 \mu\text{g/kg}$) lowering blood pressure by about 60%. Concomitant administration of apelin-13(F13A), a synthetic peptide with Ala substituted at residue 13, blocked hypotensive effects of apelin-13 suggesting that apelin-13(F13A) behaved as a functional antagonist [5]. Although apelin receptor knockout mice displayed no significant changes in baseline blood pressure compared to wild type controls, infusion of apelin transiently decreased the blood pressure of wild-type mice, which was abolished in the knock-out. Apelin receptor deficient mice had an increased pressor response to angiotensin II, and the baseline blood pressure of double mutant mice homozygous for both apelin and angiotensin-type 1a receptor was significantly elevated compared with the control. Following removal of the endothelium, [Pyr¹] apelin-13 apelin was a potent vasoconstrictor in human vessels (saphenous vein) in vitro, by a direct action on

Apelins and the Apelin Receptor. **Figure 3** Scheme illustrating the hypothesised mechanisms of control of human (a) vascular tone and (b) cardiac contractility by apelin peptides (*). In the vasculature, apelins (released via the small vesicles of the constitutive pathway) may act directly to activate apelin receptors on the underlying smooth muscle to produce vasoconstriction. This response may be modified by apelin peptides feeding back onto apelin receptors on endothelial cells to stimulate the release of dilators, such as nitric oxide. In heart, apelin peptides, released from endocardial endothelial cells, activate apelin receptors on cardiomyocytes to elicit positive inotropic actions.

vascular smooth muscle, suggesting in pathophysiological conditions of endothelial cell dysfunction, vasoconstriction may be the predominant action. A potential role for the apelin receptor system in the pathogenesis of high blood pressure has been proposed

Apelin-16 is a potent positive inotropic agent in rats and in animal models treatment with apelin improves heart function. In isolated perfused rat hearts, infusion of apelin-16 (0.01–10 nM) induced a dose-dependent positive inotropic effect with an EC_{50} value of 33 pM. Continuous infusion of apelin-16 at a rate of 0.01 $\mu\text{g}/\text{min}$ for 20 min significantly increased contractility in rats in heart failure, 6 weeks after left anterior descending coronary artery ligation. These animal studies suggest apelin may have use as an acute inotropic agent in patients with ischemic heart failure. In humans, mRNA microarrays identified the apelin receptor gene as the only one of 12,000 genes tested that showed significant increase in expression levels in heart failure after implantation of a ventricular assist device, suggesting that apelin may play a compensatory role in the early stages of this condition. Apelin mRNA is increased in human myocardium in heart failure and mRNA encoding the receptor is significantly decreased.

Fluid Homeostasis

Apelin receptor and peptides are co-expressed in two nuclei of the hypothalamus, the supraoptic and paraventricular nucleus which play a major role in

the physiological regulation of fluid homeostasis by production of \blacktriangleright vasopressin (ADH). Axonal transport translocates ADH to the posterior pituitary, where it is released in response to osmotic stimuli sensed by hypothalamic neurones in order to regulate water and sodium uptake in the kidney as well as vascular tone. Messenger RNA encoding apelin co-localised in neurones expressing ADH mRNA, suggesting a role in the regulation of fluid homeostasis. Circulating plasma ADH levels decreased (–47%) after intracerebroventricular administration of apelin-13. In mice deprived of water, intracerebroventricular administration of apelin-13 significantly reduced the water intake in the initial 30 min after re-exposure to drinking water, and apelin-17 lowered circulating ADH levels (–43%). Increased water intake was also observed in the first 60 min after intracerebroventricular administration of apelin-13 in rats [3, 4].

Apoptosis

HENNING WALCZAK

Department of Immunology, Division of Medicine, Imperial College London, London, UK

Synonyms

Programmed cell death

Definition

Apoptosis is the most common form of programmed cell death. Apoptosis is characterized morphologically by cell shrinkage, membrane blebbing (zeiosis), ▶ **DNA fragmentation**, chromatin condensation, and nuclear fragmentation [1]. Biochemically, these morphological alterations in most cases require the activation of enzymes called caspases. Apoptosis plays a role during normal development where it facilitates the shaping of organs and their plasticity, e.g. in the developing central nervous system [2]. However, apoptosis also takes place in most tissues throughout life. Older or damaged cells undergo apoptosis and they are replaced by new cells which are constantly formed by proliferation of precursor cells. Thus, there is equilibrium between apoptosis and proliferation in the different tissues. A dysbalance in this equilibrium, e.g. by external stress or by a mutation or an epigenetic alteration of an apoptosis pathway constituent which hampers normal execution of the cell death program, is often causative for a disease or a pathological condition. Hence, the interest in understanding the underlying biochemical mechanisms of cell death induction by apoptosis has increased immensely ever since the importance of apoptosis as one part of this equation has been realized.

Basic Mechanisms

Two main apoptosis pathway exist. The first one is the death receptor pathway which can be triggered from the outside of the cell when a so-called death ligand which belongs to the ▶ **tumor necrosis factor (TNF)** family of cytokines crosslinks its cognate receptor on the surface of a cell. Besides TNF also TRAIL and the CD95 (Fas/APO-1) ligand (CD95L) can directly induce apoptosis and form part of the death ligand subfamily. Cross-linking of a death receptor by its ligand or by an agonistic antibody to the receptor results in the formation of the death-inducing signaling complex (DISC). The formation of this multi-protein complex leads to the activation of the initiator caspases 8 and 10 which both form part of this signaling complex.

The other pathway is triggered when so-called BH3-only proteins interact with other members of the Bcl-2 family on mitochondria. The bcl-2 homology domain 3 (BH3 domain) of the BH3-only proteins binds to other Bcl-2 family members thereby influencing their conformation. This interaction facilitates the release of cytochrome C and other mitochondrial proteins from the intermembrane space of mitochondria. Despite much effort the exact biochemical mechanism which governs this release is not yet fully understood. The release of cytochrome C facilitates the formation of the apoptosome, the second platform for apoptosis initiation besides the DISC. At the apoptosome which is also a multi-protein complex the initiator caspase-9 is activated. At this point the two pathways converge.

Active caspases 8, 9 and 10 can convert caspase-3, the most abundant effector caspase from its pro-form to its active cleaved form. Cleavage of a number of different substrates by caspase-3 and also by caspase-6 and -7 which are two other executioner caspases besides caspase-3 then results in the typical morphology which is characteristic of apoptosis. Yet, the activation of caspase-3 and also of caspase-9 can be counteracted by IAPs, so called inhibitor of apoptosis proteins. However, concomitantly with cytochrome C also other proteins are released from mitochondria, including Smac/DIABLO. Smac/DIABLO and potentially other factors can interact with IAPs and thereby neutralize their caspase-inhibitory activity. This releases the breaks on the cell death program and allows apoptosis to ensue.

There is also crosstalk between the two pathways above the mitochondria. The BH3-only protein BID is cleaved by caspase-8 and -10 which yields truncated BID (tBID), the active pro-apoptotic fragment of BID. Thereby, even in cells in which the direct apoptosis pathway which result from death receptor crosslinking is blocked, e.g. by high expression levels of the x-linked IAP (XIAP), the activity of tBID on mitochondria can result in the activation of caspase-3 because the IAP-imposed block on full caspase-3 activation and caspase-9 activity at the apoptosome is released by Smac/DIABLO.

Pharmacological Intervention Apoptosis Induction

Cancer cells often have a survival advantage over normal cells which is usually established during the transformation process. This is often facilitated by loss of pro-apoptotic factors or the acquisition of anti-apoptotic proteins. One such acquisition led to the identification of ►Bcl-2. High expression of anti-apoptotic proteins like Bcl-2 interferes with release of cytochrome C and Smac/DIABLO by BID or other BH3-only proteins, thus hampering the activation of caspase-9 and caspase-3, thereby interfering with the induction of apoptosis. Intriguingly, however, the cancer cells are often dependent on these changes acquired during transformation. Thus, if it were possible to interfere with the activity of a given factor the transformed cells have become dependent on this would be a very suitable therapeutic target. It now appears that in many types of cancer IAPs and the anti-apoptotic ►Bcl-2 family members fulfill this criterion. In addition, the triggering of apoptosis from the outside of the cells by TRAIL receptor agonists has shown to be effective in killing tumor cells and to be non-toxic. Importantly, also in combination with conventional chemotherapeutics, novel targeted therapeutics, or radiation therapy these drugs which specifically target TRAIL-R1 (DR4) and/or TRAIL-R2 (DR5) have so far

shown no or only very few dose-limiting toxicities in a number of phase I and II clinical trials. Taken together, there are three main protein families which have been identified in the apoptosis pathways as cancer drug targets, i.e. the apoptosis-inducing TRAIL receptors [3], the anti-apoptotic ►Bcl-2 family members [4] and the IAPs [5]. As a consequence there are three novel classes of cancer drugs: TRAIL receptor agonists, BH3 mimetics and IAP antagonists. These three classes of novel drugs have recently entered clinical trials and it will be interesting to see how these trials will develop, especially considering combinatorial therapies.

Besides direct apoptosis effectors, there are a number of other drugs which influence the above explained apoptosis pathways more indirectly. This class of drugs includes molecules which inhibit survival pathways like e.g. the Ras/Raf kinase pathway, the NF- κ B pathway and many others. Also inhibitors of survival cytokines which are sometimes produced by cancer cells in an autocrine fashion can render cells susceptible to apoptosis and, hence, effective cancer therapy. These include, but are not limited to, ligands for dependence receptors and cytokines like e.g. interleukin-4.

The combinations of conventional cancer therapeutics with novel targeted drugs, whether they directly or indirectly target the cell's apoptosis pathways will open a plethora of novel intervention strategies for cancer treatment in the future. The results of the preclinical work as well as the first results from clinical trials are very encouraging, perhaps promising. It seems that some of the new combinations which are now possible may finally allow the breaking of tolerance of cancer to most currently used therapies. The results of clinical studies with these new multi-target therapeutic strategies will teach us whether we will have managed to outmaneuver the cancer by depriving it of its capacity to generate a viable therapy-resistant variant.

Apoptosis Prevention

Often cells undergo apoptosis at a stage when they were not yet supposed to die, at least under normal physiological conditions. One such condition is reached when cells are deprived of oxygen. This is the case in stroke and acute myocardial infarction. At the core of the lesion the cells die by ►necrosis in both, the ischemic part of the heart and the oxygen-deprived part of the brain, as a consequence of complete deprivation of oxygen for too long a time period. Yet, in the penumbra, i.e. the region surrounding this central necrotic lesion, the cells are only deprived of oxygen for a limited period of time. However, if no intervention takes place, many of the cells in the penumbra die within the next days by apoptosis. Therefore pharmacological intervention has aimed at blocking the death of these cells by interfering with apoptosis. For quite some time caspase inhibitors were thought to be drugs

which are potentially useful in these diseases because of their apoptosis-inhibitory capacity *in vitro*. Currently caspase inhibitors are still being evaluated in the context of acute liver failure and first results are encouraging. However, it was discovered that in order to efficiently block cell death with caspase inhibitors it is necessary to very efficiently block caspase activity (i.e. by more than 98%) at any given time in a cell which has been triggered to undergo apoptosis. Since this is very difficult to achieve *in vivo* the attention has shifted towards inhibitors of the initial triggers of the cascade. Death ligands are one class of such triggers. Inhibition of death ligands can be achieved already outside the cell, i.e. before the apoptosis signal is transmitted to the inside of the cell. Hence, interference with death ligand binding to its cognate receptor(s) should allow for efficient inhibition of apoptosis. Consequently, in cases in which a given death receptor-ligand system has been implicated in a specific pathological conditions it should be possible to intervene therapeutically with a blocker of a given death ligand. In the case of TNF the concept of using TNF blockers, i.e. soluble TNF receptor Fc fusion proteins or anti-TNF antibodies, has been demonstrated to be very efficient in blocking the action of TNF in diseases such as rheumatoid arthritis and psoriasis, amongst many other diseases. Also for CD95L this concept has recently been shown to be very promising: in animal models of e.g. myocardial infarction, stroke, spinal cord injury, acute liver failure and graft-versus-host disease as inhibition of CD95L by CD95 blockers, i.e. soluble CD95 receptor Fc fusion proteins or antibodies to CD95L, has resulted in a therapeutic effect. Consequently, efforts are under way to test whether inhibition of CD95L can interfere with the tissue damage in these different disease situations in humans.

Apoptotic Executioner Caspases

Apoptotic executioner caspases (caspase-3, -6, -7) constitute a subgroup of the caspase family. These proteases are the workhorses of the apoptotic process as they are responsible for cleaving many down-stream substrates important for cellular morphology, organelle homeostasis, cell cycle arrest, and regulation of transcription and translation.

Apoptotic Initiator Caspases

Apoptotic initiator caspases (caspase-2, -8, -9 and -10) constitute a subgroup of the caspase family. These caspases are the first to become proteolytically active in the apoptotic cascade. Their activation takes place in multiprotein complexes initiated by pro-apoptotic stimuli, such as TNF α , α -Fas, staurosporine. Once activated, they can process their substrates, which include the apoptotic executioner caspases.

Synonyms

Control of food intake; Regulation of ingestive behaviour

Definition

Appetite control is a complex function of the brain that regulates feeding behaviour. This function integrates cognitive and emotional factors with a complex array of signals from the gastrointestinal tract and from adipose tissue.

Basic Mechanisms

Feeding behaviour is subjected to both short-term regulation during a single-meal and long-term regulation related to the maintenance of body weight and fat content. As a complex function of the brain, ingestive behaviour is controlled by psychological and cognitive factors such as sociocultural context (e.g. eating habits), experience (sensory preferences) or emotional status (mood). Appetite control also integrates information about the status of peripheral organs, particularly the gastrointestinal tract and adipose tissue [1]. Two main groups of signals can be distinguished: (i) satiety signals secreted from gastrointestinal organs, and (ii) adiposity signals that are proportionate to body fat stores. A key factor of this control system is that energy intake is primarily controlled by adjustment of meal size rather than meal onset, allowing the organism to initiate meals at times that are convenient and to adapt eating patterns to individual constraints (food availability) and activities (circadian rhythm).

Satiety Signals

Satiety-inducing signals are conveyed to the brain by afferent nerve fibers that are sensitive to mechanical or chemical stimulation of the stomach and small intestine during food ingestion. In addition, humoral signals such as ►**cholecystokinin** (CCK) are released upon nutrient stimulation of neuroendocrine cells located in the gastrointestinal wall. These satiety signals converge in the nucleus tractus solitarius in the brainstem and induce meal termination in the absence of hypothalamic control, as demonstrated in decerebrated rats. ►CCK is the paradigmatic humoral satiety signal, and its action has been studied extensively in multiple species

including human. Exogenous administration of ►CCK dose-dependently reduces meal size. This effect is synergistically enhanced by other factors that limit meal size, such as gastric distension. Specific CCK-A receptor antagonists stimulate food intake in rats, indicating that endogenous ►CCK contributes to the termination of meals. However, repeated administration of ►CCK before each meal does not reduce caloric intake of free-feeding mice or rats, because the animals compensate the reduced meal size by increasing the number of meals.

Adiposity Signals

Insulin as a Satiety/Adiposity Signal

The first hormonal signal found to comply with the characteristics of both a satiety and an adiposity signal was insulin [1]. Insulin levels reflect substrate (carbohydrate) intake and stores, as they rise with blood glucose levels and fall with starvation. In addition, they may reflect the size of adipose stores, because a fatter person secretes more insulin than a lean individual in response to a given increase of blood glucose. This increased insulin secretion in obesity can be explained by the reduced insulin sensitivity of liver, muscle, and adipose tissue. Insulin is known to enter the brain, and direct administration of insulin to the brain reduces food intake. The adipostatic role of insulin is supported by the observation that mutant mice lacking the neuronal insulin receptor (NIRKO mice) develop obesity.

Leptin as an Adiposity Signal

►Leptin is a cytokine produced and secreted by adipose tissue in proportion to the body fat content [3]. Mice and humans lacking leptin or its receptor develop a severe hyperphagia and a dramatic degree of obesity which is considerably more pronounced than that of the NIRKO mouse. Thus, leptin is the key adiposity signal in rodents and humans. Leptin secretion appears to reflect the metabolic status of the adipocyte rather than the sheer size of triglyceride deposits, and leptin levels may transiently be dissociated from total body fat. Nonetheless, over the course of a day with unrestricted food supply, plasma leptin levels reliably reflect the amount of total body fat. Local administration of leptin into the brain results in reduced food intake. The vast majority of patients with obesity have elevated serum levels of leptin. Thus, it is believed that the polygenic obesity is due to leptin resistance rather than to inadequate leptin secretion, or to a reduced blood/brain transport of the cytokine.

Appetite-Regulating Pathways in the Arcuate Nucleus of the Hypothalamus

Two distinct populations of neurons in the arcuate nucleus have been identified as the most relevant target cells of leptin (Fig. 1, [2, 4]). Leptin inhibits expression

Appetite Control. Figure 1 Diagram of pathways integrating appetite control. Satiety is the net output from brainstem centres that leads to the termination of an individual meal. Satiety is primarily determined by neural and humoral inputs from the gastrointestinal tract (satiety signals). Response to satiety signals is modulated by descending anabolic or catabolic pathways originating in the hypothalamus. Appetite regulating hormones are released in proportion to total body fat (leptin), glucose levels (insulin), or changes in food intake (ghrelin). Leptin and insulin stimulate secretion of anorexigenic peptides (α MSH, CART), and inhibit expression of orexigenic ones (NPY, AgRP) in the arcuate nucleus (ARC), whereas ghrelin exerts opposite effects. Secondary target neurons in the paraventricular nucleus (PVN) and the lateral hypothalamic area (LHA) integrate signals from neurons in the ARC, and connect them with satiety centers in the brainstem. In addition, recent evidence shows that afferent signals such as leptin and ghrelin also directly target brain centres known to play a key role in reward and addiction. Areas where such neurocircuitry is located include the ventral tegmental area (VTA) or the nucleus accumbens and appear to control mostly the hedonic components of feeding behaviour.

of the orexigenic peptides NPY (▶neuropeptide Y) and AgRP (▶agouti-related protein) in one subset of neurons, and stimulates production of the anorexigenic peptides α MSH (▶ α -melanocyte-stimulating hormone) and ▶CART (cocaine- and amphetamine-regulated transcript) in the other. Insulin receptors are also highly concentrated in the arcuate nucleus, and insulin appears to elicit similar changes in these neuropeptides as leptin.

The Melanocortin Signalling System

Considerable evidence indicates that the molecules of the melanocortin system are key mediators of the response to leptin. AgRP and α MSH are antagonistic ligands for a common receptor, the melanocortin-4 receptor (MC4R). α MSH is an anorexigenic neuropeptide that activates MC4R and thereby reduces appetite, whereas AgRP is an orexigen that acts as an endogenous antagonist of the receptor and suppresses its activation by α MSH. The critical role of the melanocortin system in appetite regulation is supported by the effects of spontaneous and experimental mutations of AgRP, α MSH, and MC4R in mice. Moreover, patients with complete loss of ▶proopiomelanocortin (POMC), the precursor molecule of α MSH, develop severe hyperphagia and overweight,

and 4–5% of all cases of severe human obesity appear to be due to mutations in the *MC4R* gene.

Role of NPY/AGRP Neurons

NPY has long been known to be a potent orexigen when directly injected into the hypothalamus. Hyperphagia of the leptin-deficient *ob/ob* mice is attenuated by knockout of NPY, supporting the role of NPY as a downstream effector of leptin. The effects of NPY on appetite regulation appears to be mediated by different receptor subtypes (NPY1R, NPY2R, and NPY5R). However, the neuropeptide is not an indispensable transmitter of adiposity signals, since lean mice which lack NPY show a normal feeding behaviour. On the other hand, it has recently been shown that the NPY/AGRP neurons play an essential role for basal orexigenic drive. If these neurons are completely ablated from the arcuate nucleus, adult mice stop feeding almost completely and lose substantial amounts of body fat. In conclusion, the NPY/AGRP neuron likely plays an essential role in the control of feeding behaviour, but their function can not be easily explained solely based on the expression of the neuropeptides NPY and AgRP.

Second-Order Hypothalamic Targets in Adiposity Signalling

Lesions of the ►lateral hypothalamic area (LHA) cause anorexia, whereas ablation of the ►paraventricular nucleus (PVN) cause a hyperphagic obesity syndrome. Consistent with these results, LHA neurons express the orexigenic neuropeptides MCH and ►orexin. PVN neurons produce several neuropeptides that are anorexigenic when administered directly into the brain (CRH, TRH, oxytocin), in addition to their better known roles as endocrine regulators. LHA and PVN receive rich inputs from axons of NPY/AgRP and α MSH/CART-producing neurons in the arcuate nucleus.

Other Hormones, Peptides, and Neurotransmitters Involved in Appetite Control

Many other peptides including galanin, ghrelin, and ►glucagon-like peptide-1 and 2 (GLP-1/GLP-2) have been described to participate in appetite control (Table 1). In addition, the neurotransmitters norepinephrine, dopamine, and serotonin are known to be involved in appetite regulation. The role of the monoamines in energy homeostasis is illustrated by effects of drugs (see below). Agonists of α_1 adrenoceptors, 5-HT_{2C} serotonin receptors, and dopamin receptors (D1 and/or D2) suppress appetite. However, the relevant neural circuits that use these transmitters are not very well defined. A control system mediating appetite-stimulating effects is the cannabinoid signalling. Recently, endocannabinoids have been added to the list of signals that act downstream of leptin. Leptin reduces levels of the endocannabinoid anandamide in the hypothalamus of normal rats, and mice that lack the cannabinoid receptor 1 (CB1) showed reduced food intake under conditions of low leptin levels (after fasting).

Pharmacological Intervention Appetite-Suppressing Drugs

The increasing prevalence of obesity and its consequences has stimulated the search for appetite-suppressing drugs as anti-obesity agents [5]. Therapy based on nutritional and behavioural counselling produces almost always only a temporary weight loss. The existing drugs that target adrenergic and serotonergic pathways (e.g. metamphetamine, phentermine, fenfluramine, sibutramine) have a negative reputation of toxicity and limited efficacy. The recent insights in appetite control as outlined above have provided new candidate targets for the search of appetite suppressing drugs. Since obesity is usually a chronic disorder which requires life-long therapy, anti-obesity drugs need to meet high safety standards.

β -Phenylethylamine Drugs

The appetite-suppressing effect of β -phenylethylamine drugs is either related to their sympathomimetic effect (metamphetamine, phentermine, diethylpropion), to

increased serotonergic transmission (fenfluramine), or both (sibutramine). Compared with metamphetamine, phentermine and diethylpropion appear to have little abuse potential but exhibit the typical side effects of sympathomimetic drugs (insomnia, hypertension). Use of fenfluramine was terminated after a high incidence of valvular heart disease was reported in patients treated with a combination of phentermine and fenfluramine. The same rationale to combine serotonergic and noradrenergic action underlies the therapy with sibutramine, a serotonin-norepinephrine reuptake inhibitor. Weight reduction by 5–10% was achieved over 24 weeks of treatment with sibutramine in doses from 10–15 mg/d. Weight was regained when the drug was stopped, indicating that a continuous therapy would be necessary to achieve the useful, but limited therapeutic effect. This general limitation is likely to apply for any novel drug that targets central noradrenergic and/or serotonergic pathways, e.g. agonists of the 5-HT_{2C} serotonin receptor.

Cannabinoid-1 Receptor Antagonists

These compounds are a novel class of anti-obesity agents which block the cannabinoid-1 (CB-1) receptor. Rimonabant, the only CB-1 receptor antagonist currently on the market, produces a weight loss of 3.4 or 6.6 kg with daily doses of 5 and 20 mg, respectively. In addition, the agent reduces plasma triglycerides and increases HDL cholesterol. The beneficial effects of rimonabant are probably mediated by both central and peripheral CB-1 receptors. Adverse effects were nausea, diarrhoea, dizziness, anxiety and depression. A second CB-1 receptor antagonist presently being tested in clinical trials is CP 945598.

Incretin-Mimetic Agents

Exenatide, a 39-amino acid peptide from the Gila monster (*Heloderma suspectum*), is a functional analog of human glucagon-like peptide-1 (GLP-1). Because of its resistance to degradation, in-vivo potency of exenatide is much greater than that of GLP-1. Exenatide improves glycemic control through glucose-dependent secretion of insulin, suppression of high glucagon levels in patients with type 2 diabetes, delay of gastric emptying, and reduction of food intake. Exenatide is administered at doses of 5 and 10 μ g twice daily; its most frequent adverse effects were nausea and hypoglycaemia.

Leptin

Leptin has been shown to markedly reduce appetite and weight in the extremely rare individuals who lack leptin. In contrast, in the first clinical study of patients with polygenic obesity and elevated leptin levels, weight loss was variable and relatively small. This disappointing result may be explained by the leptin resistance consistently observed in obese humans and rodents. However, it cannot be excluded that a small

subpopulation of obese patients is susceptible to the cytokine. Major efforts are currently underway to develop new drugs that target hypothalamic pathways downstream of leptin (e.g., NPY receptor antagonists, MC4R agonists, CRH agonists).

Drugs with Appetite-Stimulating Effects

Psychotropic Drugs

Stimulation of appetite and weight gain has frequently been observed as a side effect of long-term therapy with various psychoactive drugs. Prominent examples not

only are the tricyclic (e.g. imipramine) and heterocyclic (e.g. mirtazepine) antidepressants but also selective serotonin reuptake inhibitors (e.g. paroxetine), neuroleptic drugs (e.g. olanzapine), and lithium. Although it is reasonable to assume that these drugs interfere with central serotonergic and/or adrenergic signalling, the exact mechanism of their appetite-stimulating effect and the receptors involved are unknown. Stimulation of appetite by cyproheptadine, an antihistamin/antiserotonin agent, is believed to reflect antagonism of serotonin receptors.

Treatment of Cachexia and Anorexia

In the palliative treatment of cachexia and anorexia in advanced cancer and AIDS patients, modest relief can be achieved with appetite-stimulating drugs. Various pharmacologic strategies have been tested, including corticosteroids, anabolic steroids, megestrol acetate, cyproheptadine, melatonin, and dronabinol (delta-9-tetrahydrocannabinol). The cannabinoid receptor agonist dronabinol is approved in the US for stimulation of appetite in AIDS patients. Thalidomide also improves appetite and progressive weight gain in AIDS patients. Megestrol is so far the only agent associated with increased appetite and weight gain in patients with cancer.

Water channels

Definition

Aquaporins (AQP) are a family of integral membrane proteins expressed in all organisms and play a fundamental role in the regulation of water transport into and out of cells.

Basic Mechanisms Background

Aquaporins are central players in mammalian physiology, but are also important in microorganisms and plants. The number of AQPs in plants is quite high; angiosperms species, for example, express approximately 35 different AQPs divided into four families on the basis of their sequence. Moreover, plant AQPs might be considered multifunctional channels for their different transport properties.

To date, 13 different AQPs have been identified in mammals (AQP0–AQP12). Most of these proteins allow efficient water transport through the cell membrane. However, several studies revealed that some AQPs also mediate the transport of various small molecules such as hydrogen peroxide, urea, glycerol or anions. On the basis of their different transport properties, AQPs can be divided in two major groups: classical AQPs and aquaglyceroporins. Functional studies revealed that all AQPs transport water to a particular extent. AQP0, 1, 2, 4 and 5 are classical aquaporins being only permeable to water, while AQP3, 7, 9, 10 and 12 can also facilitate the transport of other small molecules, such as glycerol and urea. AQP6 has been suggested to function as a pH-sensitive chloride channel, while AQP8 is permeable to urea and hydrogen peroxide. AQP7 and 9 also transport heavy metal salts, such as arsenite, while AQP9 is additionally permeable to other solutes, such as urea, linear polyols, purines, pyrimidines and nucleosides. The water transport properties of AQP11 are unknown, but it is

impermeable to any of the small molecules mentioned above. Considering the importance of water transport in several biological processes and the expression and distribution of AQPs in all organisms, it is likely that mutations in these genes contribute to various diseases.

Structure of AQPs

Hydrophobicity plots of AQPs indicated that these proteins consist of six transmembrane α -helices (H1–H6 in Fig. 1a) connected by five connecting loops (A–E), and flanked by cytosolic N- and C-termini. The second half of the molecule is an evolutionary duplicate and inverse orientation of the first half of the molecule. Loops B and E of the channel bend into the membrane with an α -helical conformation (HB, HE in Fig. 1b) and meet and each other at their so-called Asn-Pro-Ala (NPA) boxes. These NPA motifs are the hallmark of AQPs and form the actual selective pore of the channel, as at this location, the diameter is of that of a water molecule (3 Å; Fig. 1a and b). Based on the narrowing of the channel from both membrane sides to this small

Aquaporins. Figure 1 (a) The hour-glass model. The scheme depicts the six transmembrane helices (H1–H6), the connecting loops A–E, including the helical parts of loops B ((H)B) and E (E(H)), and the conserved NPA (Asn-Pro-Ala) motif of canonical aquaporins. (b) Structure of the conserved NPA motif region, flanked by the indicated helices. (c) Crystallographic structure of AQP1 tetramer. The four water pores in a tetramer are indicated [1].

pore, an “hour-glass” structure model was proposed, which has later been proven by electron and X-ray crystal studies of AQP1 [1]. Movement of water through the channel occurs in single file and at a speed indifferent from water molecule movement within water. This latter item means that water does not interact with the channel at its narrowest point, i.e., the NPA box region. Indeed, six water molecules form a single file through the channel of AQP1 and hydrogen bonds only occur within the AQP pore between water and six residues (Gly74, Ala75, and His76 on the cytoplasmic side and Gly190, Cys191, and Gly192 on the extracellular side), but not at the NPA motif. At this latter point, water molecules reorient to form a transient hydrogen bond with the conserved asparagine in the NPA triplet, thereby impairing the conduction of protons. Interestingly, the most recently identified AQPs, AQP11 and AQP12, have their E-loop NPA motif, but the alanine in the loop B NPA motif is replaced by cysteine (AQP11) or threonine (AQP12). The functional consequences are at present unclear.

Although freeze-fracture experiments have demonstrated that monomers are assembled into stable tetramers in the membranes, radiation inactivation studies and, later, expression studies revealed that each monomer is a functional water channel (Fig. 1c).

Tissue Distribution of AQPs

The presently known mammalian AQP0-AQP12 have been localized in tissues involved in fluid transport as well as in nonfluid-transporting tissues (Table 1). Most AQPs are constitutively present in the plasma membrane, whereas some water channels can be triggered to shuttle between intracellular vesicles and the plasma membrane [2].

AQP0, formerly known as the Major Intrinsic Protein of 26 kDa (MIP26), is specifically expressed in the plasma membrane of eye lens fiber cells. It transports water to a low degree, but has also been implicated in cell adhesion and gap junction formation. Its main role is to maintain the transparency of the lens by maintaining a tight cellular connection to neighboring cells and/or by controlling the fluid circulation.

AQP1, till the renaming to AQPs referred to as CHIP28, is widely expressed throughout the body. AQP1 is located in the proximal tubule, thin descending limb of Henle and descending vasa recta in the kidney. Outside the kidney, AQP1 is present in endothelial cells of capillaries and small vessels throughout the whole digestive system, including salivary gland, esophagus, stomach, intestine, liver, gallbladder and pancreas. In addition, AQP1 is found in red blood cells, ear, eye, lung, male reproductive system and the choroid plexus. In contrast to its other locations, AQP1 shuttles to the apical membrane of cholangiocytes, which is under hormonal regulation.

The AQP2 water channel is highly expressed in the principal cells of renal collecting duct [3]. Whereas most AQPs are constitutively present on the plasma membrane, AQP2 shuttles between intracellular storage vesicles and the apical membrane. The localization of AQP2 within the principal cell is mainly controlled by the antidiuretic hormone vasopressin. In states of dehydration or hypovolemia, vasopressin is released into blood and binds its receptor on renal principal cells. Binding of vasopressin initiates a cAMP signaling cascade resulting in a fast translocation of AQP2 bearing vesicles to the apical membrane, rendering the membrane permeable to water (Fig. 2). In extrarenal tissues, AQP2 can be found in vas deferens and in the inner ear.

Aquaporins. Table 1 Localization of AQPs

AQP	Localization
0	Eye lens fiber cells
1	Kidney tubules, salivary gland, esophagus, stomach, intestine, liver, gallbladder, pancreas, red blood cells, ear, eye, lung, male reproductive system, the choroid plexus
2	Kidney collecting duct, vas deferens, inner ear
3	Kidney collecting duct, skin, bladder epithelium, digestive tract, respiratory tract, eye, brain
4	CNS, kidney collecting duct, glandular epithelia, airways, skeletal muscle, stomach, retina and ear
5	Glandular epithelia, lung epithelium, gastrointestinal tract, pancreas, ear
6	Kidney collecting duct
7	Adipose tissue, kidney proximal tubule, testis, gastrointestinal tract, immature dendritic cells and ear
8	Gallbladder, liver, pancreas, intestine, salivary gland, testis, heart, kidney, lung, placenta
9	Liver, intestinal wall, lung, leukocytes, testis, ear, brain
10	Small intestine
11	Kidney, liver, testis, brain
12	Pancreatic acinar cells

Aquaporins. Figure 2 Model showing the vasopressin dependent AQP2 trafficking in renal collecting duct cells. Vasopressin binding to its V2 receptor results in the activation and dissociation of a stimulatory G protein (Gs), of which the GTP-bound α -subunit activates adenylate cyclase. The consequent increase in cAMP activates protein kinase A, which phosphorylates several proteins, including AQP2 at Ser256, which is located in its C-terminus. This event is essential for the steady-state redistribution of AQP2 to the apical membrane. Upon restored water homeostasis, blood AVP levels are decreased and AQP2 will be internalized from the apical membrane.

Similar to AQP1, AQP3 expression can be found in many different tissues, including kidney collecting duct, bladder epithelium, digestive tract, respiratory tract, eye and brain. In kidney, AQP3 is present in the basolateral membrane of collecting duct principal cells. In the digestive tract, AQP3 is expressed in epithelial cells ranging from the oral cavity to the stomach and from the distal colon to the anus. AQP3 is also expressed in skin, where it is involved in skin hydration and elasticity.

AQP4 is the predominant water channel in the central nervous system (CNS), where it is involved in maintaining brain water balance and neural signal transduction. It is mainly expressed in astroglial cells, which support the neurons. Outside the CNS, AQP4 has been found in the basolateral membrane of renal principal cells as well as in various glandular epithelia, airways, skeletal muscle, stomach, retina and ear.

AQP5 is expressed in lung epithelium, gastrointestinal tract, pancreas and ear. Several glandular epithelia also express AQP5, including airway submucosal glands, salivary glands, lachrymal glands and sweat glands suggesting a role for AQP5 in the release of airway fluids, saliva, tears and sweat.

AQP6 is expressed in the intercalated cells of the kidney collecting duct. This channel is hardly permeable to water, but capable of transporting anions, including chloride, and is therefore thought to play a role in maintenance of body acid-base balance or in intracellular vesicle acidification.

AQP7 is expressed in the proximal tubule of the kidney, testis, gastrointestinal tract, immature dendritic cells and ear. This glycerol channel is also highly expressed in adipocytes where it is thought to control the release of triglycerides.

Also AQP8 is widely expressed in organs including liver, pancreas, intestine, salivary gland, testis, heart, kidney, lung and placenta. AQP8 expression in gallbladder epithelium suggests a role in secretion of bile. Several groups also found AQP8 to be expressed in mitochondria, but a role for AQP8 in mitochondrial processes remains to be established.

AQP9, a channel highly permeable to water and solutes, is localized in liver, intestinal wall, lung, leukocytes, testis, ear and brain. Liver AQP9 is suggested to act in conjunction with AQP7 in fat metabolism. While AQP7 is involved in the release of glycerol from adipocytes, AQP9 facilitates its transport

into the hepatocytes. Based on its putative function in hepatocytes, AQP9 expression in the brain is suggested to play a role in brain energy metabolism.

AQP10 has only been identified in the small intestine so far and is thought to play a role in hormonal secretion. AQP11 is expressed in kidney, liver, testis and brain, but no function has been found so far. AQP12 has been identified in pancreatic acinar cells, where it is thought to facilitate the release of digestive enzymes into the pancreatic duct.

AQP-associated Pathologies

Knocking out genes and identification of mutations in the human genes provide information on the role of AQPs in normal physiology. The lack of some AQPs directly results in a disease phenotype, while the physiological role of many becomes clear when the putative function is challenged.

Mutations in two genes directly lead to a disease. Mutations in the AQP0 gene lead to dominantly inherited cataract. Single amino acid substitution in the AQP0 gene in both mice and humans result in proteins with impaired trafficking to the plasma membrane and cataract formation, due to loss of the integrity of the lens.

Mutations in the AQP2 gene can cause severe problems, as they result in nephrogenic diabetes insipidus (NDI), a disorder in which patients are unable to concentrate their urine. Congenital NDI can be caused by mutations in the V2R gene (X-linked NDI) or the AQP2 gene (autosomal recessive or dominant NDI) [4, 5]. Missense mutations in the AQP2 gene in recessive NDI affect amino acids located in between the first and last transmembrane domain. Although they might be functional water channels, the mutation leads to a misfolded protein, which is retained by the cellular quality control of the endoplasmic reticulum. In dominant NDI, the mutations are found in the AQP2 C-terminus, resulting in AQP2 mutants that are, in complex with wild-type AQP2, sorted to other subcellular destinations than the apical membrane. Consequently, inadequate amounts of AQP2 are expressed in the apical membrane, resulting in reduced water absorption and increased urine volumes.

Humans lacking AQP1 do not suffer from any severe symptoms. The only phenotype that can be observed in these individuals is a mild renal concentration defect.

Still, the list of diseases in which AQPs may play a role is expanding. AQP3 knockout mice developed NDI and showed polyuria. In addition, these mice showed dry skin and delayed wound healing. Humans lacking a functional AQP3, however, are symptom less. AQP4 knockout mice revealed an important role for AQP4 in recovery after brain injury. AQP5 expression is decreased in patients with Sjögren's syndrome, a disorder characterized by dry eyes, dry mouth and pulmonary problems, but a causal relationship has not

been established yet. AQP7 expression is reduced in obese people compared to lean people, which may indicate that a lack of AQP7 in adipocytes may underlie congenital forms of obesity. The lack of AQP11 results in polycystic kidneys in mice, but whether such a relationship exists in humans is unknown.

Pharmacological Interventions

Although aquaporins play a fundamental role in the regulation of water homeostasis, specific pharmacological therapies are still not available. Several substances like mercurial derivatives, silver, and gold have been demonstrated to inhibit water permeability mediated by aquaporins in oocytes, but most of them are nonspecific and too toxic to be used *in vivo*. Recent studies have shown that tetra-ethyl ammonium (TEA) selectively inhibits AQP1, AQP2 and AQP4 but not AQP3 and AQP5, indicating that quaternary ammonium compounds and in particular TEA may be a good lead compound for the development of specific aquaporin inhibitors.

Aquaretic Agents

Substances which promote the elimination of water by the kidney without major losses of salts (e.g. conivaptan, tolvaptan, SR121463A/B). They are particularly useful in situations where excess water needs to be eliminated without affecting the salt metabolism, like eu- or hypervolemic hyponatraemia, congestive heart failure, some stages of hypertension and some metabolic states.

Aromatase

D SHAHEENAH, SUSAN G KOMEN FELLOW,

University of Texas, M.D. Anderson Cancer Center,
Houston, TX, USA

Definition

Aromatase is a cytochrome P450, hemoprotein-containing enzyme, located in the endoplasmic reticulum, which catalyzes the rate-limiting step in the conversion of ► [androgens](#) (androstenedione and testosterone), to ► [estrogens](#) (estrone and estradiol). Agents that inhibit aromatase (aromatase inhibitors) are widely used to prevent the development and progression of ► [estrogen](#) dependent breast cancers.

Basic Characteristics

Estrogen biosynthesis is mediated by the aromatase enzyme, which is a product of the CYP19 gene. The aromatase enzyme is a complex that consists of cytochrome P450 hemoprotein and a flavoprotein, NADPH-cytochrome P450 reductase. This complex is responsible for catalyzing the conversion of steroidal C-19 androgens (androstenedione and testosterone) to C-18 estrogens (estrone and estradiol), which is the rate-limiting final step in the synthesis of estrogens (Fig. 1). This enzymatic reaction is comprised of three steps each of which requires 1M equiv. of NADPH and oxygen. The first step involves hydroxylation of the androgen substrate at C-19 to produce a 19-hydroxy intermediate. In the second step the 19-hydroxy intermediate is oxidized to produce a 19-oxo compound. The last step in the aromatization reaction is less well defined but is thought to involve the oxidative cleavage of the C10-19 bond to produce ► [estrogens](#) (estrone and estradiol) and formic acid.

Aromatase activity, and hence the capacity to synthesize estrogens, is found in a variety of tissues in the body. Gonadal sites include the ovaries in premenopausal women and the testes in men. Important extragonadal sites of aromatase activity include the placenta, chondrocytes and osteoblasts of bone, adipose tissue, muscle and brain. Aromatase plays an important

Aromatase. Figure 1 Androgens converted to estrogens by aromatase.

role in a number of important biological processes including breast development during puberty and uterine growth and bone maturation during adolescence. In adults aromatase influences bone mineralization, lipid metabolism and cardiovascular risk. In pregnant women it protects against the virilizing effects of fetal androgens.

Drugs

Estrogen is known to be an important stimulus in the development and progression of some breast tumors. Thus targeting the disruption of either the synthesis (i.e., inhibiting aromatase enzyme) or the activity (i.e., blocking [estrogen receptors](#)) of estrogens are potential mechanisms for the prevention and treatment of hormone sensitive breast cancer. Since aromatization is a unique reaction and is the terminal step of the estrogen biosynthetic pathway, agents that block this reaction would not potentially affect the production of other steroids.

In premenopausal women the ovary is the richest source of aromatase and hence estrogen. Aromatase is confined to the granulosa cells and is produced under the influence of [gonadotropins](#) (FSH and LH). Despite being a rich source of aromatase, three separate studies have shown that aromatase inhibitors are unable to sufficiently suppress ovarian estrogen production to postmenopausal levels. One explanation for this phenomenon may be a compensatory rise in gonadotrophins which maintains adequate estrogen production, despite the presence of the inhibitor. As such aromatase inhibitors cannot be used in premenopausal breast cancer patients. After menopause, ovarian

production of estrogen ceases. However estrogen production continues from peripheral sources of aromatase activity that convert adrenal androgens to estrogens. Aromatase inhibitors have been shown to adequately suppress estrogen production in postmenopausal women, and in this setting are used in the treatment of both early and advanced stage [estrogen receptor](#) positive breast cancer.

Over the last 30 years a number of aromatase inhibitors ([Fig. 2](#)) have been developed. The first (aminoglutethimide) and second (Fadrozole and Fromestane) generation aromatase inhibitors are not commonly used due to their lack of specificity in inhibiting the aromatase enzyme and associated significant side-effects. Two types of third generation aromatase inhibitors are commercially available and have been shown to be either equal to or superior to tamoxifen in the treatment of metastatic estrogen receptor positive breast cancer. Type I (suicidal, noncompetitive) inhibitors bind irreversible with the aromatase enzyme thereby permanently blocking its activity. Exemestane is an example of a type I inhibitor. Type II inhibitors bind reversible with the aromatase enzyme, examples of which include letrozole and anastrozole.

Aminoglutethimide

Aminoglutethimide was the first aromatase inhibitor to be used in patients with metastatic breast cancer, where response rates of up to 30% have been reported. Unfortunately, due to its lack of selectivity for aromatase, it induced a medical adrenalectomy that resulted in suppression of aldosterone and cortisol. With the development of more selective aromatase

Aromatase. Figure 2 Aromatase Inhibitors.

inhibitors, aminoglutethimide is now rarely used for the treatment of breast cancer. It is occasionally used for the treatment of medical conditions involving excess hormone production such as [▶Cushing's syndrome](#).

Anastrozole

Anastrozole is a nonsteroidal, type II, aromatase inhibitor that is 200 times more potent than aminoglutethimide. It is eliminated primarily via hepatic metabolism, has a terminal half life of 50 h with steady state concentrations achieved approximately 10 days with once daily dosing regimens. It is administered orally at a dose of 1 mg/day that achieves near maximal aromatase inhibition and hence estrogen suppression in breast cancer patients. No effect on adrenal steroidogenesis has been observed at up to ten times the daily recommended dose. When used in the metastatic setting, anastrozole has been shown

to increase time to progression when compared to tamoxifen. In the ATAC (Arimidex, [▶Tamoxifen](#), Alone or in Combination) trial over 9,000 patients with early stage breast cancer were randomized to 5 years of anastrozole 1 mg/day or 5 years of tamoxifen 20 mg/day or a combination of both. At a median follow up of 33 months, 47 months, and 68 months, compared to tamoxifen, anastrozole upfront significantly increased disease free survival and time to recurrence and reduced the risk of contra lateral breast cancer. The combination arm of the trial was closed as it was no more efficacious than tamoxifen alone. Currently trials are ongoing evaluating anastrozole as chemopreventive agent for breast cancer.

Letrozole

Like anastrozole, letrozole is a third generation, type II nonsteroidal aromatase inhibitor. Renal excretion of its

inactive glucuronide metabolite represents its main pathway of clearance. It has a half-life of 2 days and at the recommended daily dose of 2.5 mg steady-state plasma levels is reached in 2–6 weeks. Letrozole has proved effective when used either sequentially after tamoxifen or upfront in the treatment of patients with early stage breast cancer. The MA-17 trial randomized approximately 5,000 postmenopausal breast cancer patients who had received 5 years of tamoxifen to either placebo or 5 years of letrozole. The Breast International Group (BIG) 1–98 trial randomized postmenopausal breast cancer patients to 5 years of tamoxifen, 5 years of letrozole, or 2 years of either agent (i.e., tamoxifen or letrozole) followed by three years of the other agent (i.e., tamoxifen or letrozole). In terms of disease free survival the MA-17 trial showed an advantage to switching to letrozole and the BIG 1–98 trial showed an advantage to up front letrozole with results awaited for the switching group.

Exemestane

Exemestane is a type II, steroidal aromatase inhibitor with an androgen structure. It is metabolized by CYP3A4 enzyme and has a half-life of 27 h. At the recommended once daily dose of 25 mg no effect is seen on adrenal steroid production and maximal estrogen suppression is achieved in 7 days. In early breast cancer treatment it has been studied as a sequential agent after several years of tamoxifen. The Intergroup Exemestane Study (IES) randomized over 4000 patients to either 5 years of tamoxifen 20 mg/day or 2–3 years of tamoxifen followed by exemestane 25 mg/day. A significant reduction in disease free survival (hazard ratio, 0.76, $p = 0.0001$) and risk of contralateral breast cancer favoring the group switching to exemestane was observed.

Side Effects

Aromatase inhibitors are relatively well tolerated; however have a number of distinct side effects are observed that stem from the state of estrogen deprivation induced by aromatase inhibitors. Side effects include hot flashes, joint and muscle aches, vasomotor symptoms and vaginal dryness. Variable effects of aromatase inhibitors on lipid levels have been observed. Trials comparing third generation aromatase inhibitors to tamoxifen have also reported an increased risk of cardiovascular events in the group receiving aromatase inhibitors.

Other Uses

Aromatase inhibitors have also been used in premenopausal women for the treatment of ►endometriosis and to induce ovarian folliculogenesis as part of the treatment for infertility.

Aromatase Inhibitor

An aromatase inhibitor is a class of antiestrogens that inhibits the enzyme aromatase and by that means lowers the level of the estrogen estradiol. Aromatase catalyzes the conversion of testosterone to estradiol in many tissues including the adrenal glands, ovaries, placenta, testicles, adipose tissue, and brain. Estrogen is produced directly by the ovaries and is also made by the body using aromatase. Aromatase inhibitors cannot do anything about estrogen produced by the ovaries, but they do interfere with the body's use of aromatase.

Arousal

Arousal is a state of vigilance regulated by subcortical parts of the nervous system, especially connections between the nuclei of the amygdala, the hypothalamus and the brain stem. These unconscious responses prepare the body for action.

In terms of sleep/wake regulation, the arousal systems are those that have highest activity during wake, for example the aminergic (noradrenaline, 5-HT, histamine) systems. The arousal systems inhibit, and are themselves inhibited by the GABAergic system emanating from the ventrolateral preoptic nucleus (VLPO), in a so-called “flip flop” arrangement that is stabilised via orexinergic activity.

AhR

Definition

Members of the CYP1 family and some other drug metabolizing enzymes including UGT1A6 are collectively induced by polycyclic aromatic hydrocarbons (PAH) and other ligands (e.g. 2,3,7,8-tetrachlorodibenzo-p-dioxin, TCDD) of this basic helix-loop-helix (bHLH) transcription factor. In the absence of ligand AhR is inactive while bound to HSP90 in the cytoplasm. Upon binding of ligand, it moves to the nucleus and dimerizes with Arnt (AhR nuclear translocator protein) to form the active transcription factor that binds to xenobiotic response elements (XRE) in the promotor regions of target genes. AhR furthermore plays a role in regulating hepatic cell regeneration.

Synonyms

Arteriosclerosis (see definition)

Definition

Atherosclerosis, from the Greek words *athera* – porridge, and *sclereni* – hardening, literally is a hardening of medium- and large-sized arteries specifically due to an atheromatous plaque, whereas arteriosclerosis is a more general term describing any hardening of medium and large arteries. A typical atherosclerotic **▶plaque** consists of a fibrous cap (A structure composed of a dense collagen-rich extracellular matrix with occasional smooth muscle cells, macrophages and T-cells that typically overlies the characteristic central lipid core of plaques.) overlying a lipid-rich core. In addition to the long recognized lipid accumulation, these lesions, known as atheromata, also harbor inflammation and cell recruitment and turnover (proliferation and death). Collectively, the process of atheroma development within an individual is called atherogenesis, and the overall result of the disease process is termed atherosclerosis.

Basic Mechanisms

General

The traditional view of atherosclerosis as a bland cholesterol storage disease falters in the wake of extensive evidence that inflammation plays a central role in all stages of this pathology, from the initial lesion to the final devastating thrombotic complications [1, 2]. Atherosclerosis is a chronic systemic disease preferentially affecting particular circulatory beds; in the coronary arteries, it commonly causes **▶angina pectoris** and **▶myocardial infarction**, in the central nervous system it often leads to transient ischemic attack and **▶ischemic stroke**, and in the periphery it results in **▶intermittent claudication** and critical limb ischemia. The renal and splanchnic beds can also develop atherosclerosis. This disease may manifest clinically with chronic symptoms, such as stable angina or intermittent claudication, acutely as in myocardial infarction or cerebrovascular accident, or may remain clinically silent. Despite a broad array of pharmacologic and procedural interventions to combat this scourge, atherosclerosis remains the leading cause of death and disability in the developed world.

Lesion Initiation and Development of the Fatty Streak

Inflammation participates in atherosclerosis from its inception and onwards (Fig. 1). Even children can develop the “fatty streak,” the initial lesion of atherosclerosis. Fatty streaks do not cause symptoms, and may progress to more complex lesions, or eventually disappear. Fatty streaks have focal increases in the content of lipoproteins within regions of the **▶intima** where they associate with constituents of the extracellular matrix such as proteoglycans, slowing their egress. This retention sequesters lipoproteins within the intima, isolating them from plasma antioxidants, thus favoring their oxidative modification. Oxidatively modified low-density lipoprotein particles (LDL) comprise an incompletely defined mixture, as both the lipid and protein moieties can undergo oxidative modification. Constituents of such modified lipoprotein particles can induce a local inflammatory response.

Endothelial cells (ECs) normally resist leukocyte adhesion. Proinflammatory stimuli that include high-saturated-fat diet, hypercholesterolemia, obesity, hyperglycemia, insulin resistance, hypertension, and smoking trigger the endothelial expression of adhesion molecules such as vascular cell adhesion molecule-1 (VCAM-1) and P-selectin that mediate the attachment of circulating monocytes and lymphocytes. Interestingly, atherosclerotic lesions often form at bifurcations of arteries, regions characterized by a disturbed blood flow which reduces the activity of endothelial atheroprotective molecules. Laminar flow induces the expression of atheroprotective genes such as the antioxidant enzyme superoxide dismutase as well as the synthase that produces nitric oxide, an endogenous vasodilator that can also limit inflammation, for example by limiting VCAM-1 expression.

Chemoattractant factors that include monocyte chemoattractant protein-1 (MCP-1) produced by vascular wall cells in response to modified lipoproteins, direct the migration and diapedesis of adherent monocytes. MCP-1 binds to CCR2 (a chemokine receptor containing two adjacent cysteine residues) on the surface of the migrating monocyte to exert this effect. Experimental evidence and human observations support the involvement of several other chemokines in leukocyte recruitment into the nascent atherosclerotic lesion, including IL-8 and fractalkine. Within the intima, monocytes mature into macrophages under the influence of macrophage colony-stimulating factor (M-CSF), overexpressed in the inflamed intima. M-CSF stimulation also leads to increased macrophage expression of **▶scavenger receptors**, members of the pattern-recognition receptor superfamily, which engulf modified lipoproteins through receptor-mediated endocytosis. Accumulation of cholesterol esters in the cytoplasm changes macrophages into **▶foam cells**, i.e. lipid-laden macrophages characteristic

Atherosclerosis. Figure 1 Initiation, progression, and complication of human coronary atherosclerotic plaque. Top, Longitudinal section of artery depicting “timeline” of human atherogenesis from normal artery (1) to atheroma that caused clinical manifestations by thrombosis or stenosis (5–7). Bottom, Cross sections of artery during various stages of atheroma evolution. 1, Normal artery. Note that in human arteries, the intimal layer is much better developed than in most other species. The intima of human arteries contains resident smooth muscle cells (SMCs) often as early as first year of life. 2, Lesion initiation occurs when endothelial cells, activated by risk factors such as hyperlipoproteinemia, express adhesion and chemoattractant molecules that recruit inflammatory leukocytes such as monocytes and T lymphocytes. Extracellular lipid begins to accumulate in intima at this stage. 3, Evolution to fibrofatty stage. Monocytes recruited to artery wall become macrophages and express scavenger receptors that bind modified lipoproteins. Macrophages become lipid-laden foam cells by engulfing modified lipoproteins. Leukocytes and resident vascular wall cells can secrete inflammatory cytokines and growth factors that amplify leukocyte recruitment and cause smooth muscle cell migration and proliferation. 4, As lesion progresses, inflammatory mediators cause expression of tissue factor, a potent procoagulant, and of matrix-degrading proteinases that weaken fibrous cap of plaque. 5, If fibrous cap ruptures at point of weakening, coagulation factors in blood can gain access to thrombogenic, tissue factor-containing lipid core, causing thrombosis on nonocclusive atherosclerotic plaque. If balance between prothrombotic and fibrinolytic mechanisms prevailing at that particular region and at that particular time is unfavorable, occlusive thrombus causing acute coronary syndromes may result. 6, When thrombus resorbs, products associated with thrombosis such as thrombin and mediators released from degranulating platelets, including platelet-derived growth factor (PDGF) and transforming growth factor- β (TGF- β), can cause healing response, leading to increased collagen accumulation and smooth muscle cell growth. In this manner, the fibrofatty lesion can evolve into advanced fibrous and often calcified plaque, one that may cause significant stenosis, and produce symptoms of stable angina pectoris. 7, In some cases, occlusive thrombi arise not from fracture of fibrous cap but from superficial erosion of endothelial layer. Resulting mural thrombus, again dependent on local prothrombotic and fibrinolytic balance, can cause acute myocardial infarction. Superficial erosions often complicate advanced and stenotic lesions, as shown here. However, superficial erosions do not necessarily occur after fibrous cap rupture, as depicted in this idealized diagram. (Libby P (2001) Current concepts of the pathogenesis of the acute coronary syndromes. *Circulation* 104:365–372.)

of the early stages of atherosclerosis. In parallel, macrophages proliferate and amplify the inflammatory response through the secretion of numerous growth factors and cytokines, including tumor necrosis factor- α (TNF- α) and interleukin-1 β (IL-1 β).

T-cells, representing the adaptive arm of the immune response, also play a critical role in atherogenesis, and enter lesions in response to the chemokines inducible protein-10 (IP-10), monokine induced by IFN- γ (MIG), and IFN-inducible T-cell α -chemoattractant (I-TAC), which bind CXCR3 (a chemokine receptor containing two cysteine residues separated by one amino acid), highly expressed by T lymphocytes in the plaque. The

CD4⁺ subtype, which recognizes antigens presented as fragments bound to major histocompatibility complex (MHC) class II molecules, predominates in the lesion. Interestingly, CD4⁺ T-cells reactive to the disease-related antigens associated with oxidized LDL have been cloned from human lesions. The atherosclerotic lesion contains cytokines that promote a Th1 response, inducing activated T-cells to differentiate into Th1 effector cells. These cells amplify the local inflammatory activity by releasing proinflammatory cytokines such as IFN- γ and CD40 ligand (CD40L, CD154).

The atherosclerotic plaque overexpresses another chemoattractant, eotaxin, that may mediate mast cell

migration to the lesion through CXCR3. Multiple studies suggest that mast cells promote atherogenesis by releasing cytokines such as TNF- α , IFN- γ , and IL-6 as well as chemokines that attract other leukocytes and proteases that activate matrix metalloproteinases (MMPs) and participate in arterial remodeling. Although the subject of much debate for several decades, recent results in mice support a role for this cell type in lesion progression and complication.

Progression to Complex Plaque

Macrophages, T-cells, and mast cells infiltrate the lesion and localize particularly in the shoulder region where the atheroma grows. While accumulation of foam cells characterizes fatty streaks, deposition of fibrous tissue defines the more advanced atherosclerotic lesion. Smooth muscle cells (SMCs) synthesize the bulk of the extracellular matrix that characterizes this phase of plaque evolution. In response to platelet-derived growth factor (PDGF) released by activated macrophages and endothelial cells, SMCs migrate from the tunica media into the intima, where they proliferate under the influence of various growth factors and secrete extracellular matrix proteins, including interstitial collagen, especially in response to transforming growth factor- β (TGF- β) and PDGF. The ►**fibrous cap** covering the atherosclerotic plaque, formed during this phase, owes its biomechanical strength to interstitial collagen (types I and III).

Neovascularization arising from the artery's ►**vasa vasorum** contributes to lesion progression in many ways. First, it provides another entry route for leukocytes into established atherosclerotic lesions. Second, as these neovessels are friable, they can favor focal intraplaque hemorrhage that furnishes one mechanism for the discontinuous increments seen in plaque growth. Hemorrhage in turn generates thrombin, stimulating the release of PDGF from ECs as well as directly stimulating SMC proliferation and cytokine production.

CD40L plays an important role in this phase of atherogenesis. All the main cell types involved in atherosclerosis, including macrophages, T-cells, ECs, SMCs, and platelets, express this proinflammatory cytokine as well as its receptor, CD40. Ligation of CD40 triggers the expression of adhesion molecules and the secretion of numerous cytokines and MMPs involved in extracellular matrix degradation. Importantly, CD40L has a prothrombotic effect by inducing macrophage expression of ►**tissue factor** (also called thromboplastin, factor III, or CD142), which once exposed to factor VII initiates the coagulation cascade.

Plaque Rupture

Plaque rupture and the ensuing thrombosis commonly cause the most dreaded acute complications of

atherosclerosis. In many cases, the culprit lesion of acute coronary artery thrombosis does not produce a critical arterial narrowing, rendering their identification a priori problematic by use of standard angiographic methods. Decades usually separate the initiation of atherosclerosis with the development of the fatty streak from the final thrombotic stages of this disease. This time lag results in part from the initial compensatory centrifugal remodeling (“compensatory enlargement”) of the diseased vessel wall, allowing preservation of blood flow until the stenosis encroaches on >70% of the arterial lumen.

Indeed, it now appears that inflammatory activation rather than the degree of stenosis renders the plaque rupture-prone and precipitates thrombosis and resultant tissue ischemia. Advanced complex atheromata exhibit a paucity of SMCs at sites of rupture, and an abundant macrophage accumulation, key characteristics of plaques that have ruptured and caused fatal coronary thrombosis. Simply put, the fibrous cap is all that stands between coagulation factors in the circulation and the plaque core; the thinner the cap, the greater its propensity to rupture and cause thrombosis. Inflammation can interfere with the integrity of the cap's interstitial collagen by stimulating the destruction of existing collagen fibers while in parallel blocking the creation of new collagen. IFN- γ , secreted by activated T-cells, inhibits basal collagen production by SMCs. T-lymphocytes can also contribute to the control of collagenolysis. CD40L as well as IL-1 produced by T-cells induce macrophages to release interstitial collagenases, including MMPs 1, 8, and 13. Members of the cysteine protease family, such as Cathepsin S, can also participate in plaque evolution and destabilization.

Acute coronary syndromes most often result from a physical disruption of the fibrous cap, either frank cap fracture or superficial endothelial erosion, allowing the blood to make contact with the thrombogenic material in the lipid core or the subendothelial region of the intima. This contact initiates the formation of a thrombus, which can lead to a sudden and dramatic blockade of blood flow through the affected artery. If the thrombus is nonocclusive or transient, it may either be clinically silent or manifest as symptoms characteristic of ►**unstable angina**. Importantly, if collateral vessels have previously formed, for example, due to chronic ischemia produced by multivessel disease, even total occlusion of one coronary artery may not lead to an acute myocardial infarction.

Pharmacological Intervention

General

Classic risk factors of atherosclerosis must first and foremost be fought with lifestyle interventions such as diet, physical activity, and smoking cessation. Indeed, and although it effectively relieves angina, simply

treating stenotic blood vessels by invasive procedures such as ►angioplasty or coronary artery bypass grafting has not been shown to prolong life in broad groups of patients.

Pharmacological management of risk factors through antihypertensive, antihyperlipidemic, and antidiabetic therapy coupled with antiplatelet drugs comprise the

next step in the primary and secondary prevention of atherosclerosis, usually instituted together with lifestyle measures [3]. Moreover, medication can in some cases modify or dampen inflammatory processes (Fig. 2). The following review will emphasize the sometimes unforeseen antiinflammatory effects of certain classes of antiatherosclerotic drugs.

Atherosclerosis. Figure 2 Evolution and stabilization of rupture-prone, or “vulnerable,” atherosclerotic plaques. The nonatherosclerotic artery (left) has a trilaminar structure; the intima is lined by endothelial cells (ECs) in contact with blood. The underlying media is composed largely of smooth muscle cells (SMCs) and embedded in a dense extracellular matrix. The adventitia, the outermost layer, contains loose connective tissue and nerves. During the early stage in the development of atherosclerosis, the atheroma often grows outward and preserves the caliber of the lumen (middle). Such “compensatory enlargement” or “outward remodeling” explains in part why angiography underestimates the degree of atherosclerosis. Pathological studies have demonstrated that the majority of atheroma that have ruptured and triggered an acute myocardial infarction contain a prominent lipid pool and numerous inflammatory cells, in particular, macrophages. The activated inflammatory cells secrete mediators that thin and weaken the fibrous cap that overlies the lipid-rich core of the lesion by reducing synthesis and increasing degradation of collagen. SMC apoptosis may also contribute to depletion of collagen in the fibrous cap. Activated macrophages express tissue factor, a potent activator of coagulation cascade. Disruption of the thin fibrous cap of such vulnerable plaques causes the direct contact of blood coagulation factors to tissue factor and can trigger occlusive thrombus formation. A new therapeutic goal, stabilization of lesions, aims to reduce the incidence of acute coronary events by influencing the nature of the vulnerable plaque qualitatively or functionally rather than by shrinking the lesion (right). Lowering of LDL (low-density lipoprotein) can reduce cholesterol delivery, and increased HDL (high-density lipoprotein) may enhance cholesterol efflux from the atheroma. LDL reduction and inhibition of angiotensin II signaling may limit oxidative stress (for example, reactive oxygen species production, lipid peroxidation and oxidized LDL accumulation) in atheroma. Future research should evaluate the effects of other therapeutic measures on inflammatory processes mentioned in the text, extracellular matrix metabolism, the thrombotic/fibrinolytic balance, and other functional features of plaque, as well as the effects on lipids and the size of lesions. Conversion of unstable to stable plaques by altering their biological properties should prevent cardiovascular events such as myocardial infarction and stroke by a noninvasive strategy rather than helping in the traditional mechanical approach (bypass surgery, endarterectomy, or angioplasty). (Libby P, Aikawa M (2002) Stabilization of atherosclerotic plaques: new mechanisms and clinical targets. *Nat Med* 8:1257–1262.)

Pharmacotherapy

Statins (3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase Inhibitors)

This lipid-lowering class of drugs efficiently lowers LDL cholesterol levels and reduces cardiovascular events significantly, even in patients with average LDL concentrations. Importantly, statins produce modest effects on the actual degree of arterial stenoses, reemphasizing that the functional state of the atherosclerotic plaque, and not merely its size, determines the propensity of a plaque to precipitate an acute coronary syndrome. This observation suggests that lipid lowering in and of itself may have actions beyond regression of stenoses. Indeed, several inflammatory markers that associate with cardiovascular disease risk, most notably ► **C-reactive protein (CRP)**, decrease in response to statin treatment.

The antiinflammatory effects of statins likely result from their ability to inhibit the formation of mevalonic acid. Downstream products of this molecule include not only the end product, cholesterol, but also several isoprenoid intermediates that covalently modify (“prenylate”) certain key intracellular signaling molecules. Statin treatment reduces leukocyte adhesion, accumulation of macrophages, MMPs, tissue factor, and other proinflammatory mediators. By acting on the MHC class II transactivator (CIITA), statins also interfere with antigen presentation and subsequent T-cell activation. Statin treatment can also limit platelet activation in some assays as well. All these results support the concept that in addition to their favorable effect on the lipid profile, statins can also exert an array of antiinflammatory and immunomodulatory actions.

Peroxisome Proliferator-Activated Receptor Agonists

Peroxisome proliferator-activated receptors (PPARs) belong to the nuclear receptor family, and include three forms (α , γ , and δ) [4]. PPAR- α activators (fibrates such as gemfibrozil or fenofibrate) act as triglyceride-lowering/HDL-raising drugs, and PPAR- γ activators (thiazolidinediones such as pioglitazone or rosiglitazone) as insulin-sensitizing agents. The identity of endogenous PPAR ligands remains elusive, with recent work pointing towards a role for lipases such as lipoprotein lipase and endothelial lipase as well as lipoprotein substrates such as very low density lipoprotein (VLDL) and HDL in generating such ligands.

Current evidence suggests that PPAR activation may limit inflammation and hence atherosclerosis. Both PPAR- α and PPAR- γ can reduce T-cell activation, as shown by decreased production of IFN- γ . PPAR- α agonists also repress endothelial VCAM-1 expression and inhibit the inflammatory activation of vascular SMCs, while PPAR- γ agonists repress endothelial chemokine expression and decrease macrophage MMP production.

In humans, biomarker responses to PPAR agonists by and large support possible antiatherosclerotic benefits, although recent clinical trial results have not proven conclusive. Further large-scale trials should help define the role of PPAR agonist therapy on cardiovascular events in at-risk populations.

Angiotensin-Converting Enzyme Inhibitors/Angiotensin-Receptor Blockers

Agents that interfere with signaling of angiotensin II, originally designed to treat hypertension, may also have antiinflammatory effects relevant to atherosclerosis. In addition to its vasoconstrictor and sodium-retaining effects, angiotensin II may act as a proinflammatory cytokine that can elicit VCAM-1 and MCP-1 expression by endothelial cells. Treatment with inhibitors of angiotensin-converting enzyme can reduce signs of inflammation, thereby providing a potential link between antihypertensive and antiatherosclerotic therapy.

Aspirin (Acetylsalicylic Acid)

Randomized trials have clearly established that low-dose aspirin prevents arterial thrombosis, including first myocardial infarction in men, stroke in women, and recurrent vascular events among patients with known atherosclerotic disease. Due to the irreversible inactivation by acetylation of ► **cyclooxygenases (COX)**-1 and -2, key enzymes in platelet biology, only the generation of new platelets can reverse the antiaggregatory effect of aspirin. The products of COX-1 include thromboxane A₂ (TXA₂), which causes irreversible platelet aggregation and amplifies the platelet response secondary to stimuli such as thrombin, collagen, and adenosine diphosphate (ADP). Importantly, TXA₂ is proatherogenic, and enhances endothelial adhesion molecule expression and subsequent leukocyte-endothelial interaction as well as vascular SMC proliferation. In addition to these specific effects of TXA₂ directly abrogated by aspirin, platelet activation in general leads to the release of proinflammatory cytokines such as CD40L and PDGF, further heightening the inflammatory burden of atherosclerosis.

Future Directions

Vaccination Against Atherosclerosis. Parenteral immunization with oxidatively modified LDL can inhibit experimental atherosclerosis. This protection occurs in parallel with increased titers of antibody specific for the immunogen, and seems to depend mostly on humoral immunity. Although this approach remains unsubstantiated in humans, a vaccination strategy might protect against atherosclerosis and its complications, a proposition that would require rigorous testing in the clinic.

Mast Cell Regulation. Recent experiments have elucidated the deleterious role of mast cell activation in atherosclerotic mice. Atheromata from mast cell

deficient mice in compound mutation with atherosclerosis susceptibility demonstrate decreased lesion size, lipid deposition, T-cell and macrophage numbers, and apoptosis, but increased collagen content and fibrous cap development. Treatment of atherosclerotic mice with the mast cell stabilizer disodium cromoglycate yields similar results. This agent blocks the release of mast cell granular contents such as IL-6 and IFN- γ , which can activate other inflammatory cells present in the atheroma. In addition, treatment with disodium cromoglycate decreases plaque levels of cathepsins and MMPs, yielding plaques with features considered more stable in human lesions.

Given the routine use of mast cell stabilizers in the clinic, for example in the setting of asthma treatment, these preclinical results may stimulate clinical evaluation in humans.

► **Cannabinoid Receptors.** Of the two known cannabinoid receptors, CB2 is expressed predominantly on immune cells. In animals, activation of CB2 can ameliorate chronic inflammation in arthritis as well as experimental allergic encephalopathy. Recent findings suggest that cannabinoids can also benefit atherosclerosis. In atherosclerotic lesions, Δ^9 -tetrahydrocannabinol (THC) blocks IFN- γ secretion by T-cells and reduces macrophage infiltration by inhibiting the expression of the chemokine receptor CCR2. Interestingly, recent findings point toward PPAR- γ as an additional potential target for cannabinoid binding.

Determining whether cannabinoids may enter the list of antiatherosclerotic therapies will require further experimental evidence as well as clinical validation.

Conclusion

The immune response is central to atherosclerosis, from its initiation and development through its thrombotic complications. Indeed, our current understanding of the biology of this scourge differs greatly from the former perspective of atherosclerosis as a lipid storage problem. We now appreciate that the inflammatory activation state of the atheromatous plaque, which ultimately leads to a thin and rupture-prone fibrous cap, rather than the actual degree of luminal encroachment, influences the clinical manifestations of this disease. This enhanced understanding of plaque biology provides new insights into the diverse ways in which atherosclerosis can present clinically and why the disease may remain silent for prolonged periods of time, interrupted by acute complications.

Our new appreciation of the role of inflammation in atherosclerosis shows the way for translation of these novel biological insights to clinical practice, for example by aiding the identification of individuals at risk of adverse cardiovascular events [5]. In this context, inflammatory biomarkers such as CRP merit rigorous consideration for inclusion in risk assessment strategies. In addition, these scientific advances provide a framework

to understand the mechanisms by which lifestyle modifications and certain medical therapies can reduce events by antiinflammatory actions that lead to stabilization of plaques. We can now conceive altering the biology of the atheroma rather than taking a mechanical approach to relieve stenosis by surgical or percutaneous revascularization. Finally, our expanded and deeper appreciation of the biology of atherogenesis should lead to new therapies as well as improved strategies for risk prediction and detection of silent disease, advances that should ultimately improve patient outcomes.

ATP

Adenosine triphosphate (ATP) is a purine nucleotide involved in extracellular signalling, as well as acting as an intracellular energy source.

► Purinergic System

ATP-binding Cassette Transporter Superfamily

ATP-binding cassette (ABC) transporters (proteins) are characterized by having so-called ATP-binding cassette domains. ABC proteins function as pumps, channels, and channel regulators (receptors). They have multiple membrane-spanning segments and nucleotide-binding folds (domains) (NBFs or NBDs) in the cytoplasmic side, which contain highly conserved Walker motifs and an ABC signature sequence. Cystic fibrosis transmembrane conductance regulator, *P*-glycoprotein, canalicular multispecific organic anion transporter, and sulfonylurea receptor are typical ABC proteins.

Synonyms

ATP-sensitive K⁺ channel; ATP-regulated K⁺ channel; K_{ATP} channel; SURx/Kir6.x channel

Definition

Key feature of K_{ATP} channels is their responsiveness to changes in intracellular ATP and ADP providing a

means to couple electrical activity to cellular metabolism in many excitable cells (e.g., pancreatic beta-cells, neurons, and cardiac myocytes). K_{ATP} channels are assembled from alpha (► **inward rectifier K⁺ channel**, Kir6.x) and beta (sulfonylurea receptor, SUR) subunits with obligate hetero-octameric stoichiometry (SUR/Kir6.x)₄. Four alpha subunits form the ion-conducting pore, which is surrounded by four beta subunits with receptor sites for drugs and ADP (Figs. 1a and b).

Basic Characteristics Assembly

Trafficking from the endoplasmic reticulum to the cell surface is regulated by arginine-rich RKR motifs on both subunits in combination with a C-terminal signal on SUR. These motifs insure correct assembly of the complex and channel surface expression. ► **14-3-3-proteins** seem to be involved in this process. Shortly after synthesis, SUR1 and Kir6.2 presumably dimerize, protecting Kir6.2 from degradation. The SUR1/Kir6.2 dimers then assemble the octameric complex. SUR and Kir6.x subunits are the products of two pairs of genes on human chromosomes 11 and 12. *ABCC8* encodes for SUR1 (OMIM 600509) and lies in position 11p15.1, 5 kb upstream of the gene for Kir6.2 (*KCNJ11*, OMIM 600937). Encoding for SUR2A and SUR2B, *ABCC9* lies in position 12p12.1, 26.2 kb upstream of the gene for Kir6.1 (*KCNJ8*; OMIM 600935). SUR2A and SUR2B result from differential splicing of the terminal exon of *ABCC9*.

Tissue Distribution

SUR1 assembles with Kir6.2, and (SUR1/Kir6.2)₄ channels are broadly distributed in the neuroendocrine system. (SUR2A/Kir6.2)₄ constitutes the K_{ATP} channels found in cardiac and skeletal muscle cells, and (SUR2B/Kir6.1)₄ those in vascular and nonvascular smooth muscle.

Kir6.x

Transmembrane helices M1 and M2 of the four Kir6.x subunits interact to form the ion-conducting pore of the channel. In analogy with a proposed mechanical mechanism for regulation of Kv channels (► **voltage-gated K⁺ channels**), gating is presumably mediated by repositioning M1 and M2 through movement of a submembrane helix termed “the slide helix” (Fig. 2). The receptor site for inhibitory ATP has been localized at the interface between adjacent Kir6.x subunits, approximately 2 nm below the outer surface of the membrane.

SURs

SURs are members of the ATP-binding cassette (ABC) family of proteins (► **ABC transporters**) with a typical ABC “core” consisting of two bundles of six

ATP-dependent K⁺ Channels. Figure 1 (a) Tetradameric architecture. K_{ATP} channels are assembled from alpha (Kir6.x) and beta (SUR) subunits with obligate hetero-octameric stoichiometry (SUR/Kir6.x)₄. Four alpha subunits form the ion-conducting pore, which is surrounded by four beta subunits. (b) Regulation by nucleotides. The receptor site for inhibitory ATP resides on the pore-forming Kir subunit, while activatory nucleotides bind to a separate nucleotide site on SUR. The NBDs of SUR bind and hydrolyse ATP. (c) Two-dimensional topology model of K_{ATP} channels. A and B symbolize the Walker A and B consensus motifs in the two NBDs, respectively; TMD: TransMembrane Domain, NBD: Nucleotide-Binding Domain, L0: intracellular linker between TMD0 and TMD1. Putative contact regions between Kir6.x (parts of M1 plus NH₂-terminus) and SUR (TMD0 plus L0) depicted in red.

transmembrane helices (TMD1 and 2) and two nucleotide-binding domains (NBD1 and 2) (Fig. 1c). Similar to several other ABCC proteins (i.e., ABCC1, 2, 3, 6, and 10), SURs have an additional amino terminal module that consists of a bundle of five transmembrane helices (TMD0). These additional helices are connected to the core via an intracellular linker termed “L0” (Fig. 2). In *ABCC8* and *9*, TMD0-L0 is the principal domain interacting with the Kir subunit. The SUR NBDs contain the canonical phosphate-binding Walker A and B motifs, the Q-loop, the signature sequence, and the H-loop, hallmarks of the ABC family. The SURs were among the first ABC proteins recognized to have degenerate, nonsymmetric NBDs with a noncanonical signature sequence, FSQGQ versus LSGGQ, in NBD2 and an aspartate (D) in place of the usual glutamate (E)

adjacent to the highly conserved D in the Walker B motif. In analogy with other ABC proteins, ATP binding and hydrolysis are expected to drive dimerization of the SUR NBDs and produce concomitant rearrangements of TMD1 and TMD2. Typically coupled to substrate transport, SURs appear unique by transducing these conformational changes in modulation of channel gating. TMD0 plus subsequent intracellular loop L0 appear to be critical in this process. Analogous to the voltage sensor in Kv2.1 channels, L0 presumably affects gating through direct interaction with the Kir “slide helix” (Fig. 2). Localization of the site of action for activatory Mg-nucleotides (e.g., MgADP, MgATP, MgGDP) on SURs is still controversial. Cytosolic [MgADP] might enhance channel activity by lowering the off-rate of MgADP from NBD2 through product

(Panel modified from [3]).

inhibition. Alternatively, evidence has been presented that Mg-nucleotides exert their activatory effect not by interaction with the catalytic NBD sites but by binding to a separate nucleotide site mainly formed by TMD2.

Role in Pancreatic Beta-Cells

The role of K_{ATP} channels in cellular function is best understood in pancreatic beta-cells (Fig. 3). Insulin release is triggered by a rise of intracellular [Ca²⁺]_i that results from Ca²⁺ influx through voltage-gated Ca²⁺ channels in the beta-cell plasma membrane. Under low serum [glucose], the Ca²⁺ channels are shut because the membrane is held hyperpolarized by potassium outward currents through K_{ATP} channels. When blood glucose levels are elevated, glucose is rapidly equilibrated across the beta-cell membrane via the GLUT2 transporter (▶ [glucose transporters](#)). In the next rate-limiting step, it is phosphorylated by glucokinase. Subsequent glycolysis and mitochondrial metabolism leads to changes in intracellular concentrations of adenine nucleotides and closure of K_{ATP} channels. This produces a membrane depolarization that opens ▶ [voltage-dependent Ca²⁺ channels](#), initiating beta-cell electrical activity and Ca²⁺ influx. The subsequent rise in [Ca²⁺]_i triggers insulin release. In resting beta-cells, 98% of plasmalemmal K_{ATP} channels are closed and hence, insulin release is induced by reducing flux through residual 2%. Cytosolic free [ATP] not below 1mM, however, predicts that even in the resting state

channel activity should be completely suppressed and a definite answer to this “ATP-paradox” is still pending. One possibility is that the concentration–inhibition curve is shifted to higher ATP levels through stimulatory effects of Mg-nucleotides. Alternatively, [ATP] in the immediate vicinity of the Kir6.2 binding pocket might be much lower than estimated by measurement of total cytosolic ATP.

Modulators

Phosphoinositides, long-chain acyl coenzyme A (CoAs), G proteins, and phosphorylation have been shown to modulate K_{ATP} function. The physiologic role of these modulators, however, has still to be established. Lower pH activates K_{ATP} channels by reducing their sensitivity to inhibitory ATP and may play a role in the regulation of vascular tone during hypercapnic acidosis. Zn²⁺ activates SUR1/Kir6.2 K_{ATP} channels via binding to two histidines on the extracellular face of SUR1. Zn²⁺ is present in high concentrations in various regions of the CNS. In pancreatic islets it is coreleased with insulin and may play an autocrine role or serve to attenuate glucagon release from alpha cells.

Neuroprotection

Substantia nigra pars reticulata is the area with highest neuronal activity and metabolic rate in the brain. This region also shows highest expression rates of SUR1/Kir6.2 channels. These K_{ATP} channels are present

ATP-dependent K⁺ Channels. Figure 3 Stimulation of insulin secretion in the beta-cell. A rise in extracellular [glucose] increases phosphorylation of glucose by glucokinase (GK), the rate-limiting enzyme for the metabolism of glucose in the beta-cell. Glycolysis results in conversion to pyruvate, which preferentially enters the mitochondria and fuels the tricarboxylic acid (TCA) cycle. The resultant increase in the [ATP/ADP] ratio leads to closure of K_{ATP} channels, depolarization of the plasma membrane, opening of voltage-gated Ca²⁺ channels, and an increase of the cytosolic Ca²⁺ concentration, which triggers the exocytosis of insulin. Sulfonylureas (SUs) inhibit the K_{ATP} channel and initiate the same chain of events, whereas diazoxide activates the channel, hyperpolarizes the beta-cell, lowers cytosolic Ca²⁺, and inhibits insulin secretion. Glucose-6-P, glucose-6-phosphate.

throughout all regions of the CNS and confer neuroprotection by rapid hyperpolarization and thus minimization of energy consumption during metabolic stresses, like hypoxia and ischemia. In substantia nigra, SUR1/Kir6.2 channels confer a specific sensor function for ATP depletion thus enabling an early generalized protective response. Fast electrical silencing of GABAergic neurons within substantia nigra results in prevention of generalized seizure by disinhibition of distant projection areas (e.g., ventral thalamic nuclei, nuclei superior colliculi, pedunculopontine nucleus).

Central Glucose Homeostasis

Central control of glucose homeostasis critically depends on the brain's ability to sense extracellular [glucose]. Within hypothalamus at least two types of neurons were identified which are presumably involved in this process. They are either glucose excited or glucose inhibited. Both types of neurons appear to be involved in the control of feeding, hepatic gluconeogenesis,

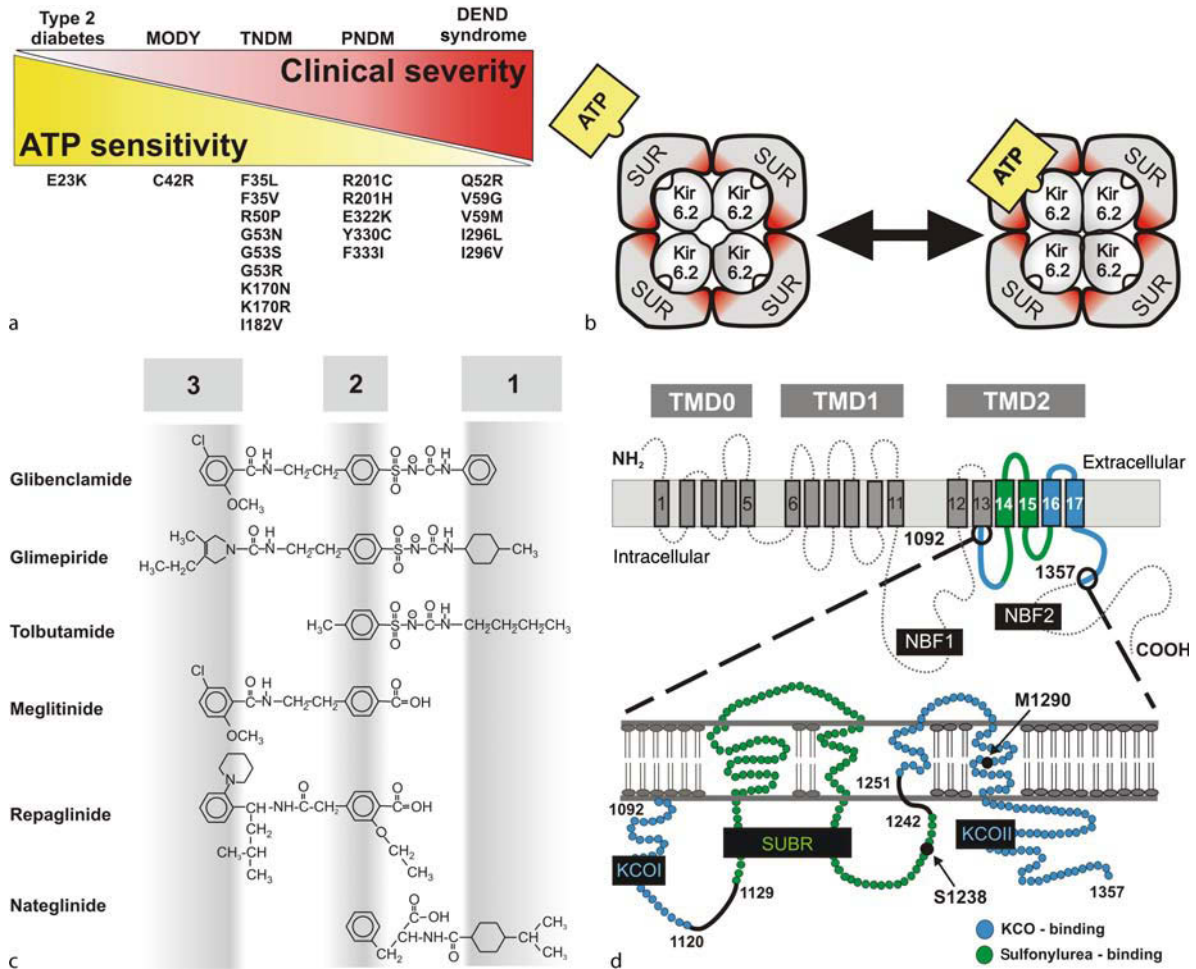

and glucagon and epinephrine secretion. In glucose excited neurons, the sensing mechanism appears to be based on SUR1/Kir6.2 channels, analogous to that in pancreatic beta-cells. Consistently, glucose sensing was lost in Kir6.2^{-/-} mice or intracerebral application of glibenclamide.

Hyperinsulinemic Hypoglycemia

Mutations in SUR1 and Kir6.2 are an established cause of ▶hyperinsulinemic hypoglycemia of infancy (HHI), characterized by excessive insulin release independent from blood [glucose]. Most cases of HI are sporadic and the disease may result from homozygous or heterozygous mutations. Mutations in SUR1 (*ABCC8*) are the most common cause of HI, accounting for almost 50% of cases. More than 100 mutations have been described, distributed throughout the gene. Class I mutations are characterized by loss of K_{ATP} channels in the plasma membrane. This may result from impaired SUR1 synthesis, abnormal SUR1 maturation, defective channel assembly, or faulty surface membrane trafficking. Class II mutations impair the ability of MgADP to stimulate channel activity. In general, class II mutations cause a milder phenotype because residual channel activity remains. They can also be causative for leucine-sensitive HI (e.g., R1353H). Most class II mutations reside in the NBDs of SUR1. To date in Kir6.2 (*KCNJ11*) five mutations have been identified that cause HI. They also act by reducing, or abolishing K_{ATP} channel activity in the surface membrane, thus inducing permanent beta-cell depolarization, uncontrolled insulin release, and hypoglycemia.

Neonatal Diabetes

Neonatal ▶diabetes mellitus (NDM) is characterized by hyperglycemia within the first 6 months of life. It is a rare disorder affecting 1 in 400,000 live births, and it may be either transient (TNDM) or permanent (PNDM). Approximately 50% of PNDM cases result from heterozygous gain-of-function mutations in Kir6.2 [2]. To date, more than 20 mutations in *KCNJ11* have been reported to cause NDM. They form striking clusters in the putative ATP-binding site (Fig. 2) and the cytosolic pore of the channel. Mutations within residues, V59 and R201, show highest frequency. A series of gain-of-function mutations cause a range of phenotypes with increasing severity (Fig. 4a). In most cases, PNDM is observed without additional symptoms. These patients show weak insulin release in response to i.v. glucose but may respond to sulfonylureas. Other mutations cause more severe phenotypes with delayed speech, walking, and muscle weakness in addition to neonatal diabetes. A third class of mutations (e.g., Q52R, V59G) produce the severe DEND syndrome (developmental delay, epilepsy, and neonatal diabetes), characterized by marked developmental retardation, muscle weakness, epilepsy, and dysmorphic

ATP-dependent K⁺ Channels. Figure 4 (a) Genotype–phenotype correlation for gain-of-function mutations in Kir6.2. (b) Stoichiometry of ATP-induced channel closure. (c) Structure of sulfonylurea and nonsulfonylurea hypoglycemic agents. Grey: lipophilic centers 1–3. (d) Regions within SUR critical for drug binding.

features besides hyperglycemia. Mutations that cause TNDM or maturity onset diabetes of the young (MODY) are also found. All PNDM mutations studied to date act by reducing the potency of ATP to close the channel and this effect correlates quite well with clinical phenotype. Channels are closed if just one of the four sites for inhibitory ATP is occupied and thus, strongly reduced ATP sensitivity is only observed in channels with four mutated subunits (Fig. 4b). Therefore, a marked increase in open probability is found in no more than 6% of the channels of heterozygotes. This effect, however, is sufficient to completely abolish insulin release (see earlier). In extrapancreatic tissues expressing Kir6.2 (skeletal muscle, cardiac muscle, and neurons throughout the brain) dependence on open probability appears less critical, explaining lack of additional symptoms in heterozygote patients with PNDM mutations (e.g., Q52R, V59G, and I296L). Mutations causing the severe DEND phenotype affect ATP sensitivity by increasing spontaneous open probability of the channel.

Here, one mutated subunit is sufficient to strongly reduce ATP sensitivity thereby inducing additional symptoms in extrapancreatic tissues. To date two mutants within SUR1 are known (I1424V and H1023Y), resulting in hyperactive channels and PNDM.

Type 2 Diabetes Mellitus

Large-scale association studies indicate that a common variant (E23K) in Kir6.2 is strongly associated with an enhanced susceptibility to type 2 diabetes [1]. Although the effect is small, the high prevalence of the K allele (34%) makes this a significant population risk. The E23K polymorphism confers an increase in intrinsic open probability, with a consequent reduction in ATP sensitivity, and enhanced activation by Mg-nucleotides and long-chain acyl-CoAs. In glucose-tolerant subjects it was demonstrated to be associated with reduced insulin and increased glucagon secretion. Polymorphisms in HNF1alpha, HNF4alpha, and glucokinase (MODY), and in genes involved in mitochondrial metabolism, have also

been associated with an increased risk of type 2 diabetes. They might influence disease susceptibility by impairing metabolic regulation of K_{ATP} channel activity.

Arrhythmias and Heart Failure

Data from Kir6.2 knockouts suggest that SUR2A/Kir6.2 channels in the heart are required for the adaptive response to acute stress and chronic hemodynamic load. Thus, deficiency is presumed to be associated with stress-induced arrhythmias, defective structural remodeling, calcium-dependent maladaptation, and predisposition to heart failure. Consistently, two mutations were identified in exon 38 of the human *ABCC9* gene that resulted in dilated cardiomyopathy. A male who was diagnosed at age 55 and died from heart failure at age 60, had a 3-bp deletion followed by a 4-bp insertion (4570–4572delTTAinsAAAT) causing a frameshift at leu1524 and introducing four anomalous terminal residues followed by a premature stop codon. The patient died at age 60 and had no family history of dilated cardiomyopathy. A female who was diagnosed at age 40 had at 1513 an alanine to threonine substitution. Her father was diagnosed at age 54 and died at age 55 of heart failure. All three individuals had ventricular tachycardia with normal coronary angiography. Both mutations were not identified in unrelated healthy controls. The C-terminus of SUR proteins contributes to K_{ATP} channel trafficking, and the frameshift and missense SUR2A mutants, reconstituted with Kir6.2, had reduced expression in the plasma membrane. Yet, mutant K_{ATP} channel complexes formed functional channels with intact pore properties. Residues ala1513 and leu1524 flank the C-terminal beta-strand in close proximity to the signature Walker A motif, required for coordination of nucleotides in the catalytic pocket of ATP-binding cassette proteins. Replacement of ala1513 with a sterically larger and more hydrophilic threonine residue or truncation of the C-terminus caused by the frameshift would disrupt folding of the C-terminal beta-strand. Nucleotide-induced K_{ATP} channel gating was aberrant in both channel mutants, suggesting that structural alterations induced by the mutations distorted ADP-dependent pore regulation through SUR2A.

Prinzmetal Angina

Mice lacking the Kir6.1 gene had a phenotype resembling Prinzmetal angina. Spontaneous vasospasms of hypercontractive coronary arteries were associated with ST elevation, atrioventricular block, and a high rate of sudden death. Results presume *KCNJ8* and *ABCC9* as candidate genes for human disease.

Drugs

K_{ATP} channels are the targets for two classes of therapeutic agents, hypoglycaemic drugs like glibenclamide or nateglinide and potassium channel openers like

diazoxide or P1075. In pancreatic beta-cells glibenclamide and analogous substances stimulate insulin secretion by closing K_{ATP} channels while diazoxide shifts the plasma membrane potential toward the potassium equilibrium potential, thus reducing electrical activity and inhibiting insulin release.

Sulfonylureas and Analogs

Hypoglycemic drugs comprise sulfonylureas (e.g., tolbutamide, glibenclamide, glimepiride) and nonsulfonylureas (e.g., meglitinide, repaglinide, nateglinide) (Fig. 4c). Except for repaglinide these compounds are weak organic acids (pK_a values 3.1–6.8). Their protonated species diffuse rapidly across the plasma membrane, dissociate and gain access to their binding site via the cytoplasmic face of SURs. Structure–activity data suggest that high affinity SUR1 selective ligands require three lipophilic centers within their molecule. Center 1 (e.g., a cyclohexyl group in glibenclamide or a cyclohexane substituted with an isopropyl group in nateglinide) is the major determinant of selectivity toward SUR1. Drugs lacking this part of the molecule (e.g., meglitinide) show same affinity for SUR1 and SUR2 isoforms.

Localization of the Binding Site

Affinity of glibenclamide for SUR1 (K_D 0.72 nM) is 350 higher than that for SUR2A/B. Based on this difference a 114 amino acid segment within TMD2 (SUBR; C1129–T1242) was identified as putative part of the receptor binding site (Fig. 4d). Substitution of S1238 within this region by Y strongly reduced glibenclamide affinity without affecting binding of meglitinide. Thus this residue was presumed to contribute to interaction with the center 1 region of the ligands. Centers 2 and 3 seem necessary for interaction with either of the SUR isoforms. Both L0 and the proximal amino terminus of Kir6.2 are likely to participate in formation of this part of the binding pocket.

Mechanism of Action

Every SUR subunit carries one site for inhibitory drugs, and hence there are four of these sites per channel complex. Analogous to ATP-induced inhibition (see earlier) occupation of just one of these sites is sufficient to close the channel. This effect is mediated by equalizing Mg-nucleotide-induced channel activation.

Therapeutic Use

Sulfonylureas and glinides are largely used to control hyperglycemia in the treatment of T2DM. In addition many patients with NDM show sulfonylurea sensitivity. Thus, in these patients the drugs appear as an alternative to insulin injections. To date, good glycemic control has been reported for several patients. In DEND patients, therapy with sulfonylureas and analogs might prove

helpful in the control of symptoms resulting from enhanced channel activity in extrapancreatic tissues (see earlier, paragraph “Neonatal Diabetes”).

K_{ATP} Channel Openers

K_{ATP} channel openers (K_{ATP}COs) comprise a structurally diverse group of compounds (e.g., pinacidil, P1075, levromakalim, rilmakalim, minoxidil sulphate, nicorandil, diazoxide) which exert their activatory effect on the channels by interaction with SURs. Some K_{ATP}COs are SUR1-selective (e.g., NN414), most, however, show clear selectivity for SUR2 isoforms (e.g., K_D of P1075 for SUR2B = 11 nM and for SUR1 = 1.02 mM).

Localization of the Binding Site

The cytosolic loop between TMs 13 and 14 (KCO I) and TMs 16–17 (KCO II) were identified as critical for K_{ATP}CO binding to SURs (Fig. 4d). T1286 and M1290 appeared to be particularly important. Close local association of sulfonylurea and KCO binding regions might represent the structural basis for negative allosteric coupling of the sites.

Mechanism of Action

K_{ATP}COs do not bind to SURs with defect NBDs indicating that affinity of the receptor site depends on the catalytic state. Similarly, defective NBDs equalize Mg-nucleotide-induced channel activation and are thus causative for HI (see earlier). In analogy to sulfonylureas K_{ATP}CO-induced channel activation is mediated by interaction with one of the four sites per tetrameric complex. Occupation of additional sites did not induce stabilization of the open state.

Therapeutic Use

Diazoxide, pinacidil, cromakalim, minoxidil sulfate, and nicorandil have been extensively studied. Although there is a broad spectrum of potential therapeutic applications (e.g., hypoglycemia, hypertension, arrhythmias, angina pectoris, cardiac ischemia, asthma), at present none of these drugs is in widespread clinical use. Nicorandil is approved for the treatment of coronary artery disease. Minoxidil sulfate serves for the therapy of severe hypertension that responds poorly to other hypertensive medications. In addition, it is applied topically to stimulate hair growth. Diazoxide is used to suppress excessive insulin secretion in forms of hyperinsulinism (HI) with responsive K_{ATP} channels. HI caused by mutations in glucokinase (*GCK*), glutamate dehydrogenase (*GLUD1*), or short-chain l-3-hydroxyacyl-CoA dehydrogenase (*SCHAD*) responds well to diazoxide. Severe forms of HI caused by mutations in SUR1 or Kir6.2, however, are refractory to diazoxide and require subtotal pancreatectomy (see earlier, paragraph Hyperinsulinemic Hypoglycemia). In some HI SUR1 mutants

(e.g., R1349H) diazoxide was shown to act as chemical ▶chaperone and correct defective surface trafficking. This effect might prove valuable in future HI therapy.

Attention Deficit Hyperactivity Disorder

Synonyms

ADHD

Definition

ADHD is a disorder of childhood. Key features of Attention Deficit Hyperactivity Disorder (ADHD) – with a highly differing prevalence of 0.1–10% – are distractibility and difficulties in sustaining attention and focusing on a task. These symptoms are associated with impulsiveness, regardless of consequences. Comorbidity is high; boy to girl ratio is 4:1. The diagnosis is made using the diagnostic and statistical manual of the American Psychiatric Society (DSM-IV). There is currently no biological test to confirm the diagnosis. The DSM-IV assessment distinguishes between three subtypes of ADHD where (i) inattentiveness, (ii) hyperactivity-impulsivity, or (iii) a combination is prevalent. The period of formal schooling is usually the most difficult life phase for persons with ADHD. At later stages, these individuals often find occupational or educational niches that accommodate their behavioral and cognitive idiosyncrasies. About 50% of children with ADHD continue to manifest dysfunctional symptoms into adulthood. There is relatively poorer occupational and educational outcome, greater psychiatric comorbidity than in control subjects, and significantly higher rates of socialization disorders and substance use disorders in adults in whom ADHD symptoms persist.

The most common treatment of ADHD is pharmacological. Psychostimulant drugs such as methylphenidate and amphetamine or atomoxetine, an inhibitor of the noradrenaline transporter can be prescribed. These agents elicit the non-exocytotic release of

noradrenaline, serotonin, and dopamine via their cognate cell surface transporters. They have considerable abuse liability.

Autoantigen

Structures expressed in the organs of an individual against his own immune system can mount an immune response. Autoantigens can be organ specific (e.g. insulin) or present in all cells (e.g. DNA).

- ▶ Autoimmune Disease
- ▶ Immune Defense

Autocrine

A mode of action of a molecular messenger such as a cytokine or hormone in which the molecule binds to receptors on, and affects the function of, the cell type that produced it.

Autoimmune Disease

KLAUS RESCH

Institute of Pharmacology, Hannover Medical School, Hannover, Germany

Definition

The immune system provides powerful defense mechanisms against infective or toxic agents. Its hallmark is the high specificity with which harmful noxes can be recognized and discriminated. Although usually prevented, the immune system sometimes can react against components of the own body resulting in a great variety of disorders, the autoimmune diseases.

Basic Mechanisms

To survive in an environment which contains a plethora of life threatening infectious agents and other harmful noxes, higher organisms have developed special defense mechanisms contained in the immune system (→ immune defense). In vertebrates, it is based on two arms. The phylogenetically older part (which can be traced back to unicellular organisms) in human beings is represented by the phagocytic leukocytes such as the monocytes/macrophages and the various granulocytes. These cells possess a restricted number of receptors, including the Toll like receptors, which recognize structural patterns common in different strains of viruses, bacteria, fungi or parasites. The major defense mechanisms consist in phagocytosis and subsequent intracellular enzymatic degradation. This is supported by the secretion of many mediators which together form an inflammatory response (→ inflammation). This “innate immunity” is present from birth, and its reaction remains identical throughout life.

Later in evolution, the second arm evolved, built up by lymphocytes. These cells exist in two main classes: B-lymphocytes which differentiate in the bone marrow, and T-lymphocytes which differentiate in the thymus. B-lymphocytes secrete antibodies into the body fluids. T-lymphocytes exert cellular defense mechanisms, such as killing of e.g. virus infected cells. They also play a central role in regulating immune reactions (→ immune defense). The novel acquisition of this “adaptive immunity” consists of two connected properties: specificity and memory. Lymphocytes can recognize and distinguish an extremely large number of molecular structures (termed in immunology antigens); in human beings this ranges up to about 10^{18} of which approximately 10^8 are realized in an individual. Each lymphocyte carries only receptors of a single specificity. When mounting an immune response – e.g. against an

invaded bacterium – cells recognizing their respective antigen proliferate and acquire their specific functions implicated in the defense mechanisms. Part of these antigen specific cells develop into memory cells, which possess the capacity to react faster and even more efficient against the same antigen (or the infective bearing this antigen). It is this property that allows an individual to adapt to an environment containing specific infectious agents.

The adaptive immune system contains effector mechanisms of its own such as cytotoxic T-lymphocytes. In most instances, however, it relies on the mechanisms of the innate immune system. Not only directs it the cells of the innate system specifically to the antigen, but also strongly enhances their capacity to deal with harmful noxes. Thus B-lymphocytes release antibodies – secreted forms of their antigen receptor – which bind to their antigens and thereby recruit and activate the phagocytic cells, and also soluble effector systems such as complement. T-lymphocytes in contact with their cognate antigens secrete (→) cytokines which boost the activity of the cells of the innate immune system.

Self Tolerance

The antigen receptors are proteins. A simple calculation shows that the antigen receptor cannot be inherited. More than 10^8 specificities, i.e. different proteins by far exceed the number of the 25–30,000 genes existing in human beings. The antigen receptors thus must be generated during the development of individual T- or B-lymphocytes. Both antigen receptors are composed of two chains. Although B- and T-cell receptors are different proteins, their generation follows closely related rules. For each of the respective receptor chains there exist inherited in the germ line two to three clusters containing up to less than 100 gene segments. These are assembled in the developing lymphocyte by somatic recombination to form the antigen binding part of the receptor chain resulting in a large combinatorial diversity. This is much increased by the insertion of random nucleotides at the junction of two gene segments during the somatic recombination.

It is clear that generated by such a random process the initial repertoire of antigen specificity in all individuals of human beings should be quite similar. This implies that initially in each individual there develop lymphocytes which recognize antigens of this very individual, i.e. ▶autoantigens.

As most humans are healthy, at least do not destroy their own organs, there must exist mechanisms which eliminate the ▶autoreactive lymphocytes. For T-lymphocytes this happens in the thymus. When cells with functional antigen receptors develop, those which react with self (= auto) antigens present in the thymus with high affinity undergo apoptosis (= programmed cell death). An elegant mechanism governed by the

transcriptional regulator AIRE (autoimmune regulator) provides that in special epithelial cells of the thymus tissue antigens of all organs of the body are ectopically (i.e. in an unusual place!) expressed. Those cells which leave the thymus to become the functional T-lymphocytes of the body thus exhibit the “central ▶self tolerance” by not reacting with ▶autoantigens in the healthy individual. Similar mechanisms are also operative for B-lymphocytes in the bone marrow. The self tolerance predominantly is secured by T-lymphocytes.

The mechanisms of the central self tolerance implies that T- and B-lymphocytes bearing receptors which recognize autoantigens with low affinity are present in the body. These cells are held under control by the mechanisms of peripheral tolerance. Several mechanisms contribute to this (Fig. 1). That T-lymphocytes are activated requires the binding of the antigen to its antigen receptor (“signal 1”), but also accessory signals (termed “signal 2”) are necessary. The antigen (peptide) has to be presented to the T-lymphocytes bound to molecules of the major histocompatibility complex (MHC); to the central T-helper cells bound to MHC class II molecules present predominantly on dendritic cells, macrophages, or B-lymphocytes (→ immune defense).

Peripheral self tolerance ensues when the strength of the antigen binding is below a certain threshold, which due to central tolerance holds generally for autoantigens. Also, self antigens elicit only weak signals 2, in sharp contrast to infectious agents. The generation of negative regulating cells (Treg), too, contributes to self tolerance

Breaking Self-Tolerance Leads to Autoimmune Disease

How self-tolerance is broken to result in autoimmune reactions leading to disease is one of the central issues that are still not completely understood. The crucial point is how the reaction barrier in T-lymphocytes is overcome. The trigger must come from the outside; accumulating evidence points to an infection. As T-lymphocytes recognize as their antigen short peptides (below 25 amino acids) one can imagine that proteins of the host as well as of microbes contain short stretches of a similar amino acid sequence. Indeed, numerous examples for this have been documented. Such a related microbial peptide can be bound by a T-cell receptor with an affinity above the threshold for activation. Moreover, other structures of the microbe can effectively generate signal 2 in the antigen-presenting cells. Both together then lead to activation of the T-lymphocytes. These proliferate and also provide sufficient help for the B-lymphocytes to also become activated.

Part of these T-lymphocytes transform into memory cells. These cells are different from their ancestors in that they are activated by a much lower antigen binding strength and also much less depend on signal 2. Now self-antigens can activate these T-lymphocytes. As during activation continuously new memory cells are formed, autoreactivity is sustained and autoimmune disease follows (Fig. 2).

Although this may suffice, additional factors contribute to this process. Activated T-lymphocytes secrete amongst other cytokines also interferon γ which

Autoimmune Disease. Figure 1 Mechanisms of self tolerance. DC, dendritic (antigen presenting) cell; T, T-lymphocyte; Th, T helper lymphocyte; Treg, T regulatory lymphocyte. For details see text.

Autoimmune Disease. Figure 2 Generation of autoreactivity. APC, antigen presenting cell; IFN, interferon; LPS, lipopolysaccharide; MHC, major histocompatibility complex; T, T-lymphocyte; TCR, T cell (antigen) receptor; TLR, toll like receptors. For details see text.

upregulates the expression of MHC molecules and thus improves antigen presentation. The activated antigen presenting cells also enhance the expression and secrete costimulatory molecules.

The activated T- and B-lymphocytes recruit and activate the cells of the innate immune system which mount an inflammatory reaction which impedes and eventually destroys the inflicted organ. On the other hand, by expressing and secreting costimulatory molecules the inflammatory cells also contribute to the activation of T-lymphocytes. Moreover, antigens not accessible to lymphocytes before and (“hidden antigens”) may be exposed, such as cartilage. The local milieu of an inflammation thus not only executes an autoimmune reaction converting it into a disease, but also plays a central role in perpetuating autoimmunity.

Autoimmune Diseases

► Autoimmune diseases may inflict on each organ or cell. Manifestations range from affecting a single cell type and its specific function (such as the β -cell of the islands in the pancreas) to systemic diseases which have a detrimental effect on an entire organ system (e.g. the vasculature) of even many different organs. Table 1 summarizes some clinically important diseases.

Also, the outcome covers a large spectrum. Auto-antibodies can specifically block an important protein (such as the gastric intrinsic factor required for the uptake of orally taken vitamin B12), or the receptor for \rightarrow acetylcholine (as in myasthenia gravis), but also can

lead to a continuous stimulation of a receptor (as in autoimmune thyroiditis). Autoimmune reactions can lead to the destruction of a single cell type, the function of which is vital (as in type 1 diabetes (IDDM), where the loss of the β -cells results in the loss of insulin synthesis). In many cases autoimmune disease is associated with chronic inflammation. In fact, most chronic inflammatory diseases are today generally regarded as autoimmune with respect to their mechanisms of perpetuation. This includes rheumatoid arthritis (RA), chronic inflammatory bowel disease (IBD), such as Crohn’s disease or ulcerative colitis, kidney diseases (glomerulonephritis, GN), multiple sclerosis (MS), or arteriosclerosis. Accumulating evidence also points to an autoimmune component in a vast array of diseases up to psychiatric syndromes such as depressive disorders.

Type 1 Diabetes Mellitus (IDDM)

Blood sugar (blood glucose) in human beings is controlled by the secretion of (\rightarrow) insulin by the beta (B- or β -) cells of the islands of Langerhans in the pancreas. Loss of insulin synthesis leads to (\rightarrow) diabetes. Type 1 diabetes (insulin dependent diabetes mellitus, IDDM) begins in juveniles as an organ-specific autoimmune reaction, the destructive insulinitis.

The cellular infiltrate contains macrophages, T- and B-lymphocytes. Lymphocytes recognize several auto-antigens of the β -cells, including insulin and its precursor proinsulin; Accordingly, auto-antibodies against these antigens are also present. With time the insulinitis leads to a

Autoimmune Disease. Table 1 Autoimmune diseases

Organ-specific autoimmune diseases
Hematologic diseases: autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, pernicious anemia
Kidney disease: Goodpasture syndrom, lipoid nephroses, minimal change glomerulonephritis
Diseases of the gastrointestinal tract: autoimmune chronic active hepatitis, autoimmune atrophic gastritis, Crohn's disease, ulcerative colitis
Neurological diseases: myasthenia gravis, multiple sklerosis, Guillain-Barré-syndrom
Endocrine diseases: autoimmune thyreoiditis, primary myxedema, Addison's disease, type 1 diabetes mellitus (IDDM)
Eye diseases: sympathetic ophthalmia, uveitis
Skin diseases: pemphigus, (sklerodermia), psoriasis
Systemic autoimmune diseases
Systemic lupus erythematosus
Rheumatoid arthritis
Mixed connective tissue disease (MCTD)
Sjögren syndrom
Polymyositis
Systemic sklerosis
Systemic vasculitis: Wegener's disease, giant cell arteritis, polyarteritis nodosa

complete and selective loss of the β -cells. What triggers the autoimmune reaction is not known. Epidemiological evidence points to virus infection as infections with coxackie virus B4.

Multiple Sklerosis

Multiple sklerosis is the most frequent neurological disease of jung adults in the western world. It results from a chronic inflammation of the central nervous system which leads to focal demyelinated lesions in brain and spinal cord. Although clinically different forms occur in the onset, it mostly proceeds intermittantly, where acute phases alternate with full or partial remissions. The disease unevitably ends in progression leading to increasing neurological defects, which lead do severe physical handicaps and eventually death.

For the pathogenesis of multiple sklerosis, autoimmune T-lymphocytes play a predominant role, which are directed against components of the neural myelin sheath. T-lymphocytes by secreting cytokines such as interferon γ maintain the chronic inflammation which destructs the myelin sheath. Also cytotoxic T-lymphocytes may participate directly. The cause of multiple sklerosis is unknown. Significantly increased antibody titers against several virusses, mostly the measles virus, point to a (latent) virus infection initiating the disease.

Rheumatoid Arthritis

Rheumatoid arthritis represents a chronic inflammatory disease of the joints. About 1% of the population in Germany suffers from this disease. Primarily the synovial membranes of the joints are affected, however, the disease can also reach other organs such as the pleura, pericardium organ and skin blood vessels. The inflamed

synovial membran becomes multicellular bearing infiltrates of predominantly lymphoid cells. The drastically increased synovial fluid (which causes swelling of the joints) contains many inflammatory cells, predominantly granulocytes, macrophages and lymphocytes. The inflammatory process leads to the destruction of the cartilage and eventually to the erosion of the bones. This is augmented by the mostly fibroblastic pannus which can invade the bone. A crucial pathophysiological role is played by the cytokines interleukin-1 and tumor necrosis factor. That rheumatoid arthritis represents an autoimmune disease is supported by many animal models. The putative autoantigens in the human disease are not known.

Systemic Lupus Erythematosus (SLE)

The disease affects predominantly young women. Nearly all of the patients suffer from symptoms such as fatigue, weight loss, and fever and have chronic arthritis. In addition, nearly all organs of the body can be affected to various degrees. Clinically, the severity of the disease can vary within wide ranges. In cases where organs are affected, the disease in former times was lethal without therapy within 10 years in 50% of the patients.

Several immunological abnormalities are found. Most important are pathogenic autoantibodies including antinuclear antibodies (amongst others against nucleoprotein particles or double stranded DNA). The blood plasma contains circulating immunocomplexes which result from an insufficient clearing due to exhaustion of complement. The regulation of the activation of T- and B-lymphocytes often exhibits abnormalities.

Chronic Inflammatory Bowel Disease

Two diseases make up for the majority of all inflammatory bowel diseases: Crohn's disease and ulcerative colitis. Crohn's disease is a chronic recurrent inflammation of all layers of the gut wall. Although it can occur anywhere, the major site of manifestation is the regional ileitis. In contrast, ulcerative colitis is restricted to the colon and the inflammation generally only affects the gut mucosa. In both diseases the inflammatory lesions contain lymphocytes which react with several gut-associated auto-antigens. In the blood also respective autoantibodies are found. To protect the host from infectious agents or toxic substances which are ingested, the gut relies on its barrier function in which its innate immune system plays a central role. At least in Crohn's disease a dysfunction of this system appears to be involved. The defective clearance of the commensal gut bacteria and the subsequent continuous flooding of the gut-associated lymphoid cells with them may lead to a perpetuating immune reaction which supports the chronic inflammation.

Pharmacological Intervention

The treatment of an autoimmune disease very much depends on the nature of the clinical outcome it causes. Although the formation of autoantibodies causes the inactivation of the gastric intrinsic factor, the subsequent shortage of vitamin B12 can be easily overcome by supplying it via an parenteral route. Lifelong immunosuppression (with all its side effects) thus is inappropriate. When, however, as in sympathetic ophthalmia, after damage of the first eye the second eye is endangered, an even drastic immunosuppression is mandatory.

A more differentiated discussion is required regarding type 1 diabetes mellitus. Although injected, now mostly human, insulin can substitute the lost function of the destroyed β -cells, it does it in an unphysiological way, requiring restrictions in the way of life. In addition, concomitant disease may cause severe problems and long-term damages cannot fully be avoided. When the disease begins, theoretically immunosuppression should be able to halt it leaving some β -cells alive to secrete insulin in a regulated manner. Clinical studies with ciclosporin (\rightarrow immunosuppressants) based on such considerations were disappointing. Thus, at least with the immunosuppressive drugs available at present, type 1 diabetes is not an indication for immunosuppressive therapy.

As discussed above, the vast majority of autoimmune diseases is associated with chronic inflammation. The therapy thus rests on two principles:

1. Antiinflammation
2. Immunosuppression

The antiinflammatory drugs include the nonsteroidal antiinflammatory drugs (NSAIDs \rightarrow analgesics) \rightarrow cyclooxygenases), the disease modifying antirheumatic

drugs (DMARDs), such as \rightarrow methotrexate or \rightarrow glucocorticoids. More recently, specific cytokine inhibitors were included which block the action of central mediators of inflammation such as tumor necrosis factor (infliximab, adalimumab, etanercept) or interleukin-1 (anakinra) (\rightarrow cytokines).

Amongst the \rightarrow immunosuppressive agents besides the \rightarrow glucocorticoids the modern nontoxic drugs have become drugs of choice including ciclosporin, tacrolimus or ascomycin.

Paving the way for a new class of drugs effective in autoimmune diseases, immunomodulators have been introduced very recently (mostly to treat rheumatoid arthritis). Abatacept by blocking accessory signals (see Fig. 1) prevents the activation of (autoimmune) T-lymphocytes. Rituximab (which has become a standard drug for treating chronic lymphatic leucemia) by decreasing the number of B-lymphocytes inhibits the formation of autoantibodies. As B-lymphocytes in chronic situation become the predominant antigen presenting cells, the activation of (autoimmune) T-lymphocytes is also impeded. Interferon β (\rightarrow interferons) has become a valuable drug to reduce the number of relapse rates multiple sclerosis. Its major effect appears to be based on tightening the (disease-associated loose) blood brain barrier, and thus preventing autoimmune lymphocytes from entering the central nervous system.

Autonomic Nervous System

The part of the vertebrate nervous system that regulates involuntary action, such as the intestines, heart and glands: it is divided into the sympathetic nervous system and the parasympathetic nervous system.

- ▶ α -Adrenergic System
- ▶ β -Adrenergic System
- ▶ Muscarinic Receptors
- ▶ Nicotinic Receptors
- ▶ Purinergic System

Autophagy

Autophagy derived from latin words “self eating” is a normal regulated cell process where cytoplasmic materials are degraded through the lysosomal machinery and the contents reused by the cell. During this process, organelles like mitochondria together with long-lived proteins are sequestered in a double-membrane vesicle delivered and degrade in lysosomes inside the cell. Autophagy is activated in case of nutrient deprivation and plays a crucial role in the destruction of bacteria, viruses, and unnecessary proteins aggregates in cell.

- ▶ Phospholipid Kinases

Autoreactive Lymphocytes

T- or B-lymphocytes which react with autoantigens. In healthy individuals kept under control by the mechanisms of self tolerance.

- ▶ Autoimmune Disease

Autoreceptor

A receptor on nerve endings within a synapse that responds to the released neurotransmitter from that neuron. This then feeds back to the same neuron and negatively regulates the synthesis and release of that neurotransmitter.

- ▶ Synaptic Transmission
- ▶ α -Adrenergic System
- ▶ Muscarinic Receptors
- ▶ Histaminergic System

Autosomal Dominant Hypocalcemia (ADH)

A form of hypoparathyroidism (hypofunction of the parathyroid glands) caused by the presence of activating mutations in the CaR, usually in the heterozygous state.

- ▶ Ca^{2+} -Sensing Receptor

Autotaxin

Autotaxin is a lysophospholipase D that occurs in plasma and serum and cleaves lysophosphatidylcholine, thereby forming lysophosphatidic acid (LPA). This enzyme occurs as a ~ 125 kDa protein, attached to intracellular vesicles with a single transmembrane domain, and as a soluble extracellular enzyme generated from the former by proteolytic processing and secretion. Autotaxin appears to be a major source of extracellular LPA. In mice expressing only one allele of autotaxin, plasma levels of LPA are half as high as in control mice. Mice with homozygous autotaxin deficiency died around embryonic day 10 with major vascular defects in yolk sac and embryo. They also had allantois malformation, neural tube defects and asymmetric headfolds. These symptoms strongly resemble the phenotype of $G\alpha_{13}$ knockout mice, suggesting that LPA-GPCR predominantly signal through $G\alpha_{13}$ in early development.

- ▶ Lysophospholipids

Axon

Long nerve-cell process transmitting the action potential and ending as the synapse.

Axon Reflex

This is an unconventional reflex mediated by capsaicin-sensitive primary afferent neurons. In fact, an adequate stimulus can directly excite a peripheral terminal

generating an action potential. The action potential orthodromically conveys the stimulus to the spinal cord (and eventually triggers a conventional reflex) and/or antidromically invades another peripheral branch of the neurons and induces the release of neuropeptides (and other mediators) at a peripheral site (axon reflex) distal to the site of stimulation.

► Tachykinins and their Receptors

primarily repulsive. There is growing evidence that the understanding of the molecular mechanisms of axonal guidance may also provide new approaches for the improvement of regenerative processes after neuronal injury.

► Plexins

Axonal Guidance

During the development of the nervous system growing axons find their ways to their final target sites due to the presence of a variety of attractive and repulsive cues in the extracellular environment. These so-called guidance factors act especially on the axonal growth cone which is localized at the tip of the growing axon. Several conserved families of axon guidance factors have been identified. Slits are secreted proteins which repel growth cones by activating Robo (roundabout) class receptors. Netrins can attract or repel axons via their receptors DCC and UNC5. Ephrins are transmembrane proteins that activate Ephs which are receptor tyrosine kinases. The ephrin/Eph system can mediate repulsive as well as attractive signals. Finally, the semaphorins which act mainly via plexins and neuropilins are

Axonal Membrane

The axonal membrane is a lipid bilayer in the nerve fibre. Ionic channels and other proteins are located in the membrane to achieve electrical activity. Action potentials are generated and conducted along the membrane.

► Local Anaesthetics

Azole

Antifungal Drugs.

B-Leukotriene

- ▶ Leukotrienes

B Lymphocyte

A B lymphocyte is a specific type of white blood cell (leucocyte) derived from bone marrow stem cells. Each B lymphocyte expresses an immunoglobulin (antibody) specific for a particular antigen. Following antigenic stimulation, a B lymphocyte may differentiate and multiply into plasma cells that secrete large quantities of monoclonal antibody.

- ▶ Immune Defense
- ▶ Humanized Monoclonal Antibodies

BAC

A Bacterial Artificial Chromosome (BAC) is a vector that allows the propagation of larger exogenous DNA fragments, up to several hundred kb. BACs are propagated in recombination-deficient strains of *E. coli*. They are more stable and easier to handle than yeast artificial chromosomes (YACs).

- ▶ Transgenic Animal Models

Back Propagation

Back propagation is the propagation of action potentials from the soma distally to dendrites. If the dendrites

are passive cable transmitting distally evoked postsynaptic potentials to the soma, the dendrites do not have to generate action potentials. Direct patch clamp measurements demonstrated the back propagation of action potentials.

Bacterial Toxins

GUDULA SCHMIDT, KLAUS AKTORIES
 Institut für Experimentelle und Klinische
 Pharmakologie und Toxikologie, Albert-Ludwigs-
 Universität Freiburg, Freiburg, Germany

Definition

Bacterial protein toxins are proteins that are released by the pathogen into the environment. Thereafter, they target eukaryotic cells to damage the membrane to induce pathogenic signaling by acting on membrane receptors or disturb cell signaling and cell function after entry into the cytosol. The three major aims of bacteria that produce toxins are (i) to enter the host organism, (ii) to inhibit the host immune system, and (iii) to produce an appropriate host niche for their own development.

Protein toxins acting intracellularly are often composed of two subunits (A/B model). One subunit is catalytic (A-subunit) and the other is responsible for binding and cell entry (B-subunit). Following binding to an extracellular membrane receptor, the toxins are endocytosed. From the endosomes, the A-subunit is directly (pH dependent) transferred into the cytosol (e.g., diphtheria toxin and anthrax toxin) or the toxin is transported in a retrograde manner via the golgi to the ER (e.g., cholera toxin), where translocation into the cytosol occurs [1].

Mechanism of Action Toxins Modifying Target Proteins

Protein toxins of this type are generally very potent and efficient because they act catalytically. The toxins usually activate or inactivate key eukaryotic proteins

involved in essential cellular functions by covalent modification. One subfamily catalyzes the ADP-ribosylation of target proteins. For unknown reasons, many toxins of this subfamily modify eukaryotic GTPases. Examples are the diphtheria toxin from toxigenic *Corynebacterium diphtheriae* and the *Pseudomonas aeruginosa* exotoxin A, which ADP-ribosylate elongation factor 2 at diphthamide to cause inhibition of protein synthesis (Table 1). Pertussis toxin from *Bordetella pertussis* and cholera toxin from *Vibrio cholerae* act on heterotrimeric G proteins. Pertussis toxin consists of the catalytic subunit S1 and five binding subunits (S2, S3, 2×S4, and S5) with masses of ~11–26 kDa. Cholera toxin consists of a ~28 kDa A-subunit and five B-subunits (~12 kDa). Although pertussis toxin ADP-ribosylates the α -subunits of the G_i subfamily of G proteins (exception G_z) at a cysteine residue, cholera toxin and the related *E. coli* heat labile toxins ADP-ribosylate α -subunits of the G_s subfamily at an arginine residue. Pertussis toxin-induced ADP-ribosylation blocks the interaction of the G protein with heptahelical receptors (GPCR). The ADP-ribosylation of G_s inhibits intrinsic GTPase activity and persistently

activates the G protein. Increase in cellular cAMP, activation of protein kinase A, and subsequent disturbance of cellular electrolyte secretion is suggested to be the cause of cholera toxin-induced diarrhea [1].

Small GTPases of the Rho family are ADP-ribosylated (e.g., at Asn41 of RhoA) and inactivated by C3-like toxins from *Clostridium botulinum*, *Clostridium limosum*, and *Staphylococcus aureus*. These proteins have a molecular mass of 23–30 kDa and consist only of the enzyme domain. Specific inhibition of Rho functions (Rho but not Rac or Cdc42 are targets) is the reason why C3 is widely used as a pharmacological tool [2].

Another subfamily of ADP-ribosylating toxins modifies G-actin (at Arg177), thereby inhibiting actin polymerization. Members of this family are, for example, *C. botulinum* C2 toxin and *Clostridium perfringens* iota toxin. These toxins are binary in structure. They consist of an enzyme component and a separate binding component, which is structurally related to the binding component of anthrax toxin [3].

The above mentioned Rho GTPases are glucosylated by the family of clostridial glucosylating cytotoxins.

Bacterial Toxins. Table 1 Intracellular acting exotoxins

Toxin	Protein substrate	Activity	Functional consequences
Diphtheria toxin, <i>Pseudomonas</i> exotoxin A	Elongation factor 2	ADP-ribosylation	Inhibition of protein synthesis (diphtheria, <i>Pseudomonas</i> infection)
Cholera toxin, heat labile <i>E. coli</i> toxins	G_s proteins	ADP-ribosylation	Activation of adenylate cyclase (cholera, "traveler"-diarrhea)
Pertussis toxin	$G_{i,o}$ proteins	ADP-ribosylation	Inhibition of G protein signaling (whooping cough)
<i>C. botulinum</i> C2-toxin and related toxins	Actin	ADP-ribosylation	Inhibition of actin polymerization
<i>C. botulinum</i> C3-toxin and related toxins	Rho proteins	ADP-ribosylation	Inhibition of RhoA, B,C Destruction of the cytoskeleton
<i>E. coli</i> CNF1 and 2, <i>Yersinia</i> CNFy	Rho proteins	Deamidation	Activation of RhoA, (Rac, Cdc42)
<i>Bordetella</i> DNT	Rho proteins	Transglutamination	Activation of RhoA, Rac, Cdc42
<i>C. difficile</i> toxin A and B	Rho proteins	Glucosylation	Inactivation of Rho proteins Destruction of the cytoskeleton
Botulinum neurotoxins (A–G), tetanus toxin	Synaptic peptides: a) Synaptobrevin b) Syntaxin c) SNAP25	Zinc dependent endoprotease	Cleavage of synaptic peptides Inhibition of transmitter release (tetanus, botulism)
Shiga toxins and related toxins from <i>E. coli</i>	No proteins (!) 28S rRNA	N-glycosidase	Cleavage of 28S rRNA Inhibition of protein synthesis
Anthrax toxin Lethal factor Lethal factor	MEKs	Endoprotease Increase in intracellular cAMP	Inhibition of MAP-kinase pathways Calmodulin dependent adenylyl cyclase

Important members of this toxin family are *Clostridium difficile* toxins A and B, which are implicated in antibiotics-associated diarrhea and pseudomembranous colitis. The large clostridial cytotoxins are single-chain toxins with molecular masses of 250–308 kDa. The enzyme domain is located at the N terminus. The toxins are taken up from an acidic endosomal compartment. They glucosylate RhoA at Thr37; also, Rac and Cdc42 are substrates. Other members of this toxin family such as *Clostridium sordellii* lethal toxin possess a different substrate specificity and modify Rac but not Rho. In addition, Ras subfamily proteins (e.g., Ras, Ral, and Rap) are modified. As for C3, they are widely used as tools to study Rho functions [2] [4].

Rho GTPases are activated by cytotoxic necrotizing factors 1 and 2 (CNF1, 2) from *Escherichia coli*, CNFy from *Yersinia pseudotuberculosis*, and by the dermonecrotic toxin (DNT) from *Bordetella*. CNF1 and CNF2 are more than 90% identical, whereas CNFy has ~60% sequence identity with CNF1. All three toxins are single-chain proteins with molecular masses of about 115 kDa. Their cell-binding domains are located at the N terminus and the catalytic domain at the C terminus of the toxins. DNT is a protein of ~160 kDa that shares significant homology with CNFs in the catalytic domain. All these toxins activate the small GTP-binding proteins of the Rho family by deamidation (CNFs) and transglutamination (DNT) of a glutamine residue (e.g., Gln63 of RhoA), which is necessary for GTP hydrolysis. Moreover, the inactivation of Rho GTPases by GTPase-activating protein (GAP) is blocked by CNFs and DNT. According to the functions of Rho GTPases, the toxins cause formation of stress fibers, filopodia, and membrane ruffles, and induce cell flattening and multinucleation. The role of CNFs in the pathogenesis of *E. coli* infections is still unclear. CNFs and DNT are dermonecrotic after intradermal application [5].

The anthrax toxin is a tripartite toxin and consists of the binding component protective antigen (PA), the lethal factor (LF), which is a metalloprotease, and the edema factor (EF), which is a calmodulin-dependent adenylcyclase. Both enzyme components are translocated via PA into target cells. PA is activated by furin-induced cleavage and forms heptamers, which are similar to the binding components of C2 toxin and iota toxin. In the low pH compartment of endosomes, the heptamers form pores to allow translocation of LF and EF. LF cleaves six of the seven MEKs (MAPK-kinases) thereby inhibiting these enzymes. The functional consequence is the blockade of the MAPK pathways that control cell proliferation, differentiation, inflammation, stress response, and survival. Whether this is the reason for the LT-induced cell death of macrophages is not clear [1].

Shiga toxin is produced (i) by *Shigella dysenterica*, the cause of bacillary dysentery, (ii) by certain *E. coli* strains (EHEC, enterohaemorrhagic *E. coli*; cause of the

hemolytic uremic syndrome, HUS), and (iii) by various enterobacteriaceae (e.g., *Enterobacter cloacae*). The toxin consists of an A-subunit (~32 kDa) and a pentameric B-subunit (7.7 kDa each). The toxin enters cells after retrograde transport to the Golgi. In the cytosol, the A-subunit acts as an *N*-glycosidase to remove one adenine residue in position 4324 of the 28S rRNA at the ribosome and blocks protein biosynthesis [1].

Clostridial neurotoxins are mainly bichain toxins having a ~50 kDa enzyme component and a ~100 kDa binding/translocation subunit. They are the cause of botulism, a generalized flaccid paralysis of skeletal muscles, mainly acquired by foodborne poisoning, and tetanus, which occurs subsequent to wound infection. Botulism is induced by *C. botulinum* neurotoxins types A, B, C1, D, E, F, and G. Tetanus is induced by tetanus toxin from *Clostridium tetani*. The toxins belong to the most potent agents known. About 1 ng of botulinum neurotoxin per kg body mass may be lethal for man or animal. The toxins are zinc metalloproteases and cleave synaptic peptides involved in transmitter release. Botulinum neurotoxins B, D, F, and G and tetanus toxin cleave synaptobrevin; neurotoxins A and E cleave SNAP25, and neurotoxin C cleaves syntaxin. The botulinum neurotoxins induce flaccid muscle paralysis (botulism) because they act presynaptically at the peripheral neuromuscular junction to block acetylcholine release. Tetanus toxin is taken up at the neuromuscular junction but is then transported in a retrograde manner to the spinal cord. Within the spinal cord, tetanus toxin migrates to interneurons and blocks the release of inhibitory transmitters to cause spastic paralysis [1].

Pasteurella multocida toxin (PMT) is the major pathogenic factor responsible for atrophic rhinitis, a disease which is characterized by bone loss in the nose of pigs. PMT is a 145 kDa single-chain exotoxin, which activates $G\alpha_q$ protein (but not $G\alpha_{11}$) and stimulates phospholipase C β . In addition, $G_{12/13}$ proteins and subsequently Rho pathways are activated.

Bacterial Phospholipases

The α -toxin from *C. perfringens* is involved in the pathogenesis of gas gangrene and the sudden death syndrome of young animals. This toxin is a zinc metalloenzyme with phospholipase activity. Other phospholipase C-toxins are from *Listeria monocytogenes* and *Mycobacterium tuberculosis*. The phospholipase C-toxin from *Bacillus cereus* is specific for phosphatidylinositol. It cleaves phosphatidylinositol and its glucosyl derivatives. In cell biology, this toxin can be used as a tool to study whether a protein is anchored to GPI. A second phospholipase C-toxin produced by *B. cereus* is specific for sphingomyelin. Cleavage of sphingomyelin generates ceramide, a second messenger involved in processes like apoptosis and differentiation.

Pore-Forming Toxins

Pore-forming toxins act by punching holes into mammalian cell membranes. Many different types are known. They can be divided into small and large pore forming toxins. Pore-forming toxins oligomerize in the plasma membrane of the mammalian cell to build circular structures. These ring-like structures can be composed of a few molecules, generating small pores that allow the exchange of ions and nucleotides (*Aeromonas aerolysin*, *S. aureus* α -toxin). Large pores, which allow the passage of peptides or proteins are formed by toxins which insert up to 50 molecules into the plasma membrane generating a pore with up to 35 nm diameter. Examples for such toxins are *Streptococcus pyogenes* streptolysin O or *C. tetani* tetanolysin.

Injected toxins are directly delivered into the cytosol of eukaryotic target cells by the bacterial type III secretion system. The pathogens (e.g., *P. aeruginosa*, *Yersinia*, and *Salmonella*) produce a set of proteins that are delivered into mammalian cells by this complex type III secretion machinery depending on the direct contact between bacterium and host cells. Some of these injected toxins (e.g., Yops in the case of *Yersinia*) do not covalently modify mammalian targets but act as modulators on important signal transduction pathways; they act as molecular mimics of cellular proteins. For example, they regulate the activity of small GTP-binding proteins as exchange factors to activate the small G proteins or as activators of GTP-hydrolysis to inhibit them. Notably, *Salmonella* produces two contrary acting molecular mimics. They inject an activator of Rho GTPases (SopE) to induce ruffling and the uptake of the bacteria into the mammalian cell, and they inject an inactivator of Rho GTPases (SptP) probably to switch off the induced cytoskeletal rearrangements.

Superantigens

Like physiological ligands, bacterial toxins can influence cells by binding to cell surface molecules. Best known are the superantigens produced by *Staphylococcus* strains. Superantigens are bivalent molecules that bind to the major histocompatibility complex (MHC) class II and to the variable regions of the T-cell receptor. This bridging leads to the activation of the T-cell receptor in the absence of an antigenic peptide. This unspecific activation of T-cells is followed by a massive release of cytokines which is thought to play a role in diseases like toxic shock syndrome and some exanthemas.

Clinical Uses

Botulinum neurotoxins are widely used as therapeutic agents to cause reduction or paralysis of skeletal muscle contraction. They are used to treat cervical dystonia, which causes regional involuntary muscle spasms often associated with pain. Moreover, they are used in strabism, blepharospasm, hemifacial spasm, and

achalasia. Meanwhile, a number of studies indicate efficacy for botulinum toxin for the treatment of tension headache, but further studies are necessary to demonstrate its short-term and long-term efficacy. Botulinum toxin is also used as a cosmetic agent and the effects occur a few days after injection into the muscle and last for several months. The treatment can be repeated several times without major development of antineurotoxin antibodies. In the case of antineurotoxin antibody production, the treatment is continued with a different botulinum neurotoxin.

Some toxins (e.g., the diphtheria toxin) fused to antibodies are used as immunotoxins against cell surface molecules, for example, to deplete T-cells as targeted therapy for cutaneous T-cell lymphoma. The use of bacteria with the type III secretion system (e.g., *Salmonella*) producing only an injected toxin-antigen fusion protein as live vaccines is under current investigation. The aim is to directly deliver protein fragments into antigen-presenting cells to improve immunization.

Bacteriophage

A bacteriophage (or phage) is a virus, made up of a DNA or RNA core and a protein coat that may infect bacteria.

- ▶ Humanized Monoclonal Antibodies

Barbiturates

Barbiturates are salts of barbituric acid. They can be used as hypnotics, sedatives, general anaesthetics, and

antiepileptics. Similar to benzodiazepines they have modulatory effects on the GABA_A receptor.

► GABAergic System

Baroreceptor Reflex

The baroreceptor reflex is a central reflex mechanism, which reduces heart rate following an increase in blood pressure. Each change in blood pressure is sensed by baroreceptors in the carotid arteries, which activate the autonomic nervous system to alter heart rate and thereby readjust blood pressure.

- Renin–Angiotensin–Aldosterone System

β Barrel

A beta barrel is a three-dimensional protein fold motif in which beta strands connected by loops form a barrel-like structure. For example, this fold motif is found in many proteins of the immunoglobulin family and of the chymotrypsin family of serine proteases.

Bartter's Syndrome

Bartter's syndrome (antenatal Bartter syndrome, hyperprostaglandin E syndrome) is an autosomal-recessive electrolyte disorder, producing hypokalemia, metabolic alkalosis, hyper-reninism, and hyperaldosteronisms. It has now been recognized to be caused by mutations in at least three transport proteins responsible for NaCl absorption in the loop of Henle. Besides mutations in the Na⁺/K⁺/2Cl⁻-cotransporter, Bartter's syndrome can also be caused by mutations in the K⁺ channel that is present in the apical membrane of the ascending limb (ROMK or KIR1.1). This K channel is a K-recycling pathway and its operation is a prerequisite for NaCl absorption through NKCC2. Clinically, Bartter syndromes types I and II are indistinguishable. In contrast, a milder form of

Bartter's syndrome is caused by mutations in the basolateral chloride channel (ClC-Kb), an exit pathway for cellular Cl.

Basal Activity

Basal activity is the enzymatic or other activity of a protein normally governed by interaction with a ligand or other activator molecule in the absence of that activator.

Basal Ganglia

Basal ganglia are a group of subcortical nuclei which are essential for the coordination of movements (so-called extrapyramidal system). They include the caudate nucleus, putamen, globus pallidus, and lenticular nucleus. Damage of the basal ganglia results in involuntary movements, as are observed in Parkinson's disease and Huntington's chorea.

BCR-ABL Fusion Protein

The discovery of the Philadelphia chromosome (in Philadelphia in 1960) led to the identification in chronic myeloid leukemia (CML) cells of the BCR-ABL fusion gene and its corresponding protein. ABL and BCR encoding genes are normally located on chromosomes 9 and 22, respectively. The ABL gene encodes a tyrosine kinase enzyme whose activity is tightly regulated. By the Philadelphia translocation, two fusion genes are generated: BCR-ABL on the Philadelphia chromosome (abbreviated chromosome 2Z) and ABL-BCR on the chromosome 9. The BCR-ABL gene encodes a protein with deregulated tyrosine kinase activity. The presence of this protein in the CML cells is strong evidence of its pathogenetic role. The efficacy in CML of a drug that inhibits the BCR-ABL tyrosine kinase has provided the final proof that the BCR-ABL oncoprotein is the unique cause of CML.

BCRP

The breast cancer resistance protein (BCRP) belongs to the G-branch of the ABC-transporter family (ABCG2). In contrast to most other ABC-proteins, BCRP consists of only one transmembrane domain (TMD) with one nucleotide binding fold (NBF) at its C-terminus. Because of this structural characteristic BCRP as well as other ABC-transporters with only one TMD are termed half transporters. To achieve functional activity these transporters have to form hetero- or homodimers. BCRP is involved in the multidrug resistance of certain tumors and transports endogenous compounds like cholesterol and steroid hormones.

Benzo(a)pyrene

One of the most studied of the polycyclic aromatic hydrocarbons (PAH) is benzo(a)pyrene (BaP), which is present in coal tar at coke oven plants. The BaP content of coal tar is between 0.1% and 1% and it contributes to the serious potential health effects on employees exposed to coke oven emissions. The largest sources of BaP are open burning and home heating with wood and coal. The latter alone contributes 40 percent of all the BaP released each year in the USA.

Industries that burn wood, gas, oil or coal contribute most of the rest of airborne B(a)P. Studies on animals have shown that contact with BaP and PAH can cause skin cancer, but the effects of breathing or ingesting them are not yet well enough studied to draw a conclusion as to other cancers. Animal tests have shown that exposure to BaP may cause reproduction difficulty. The U.S. government considers BaP a human carcinogen.

Benzodiazepine Receptor Agonists

Synonyms

BzRAs

Definition

A class of sedative/hypnotic type drug that exert their effects through the benzodiazepine binding site on GABA_A receptors. The class consists both of molecules that contain the benzodiazepine moiety, for example diazepam, lorazepam and flunitrazepam, and the newer, non-benzodiazepine compounds such as zolpidem, zopiclone, indiplon and zaleplon. BzRAs are primarily used for the treatment of anxiety, insomnia and to elicit varying levels of sedation. The wide selection of compounds currently available affords the prescribing clinician extensive options in terms of relative efficacies and durations of action.

Definition

The term benzodiazepine refers to a chemical structure, consisting of a heterocyclic ring system in which the two N atoms are mostly located in positions 1 and 4 (1,4-benzodiazepines), e.g., in diazepam (Fig. 1).

Benzodiazepines. Figure 1 (A) Chemical structure of classical [1,4] benzodiazepines. R1, R2, R2', R3, and R7 denote variable substituents. (B) Chemical structure of the prototypical benzodiazepine diazepam.

Benzodiazepines have found wide therapeutic applications as ►**anxiolytics**, sedatives, hypnotics, anticonvulsants, and central muscle relaxants.

Mechanism of Action Enhancement of GABA Response

►**GABA** is the major inhibitory neurotransmitter in the mammalian central nervous system. Its fast synaptic actions are mediated by ►**GABA_A receptors**, which are located on postsynaptic membranes. GABA_A receptors have a central pore, with selectivity for chloride ions. Upon binding of GABA to GABA_A receptors, negatively charged chloride ions flow into the postsynaptic neuron, leading – in most cases – to hyperpolarization of the postsynaptic membrane and thus functional inhibition. In addition to a binding site for the physiological neurotransmitter GABA, most GABA_A receptors contain binding sites for ►**allosteric modulators**, e.g., benzodiazepines, ►**barbiturates**, and ►**neurosteroids**. Benzodiazepines bind to a common modulatory site that is called benzodiazepine site. However, the ligands of the benzodiazepine site are not limited to ligands of the benzodiazepine structure. In particular, the imidazopyridine zolpidem, a widely used hypnotic, and zopiclone, a cyclopyrrolone, also bind to the benzodiazepine site. The basic mechanism of action of benzodiazepines and nonbenzodiazepines acting via the benzodiazepine site appears to be the same.

Benzodiazepines. Figure 2 Schematic representation of the potentiation of the GABA-induced chloride current by benzodiazepines. The GABA dose–response curve is shifted to the left in the presence of benzodiazepines (arrow 1). The chloride current that is induced by a submaximal concentration of GABA is increased (arrow 2). Benzodiazepines are effective only in the presence of GABA (use-dependence) and cannot increase the inhibition by high concentrations of GABA (self-limiting action).

The binding of a benzodiazepine to the benzodiazepine site of the GABA_A receptor enhances GABAergic inhibition by increasing the opening frequency of the GABA-gated ion channel. This leads to a shift of the GABA dose–response curve to the left, so that at any given concentration of GABA, the response is increased (Fig. 2). This can also be viewed as an increase in the affinity of GABA for the receptor. The action of benzodiazepines is use-dependent, and self-limiting. Use-dependence indicates that benzodiazepines are only active in the presence of GABA. In the absence of GABA, benzodiazepines do not have an effect on their own, i.e., their action is dependent on the precondition that GABA is present, and the respective synapse thus in use. Furthermore, benzodiazepines are not able to increase the response to GABA beyond its physiological maximum at high GABA concentrations, which is referred to as the self-limiting nature of their action. The magnitude of the effect of benzodiazepines depends on the amount of GABA present in the synapse and hence, synaptic activity. The self-limiting feature may help explain why the enhancement of GABA transmission by benzodiazepines is typically safe even at high doses, whereas overdoses with drugs that do not display this self-limiting feature, e.g., barbiturates, are life-threatening.

Subtype-Specificity of BZ Actions

GABA_A receptors that contain the $\alpha 1$, $\alpha 2$, $\alpha 3$, and $\alpha 5$ subunits in combination with β and γ subunits can bind classical benzodiazepines, e.g., diazepam, whereas GABA_A receptors that contain the $\alpha 4$ and $\alpha 6$ subunits do not bind classical benzodiazepines. Essentially, all benzodiazepines that are currently in clinical use bind indiscriminately to GABA_A receptors that contain the

$\alpha 1$, $\alpha 2$, $\alpha 3$, and $\alpha 5$ subunits. The only clinically used drug that displays a significant subtype selectivity is the imidazopyridine hypnotic, zolpidem. Zolpidem has a high affinity at GABA_A receptors containing the $\alpha 1$ subunit, an intermediate affinity at GABA_A receptors containing the $\alpha 2$ or $\alpha 3$ subunits, and no affinity at GABA_A receptors containing the $\alpha 5$ subunit. The GABA_A receptor subtype-specificity of benzodiazepine actions was assessed in genetically engineered mice. Whereas the diazepam-sensitive $\alpha 1$, $\alpha 2$, $\alpha 3$ and $\alpha 5$ subunits have a histidine residue in a conserved position in the N-terminal extracellular domain (H101 in $\alpha 1$, H101 in $\alpha 2$, H126 in $\alpha 3$, H105 in $\alpha 5$), the diazepam-insensitive $\alpha 4$ and $\alpha 6$ subunits have an arginine residue at the homologous position. By mutating the conserved histidine residue in the $\alpha 1$, $\alpha 3$, and $\alpha 5$ subunits to arginine residues, the GABA_A receptors containing the respective subunits were rendered diazepam-insensitive. Using this approach, it was discovered that the sedative and anterograde amnesic action of diazepam, and in part also the anticonvulsant action of diazepam, are mediated by GABA_A receptors containing the $\alpha 1$ subunits, while the anxiolytic action of diazepam is mediated by GABA_A receptors containing the $\alpha 2$ subunit. The central muscle relaxant action of diazepam is mediated by GABA_A receptors containing the $\alpha 2$, $\alpha 3$, or $\alpha 5$ subunits (Fig. 3) [1–5]. The anxiolytic action of diazepam is observed at much lower doses than the muscle relaxant action. Interestingly, GABA_A receptors, containing the $\alpha 3$ subunit were not involved in mediating the anxiolytic-like action of diazepam in ethological tests of anxiety, indicating that this response is not dependent on neurons in the reticular activating system, where the $\alpha 3$ subunit is expressed.

These findings demonstrate that subtype-selective drugs are likely to be of benefit, e.g., as anxiolytics

	$\alpha 1$	$\alpha 2$	$\alpha 3$	$\alpha 5$
Sedation	+	–	–	–
Anterograde amnesia	+	ND	ND	ND
Anticonvulsant activity	+	–	–	–
Anxiolysis	–	+	–	–
Myorelaxation	–	+	+	+

Benzodiazepines. Figure 3 Dissection of benzodiazepine pharmacology. The functional roles of GABA_A receptor subtypes, mediating particular actions of diazepam, are indicated. A “+” sign indicates that the respective response is mediated by the respective receptor subtype, a “–” sign indicates that the respective response is apparently not mediated by the respective receptor subtype. ND = not determined.

without sedative and anterograde amnesic side effects. A remarkable step in this direction is the development of L-838,417, which is a partial agonist at GABA_A receptors, containing the $\alpha 2$, $\alpha 3$, and $\alpha 5$ subunits, but has no activity at GABA_A receptors, containing the $\alpha 1$ subunit. This compound is active as an anxiolytic and anticonvulsant, but apparently does not impair motor performance [4].

Interestingly, while the sedative action of diazepam is mediated by GABA_A receptors containing the $\alpha 1$ subunit, its \blacktriangleright REM sleep inhibiting action, its enhancement of sleep continuity, and its effect on the \blacktriangleright EEG spectra in sleep and waking, are mediated by GABA_A receptors that do not contain the $\alpha 1$ subunit, indicating that the hypnotic effect of diazepam and its EEG fingerprint can be dissociated from its sedative action [6].

Agonists and Inverse Agonists

Drugs that bind to the benzodiazepine site of the GABA_A receptor and enhance GABA responses, are termed agonists. Essentially all ligands at the benzodiazepine site that are in clinical use are agonists. In contrast, inverse agonists diminish GABA responses. They are not in clinical use, and have effects opposite to those of the agonists, e.g., they are convulsant and anxiogenic.

The Antagonist Flumazenil

Although flumazenil binds with high affinity to the benzodiazepine site of GABA_A receptors, it has practically no action when given alone. However, flumazenil competitively blocks the action of benzodiazepine site agonists. Flumazenil can be used to terminate the action of benzodiazepines, e.g., after a benzodiazepine overdose. It may also serve as a diagnostic tool in this regard.

Pharmacokinetic Considerations

The benzodiazepines, currently on the market differ in their pharmacokinetic properties, in particular, the duration of action, which guides the use of the drug to be used. The half-life is largely determined by the rate of metabolic degradation of the parent drug. In addition, long-acting metabolites (e.g. desmethyldiazepam) are generated that may contribute to the duration of action. Short-acting drugs might be used for patients with difficulties to fall asleep, with the expectation that there is no hangover effect on the next day. Long-acting drugs may be used if reawakening during the entire night is to be prevented. Short-acting benzodiazepines may have a half-life in the range of 2–6 h, e.g., midazolam, triazolam, and oxazepam, medium-acting benzodiazepines with a half-life in the range of 10–12 h, e.g., lorazepam and lorazepam, and long-acting benzodiazepines with a half-life in the range of 20–50 h, e.g., diazepam and clobazam.

Clinical Use

Benzodiazepines are amongst the most frequently prescribed drugs; they have well-established uses in the treatment of anxiety disorders (anxiolytics) and insomnia, preanaesthetic sedation, suppression of seizures, and muscle relaxation.

Benzodiazepines are used as tranquilizers to relieve anxiety states, e.g., in generalized anxiety disorder and panic attacks. The anxiolytic effects are observed at low doses, suggesting that only a small number of GABA_A receptors need to be modulated to obtain the anxiolytic effect. As outlined previously, this action is, most likely, mediated by GABA_A receptors containing the $\alpha 2$ subunit. In contrast, higher doses of benzodiazepines and thus a higher receptor occupancy is needed for the sedative action of diazepam, which is mediated by GABA_A receptors containing the $\alpha 1$ subunit. When diazepam is used as an anxiolytic, sedative side effects are frequently troublesome. The reduction of the reactivity to external stimuli is the basis for the use of benzodiazepines as hypnotics in the treatment of sleep disorders. The anticonvulsant activity of diazepam can be explained by the GABAergic inhibition of neuronal responsiveness to excitatory inputs. Benzodiazepines (lorazepam and diazepam) are the drugs of choice in the treatment of status epilepticus. Their use in the chronic treatment of epilepsy (e.g. clonazepam) is limited by the development of ►tolerance.

The definition of desired therapeutic and side effects in the case of the benzodiazepines very much depends on the clinical problem in question. The sedative and hypnotic actions are desired effects in the treatment of insomnia, but undesired effects in the treatment of anxiety disorders. Effects that are usually undesired include daytime drowsiness, potentiation of the sedative effects of ethanol, and anterograde amnesia. They are mediated via the benzodiazepine site of GABA_A receptors, since they can be antagonized with flumazenil.

Repeated administration may lead to the development of tolerance to certain benzodiazepine effects, in particular, to the sedative, anticonvulsant and muscle relaxant effects, and to the development of ►physical dependence, which can include withdrawal anxiety, insomnia, convulsions, and sensory hyperactivity and thus being similar to the symptoms that lead to the treatment. To avoid ►withdrawal symptoms, chronic treatment is discontinued by gradually tapering out the dose over a long period of time. The neurobiological nature of the adaptive changes, which occur after long-term treatment or withdrawal from long-term treatment, are poorly understood. Because of the adaptive changes that occur under chronic treatment, the long-term use of benzodiazepines is generally not recommended. For treatment of insomnia, benzodiazepines should not be given for more than e.g., 4 weeks. For the treatment of

anxiety disorders, benzodiazepines should not be used for more than e.g., 6 months. Because of their potentiation of the sedative action of ethanol, benzodiazepines should not be used in patients with alcohol abuse. Likewise, the potential nontherapeutic use of benzodiazepines, for the purpose of euphoria, has to be kept in mind, and particular care should be taken while treating patients with a history of drug abuse.

Benzothiazepines

Benzothiazepines (e.g. Diltiazem) block dihydropyridine-sensitive HVA calcium channels.

- Ca²⁺ Channel Blockers
- Voltage-dependent Ca²⁺ Channels

Benzoylcholinesterase

- Cholinesterases

Beri-Beri

Beri-beri or clinically manifest thiamin deficiency exists in several subforms: infantile beri-beri and adult beri-beri. Infantile beri-beri occurs in exclusively breastfed infants of thiamin-deficient mothers. Adults can develop different forms of the disease, depending on their constitution, environmental conditions, the relative contribution of other nutrients to the diet as well as the duration and severity of deficiency. First of all, there is a so called dry or atrophic (paralytic or nervous) form, including peripheral degenerative polyneuropathy, muscle weakness and paralysis. Second, a wet or exudative (cardiac) form exists. In this form, typical symptoms are lung and peripheral oedema as well as ascites. Finally, there is a cerebral form, that can occur as Wernicke encephalopathy or Korsakoff psychosis. This latter form mostly affects chronic alcoholics with severe thiamin deficiency.

► Vitamin B1

BH Domain

BH domains or Bcr (breakpoint cluster region) homology domains are homologous to the GTPase activating protein domain of the Bcr gene product. Although the p85 BH domain specifically interacts with the Rho family proteins Cdc42 and Rac1, no GTPase-activating activity has been attributed to it.

► Phospholipid Kinases

Biased Agonism

This term indicates a receptor ligand having different intrinsic activities at different transduction pathways coupled to a single receptor. To quote Urban et al. (2006 JPET, #104463 PiP) and Kenakin (2007 Trends Pharmacol Sci 28:359–361) the term “biased agonism” can be considered as a synonym of “collateral efficacy,”

“functional selectivity,” “agonist-directed trafficking of receptor stimulus,” “protean agonism,” “differential engagement,” or “stimulus trafficking.”

► Tachykinins and their Receptors

Bicuculline

Bicuculline is a competitive antagonist at the GABA_A receptor. It is a plant alkaloid.

► GABA_A Receptor

BID

BID is a member of the Bcl-2 gene family, which encode proteins that function either to promote apoptosis or to inhibit apoptosis as in the proteins derived from Bcl-2. These proteins can exist as monomers or they can dimerize. For example, if two promoting Bcl-2 family proteins dimerize then apoptosis will be greatly enhanced. Conversely, if dimerization of an inhibitory and promotor protein occurs, then the effects are cancelled out. The Bcl-2 family of proteins are localized to the outer mitochondrial or outer nuclear membranes.

► Apoptosis

Biguanide

A class of drug derived from guanidine, including metformin and phenformin. Metformin is currently widely used in humans for the treatment of type 2 diabetes. Phenformin was formerly also widely used but was withdrawn because of problems with lactic acidosis.

► AMP-activated Protein Kinase

► Diabetes Mellitus

► Antidiabetic Drugs other than Insulin

Bile Acids

Synonyms

Bile salts

Definition

Bile acids are a group of molecules synthesized from cholesterol, containing a sterol nucleus, a variable number of hydroxyl groups and a side chain with a carboxyl group that can be conjugated to taurine or glycine. Their ▶**amphipathic** nature is essential to solubilize dietary lipids and fat-soluble vitamins, which subsequently promotes absorption of these molecules in the digestive tract. Besides their classic roles in dietary lipid absorption and cholesterol homeostasis, it is now evident that bile acids are also signaling molecules that play important roles in metabolic ▶**homeostasis**.

Basic Mechanisms

Gall or bile consists of bile acids, ▶**phosphatidylcholine**, cholesterol and waste products and is secreted from the ▶**hepatocytes** into the bile canaliculi ultimately ending in the hepatic duct. Most of the bile acids are present within the ▶**enterohepatic** organs. About one-half of the secreted bile is diverted to the cystic duct and stored in the gallbladder. When a meal is ingested, bile from the gallbladder flows into the duodenum and intestine. The bile acids are efficiently (95%) absorbed again by passive diffusion and active transport in the terminal ileum, and transported back to the liver via the portal vein. In the liver, the bile acids are taken up at the basolateral (sinusoidal) membrane and exported again at the apical (canalicular) membrane of the hepatocytes into the bile canaliculus (transhepatic bile acid flux). This completes their enterohepatic circulation. Each

bile acid molecule may complete multiple cycles between liver and intestine per day. Because of this efficient recirculation, only a small amount of the ▶**bile acid pool** size is derived from de novo biosynthesis. The bile acid pool presents the total amount of bile acids within the enterohepatic circulation.

Bile acids contain a variable number of hydroxyl groups, which determines their hydrophobicity and physiological properties. Humans synthesize two bile acids, cholic acid (3 α ,7 α ,12 α -trihydroxy) and chenodeoxycholic acid (3 α ,7 α -dihydroxy), which are termed primary bile acids (Fig. 1). Before secretion into the bile these bile acids are conjugated to glycine or taurine. In mice, bile acids are almost exclusively conjugated to taurine, whereas in humans glycoconjugates are usually predominant. Conjugation is important because it lowers the pK_a of bile acids, giving the molecules a charge at physiological pH, which explains the synonym bile salts. Conjugation renders bile acids more soluble and prevents passive absorption. In the colon, bile acids are subjected to deconjugation and 7 α -dehydroxylation by several microbial enzymes resulting in secondary bile acids that can become part of the circulating bile acid pool. The secondary bile acids of cholic acid and chenodeoxycholic acid are deoxycholic acid (3 α ,12 α) and lithocholic acid (3 α) respectively (Fig. 1). Lithocholic acid is toxic and due to its insolubility only poorly absorbed. Other bile acids are ursodeoxycholic acid (3 α ,7 β), hyocholic acid (3 α ,6 α ,7 α) and muricholic acid. Ursodeoxycholic acid is a bile acid found in large quantities in bear bile, but it is also a secondary bile acid that occurs naturally in humans in low quantities. Hyocholic acid is considered to be specific for pig bile. Muricholic acid is the name for a group of trihydroxy bile acids found in rodents of which β -muricholic acid (3 α ,6 β ,7 β) is the most prominent. The other stereoisomers of muricholic acid are α -(3 α ,6 β ,7 α) and ω -muricholic acid (3 α ,6 α ,7 β).

Bile acid synthesis from cholesterol is the prime pathway for cholesterol catabolism. Cholesterol is converted into bile acids via multiple pathways which involve 17 different enzymes. Many of these enzymes are predominantly expressed in the liver and are localized in several different subcellular

Bile Acids. Figure 1 Structure of selected bile acids.

compartments. Approximately 500 mg of cholesterol is converted into bile acids each day in the adult human liver. Bile acid biosynthesis involves modification of the ring structure of cholesterol, oxidation, and shortening of the side chain, and finally conjugation of the bile acid with an amino acid. All these steps and the enzymes involved are reviewed in detail by Russell [1]. The intermediates and enzymes of the classic (or neutral pathway) are displayed in Fig. 2. The classic pathway is responsible for the majority of total bile acid synthesis. The rate of synthesis is determined by cholesterol 7 α -hydroxylase, which is the first enzyme in the pathway (Fig. 2). Expression levels of this enzyme, which is encoded by the gene *CYP7A1*, are highly regulated and show a strong diurnal rhythm.

Bile acids have multiple functions [2]. The first function of bile acids is in nutrition, because they are essential to solubilize dietary lipids and fat-soluble vitamins, which subsequently promotes absorption of these molecules in the digestive tract. The second function of bile acids is bile formation. Bile acids generate bile flow from the hepatocyte and are essential for the extraction of phosphatidylcholine. As such bile acids are crucial for the excretion of certain waste products, such as ►bilirubin, heavy metals, and drug metabolites, but also cholesterol. Therefore bile formation and bile acid biosynthesis constitute the major pathways for cholesterol excretion. Besides these classic roles in dietary lipid absorption, bile formation and cholesterol homeostasis, it is now evident that bile acids are also signaling molecules [3]. Two major signaling mechanisms have been identified. Bile acids are ligands for the ►G-protein-coupled receptor (GPCR) TGR5 and ►nuclear receptors such as farnesoid X receptor (FXR). GPCRs also known as seven transmembrane receptors, are a protein family of cell surface receptors that bind an extracellular ligand and transduce this signal into G-protein activation (intracellular signal). TGR5 plays a role in the determination of the composition of gallbladder bile. Nuclear receptors are a family of transcription factors, which contains 48 members in human and are involved in the control of numerous processes, including development and metabolism [4]. Nuclear receptors typically consist of a DNA-binding domain and a ligand-binding domain. The DNA binding domain binds specific so-called response elements in the promoter of target genes. Upon binding of an intracellular ligand, nuclear receptors change conformation which induces dissociation of corepressors and the recruitment of transcriptional cofactors, resulting in the activation of transcription. The discovery of bile acids as the endogenous FXR ligands suggested a function for them in the regulation of the enterohepatic circulation and biosynthesis of bile acids, which is in line with the reported expression pattern of FXR in liver and intestine. In these tissues,

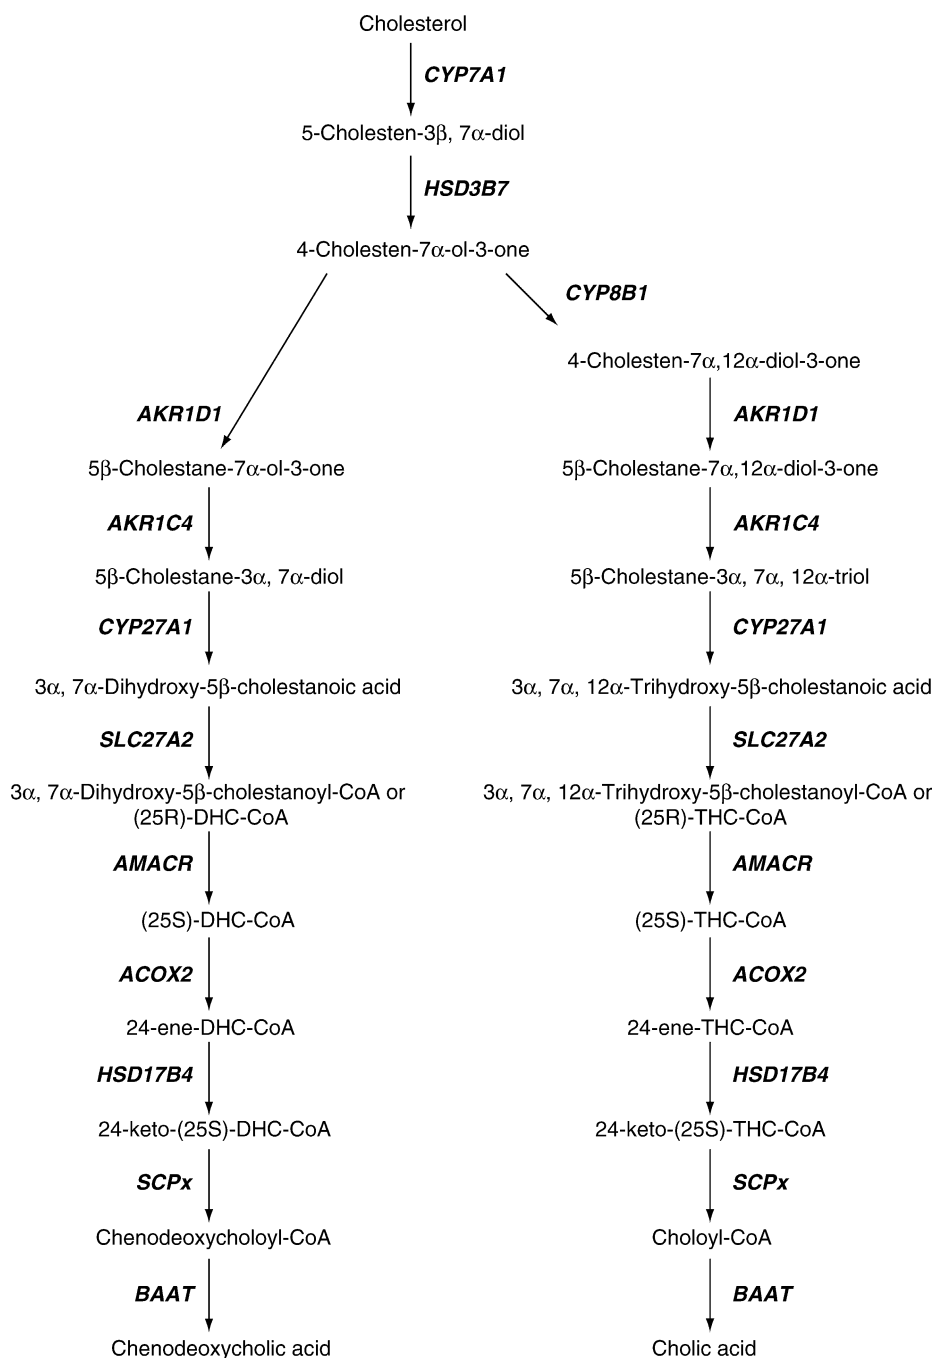

FXR activation protects against accumulation of bile acids, which is toxic (reviewed in [5]). To summarize (Fig. 3), FXR activation in the liver decreases bile acid biosynthesis and increases conjugation of bile acids followed by the excretion of bile acids from the hepatocyte into the bile canaliculus leading to an increase in the formation of bile. In the intestine, FXR activation decreases hepatic bile acid biosynthesis and increases expression of a protective bile acid binding protein and the basolateral bile acid transporters. Of particular interest is the FXR-mediated induction of the expression of short heterodimer partner (SHP) in the liver and fibroblast growth factor 19 (FGF19) in the ileum. SHP is an atypical nuclear receptor that only has a ligand-binding domain and no DNA-binding domain and inhibits the activity of several nuclear receptors. SHP induction underlies the negative feedback regulation of bile acid biosynthesis because it potently inhibits the expression of *CYP7A1*, the rate-limiting enzyme in bile acid biosynthesis. FGF19 is a secreted peptide hormone that signals to the liver and the gallbladder. In the liver, FGF19 signaling decreases expression of *CYP7A1*. FGF19 also decreases smooth muscle tension in the gallbladder allowing filling with and storage of bile. During storage, the bile is concentrated by water removal in order for bile acids to reach concentrations in the intestinal lumen high enough to solubilize dietary lipids.

In addition to regulation of their own enterohepatic circulation, bile acids can also regulate cholesterol, triglyceride, energy, and glucose homeostasis (reviewed in [3]). Bile acids decrease their own biosynthesis and as such increase hepatic and LDL-cholesterol. Interestingly bile acids also affect triglyceride homeostasis. In fact, for a long time it has been known that in man there is an inverse relationship between bile acids and hepatic VLDL production. Treatment with bile acid-binding resins, ileal exclusion or bile withdrawal interrupt the enterohepatic circulation and induce the production of VLDL. Conversely, treatment of cholesterol gallstones with chenodeoxycholic acid increases the bile acid pool and reduces hypertriglyceridemia. All these effects have been attributed to FXR-mediated downregulation of bile acid biosynthesis and lipogenesis. In mice, bile acids have been reported to inhibit diet-induced obesity and prevent the development of insulin resistance by increasing energy expenditure in brown adipose tissue via the activation of TGR5.

Pharmacological Intervention

Several pharmacological interventions target bile acid homeostasis.

Gallstones. Bile acids keep cholesterol soluble in gallbladder bile. Therefore, they are used for the dissolution of cholesterol gallstones. Initial treatment

Bile Acids. Figure 2 Schematic representation of the enzymes and intermediates in the classic bile acid biosynthesis pathway, which is responsible for ~90% of the total bile acid synthesis humans. *CYP7A1* encodes cholesterol 7 α -hydroxylase; *HSD3B7* encodes 3 β -hydroxy- Δ^5 -C₂₇-steroid oxidoreductase; *CYP8B1* encodes sterol 12 α -hydroxylase; *AKR1D1* encodes Δ^4 -3-oxosteroid 5 β -reductase; *AKR1C4* encodes 3 α -hydroxysteroid dehydrogenase; *CYP27A1* encodes sterol 27-hydroxylase; *SLC27A2* encodes bile acyl-CoA synthetase; *AMACR* encodes α -methylacyl-CoA racemase; *ACOX2* encodes branched-chain acyl-CoA oxidase; *HSD17B4* encodes D-bifunctional protein; *SCPx* encodes sterol carrier protein X; *BAAT* encodes bile acyl-CoA:amino acid *N*-acyltransferase.

with chenodeoxycholic acid was hepatotoxic and was replaced by treatment with ursodeoxycholic acid.

Hyperlipidemia. Bile acid binding resins such as cholestyramine sequester bile acids in the intestine,

preventing their uptake in the ileum and consequently their enterohepatic recirculation. Fecal loss of bile acids is compensated by increased biosynthesis of bile acids from cholesterol. Cholestyramine treatment therefore reduces

Bile Acids. Figure 3 FXR target genes involved in the enterohepatic recycling and detoxification of BAs. Genes whose expression is directly induced by bile acids and FXR are in yellow rectangles; those in pink rectangles are inhibited by bile acids. Abbreviations not used in Fig. 2 are: BACS (*SLC27A2*), bile acyl-CoA synthetase; BSEP, bile salt export pump; MDR3, multidrug resistance 3 p-glycoprotein; MRP2, multidrug resistance-associated protein 2; IBABP, ileal bile acid binding protein; NTCP, sodium taurocholate cotransporting polypeptide; ASBT, apical sodium dependent bile salt transporter; FGF, fibroblast growth factor; OST, organic solute transporter.

plasma cholesterol and was used to treat hypercholesterolemia before *statins* became available.

As described in the previous section, bile acids have evolved over the last years from regulators of bile acid homeostasis to general metabolic integrators. It is therefore not too surprising that a number of bile acid-activated signaling pathways have become attractive targets for the treatment of gallstones and other metabolic diseases, such as obesity, type 2 diabetes, hyperlipidemia, and atherosclerosis.

Biogenic Amines

Definition

Acetylcholine, serotonin, norepinephrine, epinephrine, dopamine, histamine and polyamines (spermine/putrescin) are often collectively referred to as biogenic amines. These agents play key roles in neurotransmission and other signaling functions. They are relatively small in size and contain a protonated amino group or a permanently charged ammonium moiety. Biogenic amines are synthesized in nerve cells from amino acids. They are released from vesicles localized in presynaptic terminals into the synaptic cleft. Biogenic amines bind to cell membrane located receptors at postsynaptic terminals. The synaptic cleft is cleared of biogenic amines through reuptake transporters located at the presynaptic terminal or by enzymes degrading the amines.

Definition

Bioinformatics generates knowledge from computer analysis of biological data. These can consist of the information stored in the genetic code, but also experimental results from various sources, patient statistics, and scientific literature. Research in bioinformatics includes method development for storage, retrieval, and analysis of the data. Bioinformatics is a rapidly developing branch of biology and is highly interdisciplinary, using techniques and concepts from informatics, statistics, mathematics, chemistry, biochemistry, physics, and linguistics. It has many practical applications in different areas of biology and medicine.

Description

The history of computing in biology goes back to the 1920s when scientists were already thinking of establishing biological laws solely from data analysis by induction (e.g. A.J. Lotka, *Elements of Physical Biology*, 1925). However, only the development of powerful computers, and the availability of experimental data that can be readily treated by computation (e.g. DNA or amino acid sequences and 3D structures of proteins) launched bioinformatics as an independent field. Today, practical applications of bioinformatics are readily available through the World Wide Web, and are widely used in biological and medical research. As the field is rapidly evolving, the very definition of bioinformatics is still the matter of some debate.

The relationship between computer science and biology is a natural one for several reasons. First, the phenomenal rate of biological data being produced provides challenges: massive amounts of data have to be stored, analysed, and made accessible. Second, the nature of the data is often such that a statistical method, and hence computation, is necessary. This applies in particular to the information on the building plans of proteins and of the temporal and spatial organisation of their expression in the cell encoded by the DNA. Third, there is a strong analogy between the DNA sequence and a computer program (it can be shown that the DNA represents a ▶ *turing machine*).

Analyses in bioinformatics focus on three types of datasets: genome sequences, macromolecular structures, and functional genomics experiments (e.g. expression data, yeast two-hybrid screens). But bioinformatic analysis is also applied to various other data, e.g. taxonomy trees, relationship data from metabolic pathways, the text of scientific papers, and patient statistics. A large range of techniques are used, including primary sequence alignment, protein 3D structure alignment, phylogenetic tree construction, prediction and classification of protein structure, prediction of RNA structure, prediction of protein function, and expression data clustering. The emergence of systems biology as a new branch in biology has further increased

the role of computing, and the term “computational biology” often refers to the calculation of systems behaviour. Algorithmic development is an important part of bioinformatics, and techniques and algorithms were specifically developed for the analysis of biological data (e.g. the ►dynamic programming algorithm for sequence alignment).

Bioinformatics has a large impact on biological research. Giant research projects such as the human genome project [1] would be meaningless without the bioinformatics component. The goal of sequencing projects, for example is not to corroborate or refute a hypothesis, but to provide raw data for later analysis. Once the raw data are available, hypotheses may be formulated and tested *in silico*. In this manner, computer experiments may answer biological questions which cannot be tackled by traditional approaches. This has led to the founding of dedicated bioinformatics research groups as well as to a different work practice in the average bioscience laboratory where the computer has become an essential research tool.

Three key areas are the organisation of knowledge in databases, sequence analysis, and structural bioinformatics.

Organising Biological Knowledge in Databases

Biological raw data are stored in public ►databanks (such as Genbank or EMBL for primary DNA sequences). The data can be submitted and accessed via the World Wide Web. Protein sequence databanks like trEMBL provide the most likely translation of all coding sequences in the EMBL databank. Sequence data are prominent, but also other data are stored, e.g. yeast two-hybrid screens, expression arrays, systematic gene-knock-out experiments, and metabolic pathways.

The stored data need to be accessed in a meaningful way, and often contents of several databanks or databases have to be accessed simultaneously and correlated with each other. Special languages have been developed to facilitate this task (such as the Sequence Retrieval System (SRS) and the Entrez system). An unsolved problem is the optimal design of inter-operating database systems. ►Databases provide additional functionality such as access to sequence homology searches and links to other databases and analysis results. For example, SWISSPROT [2] contains verified protein sequences and more annotations describing the function of a protein. Protein 3D structures are stored in specific databases (e.g. the Protein Data Bank [3], now primarily curated and developed by the Research Collaboratory for Structural Bioinformatics). Organism specific databases have been developed (such as ACEDB, the A C. Elegans Database for the *C. elegans* genome, FLYBASE for *D. melanogaster* etc.). A major problem is errors in

databanks and databases (mostly errors in annotation) in particular since errors propagate easily through links.

Also databases of scientific literature (such as PUBMED, MEDLINE) provide additional functionality, e.g. they can search for similar articles based on word-usage analysis. Text recognition systems are being developed that automatically extract knowledge about protein function from the abstracts of scientific articles, notably on protein–protein interactions.

Analysing Sequence Data

The primary data of sequencing projects are DNA sequences. These become only really valuable through their annotation. Several layers of analysis with bioinformatics tools are necessary to arrive from a raw DNA sequence at an annotated protein sequences:

- Establish the correct order of ►sequence contigs to obtain one continuous sequence
- Find the translation and transcription initiation sites, find promoter sites, define ►open reading frames (ORF)
- Find splice sites, introns, exons
- Translate the DNA sequence into a protein sequence, searching all six frames
- Compare the DNA sequence to known protein sequences to verify exons, etc. with homologous sequences

Some completely automated annotation systems have been developed (e.g. GENEQUIZ), which use a multitude of different programs and methods.

The protein sequences are further analysed to predict function. The function can often be inferred if a sequence of a ►homologous protein with known function can be found. Homology searches are the predominant bioinformatics application, and very efficient search methods have been developed [4]. The often difficult distinction between ►orthologous sequences and ►paralogous sequences facilitates the functional annotation in the comparison of whole genomes. Several methods detect glycosylation, myristylation and other sites, and the prediction of signal peptides in the amino acid sequence give valuable information about the subcellular location of a protein.

The ultimate goal of sequence annotation is to arrive at a complete functional description of all genes of an organism. However, function is an ill-defined concept. Thus, the simplified idea of “one gene – one protein – one structure – one function” cannot take into account proteins that have multiple functions depending on context (e.g. subcellular location and the presence of cofactors). Well-known cases of “moonlighting” proteins are lens crystalline and phosphoglucose isomerase. Currently, work on ►ontologies is under way to explicitly define a vocabulary that can be applied to all

organisms even as knowledge of gene and protein roles in cells is accumulating and changing.

Families of similar sequences contain information on sequence evolution in the form of specific conservation patterns at all sequence positions. Multiple sequence alignments are useful for

- Building ► **sequence profiles** or ► **Hidden Markov Models** to perform more sensitive homology searches. A sequence profile contains information about the variability of every sequence position, improving structure prediction methods (secondary structure prediction). Sequence profile searches have become readily available through the introduction of PsiBLAST [4]
- Studying evolutionary aspects, by the construction of phylogenetic trees from the pairwise differences between sequences: for example, the classification with 70S, 30S RNAs established the separate kingdom of archaea
- Determining active site residues, and residues specific for subfamilies
- Predicting protein–protein interactions
- Analysing ► **single nucleotide polymorphisms** to hunt for genetic sources of diseases

Many complete genomes of microorganisms and a few of eukaryotes are available [1]. By analysis of entire genome sequences a wealth of additional information can be obtained. The complete genomic sequence contains not only all protein sequences but also sequences regulating gene expression. A comparison of the genomes of genetically close organisms reveals genes responsible for specific properties of the organisms (e.g. infectivity). Protein interactions can be predicted from conservation of gene order or operon organisation in different genomes. Also the detection of gene fusion and gene fission (i.e. one protein is split into two in another genome) events helps to deduce protein interactions.

Structural Bioinformatics

This branch of bioinformatics is concerned with computational approaches to predict and analyse the spatial structure of proteins and nucleic acids. Whereas in many cases the primary sequence uniquely specifies the 3D structure, the specific rules are not well understood, and the ► **protein folding problem** remains largely unsolved. Some aspects of protein structure can already be predicted from amino acid content. Secondary structure can be deduced from the primary sequence with statistics or ► **neural networks**. When using a multiple sequence alignment, secondary structure can be predicted with an accuracy above 70%.

Three-dimensional models can be obtained most easily if the 3D structure of a homologous protein is known (homology modelling, comparative modelling). A homology model can only be as good as the sequence

alignment: whereas protein relationships can be detected at the 20% identity level and below, a correct sequence alignment becomes very difficult, and the homology model will be doubtful. From 40 to 50% identity the models are usually mostly correct; however, it is possible to have 50% identity between two carefully designed protein sequences with different topology (the so-called JANUS protein). Remote relationships that are undetectable by sequence comparisons may be detected by sequence-to-structure-fitness (or ► **threading**) approaches: the search sequence is systematically compared to all known protein structures. Ab initio prediction of protein 3D structure remains the major challenge; some progress has been made recently by combining statistical with ► **force-field** based approaches.

Membrane proteins are interesting drug targets. It is estimated that membrane receptors form 50% of all drug targets in pharmacological research. However, membrane proteins are underrepresented in the PDB structure database. Since membrane proteins are usually excluded from structural genomics initiatives due to technical problems, the prediction of transmembrane helices and solvent accessibility is very important. Modern methods can predict transmembrane helices with a reliability greater than 70%.

Understanding the 3D structure of a macromolecule is crucial for understanding its function. Many properties of the 3D structure cannot be deduced directly from the primary sequence. Obtaining better understanding of protein function is the driving force behind structural genomics efforts, which can be thus understood as part of functional genomics. Similar structure can imply similar function. General structure-to-function relationships can be obtained by statistical approaches, for example by relating secondary structure to known protein function or surface properties to cell location.

The increased speed of structure determination necessary for the structural genomics projects makes an independent validation of the structures (by comparison to expected properties) particularly important. Structure validation helps to correct obvious errors (e.g. in the covalent structure) and leads to a more standardised representation of structural data, e.g. by agreeing on a common atom name nomenclature. The knowledge of the structure quality is a prerequisite for further use of the structure, e.g. in molecular modelling or drug design.

In order to make as much data on the structure and its determination available in the databases, approaches for automated data harvesting are being developed. Structure classification schemes, as implemented for example in the SCOP, CATH, and FSSP databases, elucidate the relationship between protein folds and function and shed light on the evolution of protein domains.

Combined analysis of structural and genomic data will certainly get more importance in the near future. Protein folds can be analysed for whole genomes.

Protein–protein interactions predicted on the sequence level can be studied in more detail on the structure level. ▶ **Single Nucleotide Polymorphisms** can be mapped on 3D structures of proteins in order to elucidate specific structural causes of disease.

More detailed aspects of protein function can be obtained also by ▶ **force-field** based approaches. Whereas protein function requires protein dynamics, no experimental technique can observe it directly on an atomic scale, and motions have to be simulated by molecular dynamics (MD) simulations. Also free energy differences (e.g. between binding energies of different protein ligands) can be characterised by MD simulations. Molecular mechanics or molecular dynamics based approaches are also necessary for homology modelling and for structure refinement in X-ray crystallography and NMR structure determination.

Drug design exploits the knowledge of the 3D structure of the binding site (or the structure of the complex with a ligand) to construct potential drugs, for example inhibitors of viral proteins or RNA. In addition to the 3D structure, a ▶ **force-field** is necessary to evaluate the interaction between the protein and a ligand (to predict binding energies). In virtual screening, a library of molecules is tested on the computer for their capacities to bind to the macromolecule.

Pharmacological Relevance

Many aspects of bioinformatics are relevant for pharmacology. Drug targets in infectious organisms can be revealed by whole genome comparisons of infectious and non-infectious organisms. The analysis of single nucleotide polymorphisms reveals genes potentially responsible for genetic diseases. Prediction and analysis of protein 3D structure is used to develop drugs and understand drug resistance.

Patient databases with genetic profiles, e.g. for cardiovascular diseases, diabetes, cancer, etc. may play an important role in the future for individual health care, by integrating personal genetic profile into diagnosis, despite obvious ethical problems. The goal is to analyse a patient's individual genetic profile and compare it with a collection of reference profiles and other related information. This may improve individual diagnosis, prophylaxis, and therapy.

Definition

Biologicals are pharmaceutical agents derived or synthesized from living organisms and/or their products used for diagnostic, preventive, and therapeutic purposes necessary in the practice of human and veterinary medicine. Blood and blood products form a special category of biologicals as they are derived from repeated donation of large amounts of blood or plasma by healthy volunteers. Unlike the characterization of traditional pharmaceuticals, however, biologicals are

more difficult to characterize because of the complex molecular structure of their components and their interactions with agents used during their manufacture and/or that are present in the final products, e.g., additives, stabilizers, preservatives, and adjuvants. Thus, product safety, efficacy, and quality assurance are carried out by rigorous biological standardization that must rely on consistency approach in the manufacturing of products and their comparability with reference materials used worldwide as standards by the regulatory authorities.

Mechanisms of Action Blood and Blood Products

The discovery of ABO blood groups at the beginning of the 20th century initiated transfusion of donated human blood to replace acute blood loss suffered by patients with trauma or undergoing major surgical procedures [1]. The molecular basis of genetically determined ABH antigens and the corresponding appearance of naturally occurring antibodies in the serum for an antigen absent on the cell are illustrated in Fig. 1, which is adapted from [2]. The terminal sugars, enzymatically synthesized by genetically determined transferases, determine the antigenic specificity of the ABH antigens on cells. Reciprocally, the serum naturally contains isoantibodies against the antigens absent on the red cells; thus, group O individuals have absence of both A and B antigens on the red cell membrane and hence have anti-A and anti-B antibodies present in the serum. With subsequent discoveries of Rh and other blood groups, blood typing and pretransfusion compatibility testing or cross matching became so perfected that most serious hemolytic transfusion reactions are exceedingly rare among an estimated 25 million patients transfused worldwide each year. Landsteiner received the Nobel Prize in 1943 for his discovery of blood groups, making transfusion the most widely used procedure in clinical practice.

Blood centers collect whole blood from voluntary donors and generally divide each donation into components, viz., red cells, platelets, and leukocytes, and fresh frozen plasma (FFP) for transfusion therapy for specific diseases (see later in the section on Clinical Use). Therapeutic plasma proteins, e.g., albumin, gamma globulins, and factor VIII are derived from the plasma procured at plasmapheresis centers. Batches of several thousand liters of plasma are processed by Cohn Fractionation, which uses discrete concentrations of alcohol to precipitate and separate the principal plasma proteins (albumin and gamma globulins). Human gamma globulins (Ig) get aggregated in the Cohn fractionation and require disaggregating accomplished at low pH or by enzymatic digestion to render Ig safer for intravenous use as IVIg. Modified Cohn fractionation and chromatographic separation methods have been developed

Biologicals. Figure 1 The ABO blood group system with immunochemical specificity due to terminal sugars and reciprocal antibodies in the serum. From *Immunity: Immune Response in Inflammatory Disease* by DeFranco, Locksley and Robertson [2].

to derive not only albumin, globulins, but also clotting factor concentrates (factor VII, VIII, and IX), fibrinogen and alpha-1 antitrypsin. Recombinant DNA technology for expressing the genes encoding each of the major therapeutic plasma proteins, viz., albumin, alpha-1-antitrypsin, and clotting factors VII, VIII, and IX is feasible for providing molecularly homogeneous, clinically useful and safe blood products for transfusion therapy. However, molecularly derived products are disproportionately costly and not competitive with plasma-derived therapeutic proteins. Humanized monoclonal antibodies produced by recombinant DNA technology, e.g., hepatitis B immune globulins (HBIG) or

Rh immune globulin for intravenous use may have a place in specific transfusion therapies.

Cellular ►**cytokines** (interferons, G-CSF) and immune response modifiers originally produced from human cells, most often leukocytes, have now been replaced with recombinant products with well-defined structure/function. Futuristic advances in experimental hematology portend development of human blood cells produced from the hemopoetic stem cells. Yet for the foreseeable future, homologous blood donated by healthy, altruistic voluntary blood donors remains the principal source of safe and adequate supply of blood and blood products for transfusion therapy.

Diagnosics

In vitro or in vivo laboratory tests are tools or procedures used as part of the diagnosis process in which a physician seeks to determine the physiological or biochemical cause(s) of a patient's disease symptoms. While clinical diagnosis performed in the physician's office is based on clinical history, physical examination and measurement of blood pressure, heart rate, etc., additional lab tests are required to evaluate a list of clinical probabilities. Depending on the type of test, biological products may be used to evaluate the patient's tissues, such as blood, urine, saliva, DNA, hair, or stool, by utilizing specific interactions between the biological diagnostic and target or substance of interest. A majority of currently available tests for in vitro diagnosis (IVD) are based on hematological, microbiological, biochemical, and immunological analysis of patient specimens. This medical discipline is commonly referred to as laboratory medicine or clinical pathology.

Many of the laboratory tests are based on immunoassays for antigens/antibodies present in the patient's test specimens, by having a biologically standardized set of antigens or antibodies for the detection and quantification of corresponding analytes for IVD. Continuing expansion in the fundamental knowledge about cell biology, cell differentiation antigens (nearly 400), cellular receptors and cytokines, and various growth factors in health and disease has led to availability of both polyclonal and monoclonal antibodies used for IVD.

Therapeutics

Simply speaking, a therapeutic biological used for healing or treating any ailment is a product derived from another living being, and therefore falls under the rubric of biologicals; they are often referred to as biological medicines or biotherapeutic drugs. Recombinant DNA technology enabled expression of cloned genes to produce therapeutic proteins or biological medicines.

Major advances made in our understanding of the immune system and disease pathogenesis have

coincided with the development of several biological medicines developed during the past two decades. Cytokines, monoclonal antibodies, and cellular therapies offer promising treatments for a variety of human cancers, persistent infections, and tissue and organ transplantation. The dynamic field of immune therapies and cellular therapies is still evolving, rapidly developing, and most promising in the field of cancer and immune disorders. Principal promises pertain to the following:

- Besides the plasma-derived immunoglobulins for antibody therapies listed in the foregoing section on blood components, a variety of monoclonal antibodies and fusion proteins are prepared by molecular methods using recombinant DNA technology. The mouse monoclonal antibodies first used for therapeutic purposes could not be repeatedly given because they induce human antibodies against mouse IgG (Fc). This is overcome by genetic constructs of chimera for humanized monoclonal antibodies and for novel fusion proteins containing the constant region of IgG heavy chains (Fc) of human origin as illustrated in Figs. 2 and 3, reproduced from Johnston [3].
- The biological agents that directly or indirectly mediate beneficial effects against patient's persistent infection or response to a neoplasm are a class of biologicals termed cytokines or biological response modifiers. They include interferons (alpha, beta, and gamma), interleukins (total of 33 and growing), tumor necrosis factors, hemopoetic growth factors (granulocyte/monocyte colony stimulating factors, G/GM/M-CSF), stem cell factor (SCF), and a variety of specific monoclonal antibodies. While some of the crude cytokines such as interferons were originally derived from human leukocytes and their subsets, the recombinant DNA technology has tremendously facilitated the identification and production of a large number of the human proteins with potent effects on the function and growth of normal and neoplastic cells.
- Cellular therapies in transplantation and cancer are based on specific cells separated or sorted from human blood, bone marrow, or cord blood by means of their specific cell surface markers or cell differentiation antigens, e.g., CD3, CD4, CD8, CD14, CD19, and CD34. For example, the CD34⁺ stem cells, especially those derived from human embryos, have the capacity to differentiate in culture to generate different somatic cells, e.g., liver cells, heart cells, neurons, etc. This exploding field of research is now termed regenerative medicine.
- ►**Gene therapy** uses cloned DNA in adeno or retroviral vectors to transduce host cells for long-term therapy of certain genetic disorders with defined

Biologicals. Figure 2 Monoclonal antibody construction: the different components of the antibody structure can be derived from different genetic sources of B cells. Chimeric monoclonal antibodies are derived from mouse variable-region genetic sequences combined with constant-region genes of human origin. Fully humanized monoclonal antibodies are composed of mouse complementarity-determining regions (CDRs), the rest of the antibody being of human genetic origin. Fully human monoclonal antibodies are produced from entirely human genetic sequences.

Biologicals. Figure 3 Fusion protein construction: combination of the molecular component of interest with the constant region (Fc) of an antibody molecule, usually immunoglobulin (Ig)G1 Fc, imparts the Fc function on to the molecular component for therapeutic use. The example given is of CTLA4-Ig, derivatives of which have shown clinical efficacy in the treatment of rheumatoid arthritis and transplant rejection.

molecular mechanisms, e.g., severe combined immunodeficiency resulting from T cell defect due to adenosine deaminase deficiency. However, evolution of leukemia and lymphoma in some of the treated patients has dampened this novel therapy.

Vaccines

Vaccines are biologicals used as agents for disease prevention. Unlike their synthetic counterparts, biologically derived vaccines are made from live disease-causing agents or their products, conferring immunity against the disease each organism causes.

A successful vaccine stimulates an effective adaptive immune response directed at appropriate target antigens without causing disease. Edward Jenner achieved this through the use of the animal virus vaccinia to immunize against the related human smallpox virus. Because the two viruses are closely related, they can be recognized by the same immune cells but unlike the smallpox virus vaccinia does not cause disease in humans. Thus the vaccine is both antigenic and safe. Another crucial property of vaccinia virus is that as a natural pathogen it contains components that are recognized by the cells of the innate immune system and is thus able to induce the production of cytokines and activation of dendritic cells,

which are required to launch an effective adaptive immune response: that is, it is immunogenic.

Introduction of an antigen into the bloodstream leads to activation of the lymphocytes involved in active immunity. Special cells called antigen-presenting cells (APC) process the pathogen and present pieces of it to T cells, which are primarily involved in cell-mediated immunity, in order to initiate T cell activation. B cells, on the other hand, can interact directly with antigens in the bloodstream via surface molecules called antibodies that are specifically tailored to recognize particular nonself molecules. Once this occurs, a T cell activates the B cell, causing it to produce millions of copies of the antibody that binds the antigen; this is known as the humoral immune response. Certain offspring of dividing B and T cells will become a special cellular class known as memory cells, which can then induce a faster and fiercer immune response the next time that particular pathogen is encountered.

Clinical Uses (Including Side Effects)

Blood and Blood Products

Transfusion Therapy

Blood and blood products are used in transfusion medicine to replenish the depletion of any formed element of blood in order to optimally maintain physiological functions. There is no substitute for human blood used in life-saving transfusions employed in clinical practice. The World Health Organization (WHO) estimates that 81 million pints (500 ml units) of blood were collected worldwide in 2005. Because an average receives 3.8 units of blood, one can estimate that at least 21 million patients in the world are transfused each year; however, less blood is available for transfusion in developing countries, hence annually 25 million patients are estimated worldwide to receive blood transfusions. Of the 81 million donations, only 38% were collected in developing countries where 82% of the world population resides. It is also estimated that developing countries have access to only 20% of the world's safe blood, tested adequately for transfusion-transmitted infections (TTI), viz., hepatitis B and C (HBV, HCV) and HIV. Blood donated by healthy volunteers in North America, Europe, and Japan is screened by molecular amplification using polymerase chain reaction (PCR) or transcription-mediated amplification (TMA) of the TTI agents' genomes. Safer blood supply is a compelling need worldwide but yet unmet and hence a topic of considerable debate and current research. The frequency of TTI in developed nations is less than one in a million units of blood.

Blood Component Therapy

Each unit of blood (450 ml blood + 75 ml preservative anticoagulant solution) donated for transfusion can be divided into packed red cells used for adequate tissue

oxygenation, platelet concentrates for hemostasis, and FFP for maintaining oncotic pressure and providing coagulation factors. Whole blood can be donated five times a year by healthy volunteers. Plateletpheresis (selective removal of platelets) can be performed on blood donors at least twice a week to provide large dose of single donor platelets for patients with thrombocytopenia requiring repeated infusion. Plasmapheresis (selective removal of plasma) can be performed on healthy adults once or twice a week. This procedure permits plasma collection in large amounts for fractionation of albumin, globulins, and cryoprecipitated or purified factor VIII for maintenance therapy in hemophilia. The treatment of hemophilia with purified factor VIII principally drives procurement of plasma by plasmapheresis, supplemented with unused FFP. While human albumin (5% solution) is used as a blood volume expander, gamma globulin (5–16% solution) is most commonly used for passive prophylaxis against hepatitis A and treatment of various hematological and immunological disorders [1]. Pathogen-specific hyperimmune globulins are derived by plasmapheresis of immunized donors or convalescent patients, e.g., HBIG or Zoster immune globulins.

Adverse Effect of Transfusion

Rare hemolytic transfusion reactions are often due to human errors, which result in transfusion of blood to wrong patients. Many hemolytic transfusion reactions culminate in renal shut down with acute tubular necrosis; this is totally reversible with hemodialysis as needed until the renal function is spontaneously restored in less than 2 weeks. Thus, acute tubular necrosis in hemolytic transfusion reaction is totally reversible. Nonhemolytic transfusion reactions in contrast are commonly encountered in 1–2% of transfusion recipients and characterized by fever, urticaria, graft versus host reaction, transfusion-related acute lung injury (TRALI), or rare anaphylactic reactions. These nonhemolytic reactions are due to incompatibility with the formed elements of blood other than red cells. The immune and nonimmune mechanisms underlying nonhemolytic transfusion reactions are often difficult to define and are empirically managed in clinical practice [1].

Diagnostics

Because the sheer magnitude of the tests performed in laboratory diagnosis is so great, e.g., over 3,600 tests in the alphabetical index of the laboratory tests offered by UCLA Medical Center [4], a single example will be illuminated to demonstrate a particular use of biologically derived diagnostics in home pregnancy test.

Pregnancy Test: An Illustrative Example

The classic “pee on a stick” variety of pregnancy test remains the most common among the tests for human

chorionic gonatotropin (hCG) hormone, which is usually found in the blood and urine within a week of embryonic implantation into the uterus. This test uses a series of three antibody sets: two from mice and one from goats. Prior to manufacturing the tests themselves, mice are injected with hCG, a foreign antigen, inducing their immune system to elicit antibodies against hCG that are then harvested and purified. Similarly, goats are immunized with mouse immune globulins to elicit antimouse IgG antibodies.

When someone takes a pregnancy test, they first urinate on the end of the stick. Here, mobile mouse anti-hCG antibodies will travel up the stick with the urine, some of which will bind to hCG if it is present. Once the urine reaches the test region, it will encounter a second set of mouse anti-hCG molecules, this time bound to the test strip (stationary). Mouse antibodies that have bound hCG will be caught by the stationary antibodies, creating a literal hCG “sandwich.” Mobile mouse antibodies that did not encounter hCG (there are always more antibodies than hCG molecules) travel with the urine to the control region, where they are captured by goat anti-mouse antibodies. In both the test and control regions, the mobile mouse antibodies induce a color change in an indicator that has been inlaid in a straight line – hence the characteristic two-line system.

In general, diagnostic tests that look for a particular protein of interest use biologically derived antibodies, usually from mice. However, proteins, DNA, RNA, and other biologicals may be derived from a variety of organisms like bacteria, yeast, plants, and other mammals for use as diagnostics.

Therapeutics

- **Cytokines** and biological response modifiers represent a broad class of therapeutic agents that modify the hosts’ response to cancer or cancer therapies. The enormous body information about their clinical uses and their side effects is beyond the scope of this essay that can only give illustrative examples. For an up-to-date information the reader can resort to reference [5]. As many as 33 different interleukins are known and the list continues to grow; IL-2 used in the treatment of kidney cancer is one example. Interferon alpha is used for chronic myelogenous leukaemia, hairy cell leukaemia and Kaposi’s sarcoma. Interferons are also used in the treatment of chronic infections such as viral hepatitis. Tumor necrosis factor (alpha), G/GM/M-CSF, and several other cellular factors are used in treatment of various cancers. Many of these cytokines produce serious side effects that limit their use.
- The list of MoAb or fusion proteins used in treatment of every type of cancer is continually growing as research identifies more cancer-associated antigens. MoAb targeting a tumor-specific antigen is used

in two forms: (i) Naked, without any drug or radioactive material attached, e.g., Panitumumab for colorectal cancers or Trastuzumab for breast cancer; (ii) Conjugated with a chemotherapy drug, radioactive particle, or a toxin that poisons the targeted cells, e.g., Gemtuzumab ozogamicin for acute myeloid leukemia or tositumomab for non-Hodgkins lymphoma. Apart from being used to treat cancer, radiolabelled antibodies can also be used with special cameras to detect metastasis or spread of tumor to other organs. MoAb is given intravenously. Compared with chemotherapy, the side effects of naked MoAb are usually very mild, which include fever, chills, headache, nausea, vomiting, diarrhea, rash, and lowered blood pressure.

- Cellular therapies include treatment with natural or manipulated cells of human origin such as islet cell transplantation for the treatment of juvenile diabetes. Regenerative medicine as a new discipline has emerged from our progressive understanding of stem cell biology and our capacity to procure, grow, and differentiate embryonic stem cells. We have to await full development and differentiation of this field into specific therapies with favorable long-term outcomes.
- Dust, pollens, grass, weeds, mold spores, and danders are common allergens (see: allergy) in our environment. Food allergies to sea foods, shellfish, tree nuts, eggs, milk, wheat, soy, and their derivatives are being systematically identified and characterized for skin tests to determine potential causes of hypersensitivity or asthma. A radioallergosorbent test (RAST) uses numerous allergens (purified or semipurified) as immunosorbent.

A full discussion of each of the above categories of biological medicines and related agents covered by each of the categories is beyond the scope of this brief essay. However, ImmunoFacts is the most current and comprehensive collection of immunologic and vaccine information and is continuously updated for clinical application, including side effects [5].

Vaccines

The four traditional vaccine categories are inactivated, live attenuated, toxoid, and subunit (Fig. 4). Inactivated vaccines are created from live, virulent organisms that are killed by heat or chemicals and introduced into a host’s bloodstream to elicit an immune response against particular agents. Common examples include flu, bubonic plague, cholera, and hepatitis A. Although inactivation renders the biological harmless and diminishes the risk for infection, inactivated vaccines often produce short-lived or incomplete immunity, requiring the need for booster shots. On the other hand, live attenuated vaccines result in a more durable

Approved human vaccines

immune response because the disease agent, in a sense, is only slightly virulent. Rather than an inactivated form of the organism, attenuated vaccines employ the use of the same organism grown in conditions that inhibit its ability to cause infection, usually by limiting its ability to reproduce. Common examples include measles, mumps, rubella, and yellow fever.

While the two examples discussed so far are made from whole organisms, the following two are made from their parts. A toxoid vaccine is useful when the disease-causing agent is a toxic by-product of the organism rather than the organism itself and is made by inactivating the toxin(s) and introducing them into the blood stream. The most common examples are tetanus and diphtheria. Subunit vaccines consist of other parts of the organism that may not necessarily be pathogenic (disease-causing) but are immunogenic. Usually these consist of an organism's surface proteins, such as those of HBV (manufactured in yeast) and the major capsid protein of HPV. Often these proteins are made through recombinant DNA technology that use yeast cells as protein factories and spontaneously assemble into virus-like particles (VLP).

The science of biologically derived vaccines continues to evolve. Three experimental vaccine types are noteworthy: conjugate, recombinant, and DNA vaccines. Conjugate vaccines train the immune system to react against polysaccharides in bacterial cell walls by coupling them with harmful toxins, a strategy used to confer immunity against *haemophilus influenzae* type B. Recombinant vaccines combine the physiology of one organism with the DNA of another in order to build immunity against organisms with complex infection processes. Finally, DNA vaccines have risen as the most revolutionary new vaccine for their ability to be easily manufactured and stored. Rather than challenging the immune system with antigenic proteins or polysaccharides, DNA vaccines are integrated into the host genome, where they are transcribed and translated into functional proteins. Immunity is then launched against the proteins produced within the body; in its simplicity, this embodies the same concept as production of a normal subunit vaccine but without yeast as the middleman. However, DNA vaccines are still in experimental stages with promise to be fulfilled.

Adverse effects of vaccine administration are generally mild such as those listed for MoAb and serious side effects are exceedingly uncommon. These are considerations used by regulators in approving or licensing vaccines for general use. Opposition to vaccination has existed for some time and for various reasons. Some have argued that the side effects of vaccines are not understood well enough to weigh the benefits of immunization against its costs. Some studies have suggested a link between certain vaccines and autism because of a preservative called thimerosal, which contains ethylmercury. However, thimerosal is rarely used anymore and other studies have shown little evidence for a link between vaccination and autism. In addition, health officials argue that calculating the risk/benefit ratio should be based on benefit to the community rather than to the individual.

Biopterin

(6R)-5,6,7,8-tetrahydro-L-biopterin

Biotin

E. BACK¹, H. K. BIESALSKI²

¹Novartis Pharma GmbH, Nuremberg, Germany

²University of Hohenheim, Institute of Biological Chemistry and Nutrition, Stuttgart, Germany

Synonyms

Hexahydro-2-oxo-1H-thieno [3,4-d] imidazol-4-valeric acid

Definition

Biotin can be synthesized by the human colon flora. The question to which extent this production contributes to covering the host-organism's requirements is, however, subject to discussion. In most foods of animal origin as well as in cereals, biotin prevails in the protein (= enzyme)-bound form as ε-N-biotinyl-L-lysine (= biocytin). Brewer's yeast, liver, soya beans, and peanuts number among the biotin rich foods [1].

The chemical structure of biotin (hexahydro-2-oxo-1H-thieno [3,4-d] imidazol-4-valeric acid) is shown in Fig. 1. Of the eight stereoisomers, only d-(+)-biotin occurs naturally and is biologically active.

Mechanism of Action

Biotin is involved in carboxylation and decarboxylation reactions. It is covalently bound to its enzyme. In the carboxylase reaction, CO₂ is first attached to biotin at the ureido nitrogen, opposite the side chain in an ATP-dependent reaction. The activated CO₂ is then transferred from carboxybiotin to the substrate. The four enzymes of the intermediary metabolism requiring biotin as a prosthetic group are pyruvate carboxylase (pyruvate ▶ oxaloacetate), propionyl-CoA-carboxylase (propionyl-CoA ▶ methylmalonyl-CoA), 3-methylcrotonyl-CoA-carboxylase (metabolism of leucine), and acetyl-CoA-carboxylase (acetyl-CoA ▶ malonyl-CoA) [1].

Clinical Use (Including Side Effects)

Alimentary biotin deficiency is rare. It may, however, occur in patients on long-term parenteral nutrition lacking biotin or in persons who frequently consume raw egg white. Raw egg white contains a biotin-binding glycoprotein, called avidin, which renders biotin biologically unavailable. Pharmacological doses of the vitamin (1–10 mg/d) are then used to treat deficiency symptoms. There are no reports of toxicity for daily oral doses up to 200 mg and daily intravenous doses of up to 20 mg [2].

Biotin. Figure 1 Structure of biotin.

BiP

Molecular chaperone (relative molecular mass 78 K) found in the lumen of the ER. BiP is related to the Hsp70 family of heat-shock proteins and was originally described as immunoglobulin heavy chain binding protein.

► Protein Trafficking and Quality Control

Bipolar Disorder

Bipolar disorder or manic depressive illness, refers to a severe mental illness characterized by recurring episodes of mania and depression.

► Antidepressant Drugs
► Galanin Receptors

Bisphosphonates

Pyrophosphate analogues that accumulate in bone and inhibit osteoclast activity. Presently, nitrogen-containing bisphosphonates such as Alendronate, Risedronate, Ibandronate or Zoledronate are being distinguished from non-aminobisphosphonates such as Clodronate or Etidronate. Bisphosphonates are among first line treatments for benign and malignant bone diseases.

► Bone Metabolism

Bistability

Technical term for properties of electrical or neural circuits (flip-flop switch) to rest in two distinct states while avoiding intermediate states (e.g., behavioral state sleep–wake transitions).

► Orexins

Bisubstrate Analogs

Bisubstrate analogs are compounds that contain features of both substrates for an enzymatic reaction in which two substrates are used.

► Lipid Modifications

BK_{Ca} Channel

Big-conductance Ca²⁺ sensitive K⁺ (BK_{Ca}) channels are activated by calcium surge and membrane depolarization. BK_{Ca} channels are specifically blocked by iberiotoxin and less selectively by charybdotoxin. BK_{Ca} channels are composed of pore-forming α and auxiliary β subunits. Both BK_{Ca, α} and BK_{Ca, β} subunits as well as their efficient coupling in the heteromultimeric formation of BK_{Ca} channel complexes are important for the function of BK_{Ca} channels.

► K⁺ Channels
► Smooth Muscle Tone Regulation
► Carbon Monoxide

Blastocyst

The blastocyst is an early embryonic stage in mammalian development. Murine blastocysts can be harvested at day 3.5 p.c. Their inner cell mass contains embryonic stem cells. Multiple murine embryonic stem cell lines have been established. Embryonic stem cells carrying genetically engineered mutations are injected into blastocysts, which are subsequently implanted into pseudopregnant foster mothers.

► Transgenic Animal Models

β-Blockers

β-blockers are antagonists of β-adrenergic receptors.

► β-Adrenergic System

Blood–brain Barrier

The blood–brain barrier (BBB) forms a physiological barrier between the central nervous system and the blood circulation. It consists of glial cells and a special species of endothelial cells, which form tight junctions between each other; thereby inhibiting paracellular transport. In addition, the endothelial cells of the BBB express a variety of ABC-transporters to protect the brain tissue against toxic metabolites and xenobiotics. The BBB is permeable to water, glucose, sodium chloride and non-ionised lipid-soluble molecules but large molecules such as peptides as well as many polar substances do not readily permeate the barrier.

Blood Pressure Control

REINHOLD KREUTZ

Institut für Klinische Pharmakologie, Freie Universität Berlin, Berlin, Germany

Synonyms

Physiology of blood pressure; Control of hypertension

Definition

The blood pressure represents the tension or pressure of the blood within the arteries that is exerted against the arterial wall in vivo. Blood pressure is a quantitative trait that is highly variable. In population studies, blood pressure has a normal distribution that is slightly skewed to the right. The regulation of blood pressure within the intravascular system is a complex interaction of a number of systems and mechanisms. A chronic elevation of blood pressure or hypertension is a substantial health problem affecting 25% of the adult population in industrialized societies. Despite important advances in our understanding of the pathophysiology of hypertension and the availability of effective treatment strategies it still remains a major modifiable risk factor for cardiovascular and renal disease. There is no specific level of blood pressure where clinical complications start to occur; thus the definition of hypertension is arbitrary but needed in clinical practice for patient assessment and treatment.

The relevance of clinical conditions with chronic low blood pressure or hypotension has been questioned, with the exception of a few rare clinical syndromes. Temporary increases or decreases of blood pressure are often seen in clinical medicine in the context of acute illnesses or interventions.

Basic Mechanisms

The circulation is divided into several compartments: the high-pressure arterial circuit, which contains 13% of the blood volume, the capillary bed containing 7% of the blood volume, and the low-pressure venous bed, which contains 64% of the blood volume. The pulmonary circulation contains 9% and the heart 7% of the blood volume. Although the venous system stores and propels large volumes of blood and regulates cardiac output by venous return to the heart, in considering blood pressure control attention is focused on the high-pressure arteries. The basic function of the circulation is to provide nutrients to peripheral tissues. Blood vessels in local tissue beds regulate blood flow in relation to local needs. Blood flow (Q) is defined by Ohm's law and varies directly with the change in pressure (P) across a blood vessel and

inversely with the resistance R ($Q = P/R$). It can be seen that pressure varies directly with blood flow and resistance ($P = QR$). Blood pressure is produced by the contraction of the left ventricle (producing blood flow) and by the resistance of the arteries and arterioles. Systolic pressure, or maximum blood pressure, occurs during left ventricular systole. Diastolic pressure, or minimum blood pressure, occurs during ventricular diastole. The difference between systolic and diastolic pressure is the pulse pressure (► [systolic and diastolic blood pressure and pulse pressure](#)).

Although blood pressure control follows Ohm's law and seems to be simple, it underlies a complex circuit of interrelated systems. Hence, numerous physiologic systems that have pleiotropic effects and interact in complex fashion have been found to modulate blood pressure. Because of their number and complexity it is beyond the scope of the current account to cover all mechanisms and feedback circuits involved in blood pressure control. Rather, an overview of the clinically most relevant ones is presented. These systems include the heart, the blood vessels, the extracellular volume, the kidneys, the nervous system, a variety of humoral factors, and molecular events at the cellular level. They are intertwined to maintain adequate tissue perfusion and nutrition. Normal blood pressure control can be related to cardiac output and the total peripheral resistance. The stroke volume and the heart rate determine cardiac output. Each cycle of cardiac contraction propels a bolus of about 70 ml blood into the systemic arterial system. As one example of the interaction of these multiple systems, the stroke volume is dependent in part on intravascular volume regulated by the kidneys as well as on myocardial contractility. The latter is, in turn, a complex function involving sympathetic and parasympathetic control of heart rate; intrinsic activity of the cardiac conduction system; complex membrane transport and cellular events requiring influx of calcium, which lead to myocardial fibre shortening and relaxation; and affects the humoral substances (e.g., catecholamines) in stimulation heart rate and myocardial fibre tension.

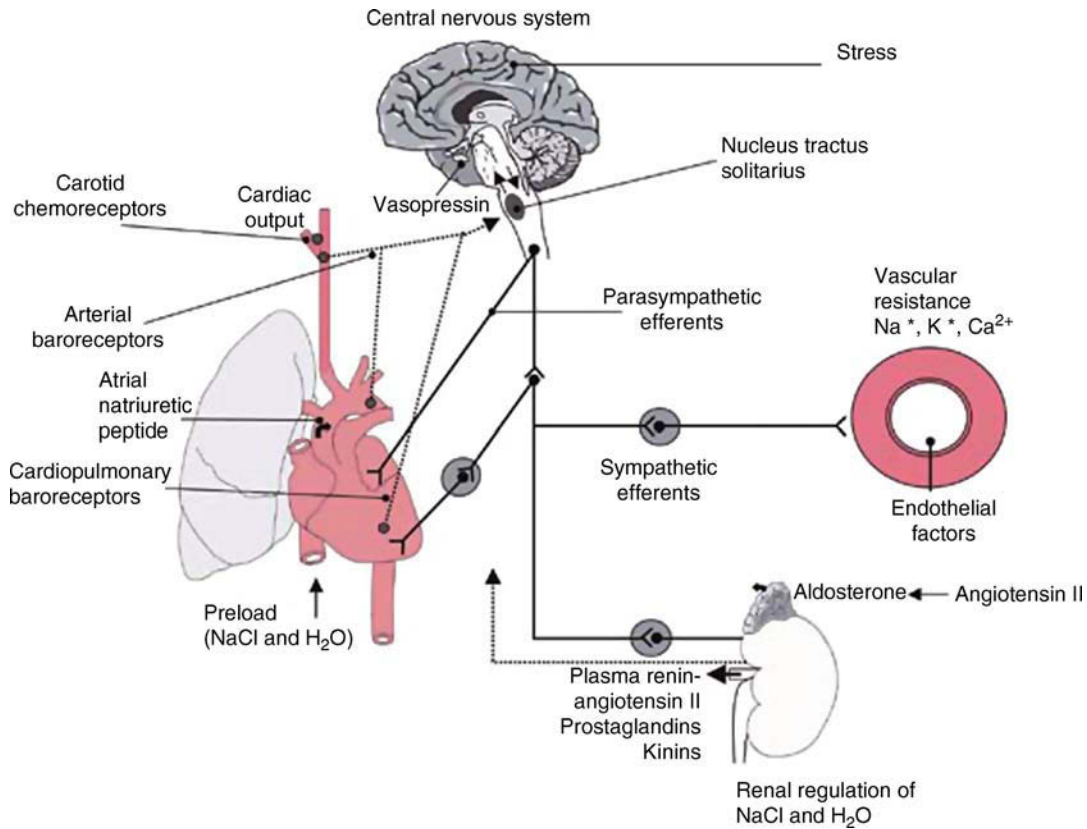

The regulation of the total peripheral resistance also involves the complex interactions of several mechanisms. These include baroreflexes and sympathetic nervous system activity; response to neurohumoral substances and endothelial factors; myogenic adjustments at the cellular level, some mediated by ion channels and events at the cellular membrane; and intercellular events mediated by receptors and mechanisms for signal transduction. As examples of some of these mechanisms, there are two major neural reflex arcs ([Fig. 1](#)). Baroreflexes are derived from high-pressure baroreceptors in the aortic arch and carotid sinus and low-pressure cardiopulmonary baroreceptors in ventricles and atria. These receptors respond to stretch (high pressure) or

filling pressures (low pressure) and send tonic inhibitory signals to the brainstem (nucleus tractus solitarius). If blood pressure increases and tonic inhibition increases, inhibition of sympathetic efferent outflow occurs and decreases vascular resistance and heart rate. If blood pressure decreases, however, less tonic inhibition ensues from the baroreflexes and both heart rate and peripheral vascular resistance increase, thereby increasing blood pressure. In addition, the neural control of renal function produces alterations in renal blood flow; glomerular filtration rate (GFR); excretion of sodium, other ions, and water; and release of renin and other vasoactive substances. These, in turn, have effects on the regulation of intravascular volume, vascular resistance and blood pressure. Activation of carotid chemoreceptors is also transmitted to the vasomotor centre and responds not only to arterial pressure but also to oxygen tension and carbon dioxide tension (in opposite directions). A drop in blood pressure, a drop in oxygen tension, or a rise in dioxide tension results in increased sympathetic outflow to the adrenal medulla, heart, and resistance vessels.

Additional cellular events linked to the activity of blood pressure regulating substances involve membrane sodium transport mechanisms; Na^+/K^+ ATPase; Na^+/Li^+ countertransport; Na^+-H^+ exchange; $\text{Na}^+-\text{Ca}^{2+}$ exchange; Na^+-K^+ 2Cl transport; passive Na^+ transport; potassium channels; cell volume and intracellular pH changes; and calcium channels.

Numerous vasoactive substances have major effects on blood vessels, the heart, the kidneys, and the central nervous system (CNS) and often serve to counterbalance one another. As examples of physiologic actions, norepinephrine (noradrenaline), via α -adrenergic mechanisms, is a potent vasoconstrictor, while epinephrine (adrenaline), via α - and β -adrenoceptors, increases primarily heart rate, stroke volume, systolic blood pressure and pulse pressure. The ► [renin-angiotensin aldosterone system](#) generates angiotensin II (Ang II). Ang II, in turn, constricts vascular smooth muscle, stimulates aldosterone secretion, potentiates sympathetic nervous system activity, leads to salt and water reabsorption in the proximal tubule, stimulates prostaglandin, nitric oxide, and endothelin release, increases thirst, and is a growth factor. Aldosterone activates the epithelial sodium channel (ENaC) in the cortical collecting duct in the kidney, leading to sodium reabsorption and potassium excretion. Prostaglandin E and prostacyclin act to counterbalance vasoconstriction by Ang II and norepinephrine.

Vasopressin (antidiuretic hormone [ADH]) secretion increases in response to decreased blood volume and/or reductions in effective blood volume via a decrease in inhibitory tone from both low-pressure and high-pressure baroreceptors to the hypothalamus. The neuronal pathways that mediate hemodynamic regulation of

Blood Pressure Control. Figure 1 Basic mechanisms involved blood pressure control. The most important organs involved in blood pressure control are shown (for explanations see text). In these organs a variety of different cell types and molecular events are related to blood pressure control. Physiological effects are initiated by a wide spectrum of vasoactive substances: (a) catecholamines such as norepinephrine and epinephrine bind to different adrenergic receptors (α_1 , α_2 , β_1 , β_2) causing protein phosphorylation and increased intracellular calcium via G-protein-coupled receptors linked to ion channels or second messengers (cyclic nucleotides, phosphoinositide hydrolysis). (b) Ang II as the effector peptide of the RAS binds to angiotensin (AT_1 , AT_2 and others)-receptors causing increased intracellular calcium and protein phosphorylation via second messenger, phosphoinositide hydrolysis, and activated protein kinases, and aldosterone secretion. (c) Endothelial derived factors such as nitric oxide (NO) increase levels of cGMP and activation of protein kinases, while endothelins (most importantly endothelin-1 [ET-1]) activate G-proteins, phospholipase C and L-type calcium channels. (d) The effects of atrial natriuretic peptide (ANP) and of brain and C-type natriuretic peptides are mediated via cGMP upon stimulation of three different receptors.

vasopressin release are completely different from those involved in osmoregulation and unlike the latter, small decreases in blood pressure or blood volume have little effect on vasopressin secretion. A rise in blood pressure causes a decrease in secretion of vasopressin related to increased baroreceptor activity, which inhibits hypothalamic vasopressin-releasing hormones. Vasopressin works by causing water conservation at the distal collecting duct of nephron. This alone, however, is a relatively inefficient mechanism of increasing intravascular volume because conserved water is distributed among total body water and only a small portion is intravascular. In addition, vasopressin is a potent vasoconstrictor and the greater vasopressin secretion observed in response to more severe hypovolemia or hypotension serves as a mechanism to stave off cardiovascular collapse

during periods of large reductions of blood pressure or blood volume. Two important endothelial derived factors have opposite effects on the blood vessels: nitric oxide is a vasodilator whereas the endothelins, particularly endothelin-1, are vasoconstrictors. The kallikrein-kinin system produces vasodilator kinins, which in turn may stimulate prostaglandins and nitric oxide. Natriuretic peptides induce vasodilation, induce natriuresis, and inhibit other vasoconstrictors (renin-angiotensin, sympathetic nervous system and endothelin).

When the temporal sequence of adjustments of blood pressure is analysed it seems, that CNS mechanisms (e.g., baroreflexes) will provide regulation of the circulation within seconds to minutes. Other mechanisms, such as the renin-angiotensin-aldosterone system and fluid shifts, occur over minutes to hours. Only the

kidneys seem to have the ability for long-term adjustment in blood pressure, predominantly through regulation of extracellular volume. This theoretical concept has recently been – although indirectly – confirmed by genetic approaches applied to the analysis of rare familial syndromes of high blood pressure, i.e., hypertension, or low blood pressure, i.e., hypotension. In those studies carried out in families with monogenetic forms of the disease several molecular pathways have been successfully delineated. All defects identified so far raise or lower blood pressure through a common pathway by increasing or decreasing salt and water reabsorption by the nephron. Thus, these studies point to the kidney as a (the) pivotal organ for chronic (genetic) determination of blood pressure.

Pharmacological Intervention

The morbid consequences of high blood pressure have been documented by epidemiologic studies, which demonstrate a strong positive and continuous correlation between blood pressure and the risk of cardiovascular disease (stroke, myocardial infarction, heart failure), renal disease and mortality. This correlation is more robust with systolic than with diastolic blood pressure. While hypertension was once thought to be “essential” for perfusion of tissues through sclerotic and narrowed blood vessels and to maintain a normal sodium balance, the pathologic nature of elevated blood pressure has become clear. Essential, primary, or idiopathic hypertension is defined as high blood pressure in which causes such as renovascular disease, renal failure, pheochromocytoma, aldosteronism, or other causes of secondary hypertension or monogenic (mendelian) forms are not present. Essential hypertension accounts for 95% of all cases of hypertension. This condition is a heterogeneous disorder, with different patients having different causal factors that lead to high blood pressure. There are no established clinical or laboratory tests to identify the factors that are responsible for the blood pressure elevation in an

individual patient. Consequently, pharmacologic treatment of essential hypertension is largely empiric. Clinical treatment algorithms try to account for comorbidities and expected or observed side effects of drugs in individual patients. Pharmacologic treatment should always be implemented “on top” of nonpharmacologic interventions such as control of body weight, alcohol intake, salt intake and modifications of lifestyle as necessary in the individual patient. Randomised trial of pharmacologic treatment of hypertension have documented that blood pressure reduction lowers morbidity and mortality, with dramatic reduction in stroke and smaller reductions in cardiac and renal disease (for details see ►antihypertensive drugs).

As a result of such studies hypertension has been operationally defined as the blood pressure level above which therapeutic intervention has clinical benefit. As increasingly aggressive intervention has continued to demonstrate benefits, this level has gradually reduced over time and is commonly defined as systolic blood pressure ≥ 140 mmHg and/or diastolic blood pressure ≥ 90 mmHg (Table 1). Isolated systolic hypertension is defined as systolic blood pressure ≥ 140 mmHg and diastolic blood pressure < 90 mmHg.

Moreover, in patients with certain comorbidities, such as diabetes mellitus, left ventricular dysfunction or chronic nephropathy, lower blood pressures levels in the range of 130/80 mmHg (125/75 mmHg for nephropathies with overt proteinuria > 1 g per day) are currently established as target blood pressure. Individuals with high normal blood pressure tend to maintain pressure that are above average for the general population and are at greater risk for development of definite hypertension and cardiovascular events than the general population. These observations leave open the question of whether there is an “optimal” blood pressure in the general population, and whether small reductions in blood pressure across the entire population, rather than larger targeted reductions, would have benefit.

Blood Pressure Control. Table 1 Definitions and classifications of blood pressure levels

Category	Systolic [mm Hg]		Diastolic [mm Hg]	Stroke mortality relative risk
Optimal	< 120	And	< 80	1.00
Normal	< 130	And	< 85	1.73
High normal	130–139	Or	85–90	2.14
Hypertension				
Stage 1 (mild)	140–149	Or	90–99	3.58
Subgroup: borderline	140–159	Or	90–94	
Stage 2 (moderate)	160–179	Or	100–109	6.90
Stage 3 (severe)	≥ 180	Or	≥ 110	9.66
Isolated systolic hypertension	≥ 140	And	< 90	
Subgroup: borderline	140–149	And	< 90	

The higher category applies, if systolic and diastolic blood pressure values of a patient fall into different categories.

Nonetheless, in patients with established hypertension according to the above criteria, antihypertensive drug treatment is one of the most important means to prevent or reduce overall cardiovascular and renal disease. There is hope that the information gained from the Human Genome Project and from ongoing research aimed at dissecting the genetic basis of hypertension in both human populations and animal models will foster the development of more effective and targeted, i.e., pharmacogenetic, treatments based on the genotype of the individual patient.

Bombesin-like Peptides

Bombesin-like peptides are a group of biologically active peptides, which are structurally related, including bombesin (a tetradecapeptide originally derived from amphibians), gastrin-releasing peptide (GRP), neuromedin B (NMB), and GRP_{18–27} (previously named “neuromedin C”). Bombesin and bombesin-like peptides have a wide range of functions. They have been shown to promote cell growth, including that of carcinoma cell lines, they are involved in smooth muscle contraction and in the regulation of the body temperature. Bombesin/bombesin-like peptides also mediate endocrine responses, such as the release of gastrin, cholecystokinin, and pancreatic polypeptide. This group of peptides has been involved in the regulation of various behavioral responses, the regulation of pain and the modulation of feeding behavior. Bombesin/bombesin-like peptides exert their effects through a group of G-protein coupled receptors, which signal through G_{q/11} (BB1, BB2, BB3). While BB1 responds mainly to NMB and bombesin, BB2 responds to GRP and bombesin.

Definition

Bone metabolism comprises the processes of bone formation and bone resorption, the key actions by which skeletal mass, structure and quality are accrued and maintained throughout life. In the mature skeleton, anabolic and catabolic actions are mostly balanced due to the tight regulation of the activity of bone forming (►osteoblast) and bone resorbing (►osteoclast) cells through circulating ►osteotropic hormones and locally active cytokines.

Basic Mechanisms

Biochemical Composition of Bone

Bone is composed of approximately 70% mineral (mainly hydroxyapatite $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$ crystals) and 30% organic matter (i.e. cells, collagen and non-collagenous proteins). Most of the latter is synthesised by local osteoblasts. Ninety per cent of the organic extracellular matrix of bone consists of type I collagen, which assembles into fibrils and is then covalently cross-linked to generate tensile strength. Of the non-collagenous proteins, osteocalcin, bone sialoprotein and osteopontin are the most abundant. Most of the non-collagenous proteins play important roles in the organisation of the extracellular matrix (cell–cell and cell–matrix attachment, cell migration, growth, development, fibril formation). Besides these components, several specific enzymes and small peptides are an integral part of the organic matrix and play an important role in skeletal metabolism (see below). The calcium–collagen–cell composite ensures the two main functions of bone: providing a structural framework and a reservoir for mineral ions.

Bone Structure

Bone is a complex structure consisting of diverse cell types, extracellular matrix and mineral. Bone matrix is composed predominantly of extensively cross-linked collagen type I but also incorporates many other proteins including osteocalcin, osteopontin, proteoglycans and growth factors. The mineral phase is calcium phosphate in the form of hydroxyapatite. This mineral component provides mechanical strength and rigidity to the skeleton and is sufficiently labile to be easily removed, enabling it to act as an ion store for supporting calcium homeostasis.

Most bones of the human skeleton are composed of two structurally distinct types of tissue: compact (dense) and trabecular (cancellous, spongy) bone. Both types contain the same elements: cells (►osteocytes) embedded in a mineralised matrix and connected by small canals (“canaliculi”). In compact bone, which makes up 85% of the skeleton, these components form elongated cylinders of concentric lamellae surrounding a central blood vessel (called osteon or Haversian system). Cancellous bone, in contrast, forms thin,

interconnected spicules. Compact bone constitutes the outer parts of many bones (“compacta”), shows a high degree of mineralisation, a comparatively low number of cells, and provides the framework for the interior cancellous parts of bone. The latter consists of a sponge-like network of small beams (trabeculae) with a larger number of cells (osteoblasts and osteoclasts) distributed over a huge surface.

Bone is under continual stress and strain as it supports the body and provides the rigid structure required for weight bearing and movement. As a result, over time, it develops fatigue damage in the form of cracks and tiny fractures, which must be repaired to maintain skeletal integrity. Bone also must be reshaped during growth and fracture healing. To shape and repair bone, and to release calcium in times of dietary calcium deficiency, the body must be able to remove, replace and increase amounts of bone as required. This ability is achieved by the coupled processes of bone formation and bone resorption, which are continuous throughout life, resulting in renewal of the entire skeleton every 7–10 years. The most important cells involved in these processes are the bone-resorbing osteoclasts, the bone-forming osteoblasts and the osteoblast-related bone lining cells and osteocytes.

Osteoclasts and Bone Resorption

Bone is resorbed by highly specialised cells called osteoclasts. Osteoclasts are related to macrophages and develop from a common monocyte precursor. Osteoclasts remove bone by adhering to bone and forming a sealed cavity against the bone surface. Along this cavity, osteoclasts then develop a specialised membranous structure, the ‘ruffled border’, through which acid (H^+) and proteases are secreted to dissolve both the mineral and matrix components of bone, creating a resorption pit also known as Howship’s lacuna. The minerals and protein fragments released during this process are absorbed into the osteoclast by endocytosis, partly processed and later secreted from the distal side of the osteoclast, from where they eventually reach the circulation.

Osteoclast recruitment and activity are each highly regulated by cells of the osteoblast lineage. Osteocytes detect strain and microdamage in bone and signal the requirement for bone resorption and repair. Osteoblasts respond to a multitude of signals, including ►parathyroid hormone (PTH) and ►vitamin D, as well paracrine signals on a more local level. Osteoblasts integrate these signals and induce bone resorption by increasing their secretion of a cytokine known as receptor activator of nuclear factor kappa (RANK) ligand (RANKL), and by reducing expression of osteoprotegerin (OPG), a natural antagonist of RANKL. RANKL acts by binding to its receptor, RANK, on osteoclast precursors to induce these cells to differentiate into osteoclasts and

also acts on existing osteoclasts to increase their bone resorbing activity. When the requirement for bone resorption is completed, the osteoblasts increase their secretion of OPG, which binds to RANKL preventing its interaction with its receptor on osteoclasts resulting in the inactivation and death of osteoclasts (Fig. 1).

Bone Formation

Osteoblasts are the primary cells responsible for bone formation. They are derived from mesenchymal (stromal) cells that first differentiate into pre-osteoblasts and then into mature, bone matrix producing osteoblasts. Inactivated or “resting” osteoblasts become “lining cells” and thus a reservoir for bone forming cells to be activated at the next remodelling cycle. Osteoblasts trapped and embedded in the mineralised matrix are called osteocytes, and are important for many properties of living bone.

During bone formation, a series of sequential changes occur in cells in the osteoblast lineage, including osteoblast chemotaxis, proliferation and differentiation, which in turn is followed by formation of mineralised bone and cessation of osteoblast activity. The osteoblast changes are preceded by osteoclast apoptosis, which may be dependent on active TGF- β released from the resorbed bone. This is followed by chemotactic attraction of osteoblasts or their precursors to the sites of the resorption defect. Chemotactic attraction of osteoblast precursors is likely mediated by local factors produced during the resorption process.

Proliferation of osteoblast precursors is an important event at the remodeling site. This is also likely to be enhanced by local osteoblast growth factors released

during the resorption process. Likely candidates include members of the TGF- β superfamily, such as platelet derived growth factor (PDGF), insulin-like growth factors (IGF) and the fibroblast growth factors (FGFs). All of these substances are stored in the bone matrix.

The next sequential event during the formation phase is the differentiation of the osteoblast precursor into the mature cell. Several of the bone-derived growth factors can cause the appearance of markers of the differentiated osteoblast phenotype, including expression of alkaline phosphatase activity, Type I collagen and osteocalcin synthesis. Most prominent of these are bone morphogenetic protein 2 (BMP-2) and IGF-I. Recent investigations demonstrate that ‘Wnt’ signalling plays a critical role in controlling osteoblast differentiation. Wnts form a dual-receptor complex with frizzled and low-density-lipoprotein (LDL)-receptor like protein 5 (LRP5) on cell surfaces. The role of LRP5 in bone mineral density (BMD) determination was initially uncovered by genetic analyses that mapped the osteoporosis pseudoglioma (OPPG) syndrome and the high bone mass (HBM) syndrome to the human chromosome 11q12–13 locus where LRP5 was identified. Circulating hormones such as PTH and PTH-related peptide (PTHrP), 1,25-dihydroxyvitamin D₃ are also important stimulators of osteoblast differentiation.

The final phase of the formation process is cessation of osteoblast activity. The resorption lacunae are usually repaired completely. It is not known how this level of time regulation is achieved. One possibility is that factors produced during osteoblast differentiation decrease osteoblast activity. One such factor could be TGF- β since active TGF- β decreases differentiated function in osteoblasts.

Bone Metabolism. Figure 1 Mechanisms of osteoclast activation.

Bone Remodelling

Bone remodelling, which continues throughout adult life, is necessary for the maintenance of normal bone structure and requires that bone formation and resorption should be balanced. Bone remodelling occurs in focal or discrete packets known as bone multicellular unit (BMU). In this process, both bone formation and resorption occur at the same place so that there is no change in the shape of the bone. After a certain amount of bone is removed as a result of osteoclastic resorption and the osteoclasts have moved away from the site, a reversal phase takes place in which a cement line is laid down. Osteoblasts then synthesize matrix, which becomes mineralised. The BMU remodeling sequence normally takes about 3 months to produce a bone structure unit (Fig. 2).

The constant remodeling of bone is important in three ways: First, bone remodeling is needed to repair fatigue damage. Bone, like other structural materials that undergo repetitive cyclical loadings, are subject to fatigue. After a number of loading cycles, tiny cracks may form. If these tiny cracks are not fixed in a timely fashion, they will accumulate and eventually lead to structural failures. Bone remodeling will replace bone-containing cracks and prevent structural failure. Secondly, bone remodeling is needed to adapt bone material properties to the mechanical demands that are placed on bones. For instance, bone remodeling will help you obtain stronger bone with exercise. Finally, bone remodeling plays a critical role in regulating calcium homeostasis, which is critical for life. Bone is a major reservoir for calcium. When serum calcium levels

fall and there is no dietary calcium intake, calcium will be mobilised from bone by osteoclasts to meet the demand.

Hormonal Regulation of Calcium Homeostasis and Bone Remodelling

PTH is the most important regulator of bone remodeling and calcium homeostasis. PTH is an 84-amino acid polypeptide and is secreted by the parathyroid glands in response to reductions in blood levels of ionised calcium. The primary physiological effect of PTH is to increase serum calcium. To this aim, PTH acts on the kidney to decrease urine calcium, increase urine phosphate, and increase the conversion of 25-OH-vitamin D to 1,25-(OH)₂-vitamin D. PTH acts on bone acutely to increase bone resorption and thus release skeletal calcium into the circulation. However, due to the coupling of bone resorption and bone formation, the longer-term effect of increased PTH secretion is to increase both bone resorption and bone formation.

The steroid hormone 1,25-dihydroxyvitamin D₃ (calcitriol) slowly increases both intestinal calcium absorption and bone resorption, and is also stimulated through low calcium levels. In contrast, **calcitonin** rapidly inhibits osteoclast activity and thus decreases serum calcium levels. Calcitonin is secreted by the clear cells of the thyroid and inhibits osteoclast activity by increasing the intracellular cyclic AMP content via binding to a specific cell surface receptor, thus causing a contraction of the resorbing cell membrane. The biological relevance of calcitonin in human calcium homeostasis is not well established.

Bone Metabolism. Figure 2 The bone remodelling cycle.

Pharmacological Interventions

In the past decade, a number of novel and effective pharmacological strategies have been developed to modulate cell differentiation and/or activity in metabolic bone diseases such as osteoporosis or Paget's disease of bone, and an even greater number of potential drugs are being explored (Table 1). Agents that inhibit osteoclast formation and/or activity are usually classified as anti-resorptive or anti-catabolic drugs, while stimulators of osteoblast formation and/or activity are called "anabolic" agents. Some compounds, such as vitamin D, strontium ranelate or oestrogens seem to affect both processes.

Oestrogens reduce bone loss by inhibiting the generation of new osteoclasts, reducing the activation frequency and promoting apoptosis of mature osteoclasts via mechanisms not well understood. Some of the effects of oestrogen seem to be mediated via the modulation of growth factors and cytokines, while others are associated with binding to at least two different oestrogen receptors (ER α , ER β). Oestrogens have been shown to reduce the risk of osteoporotic fracture (and of colon cancer), but carry a (small) risk of breast cancer and cardiovascular events. Currently, their long-term use to prevent osteoporotic fractures is not being recommended.

The presence of different ERs is also, among other facts, the basis for the development of ►selective oestrogen receptor modulators (SERMs). While Tamoxifene, a triphenylethylene compound used in the treatment of breast cancer, has long been known to moderately inhibit bone loss, newer synthetic compounds (such as raloxifene) have been shown to reduce fracture risk in postmenopausal women. The mechanism of action is probably the same as the one suspected in oestrogens, i.e. the inhibition of cytokines causing osteoclast recruitment and differentiation. Oestrogens and SERMs are not potent enough to inhibit the grossly exaggerated osteoclast activity in malignant and Paget's disease of bone.

Due to its anti-resorptive effects, calcitonin has been widely used to treat a variety of metabolic bone diseases, including osteoporosis. However, the availability of more potent drugs has led to a decline in the clinical use of calcitonin.

Bisphosphonates (BP) are today the first line treatment of benign and malignant bone diseases. As pyrophosphate analogues (Fig. 3), BP accumulate in bone and are taken up by osteoclasts. Once in the cell, the nitrogen-containing BP (N-BP) such as Alendronate, Risedronate, Ibandronate and Zoledronate effectively inhibit osteoclast resorption and induce cell

Bone Metabolism. Table 1 Current and future agents to modulate bone metabolism

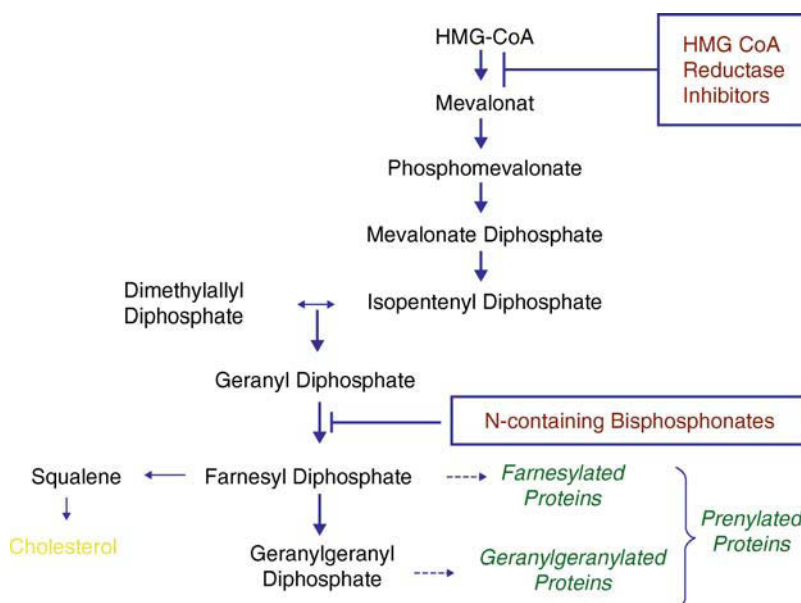

Inhibitors of osteoclast activity	Stimulators of osteoblast activity
<i>Currently in use</i>	
Bisphosphonates	Parathyroid hormone,
Selective oestrogen receptor modulators (SERMs, e.g. Raloxifene)	Calcitriol and analogues (limited use)
	Androgens (limited use)
Strontium salts (Sr Ranelate)	Fluorides (limited use)
Vitamin D	
Vitamin D metabolites and analogues	
Testosterone (limited use)	
Oestrogen (limited use)	
Calcitonin and synthetic analogues (limited use)	
<i>Under Investigation</i>	
Statins	PTH-rP and analogues
Calcium receptor modulators	High dose oestrogens
Osteoprotegerin	Statins
Denusomab (anti-RANKL mAb)	Growth factors (e.g. GH, IGFs, FGFs)
Anti-cytokines (e.g. IL-1, TNFs, IL-1 receptor constructs)	Prostaglandins and PG mimetics
	Endothelins and analogues
Proton pump inhibitors	Amylin and analogues
Nitric oxide modulators	Mechanoreceptor modulators, e.g. Glutamate
Enzyme inhibitors (e.g. metalloproteinases, cathepsin K)	Purinergic modulators
	Proteasome inhibitors
Adhesion molecule inhibitors	Intracellular signalling targets (eg SMADs)

apoptosis by inhibiting farnesyl diphosphate synthetase, an enzyme of the mevalonate pathway (Fig. 4). This in turn leads to a reduction in geranylgeranyl diphosphate and in the prenylation of GTP-binding proteins essential to osteoclast organisation and survival. Non-aminobisphosphonates such as Clodronate or Etidronate are incorporated into intracellular analogues of ATP and cause cell death.

Bisphosphonates have been shown to be highly effective in osteoporosis, cancer bone metastasis, multiple myeloma, and Paget's disease of bone. While generally very well tolerated, these drugs do have potential adverse effects. Recently, the association of long-term high dose bisphosphonate treatment with osteonecrosis of the jaw has been described. This is a potentially serious side effect seen mostly in patients with multiple myeloma or

Bone Metabolism. Figure 3 Chemical structure of pyrophosphate (a) and the bisphosphonates etidronate (b), clodronate (c), pamidronate (d), ibandronate (e), alendronate (f), risedronate (g), zoledronate (h).

Bone Metabolism. Figure 4 The mevalonate pathway. Interferences by statins and N-containing bisphosphonates are shown.

breast cancer bone metastases who receive intravenous bisphosphonate treatment. While the aetiology is uncertain, a strong association with dental pathology and interventions highlights the need for close attention to dental health in this patient group.

OPG has been shown to reduce bone turnover in postmenopausal women. More recently, Denusomab, an anti-RANKL mAb, has been tested for its ability to increase BMD and to reduce bone turnover. Results were promising and clinical phase III studies with fracture endpoints are presently under way.

Statins lower plasma cholesterol levels by inhibiting HMG-CoA reductase in the mevalonate pathway (Fig. 4). Some research has shown that certain statins (but not all) stimulate BMP-2 expression in osteoblasts, increase bone formation and mimic N-BP in that they inhibit bone resorption. The use of statins in osteoporosis is presently being investigated.

Fluorid ions stimulate bone formation by a direct mitogenic effect on osteoblasts mediated via protein kinase activation and other pathways. Further to these cellular effects, **fluorides** alter hydroxyapatite crystals in the bone matrix. In low doses, fluorides induce lamellar bone, while at higher doses abnormal woven bone with inferior quality is formed. The effect of fluorides on normal and abnormal (e.g. osteoporotic) bone therefore depends on the dose administered.

PTH has a dual effect on bone cells, depending on the temporal mode of administration: given intermittently, PTH stimulates osteoblast activity and leads to substantial increases in bone density. In contrast, when given (or secreted) continuously, PTH stimulates osteoclast-mediated bone resorption and suppresses osteoblast activity. Further to its direct effects on bone cells, PTH also enhances renal calcium re-absorption and phosphate clearance, as well as renal synthesis of 1,25-dihydroxyvitamin D. Both PTH and 1,25-dihydroxyvitamin D act synergistically on bone to increase serum calcium levels and are closely involved in the regulation of the calcium/phosphate balance. The anabolic effects of PTH on osteoblasts are probably both direct and indirect via growth factors such as IGF-1 and TGF β . The multiple signal transduction

pathways mediating the effects of PTH on bone cells include activation of cyclic AMP, intracellular protein phosphorylation, activation of phospholipase C, protein kinase C, tyrosine kinase c-src, and the generation of inositol 1,4,5-triphosphate (IP3). Teriparatide (1–34 PTH) has been shown to be highly effective in reducing the risk of osteoporotic fractures. The drug is given daily in a subcutaneous dose.

Oral calcium has long been used for the treatment of osteoporosis, both in the form of dietary and pharmacological supplements. In patients with calcium deficiency, oral calcium at doses of 1000–1500 mg/day corrects a negative calcium balance and suppresses PTH secretion. Sufficient calcium intake is most important for the accrual of peak bone mass in the young, but is also considered the basis of most anti-osteoporotic regimens. In the elderly, supplementation with oral calcium and vitamin D reduces the risk of hip fracture by about 30–40%.

Vitamin D and its metabolites are also widely used for the treatment of osteoporosis. Vitamin D₃, or cholecalciferol, is synthesised in the skin through UV radiation (sun exposure) and is the main source of vitamin D in humans. Vitamin D₂, or ergocalciferol, is derived from the diet and plays a minor role in human vitamin D supplies. Both forms are metabolised in the liver to 25-hydroxyvitamin D (calcidiol). The latter is the storage form of vitamin D and is believed to have little biologic activity. The active form of Vitamin D is generated in the kidney through the hydroxylation of C1, leading to 1,25-dihydroxyvitamin D (calcitriol). This last step is tightly controlled by a number of regulators such as PTH or serum phosphate levels. 1,25-Dihydroxyvitamin D is a potent steroid hormone with almost countless effects throughout the body. Most of these effects concern the differentiation of immature cells. As regards bone, 1,25-dihydroxyvitamin D has differentiation-inducing as well as activating effects on both osteoblasts and osteoclasts. It also increases the absorption of calcium from the gut. Data from excellent clinical trials show that the daily supplementation with 500–1200 mg of calcium +700–1000 IU of oral Vitamin D reduce the rate of bone loss in postmenopausal

Bone Formation	The building of new bone through osteoblasts. Bone formation, which is part of the bone remodelling process, includes the synthesis of organic matter (mostly collagen type I) and subsequent mineralisation.
Bone Modelling	The generation and shaping of new bone during the period of skeletal growth.
Bone Remodelling	The continuous and life-long process of renewing bone through the balanced processes of bone resorption and bone formation. Bone remodelling is stimulated by biomechanical and biochemical influences and tightly controlled through circulating osteotropic hormones and local mediators.
Bone Resorption	The removal of mineralised bone by osteoclasts. Bone resorption, which is part of the bone remodelling process, includes the release of mineral (mostly calcium and phosphate) and subsequent proteolysis of organic matter (mostly collagen).

women by 50% and reduce the number of hip and non-vertebral fractures in older and elderly men and women by 30–70%. Data on vertebral anti-fracture efficacy are sparse, but the available evidence indicates moderate efficacy at least in populations with subclinical vitamin D deficiency (= more than 80% of the European/US population aged >70 years). In contrast, “active” vitamin D-metabolites are still controversial in regard to their therapeutic use in postmenopausal and/or age-related (“senile”) osteoporosis.

Strontium salts have long been under investigation as anabolic agents for bone. In animals, strontium stimulates bone formation and substitutes for calcium in hydroxyapatite crystals. In humans, large controlled trials have shown increases in bone mass (after correction of BMD values for strontium content), a significant reduction in vertebral fractures, and a borderline reduction in non-vertebral fractures. The mechanism of action is largely unknown and may involve modulation of the calcium receptor or calcium channels.

Bone Morphogenetic Proteins

Bone morphogenetic proteins (BMPs) comprise a family of 15 cytokines involved in the growth and differentiation of various tissues and organs such as bone, heart, kidney, eyes, skin and teeth. The members of this family which influence bone remodelling stimulate the differentiation of bone marrow stem cells into bone forming cells. BMPs are currently being tested in clinical trials for their potential to promote union of fractures and healing of bone defects. Among the BMPs being tested, is BMP-7, which also stimulates the

production of erythropoietin (EPO). EPO is produced in the kidney and stimulates the generation of erythrocytes from precursor cells. In the clinic, it is used for the treatment of anemia caused by chronic renal failure.

Botulinum Toxin

Bacterial Toxins

Botulism

Botulism is a disease caused by ingestion of foods contaminated with *Clostridium botulinum* (food-borne botulism) or, very rarely, by wound infection (wound botulism) or colonization of the intestinal tract with *Clostridium botulinum* (infant botulism). The toxins block the release of acetylcholine. Botulism is characterized by generalized muscular weakness, which first affects eye and throat muscles and later extends to all skeletal muscles. Flaccid paralysis can lead to respiratory failure.

- Bacterial Toxins
- Synaptic Transmission

Bradykinesia

Bradykinesia is slowness and poverty of movement.

- Anti-Parkinson Drugs

Bradykinin

Bradykinin is a nonapeptide enzymatically produced from kallidin in the blood, where it is a potent agent of arteriolar dilation and increased capillary permeability.

Bradykinin is also released from mast cells within damaged tissues. It produces inflammation and activates nociceptors via bradykinin B1 and B2 receptors.

Asthma bronchial

Definition

According to the Global Initiative for Asthma (GINA, ▶<http://www.ginasthma.org>), asthma affects about 300 million people worldwide. Men of all ages are affected by this chronic airway disorder that, without appropriate treatment, limits quality of life and is sometimes fatal.

Asthma is a chronic inflammatory disorder of the airways associated with recurrent airway obstructions, airway hyperresponsiveness and airway remodeling. Symptoms of asthma include ▶wheezing, coughing, chest tightness, and shortness of breathing, particularly at night or in the early morning. Airway obstruction is often reversible either spontaneously or after treatment. Missing or inadequate treatment will result in airway remodeling.

Basic Mechanisms

About 90% of all asthmatics have increased serum IgE levels and suffer from Type I allergy, called extrinsic (allergic) asthma.

Allergic asthma is a chronic inflammatory disorder of the lungs with a prevailing T helper Th2 immune response to ▶allergens (Fig. 1). Allergic asthma depends on the presence of IgE bound to high affinity Fcε-receptors (FcεR) on mast cells. Without IgE allergic asthma cannot occur. Thus to understand the primary cause of allergic asthma means to understand why the B-cells of these patients produce IgE specific to the allergen. While this remains unknown at present, the popular hygiene hypothesis holds that allergic asthma is initiated early in life when the immune system is trained. When CD4+ T helper cells encounter pathogens such as viruses or bacteria, these T-helper cells develop into TH1 cells, which produce mainly TNFα and IFNγ. In the absence of such pathogens (which become uncommon with increasing hygiene), CD4+ cells preferentially develop into TH2 cells that produce ▶IL-4 and ▶IL-5. These so-called TH2 cytokines induce the maturation of naïve T-helper cells into further TH2 cells and of B cells to produce specific IgE antibodies. These responses can be downregulated by IL-10 from regulatory T-cells or macrophages, which modulate TH2 cell maturation and increase tolerance to

Bronchial Asthma. Figure 1 Pathophysiology of asthma. Th2 lymphocytes take a central position in the pathophysiology of asthma. By using various cytokine signals, they inactivate Th1 and Th17 cells, activate eosinophils, and trigger a class switch in B-lymphocytes to make them produce IgE. These IgEs bind to mast cells, where subsequent allergen contact leads to crossbridging and activation of mast cells. The mast cell mediators trigger the early allergic response (EAR), the late allergic response (LAR), the activation of Th2 cells, and other inflammation responses. The inflammatory response mobilizes eosinophils, neutrophils, macrophages, and lymphocytes that infiltrate the lung tissue and sustain the inflammation. Eosinophils release mediators that contribute to the EAR and cytotoxic agents that injure the epithelial layer. Repetitive and chronic inflammation leads to airway remodeling and airway hyperresponsiveness. The curve shows a schematic illustration of airway resistance (as a measure of bronchoconstriction) in the course of asthma showing that the asthma attacks become more frequent and more severe with disease progression. In addition baseline airway resistance increases.

allergens. Recently Th17 cells were discovered to produce IL-17, which downregulates eosinophil chemotaxis. Its release is inhibited by the products of both Th1 and Th2 cells, namely IFN γ and IL-4 [1].

Cardinal Symptoms

The activation of mast cells by allergen initiates the asthma symptoms: within minutes after allergen contact, the early allergic response (EAR), within hours the late allergic response (LAR), and within years and after repeated asthma episodes, chronic airway inflammation, airway remodeling, and airway hyperresponsiveness.

Early and Late Phase in Asthma

Immediate responses to allergen occur within minutes. Allergen, cross-linking IgE bound to mast cells, causes degranulation of preformed (histamine, proteoglycans, serine proteases, TNF) secretion of newly formed mediators (prostaglandins, cysteinyl leukotrienes, thromboxane, \blacktriangleright platelet-activating factor, cytokines). The mixture of histamine, prostaglandins, thromboxane and cysteinyl leukotrienes causes airway smooth muscle contraction.

Frequently, the EAR is followed by a late phase response 4–6 h later and it is caused by the pulmonary sequestration of eosinophils, neutrophils, mast cells, and T-lymphocytes. This leukocyte recruitment depends on mast cell-derived mediators such as TNF α and various chemokines, as well as on the expression of adhesion molecules on leukocytes (e.g. VLA-4, CD11/18) and vascular endothelial cells (e.g. VCAM-1, ICAM-1, E-selectin). Products of these leukocytes have several functions: First, they cause the second phase of bronchoconstriction, mucus secretion, and airway swelling; second, they cause tissue destruction; third, they launch and entertain the chronic inflammation.

Inflammation

Airway inflammation is a characteristic clinical feature of asthma. The distinction between the LAR and chronic inflammation becomes more difficult as the disease progresses. Infiltrated leukocytes release *cytotoxic mediators* such as \blacktriangleright reactive oxygen species (ROS) and \blacktriangleright cationic (basic) proteins causing epithelial damage and *cytokines* that perpetuate the inflammation. Sustained inflammation leads to airway hyperresponsiveness and airway remodeling.

Hyperresponsiveness

Airway hyperresponsiveness is an exaggerated airway narrowing in response to a variety of unspecific stimuli. It can be measured by bronchial provocation with histamine, methacholine or adenosine. The reason for hyperresponsiveness may be stimulation of sensory nerves that are located within the epithelium. They become easily accessible after denudation of the

epithelium. This irritation of nerves leads to reflex smooth muscle contraction, mucus secretion, and edema formation (Fig. 2).

Airway Remodeling

The term “airway remodeling” refers to structural changes in the airways and is the consequence of chronic airway inflammation. The structural changes involve a thickening of the airway wall and this may explain the incomplete reversibility of airway narrowing in asthmatic patients. Hyperplasia of goblet cells coupled with hypertrophy of submucosal glands and increased vascularity of the airway wall amplify mucus secretion and plasma protein leakage, which are responsible for the formation of the characteristic mucus plugs that obstruct the airways. Other characteristic features are smooth muscle hypertrophy and hyperplasia, and subepithelial fibrosis.

Aspirin-Sensitive Asthma

Aspirin sensitive asthma, affecting about 10% of all asthmatics, is a nonallergic response to aspirin and other agents that inhibit cyclooxygenase-1. Mechanistically, the most likely reasons are lack of bronchoprotective prostaglandin E₂ and shunting of arachidonic acid into the leukotriene pathway.

Pharmacological Interventions

Pharmacological therapy depends on the severity of the disease, which is graded into mild, mild persisting, moderate persisting, and severe asthma, depending on the frequency of asthma attacks and the duration of the disease. The pharmacological agents are divided into relievers that lead to a rapid improvement of breathing during asthma attacks (β_2 -agonists, anticholinergics), and controllers (steroids, antileukotrienes, cromones) that control the disease by suppressing the inflammation and exacerbations (Table 1). The inhaled route is preferred. At present, healing of asthma by pharmacological therapy is not possible [2,3,4].

β_2 -Receptor Agonists

β_2 -Receptor agonists relax the bronchial smooth muscle by increasing intracellular cAMP levels, which in turn decrease calcium levels and interfere indirectly with myosin light chain phosphorylation. β_2 -Receptor agonists are very effective bronchodilators and can rescue patients from asthma attacks. β_2 -Receptor agonists are classified according to the duration of their action. Terbutaline, albuterol, and fenterol have a short biological half-life of 2–6 h and are mainly used as the only therapy in nonpersisting asthma and as a standby medication at all other stages of asthma. For other levels of asthma, long-acting bronchodilator such as salmeterol, bambuterol, and aformoterol with half-lives of 15–18 h are used. Typical side effects of this class of drugs are

Bronchial Asthma. Figure 2 Mechanisms of bronchial hyperresponsiveness. Toxic products from eosinophils [cationic peptides, reactive oxygen species (ROS)] cause epithelial injury. Nerve endings become easily accessible to mediators from mast cells, eosinophils [eosinophil-derived neurotoxin (EDN)], and neutrophils, and to airborne toxicants such as SO_2 . Activation of nerve endings stimulates effector cells like mucosal glands and airway smooth muscle either directly or by cholinergic reflexes.

interactions with cardiac β_1 -receptors, leading to tremor, arrhythmias, and tachycardia.

Anticholinergics

Cholinergic smooth muscle contraction occurs mainly via M_3 receptors. The clinically used anticholinergics (ipratropium bromide, tiotropium bromide) bind competitively to M_3 and M_2 receptors on airway smooth muscle and mucosal glands, but only tiotropium dissociates quickly from the postsynaptic inhibitory M_2 receptors, contributing to its enhanced inhibitory effect and its prolonged actions (16 h instead of 6 h). However, the lag phase of 30 min after intake limits the usefulness of these drugs in asthma. Inhaled anticholinergics are useful for the treatment of nocturnal asthma and above all for the treatment of COPD. Even when anticholinergics are inhaled, parasympathetic side effects like increased heart rate, soporific effects, and dry mouth may occur.

Methylxanthines

Methylxanthines have relaxing and anti-inflammatory effects. Accumulation of intracellular cAMP by inhibition of PDE3 (phosphodiesterase-3) relaxes airway

smooth muscle, whereas inhibition of phosphodiesterase-4 (PDE4) reduces inflammation. At therapeutic concentrations, methylxanthines inhibit PDE3 activity by only 10–20%. Therefore, other mechanisms have been suggested, e.g., methylxanthines that act as adenosine (A_1)-antagonists. Naturally occurring xanthines, like caffeine or theobromine are little effective in the treatment of asthma. At the beginning of the twentieth century, xanthines were widely used as asthma drugs; today theophyllin, bamifyllin, and elixophyllin are still used as an additional therapy for severe asthma (oral) and for status asthmaticus (i.v.). All methylxanthines have a short half-life and a small therapeutic window, which limits their use and necessitates either tight control of plasma levels or the usage of slow release forms.

Phosphodiesterase-4 Inhibitors

In the airways, inhibition of PDE4 is much more anti-inflammatory than bronchodilatory. Although effective in animal experiments, the neuronal and gastric side effects of PDE4-inhibitors have so far impeded their use in humans. Two new orally active PDE4-inhibitors (roflumilast, cilomilast) have shown some effectiveness in advanced clinical trials, but have not yet been approved.

Bronchial Asthma. Table 1 Asthma therapy, according to the German guidelines for asthma and the GINA report 2006 (GINA, ►<http://www.ginasthma.org>). FEV1, forced expiratory volume in 1 s

Phenotype	Therapy on demand	Permanent therapy
Mild nonpersisting asthma		
Occasional asthma attacks, less than 2 per month	Rapid-acting inhaled β_2 -agonist	None
Mild persisting asthma		
Asthma attacks less than twice a week; FEV1 >80%	Rapid-acting inhaled β_2 -agonist	Low dose inhaled glucocorticoid or cromone (children)
Moderate asthma		
Asthma attacks more than twice a week; FEV1 60–80%; daily use of bronchodilators.	Rapid-acting inhaled β_2 -agonist	Inhaled glucocorticoid
		Plus
		Long-acting inhaled β_2 -agonist
		Leukotriene receptor antagonist
		Slow releasing theophyllin
Severe asthma		
Daily asthma attacks, often by night; FEV1 <60% reduced physical stamina; daily use of bronchodilators.	Rapid-acting inhaled β_2 -agonist	Inhaled glucocorticoid
		Plus
		Long-acting inhaled β_2 -agonist
		Plus
		Oral glucocorticoid
		Anti IgE
<i>Status asthmaticus</i>		
Severe, life-threatening asthma attacks; inhaled β_2 -agonists ineffective	Oxygen	Glucocorticoids oral or i.v.
		Plus
		Theophyllin i.v.
		Plus
Long-acting β_2 -agonist (oral or subcutaneous)		

Anti-Leukotriene Therapy

Leukotrienes have multiple roles in asthma. They cause bronchoconstriction, swelling, and mucus secretion (LTC_4 , LTD_4) as well as eosinophil recruitment (LTE_4). Antileukotriene therapy is based either on inhibition of the 5-lipoxygenase (zileuton; approved only in the USA) or on cys-LT1 receptor antagonism (montelukast, zafirlukast, pranlukast). The anti-inflammatory potential of leukotriene antagonist is smaller than that of steroids. Patients with mild or moderate asthma, especially those who cannot or will not take steroids, are possible candidates for these drugs. Antileukotriene therapy is particularly effective in the treatment of aspirin-sensitive and exercise-induced asthma.

Cromones

Cromones are used to prevent asthma attacks. To be effective they have to be taken continuously. Their mechanism of action is poorly understood. Cromones (cromolyn sodium, nedocromil) act as mast cell-stabilizing agents,

preventing the release and production of histamine and other inflammatory mediators. They do also affect macrophage activation and inflammatory cell recruitment. These compounds diminish hyperresponsiveness in asthma, suppressing the irritant nerve response of denuded pulmonary epithelium. The usage of cromones is declining; they are still used in children (because they have virtually no side effects), and sometimes in adults with moderate asthma.

Anti-IgE

Allergic or extrinsic asthma affects 90% of all asthmatics. The production of IgE by B-cells and the $Fc\epsilon R$ -dependent activation of mast cells, eosinophils, basophils, and macrophages is critical for the development of asthma. A clear correlation exists between circulating IgE levels and disease severity. Reduction of circulating IgE antibodies by a humanized mouse anti-IgE antibody (omalizumab) mitigates asthma symptoms. Owing to their long half-life, (bi)monthly subcutaneous antibody

injections are sufficient to repress IgE levels and to reduce asthma symptoms. This (expensive) drug is approved as an add-on therapy to steroids in severe asthma.

Steroids

Asthma is a chronic inflammatory disease. Therefore steroids represent the most important and most frequently used medication. Already after the first treatment, steroids reduce cellular infiltration, inflammation, and the LAR, whereas changes in the EAR require prolonged treatment to lower the existent IgE levels. The mechanisms of steroid actions are complex and only incompletely understood. Besides their general anti-inflammatory properties (see chapter ►glucocorticoids), the reduction of IL-4 and IL-5 production from T-lymphocytes is particularly important for asthma therapy. The introduction of inhaled steroids, which have dramatically limited side effects of steroids, is considered one of the most important advancements in asthma therapy. Inhaled steroids (beclomethasone, budesonide, fluticasone, triamcinolone, mometasone) are used in mild, moderate, and partially also in severe asthma; oral steroids are used only in severe asthma and the treatment of ►status asthmaticus. Minor side effects of most inhaled steroids are hoarseness and candidiasis, which are avoided by the prodrug steroid ciclesonide.

There is now good evidence that the clinical manifestations of asthma symptoms – impairment of lung function, sleep disturbances, limitations of daily activity, and the use of rescue medications – can be controlled with appropriate treatment. When asthma is controlled, there should be no more than occasional recurrence of symptoms and severe exacerbations should be rare.

Ca²⁺-binding Proteins

CLAUS W. HEIZMANN

Division of Clinical Chemistry and Biochemistry
Department of Pediatrics, University of Zurich, Zurich
Switzerland

Definition

These proteins can be subdivided into extracellular and intracellular Ca²⁺-binding proteins (Table 1).

Members of the Extracellular Proteins

▶ Noncollagenous Ca²⁺-binding proteins bind to bone minerals. They contain stretches of γ -glutamic acid residues necessary for Ca²⁺-binding.

▶ EGF-like domains were identified in extracellular proteins such as fibrillin-1. EGF-modules contain about 40–45 amino acids including six cysteine residues which normally build S–S disulfide bond bridges. Mutations in the fibrillin-1 gene cause Marfan syndrome and related disorders.

▶ Ca²⁺ sensing receptor, a member of G-protein coupled receptors, is composed of seven transmembrane spanning domains. The extracellular domain contains clusters of negatively charged amino acids sensing even small fluctuations of extracellular calcium. Mutations in this receptor cause inheritable hypo- and hypercalcemic syndromes.

Members of the Intracellular Ca²⁺-Binding Proteins

Non-EF-hand Ca²⁺-binding proteins including the annexins, C2-domain proteins, and gelsolin, and the EF-hand Ca²⁺-binding proteins.

This review will focus on the large family of EF-hand proteins characterized by a common structural motif, the EF-hand (Fig 1).

Basic Characteristics of the EF-Hand Ca²⁺-Binding Proteins

Structures and Functions

These calcium-binding proteins form a superfamily of proteins containing more than 600 members [1–3]. The

Ca²⁺-binding Proteins. Table 1 Families of Ca²⁺-binding proteins

human genome alone may contain up to 100 EF-hand containing proteins. They are characterized by the EF-hand, or helix-loop-helix motif (Fig 1). The members of this family can be subdivided into several categories (Table 1). The first group of proteins are the calcium-buffering proteins including parvalbumin, calbindin D_{28K}, and calretinin. The second group is composed of the calcium-regulatory sensor proteins that are involved in the transmission of the calcium signal. This group consists of calmodulin, the S100 proteins, and the Ca²⁺-sensor proteins. The other two groups are the penta EF-hand proteins and the calcineurins (CaNs).

Calcium-Buffering Proteins

Parvalbumin

▶ Parvalbumin (Fig 1) is a cytosolic protein expressed in fast-twitch skeletal muscles and in the nervous system. In muscles, parvalbumin controls the relaxation process. In the CNS, parvalbumin, expressed in a subpopulation of GABAergic neurons, is correlated with their firing rates, protecting the cells from Ca²⁺ overload.

Calbindins and Calretinin

Two types of ▶ calbindins have been described, calbindin D_{28K} and calbindin D_{9K}. The latter (now renamed as S100G) belongs to the S100 protein family.

Both proteins, hormonally controlled by vitamin D, are expressed in the kidney, intestine, and brain. Calbindin D_{28K} contains six EF-hands, four of which have a high affinity for Ca²⁺. Calbindin D_{28K} facilitates Ca²⁺ diffusion in Ca²⁺-transporting epithelial cells and provides protection against toxic Ca²⁺ levels by buffering the cytosolic Ca²⁺ concentrations during high Ca²⁺ influx. Recent studies have indicated that this protein may also act as a Ca²⁺ sensor (Table 1).

In the CNS, calbindin D_{28K} is widely expressed in a subpopulation of neurons distinct from those immunoreactive for parvalbumin or calretinin.

Calretinin is homologous to calbindin D_{28K}. It is abundantly expressed in the central and peripheral nervous system and other organs. The protein contains four EF-hand domains homologous to the first four of calbindin D_{28K}.

Ca²⁺Regulatory Proteins

Troponin (subunits TN-T, TN-I, TN-C)

The Ca²⁺-binding subunit TN-C is homologous to calmodulin with four EF-hands. In contrast to calmodulin, which is ubiquitously expressed in multicellular eukaryotic organisms and interacts with many targets, ▶ troponin specifically regulates muscle contraction. There are some structural differences between Troponin C in skeletal and cardiac muscles reflecting their physiological differences.

Calmodulin (CaM)

CaM is ranked among the most conserved proteins known to date, which also include proteins like histones or actin. CaM possesses four EF-hand calcium-binding sites distributed in pairs separated by a long central helix. CaM can regulate its target proteins in a calcium-dependent or -independent manner. These targets have been classified into “classic” and “nonclassic” (proteins with the IQ motif). The list of the “nonclassic” targets of CaM has grown exponentially in the last few years because of the screening of the genome sequence database.

CaM plays a key role in many cellular processes. In the CNS, it is involved in synaptic transmission and neuronal plasticity associated with short-term and long-term potentiation, and learning and memory processes.

Centrins

▶ Centrins are calmodulin-like proteins that have an important function in the organization and duplication of microtubules. Like CaM, centrin is also comprised of two structurally independent globular domains connected by a flexible tether, and each domain is

Ca²⁺-binding Proteins. Figure 1 (a) The EF-hand consists of helix E, followed by a loop (coordinating the Ca²⁺-ions) and a second helix F. This structure can be mimicked by thumb, forefinger, and bent middle finger (Ca²⁺-loop). (b) The first X-ray structure of carp parvalbumin (PV) was reported by Kretsinger and Nockolds (1973), *J Biol Chem* 248:3313. α-PV consists of six α-helices (labeled A-F) connected by loops. The helices associate in pairs to form three domains labeled AB, CD, and EF. Ca²⁺-ions are bound in the helix-loop-helix, or EF-hand, substructures of the CD-EF domain (ribbon drawing modified from Bottoms et al (2004), *Protein Sci* 13:1724–1734). For further structures, please refer to the RCSB Protein Data Bank (PDB): ► <http://www.pdb.org/>

composed of two EF-hand type calcium binding domains. However, in contrast to CaM, most centrins contain one or more nonfunctional calcium-binding sites.

Neuronal Sensor Proteins (NCS)

This family contains more than 40 members subdivided into five subfamilies [4]. The NCS have been involved in phototransduction and regulation of neurotransmitter release. The NCS have two pairs of EF-hands and, unlike CaM and S100 proteins, possess a consensus myristoylation sequence at the N-terminal responsible for the targeting of the NCS to the membrane.

Members of the first group of NCS are ► **recoverin** and ► **visinin**. Recoverin is a 23 kDa myristoylated protein found under normal conditions only in photoreceptor cells (rods and cones). The main function of recoverin is to bind to and inhibit rhodopsin kinase, thereby prolonging the light response.

A second class of neuronal calcium sensors is formed by the guanylate cyclase-activating protein (GCAP). The GCAPs are expressed only in the photoreceptor cells of the retina of vertebrates. Recoverins and GCAPs have antagonistic roles in phototransduction.

Two other NCS families, i.e., frequenins and KChIPs, are thought to regulate the release of

neurotransmitters, the biosynthesis of polyphosphoinositides, and the activity of Kv channels (KChIPs), respectively.

VILIP-1, VILIP-2, hippocalcin, neurocalcin, and VILIP-3 (also named hippocalcin-like 1 protein) are expressed in different cell types in the brain. All isoforms are neuronal-specific.

Recently, two novel sensor proteins, caldendrin and calneuron have been described. Caldendrin is abundantly expressed in neurons and is thought to play an important role in different aspects of synapto-dendritic Ca²⁺ signaling. Calneurons are homologues to caldendrin, have a different EF-hand organization, compared to other calcium sensor proteins and are prominently expressed in neurons. Despite some significant structural differences they are possibly involved in similar Ca²⁺-regulated processes as caldendrin and other neuronal calcium sensor proteins.

The Penta EF-Hand (PEF) Family

These cytosolic proteins contain five EF-hand domains and are able to translocate to the plasma membrane upon calcium binding [5]. In addition to the EF-hand domains, these proteins also have a hydrophobic glycine/proline-rich domain, important for their translocation to the membrane. To date five members of this

family have been described in human tissues, such as sorcin, calpain light and heavy chain, grancalcin, apoptosis-linked gene-2 (ALG-2), and peflin.

Sorcin (soluble resistance-related calcium binding protein) was isolated from multidrug-resistant cells and is expressed in a few mammalian tissues such as skeletal muscle, heart, and brain. In the heart, sorcin interacts with the ryanodine receptor and L-type Ca²⁺-channels regulating excitation in contraction coupling.

► **Calpains** belong to the family of cytosolic calcium-dependent cysteine proteinases and are involved in cell cycle regulation and apoptosis, and in pathophysiological processes such as Alzheimer's and Parkinson's disease. At least 14 members of the calpain family have been identified, which can be either tissue-specific or ubiquitously expressed. Most calpains are composed of heterodimers with a large catalytic subunit and a small regulatory subunit. Both large and regulatory subunits contain the penta EF-hand motif.

Calpain-10 (CAPN10) is the first diabetes gene to have been identified through a genome scan. The discovery of calpain-10 has identified it as a molecule of importance to insulin signaling and secretion that may have relevance to the future development of novel therapeutic targets for the treatment of type 2 diabetes.

ALG-2 is the first calcium-binding protein of the EF-hand family found to be directly involved in apoptosis. ALG-2 is a 22 kDa protein and like the other members of the penta EF-hand family, contains five EF-hands, with only two of them functional. ALG-2 protein is expressed in the brain and eye and was found to be upregulated in various cancer tissues. Several targets have been found, such as proteins AIP, Alix, peflin, and annexins, suggesting a putative role of ALG-2 in apoptosis.

Peflin presents 40.9% identity with ALG-2. The protein has a long hydrophobic N-terminal extension containing nine nonapeptide repeats. Peflin is ubiquitously expressed. The function of peflin is still unknown, although recent experiments have shown a role in apoptosis.

Calcineurin

► **Calcineurin** is not related to any of the family of the EF-hand calcium-binding proteins mentioned above. It is a protein phosphatase (2B) expressed in many tissues, but selectively enriched in neurons. CaN consists of a catalytic subunit (CaNA) and a regulatory subunit (CaNB). Activation of CaN requires both the interaction of Ca²⁺/calmodulin with the catalytic subunit and the binding of calcium to the regulatory subunit CaNB. CaNB possesses four functional EF-hands which bind calcium with micromolar affinity. In the brain, CaN regulates a large variety of proteins such as transcription factors, calcium channels, GABA, and glutamate receptor.

CaN Homologous Protein

Calcineurin homologous protein (CHP) is ubiquitously expressed and has four EF-hand domains and one putative site of myristoylation.

Calmyrin is closely related to human calcineurin B. Calmyrin interacts with presenilin 2 and may thus be involved in Alzheimer's disease.

Drugs

Disease Association and Molecular Drug Targets

Proteins of this family are closely associated with human diseases. They have also been proven to be valuable in diagnosis and are considered to have potential as drug targets to improve therapies.

► **Parvalbumin** was found to be a major fish allergen in approximately 70% of fish allergies, mediated by parvalbumin IgE antibodies, leading to respiratory and gastrointestinal symptoms. Parvalbumin also became of interest because of its potential use in gene therapy to correct cardiomyopathy.

► **Troponin** is a regulator of striated muscle contraction. Measurements of troponin I levels are routinely used in the diagnosis of myocardial infarction. In addition, mutations in the troponin I subunit are associated with familial hypertrophic cardiomyopathy.

► **Calmodulin** is involved in several human diseases including Parkinson's disease. Recently, new calmodulin ligands have been developed, which may become a key target for pharmacological interactions.

► **Recoverin** is aberrantly expressed in malignant tumors localized outside the nervous system. This was found to trigger the immune system resulting in the production of autoantibodies inducing the degeneration of the retina.

► **Sorcin** is associated with the development of multidrug resistances in leukemia and other cancers. Sorcin is also able to improve cardiac contractility independently of β -adrenergic stimulation and may prove beneficial in treatment of heart failure. A point mutation in sorcin causes familial hypertrophic cardiomyopathy.

► **Calpain**: Tissue specific calpains have been implicated in diabetes, cataracts, multiple sclerosis, and limb-girdle muscular dystrophy type 2A. More than 50 inhibitors of calpain have been described which have a potential for therapeutic applications.

► **Calcineurin** is involved in cardiac hypertrophy and in cognitive and behavioral defects in the brain. Inhibitors of calcineurin such as cyclosporine A and FK 506 are used clinically in transplant rejection and autoimmune diseases.

Conclusion

Ca²⁺ and Ca²⁺-binding proteins regulate a plethora of vital physiological functions and many diseases are

linked to abnormalities in the intracellular calcium sensing pathways regulated by Ca²⁺-binding proteins. These proteins have a great potential as drug targets to improve therapies in the future.

Ca²⁺ Channel

An oligomeric protein that spans a cell membrane forming a regulated pore through which Ca²⁺ can pass. Ca²⁺ channels differ considerably in their selectivity for Ca²⁺ over other cations: For example IP₃R are poorly selective, voltage-dependent Ca²⁺ channels are very selective.

Ca²⁺ channel antagonists

Definition

Ca²⁺ is an important intracellular second messenger that controls cellular functions including muscle contraction in smooth and cardiac muscle. Ca²⁺ channel blockers inhibit depolarization-induced Ca²⁺ entry into muscle cells in the cardiovascular system causing a decrease in blood pressure, decreased cardiac contractility, and antiarrhythmic effects. Therefore, these drugs are used clinically to treat hypertension, myocardial ischemia, and cardiac arrhythmias.

Mechanism of Action

Voltage-gated Ca²⁺ channels are Ca²⁺-selective pores in the plasma membrane of electrically excitable cells, such as neurons, muscle cells, (neuro) endocrine cells, and sensory cells. They open in response to membrane depolarization (e.g., an action potential) and permit the influx of Ca²⁺ along its electrochemical gradient into the cytoplasm.

Ca²⁺ Channel Physiology

The resulting increase in intracellular free Ca²⁺ triggers and/or modulates important physiological processes. Ca²⁺ influx into nerve terminals, sensory or endocrine cells initiates neurotransmitter or hormone release, respectively (stimulus-secretion coupling). Ca²⁺ entry into the soma and proximal dendrites of nerve cells leads to the activation of intracellular pathways affecting gene transcription (excitation transcription coupling) and neuronal plasticity. In smooth muscle and cardiac myocytes Ca²⁺ influx through these channels induces muscle contraction (excitation contraction coupling).

Ca²⁺ Channel Function

Like other ▶voltage-gated cation channels, Ca²⁺ channels exist in at least three states: A resting state stabilized at negative potentials (such as the resting potentials of most electrically excitable cells) that is a closed state from which the channel can open. The open state is induced by depolarization. Channels do not stay open indefinitely because they are “turned off” during prolonged depolarization by transition into an inactivated state. Inactivation is driven both by depolarization

as well as the permeating Ca^{2+} ions (Ca^{2+} -dependent inactivation), thus preventing cellular Ca^{2+} overload during prolonged stimulation. Once the cell repolarizes, inactivated channels return to the resting state and are now again available for opening. Ca^{2+} channel blockers can inhibit Ca^{2+} flux not only by obstructing the open pore but also by “allosterically” stabilizing inactivated closed states. By delaying its transition to the resting state after repolarization drugs can also increase the “refractory period” of these channels.

Ca^{2+} Channel Types

In order to accomplish these diverse physiological tasks described above, nature has created at least five different types of Ca^{2+} channels. These are termed L-, N-, P/Q-, R-, and T-type. Although they are all structurally similar (Fig. 1) they differ with respect to their biophysical properties. Some of them need only weak depolarizations to open and inactivate fast (e.g., T-type Ca^{2+} channels), whereas others require strong depolarizations and inactivate more slowly (e.g. P- or L-type Ca^{2+} channels). Channel types also differ with respect to their sensitivity to drugs. This selectivity is exploited for pharmacotherapy.

L-Type Ca^{2+} Channel Blockers

At present, only organic blockers of L-type Ca^{2+} channels (also termed “ Ca^{2+} antagonist”) are licensed

Ca^{2+} Channel Blockers. Figure 1 Most voltage-gated Ca^{2+} channels exist as a hetero-oligomeric complex of several subunits. α_1 subunits form the Ca^{2+} -selective ion pore and contain the voltage-sensors of the channel. In the case of L-type Ca^{2+} channels, they also carry binding sites for Ca^{2+} antagonist drugs. The accessory α_2 - δ , β , and γ subunits stabilize Ca^{2+} channel function and support its targeting to the plasma membrane. Notably other proteins can associate with the channel complex allowing the formation of signaling complex important for channel targeting and modulation.

for clinical use. They belong to the most frequently prescribed drugs worldwide. L-type Ca^{2+} channels are the major channel type in muscle cells mediating contraction. Although they do not support fast neurotransmitter release from nerve terminals during short action potentials L-type channels provide Ca^{2+} for neurotransmitter release sites in sensory (cochlear hair cells, retinal photoreceptors) and endocrine cells (insulin secretion in \blacktriangleright pancreatic β cells) and contribute to brain function by coupling synaptic activity to gene-transcription in neurons. Despite these multiple functions, in vivo L-type Ca^{2+} channel block by therapeutic concentrations only causes pharmacological effects in the cardiovascular system.

Signaling pathways controlling cardiac and smooth muscle contraction are depicted in Fig. 2 and Fig. 3. By blocking L-type channels in arterial smooth muscle they reduce Ca^{2+} influx during depolarization. Thus less Ca^{2+} is available for activation of calmodulin, which activates myosin-light chain kinase and thereby turns on actin–myosin interaction (Fig. 2). Note that smooth muscle also contracts after stimulation of receptor-activated pathways. Agonists of angiotensin AT1 (e.g., angiotensin II) and α_1 -adrenergic receptors (e.g., noradrenaline) release Ca^{2+} from intracellular IP_3 -sensitive stores (Fig. 2). Noradrenaline-induced contractions are much less sensitive to Ca^{2+} channel blockers. The differential contribution of depolarization-induced and receptor-activated contraction in different types of smooth muscle and under different pathophysiological conditions is one of the explanations why Ca^{2+} channel blockers are not effective muscle relaxants in other diseases (such as bronchial asthma or urethral spasms). In the heart, Ca^{2+} entering through L-type channels during the action potential serves as a trigger (“trigger Ca^{2+} ”) for further Ca^{2+} release from the sarcoplasmic reticulum that initiates contraction (Fig. 3). β -adrenergic receptor activation increases inotropy at least in part by cAMP-dependent phosphorylation of L-type channels thereby increasing Ca^{2+} entry.

Three different chemical classes of organic Ca^{2+} channel blockers can be distinguished: Dihydropyridines (DHPs; prototype nifedipine), phenylalkylamines (prototype verapamil), and benzothiazepines (prototype diltiazem). Despite their different structure they all bind within a single drug binding domain close to the pore of the channel. In radioligand binding experiments these drugs reversibly interact with this domain in a stereoselective manner and with \blacktriangleright dissociation constants in the (sub)nanomolar range (0.1–50 nM).

DHPs

Widely used DHPs are nifedipine, amlodipine, nitrendipine, nisoldipine, nicardipine, and isradipine. They directly bind to and stabilize the inactivated state of the

Ca²⁺ Channel Blockers. Figure 2 Simplified view of the pharmacological action of L-type Ca²⁺ channel blockers in arterial smooth muscle: In contrast to cardiomyocytes, action potentials are not carried by fast sodium channels in smooth muscle and depolarizations are more long lasting. Contraction requires the binding of Ca²⁺ to calmodulin, which then activates myosin light chain kinase (MLCK). MLCK phosphorylates the light chain of myosin, which initiates contraction. The Ca²⁺ for activation of this pathway can enter through L-type Ca²⁺ channels in response to depolarization. Ca²⁺ channel blockers inhibit this pathway through concentration-dependent block of Ca²⁺ entry. Alternatively, Ca²⁺ can be released from intracellular stores after activation of membrane receptors (e.g., of angiotensin II AT1 or $\alpha 1$ -adrenergic receptors) coupled to IP₃ production. IP₃ opens IP₃ receptor channels, RyR related Ca²⁺ release channels in the SR. This process does not involve L-type Ca²⁺ channels and is not inhibited by Ca²⁺ channel blockers. Store-depletion also triggers the activation of “store-operated channels” (SOC) in the plasma membrane, which are also not sensitive to Ca²⁺ channel blockers. SOC can depolarize the plasma membrane and may thus link receptor-activation to the modulation of Ca²⁺ channel activity. Receptor-mediated activation of cAMP-dependent protein kinase (cAMP-PK) results in muscle relaxation through different mechanisms. D1-R, dopamine1 receptor; AR, adrenergic receptor; PLC, phospholipase C.

channel and do not require the channel to open in order to access the binding domain. Inactivated channels are more likely to exist in arterial vascular smooth muscle because depolarizations are longer lasting than in cardiac muscle. Moreover, the arterial smooth muscle channel differs slightly from the cardiac isoform (► **alternative splicing** of $\alpha 1$ subunits) which facilitates channel block by DHPs. As a consequence, DHPs block the channels in arterial smooth muscle at lower concentrations than cardiac muscle. Their clinical use is therefore related to their vasodilating properties in arterial smooth muscle (including the coronary arteries) and not to direct actions on the myocardium and the conduction system (i.e., antiarrhythmic and cardiodepressive effects), which are observed at higher concentrations *in vitro* or at toxic plasma levels.

Phenylalkylamines

Verapamil is the most widely used phenylalkylamine. Methoxyverapamil (gallopamil) is slightly more potent and licensed for clinical use in some countries. Verapamil mainly gets access to the binding domain when the channel is open. As an organic cation it blocks the channel by interfering with Ca²⁺ ion binding to the extracellular mouth of the pore. Once bound to the open state it can promote the inactivated channel conformation. Verapamil also slows the recovery of channels from inactivation. This increases the refractory period of the drug-bound channel. As a consequence, the number of channels available for Ca²⁺ influx decreases when the time between depolarizations shortens (i.e., when stimulation frequency increases). The open channel block and slowing of recovery explains why inhibition by a

Ca²⁺ Channel Blockers. Figure 3 Simplified view of the pharmacological action of L-type Ca²⁺ channel blockers in cardiac myocytes: In cardiac myocytes, L-type Ca²⁺ channels open when the plasma membrane is depolarized by an action potential carried along the muscle cells by the opening of voltage-gated sodium-channels (Na-Ch). The action potential is terminated (an its duration is determined) by the opening of potassium channels (K-Ch). Ca²⁺ influx triggers massive release of Ca²⁺ from intracellular stores by opening ryanodine-sensitive Ca²⁺ channels (ryanodine receptors, RyR) in the sarcoplasmic reticulum, resulting in an intracellular Ca²⁺ transient. Ca²⁺ influx and released Ca²⁺ directly initiate contraction. Contraction is terminated by the rapid uptake into the SR by SR Ca²⁺ ATPases (SERCA). β -adrenergic receptor stimulation increases inotropy by phosphorylation (P) of phospholamban (PLN) and L-type channels through cAMP-dependent protein kinase (cAMP-PK). The resulting stimulation of Ca²⁺ influx and Ca²⁺-pump activity increases the load of Ca²⁺ in the SR stores. This leads to enhanced Ca²⁺ transients upon depolarization. Inhibition of Ca²⁺ influx through L-type Ca²⁺ channels by Ca²⁺ channel blockers causes decreased Ca²⁺ entry and SR load. Less Ca²⁺ influx and release results in smaller Ca²⁺ transients and a decrease in contractile force.

given verapamil concentration increases at higher heart rates. Like the lidocain block of voltage-gate sodium channels, the verapamil block of Ca²⁺ channels becomes more pronounced during tachyarrhythmias. These antiarrhythmic effects of phenylalkylamines are exploited in addition to its vasodilating and cardio-depressive actions.

Benzothiazepines

Diltiazem is the only benzothiazepine in clinical use. Its molecular mechanism of action as well as its pharmacological effects closely resemble those of phenylalkylamines.

All three classes also inhibit depolarization-induced contraction of venous smooth muscle *in vitro*. However, venous relaxation does not substantially contribute to the hemodynamic actions of Ca²⁺ channel blockers.

Clinical Use (Including Side Effects)

DHPs are potent arterial vasodilators. They act on resistance vessels and therefore reduce peripheral vascular resistance, lower arterial blood pressure, and antagonize vasospasms in coronary or peripheral arteries. By reducing afterload, DHPs also reduce cardiac oxygen demand. Together with their vascular spasmolytic effect, this explains most of the beneficial actions of DHPs in angina pectoris. Most DHPs are only licensed for the therapy of hypertension, some of them also for the treatment of angina pectoris and vasospastic (Prinzmetal) angina.

Fast DHP-induced lowering of blood pressure results in compensatory sympathetic activation and a subsequent increase in heart rate and cardiac oxygen demand. This unfavorable effect has been mainly associated with the use of short-acting DHPs, such as nonretarded formulations of nifedipine, nitrendipine, or

nicardipine. The use of such formulations that cause fluctuations in plasma levels upon multiple dosing is discouraged. Instead, DHPs with slower onset and longer duration of action (amlodipine or slow release formulations of e.g. nifedipine, nisoldipine) are recommended. Due to their vasodilating properties in the absence of negative inotropic actions, DHPs have also been evaluated as vasodilators for the treatment of congestive heart failure in addition to standard therapy. Although long-acting DHPs seem to be safe in these patients, they are not recommended for this indication.

In addition to these vasodilatory and antispastic properties, therapeutic doses of verapamil and diltiazem also exert negative inotropic, dromotropic, and chronotropic actions. As a consequence, compensatory tachycardia does not occur and heart rate may even decrease. Similar to β -adrenergic antagonists, verapamil and diltiazem inhibit exercise-induced increases in heart rate and myocardial oxygen consumption. Therefore both drugs are licensed for the treatment of angina, vasospastic angina, and hypertension. Their negative dromotropic and antiarrhythmic properties (see above) can be exploited to slow AV-conduction and to treat supraventricular arrhythmias. In patients with normal contractile function, the negative inotropic action of verapamil is partially compensated by the decreased afterload and improved myocardial perfusion. However, verapamil may decrease left ventricular function in patients with congestive heart failure. Unlike β -adrenergic blockers, verapamil and diltiazem are not recommended in cardiac failure and for early treatment or secondary prevention of myocardial infarction.

DHPs are also used to treat vasospasms of peripheral arteries (e.g., ►Raynaud's phenomenon) and ►pulmonary hypertension.

Side Effects

Many unwanted effects are related to the vasodilatory effects of Ca²⁺ channel blockers, such as flushing, headache, dizziness, and hypotension. DHPs frequently cause edema and ankle swelling upon chronic use. Constipation is a frequent side effect of verapamil due to its inhibitory action on intestinal smooth muscle. Bradycardia, atrioventricular block, or a decrease in left ventricular function are observed with verapamil (and to a lesser degree diltiazem), especially in patients taking β -adrenergic blockers or who have preexisting cardiac disease (impaired left ventricular function, atrioventricular block). Worsening of angina has also been observed with DHPs. This is most likely due to their effect on coronary resistance vessels resulting in coronary steal in the presence of hypoperfused regions. It may also be caused by the reactive sympathetic activation with increase in heart rate and cardiac oxygen consumption.

Epidemiological and case-control studies suggested that Ca²⁺ channel blockers cause increased risk for

myocardial infarction, cancer, and gastrointestinal bleeding. The increased cardiovascular morbidity was again associated with short-acting DHPs and fast release forms of verapamil and diltiazem. It was explained by the unfavorable hemodynamic effects of short-acting drugs. Enhanced cardiovascular morbidity has not been consistently shown for long-acting formulations. The increased risk of cancer and gastrointestinal bleeding was not confirmed in other large trials.

Ca²⁺ channel blockers cause no side effects expected from channel block in other tissues (e.g., cochlear inner hair cells, retinal photoreceptors or neurons, pancreatic β -cells). Despite the dependence of insulin secretion on L-type Ca²⁺ channel function, impaired glucose-tolerance is not a frequent side effect of Ca²⁺ channel blockers in clinical practice. The reason for the absence of side effects in other tissues can be explained by the lower bioavailability in these tissues, by alternatively spliced channel subunits conferring different drug sensitivity (see above) and by the existence of different L-type channel isoforms, which differ in drug sensitivity. Ca_v1.2 channels, the major L-type channel isoform in vascular smooth muscle and cardiac ventricular muscle, are more sensitive to Ca²⁺ channel blockers than Ca_v1.3 and Ca_v1.4 isoforms, the major isoforms expressed in cochlear inner hair cells and retinal photoreceptors, respectively. Notably Ca_v1.3 channels also control cardiac pacemaking in the sinoatrial node but do not contribute to cardiac inotropy and arterial tone. This may provide new opportunities to develop isoform-selective blockers as bradycardic agents lacking negative inotropic actions.

Other Pharmacological Actions of Ca²⁺ Antagonists

Adult dopamin-containing neurons in the substantia nigra rely on Ca_v1.3 channels as pacemaker channels. It appears that the resulting enhanced Ca²⁺ load renders these channels more susceptible to neurotoxic effects and neurodegeneration as observed in Parkinson's disease. Preclinical evidence suggests that block of these with dihydropyridines causes a switch to a Ca_v1.3-independent pacemaker and protects these neurons from neurotoxicity.

Some DHPs (such as nifedipine) and verapamil inhibit ►p-glycoprotein-mediated drug transport. P-glycoprotein is a drug efflux pump that can confer multidrug resistance to tumor cells. Structural analogues with potent p-glycoprotein but weak Ca²⁺ channel blocking activity were therefore developed but are of no clinical benefit for the treatment of cancer. However, inhibition of transport (and excretion) of other p-glycoprotein substrates, such as digoxin, explains the decrease of their body clearance by Ca²⁺ channel blockers.

In vitro nifedipine inhibits proliferation of colon cancer cells with a DNA mismatch repair defect that are resistant to 5-fluorouracil. Whether this also

translates into clinical efficacy in such tumors remains to be determined.

Nimodipine, but not other DHPs, is also a potent inhibitor of nucleoside transport with actions similar to known nucleoside transport inhibitors such as dipyridamol. It is likely that this mechanism also contributes to the potent vasodilating properties of this DHP.

BAYK8644 is a DHP with Ca^{2+} channel activating properties. Although some therapeutic effects can be envisaged for such drugs (such as stimulation of glucose-dependent insulin secretion, positive inotropy), severe side effects are also predicted from animal studies (dystonic neurobehavioral syndrome, hypertension, arrhythmias), which currently prevents their clinical development.

Synonyms

Calcium receptor; Extracellular calcium-sensing receptor (CaSR)

Definition

The extracellular calcium Ca_0^{2+} -sensing receptor plays a central role in maintaining a nearly constant level of extracellular calcium by sensing small changes in Ca_0^{2+} and directly and/or indirectly altering the translocation of calcium ions into or out of the extracellular fluid so as to normalize Ca_0^{2+} . Changes in the level of expression and/or function of the CaR reset the level of Ca_0^{2+} . Recently developed activators (calcimimetics)

or inhibitors (calcilytics) of the CaR permit modulation of the receptor's function in ways that can correct or improve defective Ca₀²⁺-sensing and the resultant clinical abnormalities.

Basic Characteristics

Structural and functional properties of the CaR. The calcium ion has numerous critical roles. Inside the cell, it is a key second messenger, serves structural roles in various proteins, and is a cofactor for numerous enzymes [1]. Outside the cell, it is essential for blood clotting, is an important component of various adhesion molecules, and serves as an ionic reservoir and in a structural capacity in the skeleton. The extracellular calcium (▶Ca₀²⁺)-sensing receptor (CaR or CaSR) is the mechanism by which the body “senses” the level of Ca₀²⁺ in the extracellular fluid (ECF) and facilitates maintenance of Ca₀²⁺ within a narrow range [1]. This chapter summarizes current understanding of the structure and function of the CaR, as well as its pharmacological properties, signaling pathways and biological actions in maintaining Ca₀²⁺ homeostasis. The study of inherited or acquired defects of Ca₀²⁺-sensing [2] [3] and of mice with knockout of the CaR has provided important insights into how the receptor functions, and the latter part of the chapter will summarize this information and briefly describe the emerging field of CaR-based therapeutics.

The CaR belongs to ▶subfamily C of the superfamily of G protein-coupled receptors (GPCRs), which also includes the metabotropic glutamate receptors (mGluRs) and the GABA_B receptors. All share large extracellular domains (ECD (Extracellular domain; the amino-terminal portion of the CaR and other G-protein-coupled receptors that is proximal to the first membrane-spanning domain and, in the family C receptors, contains important determinants for the binding of that receptor's respective cognate ligand.)) (~600 amino acids in the case of the CaR), which contain important binding sites for their respective ligands. These ECDs likely assume a bilobed conformation related evolutionarily to the “venus flytrap” motif of the bacterial periplasmic proteins, which serve as receptors for various extracellular ligands [2]. Molecular modeling based on the known structure of the ECD of mGluR1 supports a ▶Venus flytrap conformation of the CaR's ECD (Fig. 1). Disulfide bonds involving cys129 and cys131 link the two CaR monomers [2]. The CaR's dimeric configuration, probably combined with the presence of more than one calcium-binding site in each ECD, likely contributes to the receptor's marked positive cooperativity (Hill coefficient of 3–4). Although the locations of the CaR's calcium-binding sites are not known with certainty, a site has been modeled in the crevice between the two lobes of each receptor monomer that might favor the active, closed form of the receptor

Ca²⁺-sensing Receptor. Figure 1 Model of the structure of the isolated ECD of the CaR based on the known structure of the extracellular domains (ECD) of metabotropic glutamate receptor 1 (mGluR1). Note the bilobed structure of each monomeric ECD on the left and right hand sides of the figure. There is a predicted calcium-binding site within the crevice between the two lobes, and there are likely other binding sites as well. Upon binding ligand the two lobes are thought to approximate one another, initiating signal transduction via the transmembrane domains (TMDs), intra- and extracellular loops, and the C-terminal tail. The yellow asterisk at the top of the figure shows the positions of the two cysteines in each monomer (cys129 and cys131 – shown in yellow) that link the monomeric ECDs together. The blue dots at the bottom indicate the carboxy-termini of the monomeric ECDs (shown in gray in the model). Reproduced with permission from Bai M (2004) *Cell Calcium* 35: 197–207.

upon ligand binding. There are additional calcium-binding site(s) in the receptor's transmembrane domains (TMDs), since a "headless" receptor lacking the entire ECD still responds to polyvalent cations [2]. The CaR's extracellular domain is extensively N-glycosylated, which is essential for efficient cell surface expression.

Following the ECD is a 250 amino acid, ▶TMD motif characteristic of the GPCRs, which is followed by a carboxy-terminal tail of ~200 residues. Upon ligand binding, closure of the dimeric CaR's Venus flytrap motifs is thought to change the relative positions of the helices, thereby activating intracellular signaling. The CaR's C-tail contains several functionally important structural motifs, including protein kinase A and protein kinase C phosphorylation sites. Phosphorylation of the latter inhibits receptor-mediated activation of ▶phospholipase C (PLC). The C-tail interacts with filamin, an actin-binding protein that also serves as a scaffold for numerous other proteins, including components of the mitogen-activated protein kinase (▶MAPK) family, potassium channels and caveolin-1 [3]. The latter binds cholesterol and numerous signaling molecules (e.g., ▶G proteins) and serves as a structural framework for plasma membrane caveolae. The latter are flask-like invaginations of the plasma membrane that contain numerous signaling molecules, presumably facilitating CaR signaling, and also participate in endocytosis, exocytosis, and transcytosis. Thus the CaR interacts with two proteins that may be key participants in its capacity to regulate intracellular signaling by virtue of their capacity to bind to and organize signaling networks at key cellular locations.

The CaR undergoes regulation at several levels. Protein kinase C-mediated phosphorylation of the receptor's C-terminal tail inhibits CaR-mediated activation of PLC, as noted above. Although downregulation of the CaR (e.g., due to uncoupling of the receptor from its G protein or internalization into the cell) probably does not represent a major form of regulation *in vivo*, it can take place in heterologous expression systems. In cells in which the constant availability of functioning receptor is essential for monitoring Ca₀²⁺, filamin's capacity to inhibit agonist-induced internalization – presumably by tethering the CaR to the cytoskeleton – probably promotes resistance to desensitization by ambient levels of Ca₀²⁺. Several factors regulate the expression level of the CaR gene [3]. Both high Ca₀²⁺ and 1,25(OH)₂ vitamin D₃ upregulate the receptor in some cells, the latter doing so via a regulatory element upstream of the CaR gene. Both of these factors inhibit parathyroid function, and likely do so, in part, by upregulating expression of the CaR, which mediates suppression of ▶parathyroid hormone (PTH) secretion, PTH synthesis, and parathyroid cellular proliferation by high Ca₀²⁺. Additional factors increasing CaR gene expression are interleukin (IL)-1β and IL-6.

In addition to extracellular calcium, numerous other factors activate the CaR [3]. Almost any polycationic atom or molecule activates the receptor. The divalent cations magnesium, strontium, and barium, as well as some divalent heavy metals activate the CaR at millimolar levels. Of these, only Mg²⁺ is normally present in the ECF at concentrations capable of modulating the receptor's biological activity; indeed the CaR is thought to participate in "setting" Mg₀²⁺. Trivalent cations of the lanthanide series, e.g., La³⁺ and Gd³⁺, are also effective CaR agonists at micromolar concentrations. Various organic polycations are likewise potent stimulators of the CaR, including spermine, neomycin and other aminoglycoside antibiotics, protamine, and polyarginine.

Two other classes of molecules, in addition to polycations, modulate the CaR's activity. Some amino acids at millimolar concentrations, particularly aromatic amino acids, activate the receptor at levels of Ca₀²⁺ above 1 mM, i.e., they act as allosteric modulators [3]. The amino acid analogue, glutathione, is a much more potent activator of the receptor, acting at nanomolar concentrations, although whether it does so *in vivo* is not known. The amino acids have a predicted binding site close to the Ca²⁺-binding site in the crevice between the two lobes of each CaR monomer, potentially explaining the receptor's allosteric regulation by amino acids. Another class of molecules, known as ▶calcimimetics, is also allosteric activator of the CaR, acting at nanomolar to micromolar concentrations [4]. The early generations of these drugs, which are useful in treating various forms of hyperparathyroidism (see below), were phenylalkylamines. They bind to a site distinct from that of the amino acids, which is thought to involve the receptor's TMDs, with the amino group of the drugs binding to glutamate 837, just at the outer end of TM7. Other factors influencing the receptor are increases in ionic strength, which reduce the CaR's apparent affinity for Ca₀²⁺, and elevation in pH, which has the opposite action.

Like other GPCRs, the CaR regulates numerous signaling pathways, in many cases via the G proteins, G_{q/11} and G_i [1] [3]. The receptor activates PLA₂ (via the MAPK, ERK1/2, and/or calmodulin-dependent kinases), PLC (via G_{q/11}), and PLD (via G_{12/13}), and inhibits cAMP formation by inhibiting adenylate cyclase (via G_i or calcium-inhibitable forms of the enzyme). The receptor also activates the lipid kinases, PI3-kinase and PI4-kinase (by a rho-dependent pathway in the latter case), which phosphorylate polyphosphoinositides that are themselves mediators or can be cleaved to biologically active products (e.g., IP₃). Finally, the CaR activates multiple MAPKs, including extracellular-regulated kinase (ERK1/2), p38 MAPK, and Jun N-terminal kinase (JNK). While the precise signaling pathways that the CaR utilizes to regulate the

biological functions of some cells are known, much remains to be learned in this regard.

The CaR regulates numerous biological processes, including the expression of various genes (e.g., PTH); the secretion of hormones (PTH and calcitonin), cytokines (MCP-1), and calcium (e.g., into breast milk); the activities of channels (potassium channels) and transporters (aquaporin-2); cellular shape, motility (of macrophages), and migration; cellular adhesion (of hematopoietic stem cells); and cellular proliferation (of colonocytes), differentiation (of keratinocytes), and apoptosis (of H-500 leydig cancer cells) [3].

Role of the CaR in Ca₀²⁺ homeostasis. The CaR plays a central role in orchestrating the responses of the homeostatic system governing extracellular calcium homeostasis to alterations in Ca₀²⁺. In response to hypocalcemia, for instance, the CaR in the parathyroid gland senses the change in Ca₀²⁺ and responds with increases in the biosynthesis and secretion of PTH as well as enhanced parathyroid cellular proliferation [3]. PTH acts on the kidney to increase tubular reabsorption of calcium and enhance the synthesis of the active vitamin D metabolite, ►1,25(OH)₂D₃. The latter increases intestinal calcium absorption and, together with PTH, stimulates skeletal release of calcium. Increased influx of calcium into the ECF from intestine and bone, coupled with reduced excretion of calcium by the kidney in most cases effectively normalizes Ca₀²⁺. In addition to being present in the parathyroid, however, the CaR is also expressed in the kidney, where it enhances renal excretion of calcium in response to hypercalcemia and may inhibit the synthesis of 1,25(OH)₂D₃. The receptor is likewise expressed in intestine and bone, where it may carry out physiologically relevant actions [3]. In bone, for example, raising Ca₀²⁺ stimulates the activity of bone-forming osteoblasts and inhibits the activity of bone-resorbing osteoclasts, actions that would promote a homeostatically appropriate lowering of Ca₀²⁺. Available evidence, however, is conflicting as to whether the CaR or some other Ca₀²⁺-sensing receptor mediates these skeletal actions of Ca₀²⁺.

Disorders with reduced sensitivity of the CaR to Ca₀²⁺. Two conditions result from heterozygous or homozygous inactivation of the CaR, ►familial hypocalciuric hypercalcemia (FHH) and neonatal severe hyperparathyroidism (NSHPT), Familial hypocalciuric hypercalcemia and neonatal severe hyper parathyroidism; two forms of PTH-dependent hypercalcemia that result, respectively, from the presence of one or two CaR alleles bearing inactivating mutations, respectively (Fig. 2) [1–3]. The former manifests as mild to moderate hypercalcemia without the usual symptoms and complications of hypercalcemia. In addition to exhibiting PTH-dependent hypercalcemia, these patients excrete normal or frankly low amounts of calcium in their urine despite being

hypercalcemic, which in other settings would be expected to produce hypercalciuria. Because of their benign clinical course and tendency to rapid recurrence of hypercalcemia unless all parathyroid tissue is removed, most FHH patients should simply be followed untreated. NSHPT is a severe form of hyperparathyroidism encountered in the first 6 months of life often complicated by excessive, PTH-mediated bone loss, fractures and marked elevation in serum calcium concentration. These infants require urgent medical treatment of their hypercalcemia and in very severe cases may require total parathyroidectomy to restore normocalcemia and heal their bone disease.

Well over a hundred inactivating mutations of the CaR have been described, including missense, splice site, deletion, insertion, and deletion mutations. These mutations reduce the activity of the CaR by interfering with its biosynthesis and cell surface expression, reducing its affinity for Ca₀²⁺ and/or interfering with signal transduction. In addition to the reduction in CaR signaling in FHH resulting from the loss of one normal CaR allele, some mutant receptors exert a dominant negative action on the normal CaR when present within wild type-mutant heterodimers.

The parathyroid glands in FHH are reset to maintain a higher than normal serum calcium concentration owing to impaired suppression of PTH release in the face of hypercalcemia (e.g., “resistance” to Ca₀²⁺) (Fig. 2). Similarly the kidneys show a reduced calciuric response to hypercalcemia, which contributes to the hypercalcemia by promoting inappropriately reabsorption of calcium. Mouse models of FHH and NSHPT result from targeted inactivation of one or both CaR alleles, respectively [1,3]. These animals have provided valuable insights into the alterations in tissue function resulting from loss of the receptor.

Several patients have exhibited a clinical picture resembling FHH, but no CaR mutations could be identified. These individuals also exhibited various forms of autoimmunity (e.g., antithyroid antibodies) and harbored anti-CaR antibodies that reduced the high Ca₀²⁺-evoked stimulation of MAPK and PLC in cells transfected with the wild type receptor. Thus both antireceptor antibodies and mutations in the CaR can render the receptor resistant to activation by Ca₀²⁺, producing a clinical picture of mild, PTH-dependent hypocalciuric hypercalcemia [3].

A common cause of PTH-dependent hypercalcemia results from benign, or occasionally malignant, enlargement of one or more parathyroid glands, a condition known as ►primary hyperparathyroidism (PHPT). Although many patients with PHPT present in an asymptomatic state that does not require medical intervention, some are afflicted with excess bone loss, kidney stones, or other complications. If patients are

Ca^{2+} -sensing Receptor. Figure 2 Schematic illustration of the diseases of the CaR and their treatments with calcimimetics or calcilytics. The CaR becomes resistant to extracellular calcium in diseases resulting from inactivating mutations (familial hypocalciuric hypercalcemia /neonatal severe hyperparathyroidism; FHHNSHPT) or antibodies to the CaR as well as in primary hyperparathyroidism. This leads to “resetting” of the serum calcium concentration upward as a result of failure of the parathyroid cells to appropriately suppress PTH secretion in response to hypercalcemia. The parathyroid glands can be “resensitized” to Ca_0^{2+} with a calcimimetic, thereby resetting the level of calcium back toward normal. These drugs are only currently approved, however, for use in secondary hyperparathyroidism (SHPT) in patients with end stage renal failure as a means of lowering the elevated parathyroid hormone (PTH) levels frequently encountered in this condition to the desired concentration. In contrast, activating mutations or antibodies render the receptor too sensitive to Ca_0^{2+} , resetting calcium in the blood to a lower level. A calcilytic would likely be useful in this setting to raise the level of blood calcium toward normal, but this class of drugs has not been approved for this use. Another application of calcilytic currently under investigation is to stimulate endogenous PTH release by “tricking” the parathyroid glands into sensing hypocalcemia, thereby releasing a pulse of PTH, as a potential anabolic therapy for osteoporosis, analogous to the daily injections of PTH currently being used for this purpose. Reproduced with permission from Stewart AF (2004) *N Engl J Med* 351: 324–326.

symptomatic or show signs of end organ damage, they should undergo removal of the enlarged, neoplastic parathyroid gland(s), although the newly developed calcimimetic CaR activators may in the future represent an effective form of medical therapy. There is a reduced level of CaR expression in pathological parathyroid glands from patients with PHPT, although it has not been established that reduced CaR expression causes the resistance of the parathyroid to Ca_0^{2+} in PHPT. Indeed, there can also be reductions in components of the parathyroid CaR “signaling complex,” i.e., $\text{G}_{q/11}$ and/or caveolin-1, which may also contribute. The parathyroid glands of patients with the severe ▶secondary hyperparathyroidism (SHPT) observed in some patients with renal failure also exhibit reduced CaR expression, although the biological significance of this change is still under investigation.

Disorders with enhanced sensitivity of the CaR to Ca_0^{2+} . In contrast to inactivating mutations of the CaR, activating antibodies produce a syndrome of ▶autosomal

dominant hypocalcemia (ADH) accompanied by absolute or relative hypercalciuria (e.g., inappropriately high in the face of hypocalcemia) (Fig. 2) [3]. This clinical syndrome is generally benign, although some patients experience seizures or other manifestations of severe hypocalcemia. Only symptomatic patients should be treated with calcium and vitamin D, and serum calcium should be raised only enough to ameliorate symptoms, as these patients are prone to develop severe hypercalciuria with attendant risk of kidney stones or renal calcification during treatment.

Some patients with reduced or absent parathyroid function, e.g., primary hypoparathyroidism, harbor anti-CaR antibodies (Fig. 2) [4]. In two patients, the antibodies were shown to activate the CaR as assessed by stimulation of MAPK and PLC. Thus, analogous to activating mutations of the CaR, anti-CaR antibodies can increase the sensitivity of the receptor to Ca_0^{2+} , thereby resetting parathyroid and kidney to maintain hypocalcemia.

Drugs

Calcimimetics, potent allosteric activators of the CaR, provide an effective medical therapy for certain forms of hyperparathyroidism (Fig. 2) [4]. In patients receiving dialysis treatment for end stage renal disease (ESRD), markedly elevated PTH levels can promote excessive loss of calcium from the skeleton leading to bone pain and increased risk of fracture. Chronically elevated PTH levels as well as phosphate retention also increase the risk of cardiovascular disease, particularly myocardial infarction. The US National Kidney Foundation has published guidelines for therapeutic targets expected to reduce cardiovascular risk and other complications of ESRD. These include serum calcium and phosphate concentrations close to the normal range (Ca²⁺, 2.1–2.4 mmol/L; phosphate 1.12–1.76 mmol/L) and PTH levels about 3-fold to 5-fold above normal 150–300 pg/ml (levels of PTH thought to maintain normal bone turnover in ESRD). In a substantial number of patients, PTH levels remain excessively elevated despite therapy with conventional forms of therapy, i.e., active metabolites of vitamin D and phosphate binders.

It is in this group of patients that the calcimimetics promised an effective means of lowering PTH levels further [4] [5]. Clinical trials have shown that the calcimimetic, Cinacalcet (also known as Sensipar in the US and Mimpara in Europe), which has been approved by the US Food and Drug Administration, lowers PTH to the target range in more than 50% of patients unresponsive to conventional therapies, while maintaining serum calcium and phosphate close to normal range in most patients. Unexpectedly, Cinacalcet also lowered the calcium–phosphate product (serum calcium multiplied by serum phosphate) by about 15%, a response expected to reduce cardiovascular complications. A small meta-analysis pooling data from several clinical trials with Cinacalcet showed that it reduced risk of fracture, parathyroidectomy, and hospitalization for cardiovascular complications.

Although not yet approved by the FDA for use in PHPT, clinical trials have shown that Cinacalcet restores normocalcemia in nearly three quarters of patients with this condition [3]. In parathyroid cancer, a rare form of PHPT, available data indicate that it lowers serum calcium concentration in about 60% of patients, although generally not to normal levels. Whether by reducing morbidity or mortality associated with severe hypercalcemia, it lengthens life or promotes improved quality of life in this latter setting remains to be determined.

► **Calcilytics**, in contrast to calcimimetics, block rather than mimic the actions of Ca₀²⁺ on the CaR. Administering a rapidly acting calcilytic causes a transient increase in circulating PTH by “tricking” the parathyroid glands into sensing hypocalcemia (Fig. 2) [4]. Ongoing studies are exploring the possible utility of calcilytics as an oral form of treatment for osteoporosis

that mimics the increase in circulating PTH levels resulting from administration of PTH by injection – a known anabolic treatment for osteoporosis.

Ca²⁺ Sparks

Ca²⁺ sparks are localized and transient Ca²⁺ release observed recurrently in muscle cells and skinned fibres. A Ca²⁺ spark is considered to be the elementary process of Ca²⁺ release in situ from one to a few ryanodine receptors.

► Ryanodine Receptor

Ca²⁺ Spikes

Short (typically lasting no more than a few seconds) increases in cytosolic Ca²⁺ concentration that periodically interrupts the stable resting level. Many Ca²⁺ signals are delivered to cells as frequency-coded Ca²⁺ spikes.

► IP₃ Receptors

Ca²⁺ Transient

A typically prolonged transient increase in intracellular Ca²⁺ concentration, which is detected by a Ca²⁺ indicator. The increased Ca²⁺ levels are due to Ca²⁺

release from intracellular Ca^{2+} -stores and to Ca^{2+} influx from the external medium.

- ▶ IP_3 Receptor
- ▶ Ryanodine Receptor
- ▶ Non-selective Cations Channels
- ▶ TRP Channels

Ca^{2+} Waves

Local and transient Ca^{2+} increases that propagate throughout the cytosol of individual cells in the form of waves. Ca^{2+} waves are generated by a positive feedback activation of Ca^{2+} release from the intracellular Ca^{2+} stores through ryanodine receptors or inositol IP_3 receptors.

- ▶ IP_3 Receptor
- ▶ Ryanodine Receptor

Cachexia

Cachexia refers to a physical wasting due to loss of muscle and fat. Cachexia is often found in end-stage cancer patients but is also caused by autoimmune disorders or by infectious diseases such as AIDS and tuberculosis.

Synonyms

Calcium-dependent adhesion protein/plakoglobin

Definition

Cadherins (Calcium-dependent adhesion proteins) are transmembrane proteins, which consist of an extracellular domain composed of cadherin-repeats, a transmembrane domain, and a cytoplasmic domain that interacts with catenins and/or other cytoplasmic proteins.

Catenins are defined as cytoplasmic interaction partners of cadherins that form a chain of proteins (“catena,” latin for chain), which connects cadherins to the actin cytoskeleton.

Basic Characteristics

Structural Characteristics

Cadherins are a superfamily of Ca^{2+} -sensitive cell–cell adhesion molecules, which cause ▶[homophilic cell interactions](#). Cadherins can be divided into different subfamilies, namely, classical cadherins, desmosomal cadherins, protocadherins, and nonconventional cadherins (7TM cadherins, T-cadherin, FAT). Classical cadherins are often denoted by a prefix reflecting their principal expression domains; e.g., E is epithelial, N is neuronal, and P is placental. However, this classification is not stringent, as for instance E-cadherin can also be found in certain neuronal tissues, and N-cadherin is also found in epithelial cells. Among the desmosomal cadherins, two subfamilies can be distinguished: the desmocollins 1–3 and the desmogleins 1–4.

The extracellular domain of cadherins consists of a variable number of a repeated sequence of about 110 amino acids. This sequence is termed the “cadherin repeat” and resembles in overall structure, but not in sequence, the Ig like domains. The cadherin repeat is the characteristic motive common to all members of the cadherin superfamily. Classical and desmosomal cadherins contain five cadherin repeats, but as many as 34 repeats have been found in the FAT cadherin (see below). Cadherins are calcium-dependent cell adhesion molecules, which means that removal of Ca^{2+} , e.g., by chelating agents such as EDTA, leads to loss of cadherin function. The Ca^{2+} -binding pockets are made up of amino acids from two consecutive cadherin repeats, which form a characteristic tertiary structure to coordinate a single Ca^{2+} ion [1].

The classical cadherins are translated as precursor because they are N-terminally cleaved to reveal the mature proteins. This processing is required to activate the cell adhesion function of cadherins. Cadherins interact in trans (i.e., from opposite cells) via the most N-terminal cadherin repeats. A short amino acid sequence within this repeat, histidine–alanine–valine (HAV), has been implicated in mediating cell–cell contacts as HAV peptides can disrupt cadherin-dependent cell adhesion. Besides the trans-interactions of cadherins, the extracellular domains are also capable of forming cis-dimers through lateral amino acid contacts between cadherin molecules on one cell. This dimerization again mainly involves the first cadherin repeat. A zipper model based on the pattern of alternating cis- and trans-dimers [1] for the adhesive interactions has been proposed.

Several nonconventional cadherins that contain cadherin repeats have been described but they have specific features not found in the classical cadherins [1]. The cadherin Flamingo, originally detected in *Drosophila*, contains seven transmembrane segments and in this respect resembles G protein-coupled receptors. The extracellular domain of Flamingo and its mammalian homologs is composed of cadherin repeats as well as EGF-like and laminin motifs. The seven transmembrane span cadherins have a role in homotypic cell interactions and in the establishment of cell polarity. The FAT-related cadherins are characterized by a large number of cadherin repeats (34 in FAT and 27 in dachsous). Their cytoplasmic domains can bind to catenins. T- (=truncated-)cadherin differs from other cadherins in that it has no transmembrane domain but is attached to the cell membrane via a ►glycosylphosphatidylinositol anchor.

Cytoplasmic Interactions of Cadherins

The cytoplasmic domains of cadherins bind to various proteins. The most C-terminal portion of classical cadherins directly associates with either β -catenin or the structurally related γ -catenin (more commonly called plakoglobin). β -Catenin/plakoglobin in turn binds to α -catenin, which is related to the cytoskeletal protein vinculin and associates with actin-binding proteins. Thus, β - and α -catenin provide a link of cadherins to the actin cytoskeleton, although recent evidence indicates that this is indirect, i.e., α -catenin interacts with actin and β -catenin in separate complexes. Another catenin, p120^{ctn} binds to the cytoplasmic juxtamembrane domain of cadherins and appears to be involved in the cis-dimerization and clustering of cadherins. Based on their structure, β -catenin, plakoglobin, and p120^{ctn} belong to a protein superfamily, called the armadillo repeat family [2]. These proteins contain repeats of about 40 amino acid that were initially identified in armadillo, the *Drosophila* homolog of β -catenin. The armadillo repeats are built up of three α -helices that form a

superhelix. The number of repeats varies between different members of the family; for instance, β -catenin contains 12 consecutive armadillo repeats. More distantly related members of the armadillo family include nonjunctional proteins, such as the importins, which are involved in nuclear protein import, and the tumor suppressor APC. p120^{ctn} is the founding member of a subfamily of armadillo proteins that include the plakophilins 1–3, p0071, ARVCF, and the nervous system specific δ -catenin; the latter two are binding to the same region of cadherins as p120^{ctn}. Interestingly, the p120^{ctn} related proteins are also found in the cell nucleus. p120^{ctn} binds to the transcription factor Kaiso relieving its repressor activity, and plakophilin 2 is associated with RNA polymerase III complexes. Loss of p120^{ctn} function in mice leads to activation of NF κ B signaling and inflammation. The desmosomal cadherins also associate with plakoglobin but not with β -catenin, and in addition they bind to plakophilins. Plakoglobin and plakophilins connect desmosomal cadherins to the desmosome specific component ►desmoplakin, which links the complexes to the intermediate filament network (mainly ►cytokeratins in epithelial cells).

The cytoplasmic domains of protocadherins are unrelated to those of classical cadherins. They do not bind catenins and it is not clear whether they are associated with the cytoskeleton [1]. Some protocadherins interact with the c-►src-related kinase ►Fyn, indicating a role in signal transduction (see below).

Gene Organization

Several classical cadherin genes (e.g., E-, P-, VE-cadherins and others) are found in a cluster on human chromosome 16 or on the syntenic mouse chromosome 8. The gene clustering is even more pronounced in the case of the desmosomal cadherins, which are all located on human chromosome 18q12 in relatively close vicinity to each other. Interestingly, the desmocollin and desmoglein genes (termed *DSC* and *DSG*) form two subclusters that have opposite transcriptional orientation. Protocadherins show a particularly striking genome organization. Subfamilies of protocadherins can be defined as those that share a common intracellular domain but differ in their extracellular domains [1].

Functional Characteristics

Classical and desmosomal cadherins are constituents of different types of intercellular junctions. E-cadherin, the classical cadherin of epithelial cells, is part of the adherens junction (zonula adherens), which is attached to a belt of actin via the catenins. As the name says, desmosomal cadherins are part of the desmosomes, which are rivet-like structures that make focal connections between cells. Desmosomes are characterized by a

prominent intracellular plaque structure, which serves as an attachment point for intermediate filaments.

Functional studies show the adhesive role of cadherins [1]. For example, cell–cell adhesion *in vitro* can be blocked by treatment of cultured cells with anti-cadherin antibodies, resulting in dissociation of the cell monolayer. Conversely, forced expression of cadherins by cDNA transfection in cells lacking these molecules leads to establishment of intercellular contacts. Thus, cadherins act as an adhesive glue that efficiently holds cells together. However, they may also have signaling function, as several *in vitro* studies show that cadherins influence differentiation and growth of cells. *In vitro*, cadherins can mediate the ▶**sorting out** of cells, i.e., cells transfected with different cadherins separate from each other and forming homotypic aggregates. Accordingly, one of the main functions of cadherins might be in the delineation of tissue boundaries. Gene knockout experiments have revealed essential and cell-type specific functions of cadherins *in vivo*. The knockout of the E-cadherin gene results in dissociation of cells of blastocyst-stage mouse embryos. The α -catenin knockout has a similar phenotype, while loss of plakoglobin leads to defects in cell adhesion of heart muscle cells. The knockout of β -catenin does not affect cell junctions but rather has a Wnt signaling phenotype (see below), which is manifested at early stages of embryonic development. Apparently, plakoglobin, which is also present in the affected cells, can overtake the adhesive function of β -catenin under these circumstances. The mutation of desmosomal cadherins frequently leads to the disruption of skin layers. These phenotypes resemble those of the ▶**phemphigus blistering diseases** in humans, which are caused by autoantibodies against desmocolins and desmoplakins.

E-cadherin appears to play a major role in cancer as its expression is frequently downregulated in dedifferentiated, metastasizing tumors as well as during ▶**epithelial-mesenchymal transitions** in embryonic development. E-cadherin gene expression is repressed by transcription factors of the Snail/Slug and ZEB1/ZEB2 families, as well as by Twist and E12/47 transcriptional repressors, which all bind to specific DNA elements in the E-cadherin promoter. E-cadherin inhibits invasion of tumor cells in *in vitro* systems and prevents tumor progression *in vivo* animal models. Moreover, loss of function mutations of the E-cadherin gene occurs in gastric carcinomas and certain types of breast tumors. The function of cadherins can be modulated by signaling pathways involving tyrosine kinases, which disrupt cell contacts, as well as by RhoA family GTPases. Conversely, E-cadherin can modulate the activity of these GTPases, although these signaling events have not been clearly defined in molecular terms so far [1].

It is not clear whether protocadherins are true cell adhesion molecules since some of them show only moderate activity in classical cell aggregation assays [1]. However, in *Xenopus* embryos, expression of a dominant-negative mutant of NF-protocadherin leads to disruption of the embryonic ectoderm, indicating a role of this protocadherin in maintaining tissue integrity. Biochemical and embryological evidence indicates that protocadherins also have a role in intercellular signaling. A subfamily of protocadherins, termed CNRs (cadherin-related neuronal receptors), associates with ▶**Fyn**, a cytoplasmic tyrosine kinase related to ▶**c-src**. The extracellular matrix protein ▶**reelin** binds to these CNRs and activates the Fyn kinase, which leads to phosphorylation of a downstream signaling protein, mDAB. This pathway appears to be important for certain steps in cortical neuron development, as antibodies to the reelin-binding domain of CNRs perturb the arrangement of cortical neurons. Since there are so many members of the protocadherin family, which are mostly expressed in the nervous system, it has been speculated that protocadherins play discrete roles in setting up neuronal networks [1].

In *Drosophila*, *Fat* functions as a ▶**tumor suppressor gene** and *dachsous* is involved in thorax, leg, and wing development. Several human and mouse *FAT* homologs have been identified. *FAT1* regulates actin filaments, and the *Fat1* knockout leads to defects in glomerular slit formation [3].

β -Catenin in the Wnt pathway

Besides its role in cell adhesion, β -catenin has an important function as a central signal transduction component in the Wnt pathway [4, 5]. Wnts are a family of secreted glycoproteins that regulate a variety of developmental processes. Binding of Wnts to Frizzled receptors, which are ▶**seven transmembrane span proteins**, induces stabilization of β -catenin. This pool of β -catenin is not associated with cadherins but accumulates in the cytoplasm and eventually enters the nucleus, where it teams up with transcription factors of the TCF family. TCFs bind to specific DNA sequences in Wnt-target promoters via an ▶**HMG box** but lack transactivation domains. In the absence of β -catenin, TCFs behave as transcriptional silencers, in part, because they bind to diverse transcriptional repressors. β -Catenin lacks DNA-binding activity but contains strong transactivating sequences in its N- and C-terminal domains. Thus, when β -catenin binds to TCFs a bipartite transcription factor is formed in which DNA-binding and transactivation domains reside on separate molecules. The TCF/ β -catenin complexes can activate specific Wnt-target genes involved in determining cell fate and differentiation and inducing cancer (see below). For a list of Wnt-target genes see ▶www.stanford.edu/~rnusse/wntwindow.html.

Cadherins/Catenins. Figure 1 Overview of cadherin-mediated cell adhesion and the Wnt signaling pathway. Schematic representation of classical and desmosomal cadherins showing extracellular cadherin repeats and Ca^{2+} -binding sites, and cytoplasmic interaction partners (the latter being depicted in the left cell only, which also shows association of p120^{ctn} and plakophilin 2 with transcriptional regulators in the nucleus). The hypothetical cadherin zipper, which is made up of consecutive cis- and trans-dimers is indicated [1]. The basic outline of the Wnt pathway is shown in the right cell. LRP (lipoprotein receptor-related protein) is a coreceptor for Wnts. PG, plakoglobin, PP, plakophilin.

In the absence of Wnts, cytoplasmic “free” β -catenin is targeted for degradation by a multiprotein complex containing the scaffold component axin or the related protein conductin, the **tumor suppressor APC** (adenomatous polyposis coli), and the serine/threonine kinases CK1 and GSK3 β . When β -Catenin binds to axin it becomes phosphorylated by CK1 and GSK3 β . Hyperphosphorylated β -catenin is recognized by the **E3 ligase β TrCP/slimb**, a component of the ubiquitination machinery, ubiquitinated, and finally degraded in proteasomes [4]. APC has several β -catenin and axin-binding sites and may function by sequestering free β -catenin and delivering it to the axin complex [4]. Thus, APC acts as a safeguard to prevent aberrant accumulation of β -catenin. Mutations of APC occur in up to 80% of colorectal carcinomas and lead to the formation of truncated proteins that are no longer able to interact with axin/conductin and to induce degradation of β -catenin. Therefore, these mutations result in the stabilization of β -catenin and in the formation of constitutive TCF/ β -catenin complexes, which activate transcription of oncogenic target genes in a Wnt-independent fashion. In some colorectal tumors, and more frequently in other tumor types (e.g., hepatoblastomas), stabilization of β -catenin occurs through mutations of the critical serine or threonine residues normally phosphorylated by GSK3 β . Thus both genetically and functionally β -catenin behaves as an oncogene and the Wnt pathway has a major role in tumorigenesis (Fig. 1).

Drugs

There are several potential approaches for pharmacological interference with the cadherin/catenin system. Drugs that upregulate E-cadherin in tumors could be of potential benefit as part of a differentiation strategy to “normalize” epithelial cancers and to prevent metastasis formation, although such substances have not yet been described. In contrast, drugs that affect components of the Wnt pathway, e.g., by blocking the interaction of TCFs with β -catenin, have been identified and are candidates for interference with tumor growth [5].

cADP-ribose

cADP-ribose (cyclic ADP-ribose) has been shown to trigger the release of calcium from the endoplasmic reticulum via ryanodine receptors (calcium release channels). Cyclic ADP-ribose is enzymatically formed and appears to act as a second messenger, which mediates a sustained increase in cytosolic calcium in various activated eucaryotic cells including T lymphocytes.

- ▶ Ryamodine Receptor

Calbindins

Calbindins are hormonally controlled by vitamin D and are expressed in the kidney, intestine, and brain.

- ▶ Ca²⁺-binding Proteins

Calcilytics

A class of drugs that blocks the activation of the Ca²⁺-sensing receptor by extracellular Ca²⁺.

- ▶ Ca²⁺-sensing Receptor

Calcimimetics

A class of allosteric activators of the Ca²⁺-sensing receptor that sensitizes the receptor to extracellular calcium and acts only in the presence but not in the absence of calcium. Calcimimetics can be used to treat various forms of hyperparathyroidism, although they are only approved for use in patients with end stage renal disease receiving dialysis treatment.

- ▶ Ca²⁺-sensing Receptor

Calcineurin

Calcium-dependent serine/threonine phosphatase (also known as protein phosphatase 2B or PP2B). Calcineurin is a heterodimer composed of a catalytic subunit (Calcineurin A) and a regulatory subunit that contains an autoinhibitory domain (Calcineurin B). The catalytic subunit also contains a calmodulin-binding domain. Binding of calcium to the regulatory subunit allows the binding of calmodulin to the catalytic subunit, resulting in displacement of the autoinhibitory domain and enzymatic activation. Calcineurin has many functions within eukaryote cells but is best known for its role in activating transcription of the interleukin 2 (IL-2) gene. IL-2 is required for activation of B- and T- cells and thus calcineurin inhibitors such as cyclosporin A and FK506, are potent immunosuppressants.

Calcitonin

A peptide hormone rapidly inhibiting osteoclast activity. The relevance of calcitonin in human calcium homeostasis is not well understood. Calcitonin has been used for the treatment of osteoporosis, although due to the availability of more potent drugs with less side effects, and the lack of clear data on the anti-fracture efficacy of calcitonin, its clinical use has been steadily declining.

- ▶ Bone Metabolism

Calcitonin Gene Related Peptide

Calcitonin gene related peptide (CGRP) is one of the numerous peptides found in neurons and acting as cotransmitters. It is derived from the gene encoding calcitonin by alternative splicing of mRNA and by proteolytic processing of a precursor peptide. It is mainly found in sensory neurons of the central nervous system. Its prime target is the CGRP receptor, a member

of the family of G protein-coupled receptors. In contrast to calcitonin, which is involved in calcium homeostasis and bone remodeling, CGRP causes vasodilatation and vascular leakage. It is also expressed in C-fiber sensory neurons. It works as a stimulatory (pronociceptive) neurotransmitter when it is released centrally, and as a proinflammatory mediator when it is released peripherally. The central role of CGRP in primary headaches has led to a search for suitable antagonists of CGRP receptors.

► Analgesics

Calmodulin

Small ubiquitous calcium-binding protein. Calmodulin binds and regulates the activity of many protein targets involved in cellular signal transduction pathways mediated by calcium. Calmodulin is ranked among the most conserved proteins and plays a key role in many cellular processes.

Institute, University of São Paulo, São Paulo, Brazil

Synonyms

Ca²⁺-dependent cysteine proteases

Definition

Calpains are proteolytic ►enzymes with cysteine in the catalytic site. In general, calpains are found as intracellular ►proteases. These proteases are associated with many physiological basic processes of the cell.

Basic Characteristics

Calpain Superfamily

In higher organisms, calpain superfamily contains 16 independent genes that modulate cellular function. Out of them, 14 are Ca²⁺-dependent cysteine proteases. The other two encode smaller regulatory proteins that

associate with some of the catalytic subunits to form heterodimeric proteases. Homologous of the calpain catalytic subunits are also present in lower organisms including nematodes, plants, flies, and yeasts. Substantial proportion of the calpains is not free in the cell cytoplasm, but associated with subcellular structures. Several calpain genes are expressed in specific tissues (calpains 3, 6, 8, 9, 11, and 12), whereas others are ubiquitously expressed (calpains 1, 2, 5, 7, 10, 13, and 15).

Calpain Structure

Two members of calpain superfamily, calpain 1 (μ-calpain) and 2 (m-calpain), have been extensively studied. Calpain 1 and 2 differ in their sensitivity to Ca²⁺ and each one of them contains two different polypeptide subunits existing as heterodimers (Fig. 1). The larger subunit (80 KDa) has catalytic activity, whereas the smaller (28 KDa) subunit has a regulatory function. Calpains 3, 8a, 9, 11, 12, and 13 also have the 80-KDa and 28-KDa subunits. The enzymatically active (large) subunit comprises up to four domains: domain I is the N-terminal anchoring α-helix domain, which is important for regulating the activity and dissociation of the subunit. This domain has no sequence homology with any polypeptide sequenced thus far, while sequence homology of domain I among different species (human, chicken, rat, and porcine) is 72–86%; domain II comprises the protease domain that contains the active site catalytic triad Cys105, His262, and Asn286. The ►active site Cys is in domain IIa, whereas the His and Asn that constitute the remainder of the catalytic triad are in domain IIb. Each of these IIa and IIb domains binds one atom of Ca²⁺ in a peptide loop consisting of 8 (IIa) or 9 (IIb) ►amino acids. Sequence Homology of domain II among different species is high, ranging from 85 to 93%; domain III is involved in binding phospholipids and in regulating calpain activity by its participating critical electrostatic interactions. This domain also contains two potential EF-hand Ca²⁺-binding sequences, one at the domain II/III boundary, and the other at the domain III/IV boundary; and domain IV, also called as the penta-EF-hand domain (an EF-hand unit consists of two peptide helix connected by a Ca²⁺-binding loop), is involved in dimerization of the 80-KDa and 28-KDa subunits. Sequence homology among the species ranges from 65 to 93% for this domain. The 28-KDa regulatory subunit of calpain 1, 2, and 9 consists of two domains: domain V is the N-terminal, glycine-rich, hydrophobic domain; and domain VI, the penta-EF-hand domain, which is similar to domain IV of the catalytic subunit. The 80-KDa subunit of the other calpains (3, 8a, 11, 12, and 13) does not interact with the 28-KDa subunit, although having domain IV. Calpains 5, 6, 7, 8b, 10, and 15 are atypical calpains, in that some of their domains have been deleted or replaced. They lack domain IV and therefore presumably do not associate with the 28-KDa subunit.

Calpains. Figure 1 Domain structures of calpain superfamily. Figure kindly provided by Dr. Hiroyuki Sorimachi, Laboratory of Biological Function, University of Tokyo, Japan.

Calpain Regulation

An intricate strategy for the regulation of calpain activity seems necessary since calpain is an abundant cytoplasmic **▶protease** and large amount of proteins can be identified as substrates. Among them are transcription factors, transmembrane receptors, signaling enzymes, and cytoskeleton proteins. Most of the substrates are cleaved in a limited fashion, resulting in stable protein fragments that can have functions different from those of their intact form. Recognition and proteolysis seems to be controlled by multiple determinants, including the formation of secondary structures and the existence of specific recognition sequences. There is a significant preference for particular sequences immediately surrounding the site of proteolysis. Calpain contains many sites of **▶phosphorylation** that are physiologically relevant and regulate its activity. Also membrane localization of calpains is an important mechanism for this regulation. It seems that its interaction with the membrane may facilitate the binding to the substrate. Once activated on the membrane, the calpain presumably diffuses into the cytosol and becomes

resistant to the inhibitory action of the calpastatin, the calpain endogenous inhibitor. In the presence of Ca^{2+} , there is a rapid autolysis of calpain. The same autolysis reduces mass of the 80-KDa and 28-KDa subunits of calpain by cutting out some of its amino acids. Ca^{2+} levels, required to initiate autolysis, are as high as or even slightly higher than the levels required for proteolytic activity and are much greater than the free Ca^{2+} levels in living cell. The presence of phospholipids, with phosphatidylinositol, lowers the Ca^{2+} levels required for this autolysis. However, autolysis of calpains does not unblock the active sites as autolysis of other cysteine proteases do. It seems, therefore, that autolysis has some important role in calpain function. The nature of this role is not yet clear. It is possible that the peptides released during autolysis of the calpains may have important properties.

Physiological and Pathological Conditions Associated to Calpains

The calpain system has a number of different roles in cells, including remodeling of cytoskeleton attachments

to the plasma membrane during cell fusion and cell motility, proteolytic modification of molecules in signal transduction pathways, degradation of enzymes controlling progression through the cell cycle, regulation of gene expression, *substrate* degradation in some apoptotic pathways, and an involvement in long-term potentiation. With so much to contribute in the physiological aspects of the cell, it is not surprising that a great number of pathological conditions may also be associated to calpains disturbances (Table 1). They include type II diabetes, cataract, Duchenne's muscular dystrophy, Limb girdle muscular dystrophy (LGMD2A), Parkinson's disease, Alzheimer's disease, rheumatoid arthritis, ischemia, stroke and brain trauma, various platelet syndromes, hypertension, liver dysfunction, and some types of cancer (several oncogenes and tumor suppressor genes products are substrates for members of the calpain family). Abnormalities in expression of calpain homologs, calpain 3a, calpain 9, and calpain 10, are related to LGMD2A, gastric cancer, and type II diabetes, respectively. The others "calpain pathologies" involve loss of Ca^{2+} homeostasis by cell/tissues and inappropriate/excessive degradation of proteins that are known calpain substrates.

Drugs

Calpain inhibition may represent an important mechanism for future drug development. Control of calpain activity may limit the invasive properties of cells and thereby provides a possible mechanism to limit the invasiveness of tumors or inhibits the development of chronic inflammation. For the moment, pharmacological inhibitors of calpains are still not capable of differentiating among different calpain isoforms in cellular systems or in vivo. The importance of calpains in diseases will continue to stimulate the development of new and better inhibitors.

Calpain Inhibitors

More than 50 endogenous and exogenous inhibitors of the calpains have been described as either transition-state reversible or irreversible inhibitors. The first transition-state inhibitors were the peptide aldehydes (e.g., leupeptin). Using this compound, new ones were synthesized that exhibited improved membrane permeability and calpain specificity (e.g., calpeptin). Other groups of inhibitors have since been discovered: α -dicarbonyls (originally developed as serine protease inhibitors), nonpeptide quinolinecarboxamides,

Calpains. Table 1 Examples of pathological conditions that have been associated to the calpains (Adapted from Goll et al.)

Diseases	Observations
LGMD2A	Caused by mutations in the <i>calpain-3</i> gene and probable loss of calpain-3 proteolytic activity ³³
Gastric cancer	Associated to downregulation of <i>Capn9</i> gene ³⁴
Type 2 diabetes mellitus	Mutations in intron 3 of <i>Capn10</i> gene is associated with increased incidence of type 2 diabetes in some populations ³⁵
DMD and BMD	DMD and BMD are caused by the absence or deficiency of dystrophin a membrane-associated protein, resulting in increased Ca^{2+} concentration in muscle, loss of Ca^{2+} homeostasis, and inappropriate calpain activity ³⁶
Alzheimer's disease	Amount of m-calpain in the cytosolic but not the membranous fractions and in the neurofibrillary tangles of brain from Alzheimer's patients is increased ^{37,38}
Cataract formation	Ca^{2+} influx activates m-calpain, the predominant calpain in lens, cleaving α - and β - but not γ -crystallins. The crystallin fragments aggregate to form cataracts ³⁹
Myocardial infarcts	Ca^{2+} homeostasis is lost in ischemic areas, triggering inappropriate calpain activity. Desmin and α -spectrin are degraded in ischemic hearts by synthetic calpain inhibitors. Protein and mRNA levels of m and u-calpain increase after myocardial infarction ^{40–43}
Multiple sclerosis	The 150-kDa calpain specific degradation product of α -spectrin increases 50% in human MS plaques. ⁴⁴ Degradation of the 68-kDa neurofilament protein is inhibited by a synthetic calpain inhibitor ⁴⁵
Obsessive-compulsive disorders	Erythrocytes from patients with obsessive-compulsive disorder have significantly higher calpain activities than normal controls which could not be attributed to differences in memory function ⁴⁶
Neuronal ischemia (stroke)	Calpastatin is degraded by calpain to a membrane-bound 50-kDa polypeptide in ischemic brain. ⁴⁷ Calpains participate in both apoptosis and necrosis in tissue damage in ischemic areas

LGMD, limb girdle muscular dystrophy; DMD, Duchenne muscular dystrophies; BMD, Becker muscular dystrophies

nonpeptide α -mercaptoacrylic acids, and phosphorus derivatives. The acid derivatives are particularly interesting because they mediate their inhibitory activity by interacting with Ca^{2+} -binding domain of the calpain I and II large subunits. Irreversible inhibitors include the epoxysuccinates (nonspecific cysteine protease inhibitors), acetoxymethyl ketones, halomethyl ketones, sulfonium methyl ketones (potent and highly calpain II selective), and diazomethyl ketones. The epoxysuccinate inhibitor E64 is a commonly used irreversible calpain inhibitor. Drugs such as iodoacetate, iodoacetamide, and N-ethylmaleimide, which are inhibitors of cysteine proteases, are also commonly used as inhibitors.

Calpastatin

Calpastatin is the only known ►protein inhibitor specific for the calpains. It is a heat-stable protein, with molecular mass varying from 34 to 300 KDa and resistant to a wide variety of denaturing agents. Although, only one calpastatin gene exists on chromosome 5, the use of different promoters or alternative splicing mechanisms allows the presence of different calpastatin isoforms produced from this single gene. Frequently, more than one isoform exists in a single tissue. Neither calpastatin nor calpastatin-like activities have been reported in invertebrate's tissues, and genes having sequence homologies to calpastatin have not been detected in *Drosophila*, *C. elegans*, or *S. Cerevisiae*. Hence calpastatin may be restricted to vertebrates. The intracellular level of calpastatin correlates directly with calpain activation and the affinity of calpastatin for the activated forms of the calpains is greater than its affinity for the proenzyme, indicating that both structural and conformational changes due to autolysis favor formation of the enzyme–inhibitor complex. Ca^{2+} is required for calpastatin to bind and to inhibit the calpains. It is also known that Ca^{2+} concentrations required to make this inhibition is dependent on the calpain molecule and this inhibition is reversible, releasing the calpain in an undegraded form. The calpain/calpastatin interaction has been well characterized. It is clear that calpastatin has an important role in regulating activity of calpains, but exactly how it acts in this regulation is not well understood. However, it is not difficult to realize that this specific inhibitor has possible therapeutic applications in diseases involving the calpains.

Calsequestrin

Calsequestrin is the major calcium storage protein of the sarcoplasmic reticulum in skeletal and cardiac muscles. It is highly acidic and has a large capacity for Ca^{2+} . Calsequestrin functions to localize calcium near the junctional face of the terminal cisternae from which calcium can be released into the cytosol via the ryanodine receptor.

Camptothecins

YVES POMMIER

Laboratory of Molecular Pharmacology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

Definition

Camptothecin is a plant alkaloid that selectively targets topoisomerase I (Top1). It produces DNA damage leading to the destruction of eukaryotic cells. Because

of selectivity against cancer cells, camptothecin derivatives are used as anticancer drugs. Camptothecin comes from *Camptotheca acuminata*, a deciduous tree found in southern China. Stem woods of *Nothopodytes foetida* (previously known as *Mappia foetida*) found in the Western Ghats of India are an even better source of camptothecin.

Historical Perspective

Camptothecin was discovered as an active anticancer drug isolated from the bark of *Camptotheca acuminata*. The anticancer activity of camptothecin was discovered in the 1960s by the National Cancer Institute (NCI) as part of a systematic effort to screen for novel anticancer agents derived from natural products. Monroe Wall and Mansuhk Wani identified the chemical structure of camptothecin. They also identified the chemical structure of taxol, again under the auspices of the NCI. Susan Horwitz was contracted by the NCI to elucidate the anticancer mechanisms of camptothecin. She found in the early 1970s that camptothecin induced DNA breaks and arrested DNA and RNA synthesis. However, it is approximately 12 years later, only after DNA topoisomerase I (Top1) had been identified in human cells, that Leroy Liu and his coworkers found that Top1 was the cellular target of camptothecin [reviewed in [1]].

Camptothecin is highly insoluble, which facilitated its crystallization and chemical structure determination.

The first clinical trials were performed in the 1970's using a sodium salt derivative with an open E-ring (Fig. 1). However, the clinical efficacy was limited and severe bladder toxicity led to the termination of the clinical trials. The poor efficacy of the camptothecin sodium salt in those clinical trials was probably due to the fact that the open E-ring form of camptothecin (carboxylate derivative) is inactive as a Top1 inhibitor. Following the identification of Top1 as a target of camptothecin, water-soluble derivatives were produced by the pharmaceutical industry. Two of these water-soluble derivatives have been approved by the FDA for cancer treatment in the early 2000s: ▶topotecan and ▶irinotecan.

Mechanism of Action

The natural isomer of camptothecin: 20-*S*-camptothecin (Fig. 1) is a highly specific Top1 inhibitor. By contrast, the 20-*R* derivative obtained by chemical synthesis by Monroe Wall and Mansuhk Wani is inactive against Top1 and as an antitumor agent. Top1 is the only cellular target of camptothecins as human cell lines selected for drug resistance consistently mutate their Top1 in such a way that those mutant enzymes become highly resistant to camptothecins while remaining catalytically active. TOP1 is an essential gene in metazoans whereas yeast strains with TOP1 gene deletion are viable but immune to camptothecins.

Camptothecins. Figure 1 Chemical structures.

Top1 is an essential enzyme in metazoans because it is required to relax DNA supercoiling generated by chromatin remodeling during transcription and replication (Figs 2a, b). Camptothecin binds to the Top1-DNA cleavage complex by intercalating between the base pairs flanking the DNA cleavage site (Fig. 2c). As a result, camptothecins slow down the re-ligation of Top1 cleavage complexes. Cocystal structures show that camptothecins not only binds to the Top1-DNA complex by stacking interactions with the DNA but also by forming a network of hydrogen bonds with amino acids residues of Top1. Those amino acid residues are those whose mutations confer CPT resistance (Fig. 2d, e). Thus, CPT is a paradigm for “▶interfacial inhibitors”, i.e. drugs that bind at the interface of macromolecular complexes [2].

Cancer cells are killed by camptothecins as a result of the trapping of Top1-DNA cleavage complexes. Those

trapped Top1 cleavage complexes preferentially kill replicating cells as they produce collision with DNA replication forks (Fig. 3).

Clinical Use (Including Side Effects)

Topotecan (Hycamtin[®]) is routinely used to treat ovarian cancers and small-cell lung cancers (SCLC). It is given by intravenous infusion. Hematological toxicity is a common side effect due to the destruction of bone marrow progenitors. Infections are due to loss of white blood cells, bruising or bleeding to the loss of platelets, and anemia with fatigue to loss of red blood cells. Within a day following infusion, patients generally feel sick with nausea and possibly vomiting. They can be controlled with anti-emetic drugs. Loss of appetite for a day or so is common. Patients may also feel tired during the first weeks of treatment. Hair loss starts 3–4 weeks after the first dose. It is temporary. Hair regrows once the

Camptothecins. Figure 2 (a) Topoisomerase I (Top1) is an abundant enzyme. It is mostly associated noncovalently with chromatin. (b) Top1 relaxes DNA by making single-strand breaks that are generated by the covalent linkage of Top1 to the 3'-end of DNA. (c) Camptothecin binds reversibly to the Top1-DNA cleavage complex and slows down DNA re-ligation. (d) Ternary complex including Top1 (yellow), DNA (dark blue ribbons), and camptothecin (green and red in the middle). (e) Same structure except Top1 is in ribbon representation.

Camptothecins. Figure 3 Conversion of reversible Top1-DNA cleavage complexes into DNA damage by collision of a replication fork (the DNA polymerase complex is not shown).

treatment is finished. Because of potential ►**teratogenic** effects, it is recommended to use contraception during topotecan treatment and a few months afterwards.

Irinotecan (CPT-11) is approved for colorectal tumors. It is given by intravenous infusion. The most severe side effect is diarrhea, which can be severe and needs to be treated by a physician. Temporary liver dysfunction is generally asymptomatic. The other side effects are the same as those produced by topotecan.

Cancer, Molecular Mechanisms of Therapy

FRED BUNZ

The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, The Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Malignant tumor; Malignant neoplasm

Definition

Cancers are tumors that have acquired the ability to invade and disrupt surrounding normal tissues. Such lesions can arise in any tissue of the human body, and so cancers represent a heterogeneous group of diseases that have certain biological features in common.

A tumor begins as an outgrowth of a clonal population of cells that follows a loss of tissue homeostasis, and progresses into a cancer as it grows in size and becomes invasive. During the later stages of cancer progression, cancer cells can enter the bloodstream or lymphatic system and grow in distant sites. This process is known as metastasis. The invasive and metastatic properties of cancers lead to the lethal destruction of normal tissues.

Basic Mechanisms

Many anticancer agents currently in use, including chemotherapeutic drugs and radiation, are potent inducers of ►**apoptosis** and ►**cell-cycle arrest**. It is believed that induction of these molecular pathways is central to the efficacy of such agents [1]. Genetic and epigenetic alterations that contribute to tumorigenesis

often disable the pathways that lead to apoptosis and growth arrest and therefore affect the way that cancer cells respond to therapy. Recent advances in the understanding of how cellular pathways of growth and death work have led to insights as to how therapy might be optimized.

The regulatory apparatus that controls the cell division cycle is the frequent target of inactivating mutations, and some of these mutated genes can be inherited in cancer-prone families. Similarly, mutations can affect apoptotic pathways. Many cancer-derived cell lines demonstrate a resistance to experimental apoptotic stimuli and recent evidence supports the idea that alterations in genetically defined apoptotic pathways are actively selected for during tumor development. It thus appears that inactivation of the pathways that lead to cell-cycle arrest and apoptosis confer a selective growth advantage.

The relative contributions of cell-cycle arrest and apoptosis to the death of tumor cells following therapy remain a point of controversy [2]. In vitro, cell death triggered by anticancer agents can occur as a result of an immediate apoptotic program or, alternatively, following a substantial delay as a result of dysregulated cell-cycle arrest. These pathways and the drugs that trigger them have been experimentally defined in a colon cancer cell system (Fig. 1). At present it appears likely that different pathways dominate in different cell types. Furthermore, it is important to understand that the experimental systems currently in use are imperfect representations of tumors and these no doubt fail to fully represent complex cellular responses of human cancers. The development of model systems that better emulate cancers in situ will likely aid in understanding how death pathways can work in a clinical setting.

Apoptosis

A substantial amount of indirect evidence supports the contention that the induction of apoptosis in tumor cells is critical to successful therapy. Cancer therapy might therefore be viewed as an attempt to induce apoptosis in a population of cells that have undergone selection for apoptotic defects. If correct, this hypothesis would suggest why cancer therapy is in many cases unsuccessful. However, recent studies indicate that this fundamental problem can be circumvented. Progress in the identification of molecules key to the cell death pathways has led to a growing understanding of how apoptosis occurs [3]. It has become clear that pathways to apoptosis are numerous and often interconnected. A solution to the clinical problem of therapeutic resistance, then, may lie in the fact that there appears to be multiple ways that a cell death program can be implemented.

Apoptosis occurs as a result of a cascade of proteolysis that culminates in the destruction of the cell. Apoptotic proteolysis is catalyzed by the ►**caspase** family of

Cancer, Molecular Mechanisms of Therapy. Figure 1 Cancer therapy and cell death. There are at least two pathways by which therapeutic and preventive agents can cause the death of colon cancer cells. A. Antimetabolites and cyclooxygenase inhibitors can trigger apoptotic signals. The apoptotic signaling pathways can be disrupted in different stages by a number of cancer-related gene mutations and overexpressed proteins, leading to relative therapeutic resistance. B. Therapeutic agents that damage chromosomal DNA can activate a signal transduction pathway that normally results in a protective arrest of the cell-cycle. When disrupted by cancer-related mutations, this pathway can fail resulting in progression of the cell-cycle, which leads to the dysregulated replication and segregation of damaged chromosomes. Cells that escape cell-cycle arrest are subsequently eliminated by apoptotic effector proteins, resulting in relative therapeutic sensitivity.

proteases and can occur via the activation of one of two major pathways. In the intrinsic, or mitochondrial apoptotic pathway, an intracellular death signal causes the disruption of mitochondria, which liberates into the cytoplasm proteins that facilitate caspase activation. Proapoptotic members of the *Bcl2* family appear to play a central role in the physical disruption of the mitochondrial membranes. An extrinsic apoptotic pathway uses the same downstream effector proteases as the intrinsic pathway, but in this case the death signal originates from the cell surface. External death-inducing ligands bind a family of death receptors such as CD95 (also known as Fas and Apo-1), tumor necrosis factor receptor 1 and TRAIL (also known as DR5 and KILLER). Ligand binding induces multimerization of these receptors that results in caspase activation.

Negative regulation of apoptosis is effected by inhibitor of apoptosis proteins. Another means of controlling apoptosis is by altering the stabilization of mitochondria, which is largely determined by the interplay between the pro- and antiapoptotic members of the *Bcl2* family [4].

Alterations to the *P53* gene are the most common genetic defects known in cancer [5]. The protein product of *P53* is involved in a number of pathways that directly and indirectly lead to apoptosis. Many genes that are involved in apoptosis can be induced by this protein, which is a transcriptional transactivator. The emerging hypothesis is that p53 is a central node of a complex apoptotic network that may function differently in diverse cell types and tissues. For example, *Bax*, the prototype proapoptotic member of the *Bcl2* family, can be transcriptionally induced by p53 in certain, but not all, cell types. Like *p53*, *Bax* can modulate the extent to which cells are sensitive to apoptosis caused by therapeutic agents.

Cell-Cycle Regulation

Ionizing radiation and radiomimetic drugs that cause DNA damage are among the most frequently used anticancer agents. In the presence of damaged chromosomes, cellular pathways are triggered which bring to the progression of the cell-cycle to a halt, a status known as cell-cycle arrest. Cell-cycle arrest is mediated

by the activation of checkpoints. Checkpoints block specific processes that occur during cell growth. In this way, cells with intact checkpoints prevent the replication and segregation of damaged chromosomes. In cells that have disrupted checkpoint pathways, DNA damage can lead to the aberrant progression of the cell-cycle, which can result in lethal reduplication of genomic DNA and inappropriate timing of cell division. Analysis of genetic alterations that occur in hereditary cancers suggests that the G₂ checkpoint, which prevents the entry of cells with damaged chromosomes into mitosis, is a particularly important target of mutational inactivation during carcinogenesis.

In addition to its role as a mediator of apoptosis, the p53 protein is part of a checkpoint mechanism that causes arrest of the cell-cycle. Whether p53 activation causes apoptosis or cell-cycle arrest depends upon the stimulus applied and upon the cell type being observed [5]. In response to DNA damage, p53 can be activated by the Chk2 kinase, which is in turn activated by the ATM (Ataxia Telangiectasia Mutated) kinase. The checkpoint functions of these tumor suppressor genes, which are mutated in a broad spectrum of sporadic and inherited cancers, supports the idea that the inactivation of the G₂ checkpoint is a frequent event during carcinogenesis and that many tumors are likely to be checkpoint defective. An understanding of how cancer cells differ from normal cells in their responses to DNA damage appears likely to prove useful in devising therapy of maximal efficacy.

Pharmacological Intervention

Most of the therapeutic anticancer agents currently in use were developed empirically, without any prior knowledge of apoptotic or cell-cycle control mechanisms. Subsequently, it has become apparent that apoptosis and cell-cycle arrest are triggered upon exposure of tumor cells to these agents. Recent advances in our understanding of the molecular mechanisms of apoptosis and cell-cycle regulation have illuminated the mode of action of many of the common anticancer agents and suggested why some cancers are resistant to therapy.

Therapeutic Induction of Apoptosis

Many of the agents currently in use for the therapy of cancer can trigger apoptosis in cancer cells. Cancer-associated alterations of the genes that regulate apoptosis would therefore be predicted to affect sensitivity to these agents.

One commonly used agent is the ▶**antimetabolite** 5-fluorouracil (5-FU), which is frequently used as an adjuvant therapy in conjunction with surgical excision in the treatment of solid tumors. p53 can directly trigger apoptosis in cells exposed to 5-FU *in vitro* [1]. In addition, there is a substantial amount of clinical

evidence that suggests that p53 status may be predictive of the response of patients to 5-FU therapy.

The pro- and antiapoptotic members of the *Bcl2* family affect cellular sensitivity to apoptosis and thus to many chemotherapeutic agents [4]. For example, overexpression of the antiapoptotic genes *Bcl2* and *Bcl-XL* in some cell lines and tumors can confer resistance to apoptosis triggered by ionizing radiation. Conversely, overexpression of proapoptotic *Bax* in experimental tumors can induce apoptosis directly or render such tumors more sensitive to cisplatin and 5-FU.

Nonsteroidal antiinflammatory drugs, such as sulindac and indomethacin, are important chemopreventive agents for patients genetically predisposed to colorectal cancer. This class of compounds, which bind and inhibit ▶**cyclooxygenases**, has been found to cause apoptosis in cultured gastrointestinal epithelial cells. Strikingly, the experimental deletion of the *Bax* gene in tumor-derived colon cancers has been found to disrupt the apoptotic response to this class of drugs, demonstrating the potential importance of this pathway in chemoprevention.

Therapeutic Activation of Cell-Cycle Checkpoints

While induction of apoptosis is the most well recognized molecular mechanism of action of anticancer agents, it is becoming clear that many agents can exploit the checkpoint defects that often occur during cancer development. In fact, ionizing radiation and ▶**radiomimetic** drugs such as doxorubicin and bleomycin that cause DNA damage are among the most frequently used anticancer agents.

Exposure of many types of normal cells to DNA damaging agents results in the activation of cell-cycle checkpoints, which implement a protective cell-cycle arrest. In cancer cells that have checkpoint defects, such treatment would be predicted to lead to arrest failure, cell-cycle dysregulation, and eventual cell death. The observed sensitivity of cancer cells, then, is thought to result from their failure to undergo a protective cell-cycle arrest in response to treatment. Ultimately, the cell death that follows cell-cycle dysregulation may occur through apoptotic pathways, demonstrating a complex relationship between these fundamental processes.

Though DNA damage-based therapies have been in use for many years, it has remained unclear why such treatment often causes the selective death of tumor cells while sparing adjacent normal tissue. The genetic alterations that occur in cancers that alter the DNA damage response may explain why such therapy can be efficacious.

Cannabinoid Receptors

The two G-protein-coupled receptors for Cannabis psychotropic component, Δ^9 -tetrahydrocannabinol (THC) cloned to date, the cannabinoid CB₁ and CB₂ receptors.

► Endocannabinoids

Cannabinoids

Group of compounds which naturally occur in the hemp plant, *Cannabis sativa*. Most of them are insoluble in water. The most abundant cannabinoids are Δ^9 -tetrahydrocannabinol (THC), its precursor cannabidiol and cannabinol, which is formed spontaneously from THC. Cannabinoids exert their effects through G-protein coupled cannabinoid receptors (CB₁/CB₂).

► Endocannabinoids

Cannabis

The plant *Cannabis sativa* produces the psychoactive drug Δ^9 -tetrahydrocannabinol (THC). Recreationally, THC is consumed in form of marijuana (dried flowers and leaves) or hashish (resin). The cultivation and possession of *Cannabis* for recreational use is not

allowed in most countries. THC is medically used as antiemetic in patients receiving cancer chemotherapy and administered to AIDS patients to stimulate appetite. THC binds to and activates ►cannabinoid receptors (CB₁ and CB₂) belonging to the superfamily of ►G-protein coupled receptors.

Capsaicin

Capsaicin, also known as N-Vanillyl-8-methyl-6-(E)-nonamide, is the most pungent of the group of compounds called capsaicinoids: It is a common ingredient in varieties of pepper such as habanero, Thai, tabasco, cayenne etc. One target with which capsaicin interacts is the capsaicin receptor, an ion channel belonging to the superfamily of TRP channels. Because of the structural relation to other TRP channels and because the vanilloid moiety is an essential component of capsaicin, the capsaicin receptor is also called TRPV1 or vanilloid receptor (VR1). It is involved in heat and pain perception.

► Nociception
 ► Non-selective Cation Channels
 ► TRP Channels

Capsaicin-sensitive Primary Afferent Neurons

These are a subset of sensory neurons having their cell bodies (small to medium size) in dorsal root and in cranial nerve ganglia and possessing nonmyelinated (C-type) or thinly myelinated (A-delta type) fibres. This subset of neurons express transient receptor potential vanilloid type 1 (TRPV1, or vanilloid, or capsaicin receptor) that is excited by capsaicin, the pungent ingredient of chilli. These neurons have been classified as polymodal nociceptors because they can be excited by various noxious stimuli.

Carbon Monoxide

RUI WANG

Lakehead University, Thunder Bay, ONT, Canada

Synonyms

Carbonic oxide; Coal gas; CO

Definition

Carbon monoxide (CO) is a colorless and odorless gas molecule. This inorganic compound, at standard temperature and pressure, is chemically stable with low solubility in water but high solubility in alcohol and benzene. Incomplete oxidation of carbon in combustion is the major source of environmental production of CO. When it burns, CO yields a violet flame. The specific gravity of CO is 0.96716 with a boiling point of -190°C and a solidification point of -207°C . The specific volume of CO is 13.8 cu ft/lb (70°F).

Basic Characteristics

All mammalian cells are virtually capable of producing CO with heme as the main substrate (Fig. 1) [5]. Enzymatic heme metabolism *in vivo* is mainly catalyzed by heme oxygenase (HO). In the presence of HO, the porphyrin ring of heme is broken and oxidized at the α -methene bridge, producing equimolar amounts of CO, ferrous iron, and biliverdin. Three isoforms of HO have been identified. Inducible HO-1 (32 kDa) is mostly recognized for its upregulation in response

to physiological and pathophysiological stimulations to increase oxidation of heme and production of CO and biliverdin. HO-2 (36 kDa) is a constitutive form of HO with relative stable expression level in almost every type of mammalian cells. HO-3 is also constitutively expressed in a limited number of mammalian cells. The function of HO-2 appears to be the regulation of basal heme metabolism. As a poor heme catalyst, the biological function or necessity of HO-3 is not clear.

CO has been known as a silent or invisible killer because severe CO intoxication leads to death, due to its binding to hemoglobin and reducing the oxygen carrying capacity of blood. Neurological disorders are often encountered in patients with mild CO intoxication, including impaired vision and coordination, headaches, dizziness, faintness, disorientation, nausea, and fatigue, etc.

At physiologically relevant concentrations, CO plays profound and important physiological roles in regulating cellular functions. In the cardiovascular system, CO exerts different vasorelaxant effects on different types of blood vessels, protects myocardial cells and isolated heart preparations from ischemia/reperfusion damage, and inhibits platelet aggregation [2]. Modulation of hypothalamic-pituitary-adrenal axis, control of circadian rhythm, and adaptation of odor response are examples of the neuronal effects of CO. Moreover, endogenous CO is involved in nociception and chemoreception, thermal regulation, vision, hearing, learning, memory, and behavior. Due to its strong anti-inflammatory and antiproliferation effect, CO may also suppress the development of pulmonary fibrosis. A basal level of endogenous CO is important in supporting female reproductive processes and lactation, and in regulating penile erection and ejaculation in male. Depending on the concentration range, CO affects baseline bile output and the occurrence of choleresis. Increased renal production of CO has been shown to be renal protective. By modulating calcium handling of pancreatic islet beta cells, CO increases insulin release. Abnormalities in endogenous CO metabolism contribute to various pathological situations, including hypertension, neurodegeneration disorders, cardiac failure, and inflammation, to name a few [5].

The cellular and molecular mechanisms for the biological functions of CO are closely related to the chemical nature of CO. As a ►**gasotransmitter**, CO is freely permeable to cell membrane and its cellular effect is not mediated by specific membrane ►**receptors**. CO binds to reduced iron [Fe(II)] in the center of heme-containing proteins. This binding subsequently alters functions of the affected heme-containing proteins, such as hemoglobin, myoglobin, prostaglandin endoperoxide synthase, NOS, catalase, peroxidases, respiratory burst oxidase, pyrrolases, cytochrome c oxidase, cytochrome P450, soluble guanylyl cyclase

Carbon Monoxide. Figure 1 Heme oxygenase catalyzed heme metabolism (from *Pharmacol Rev* 57:585–630,

(sGC), tryptophan dioxygenase, and many others. The binding of CO to heme-containing proteins can lead to either activation or inactivation of these proteins. The binding of CO to HbA inhibits its O₂ carrier function since both O₂ binding to, and its release from HbA are suppressed. The binding of CO to sGC, on the other hand, activates this enzyme. The activation of sGC leads to increased production of \blacktriangleright cGMP, which activates cGMP-dependent protein kinase. The latter phosphorylates several important regulators of [Ca²⁺]_i, inhibiting Ca²⁺ gates and activating Ca²⁺ pumps on the endoplasmic reticulum, and activating K_{Ca} channels on the plasma membrane. cGMP also regulates several classes of phosphodiesterases and is itself rapidly degraded by phosphodiesterases.

In addition to intracellular heme-containing proteins, big-conductance calcium-dependent \blacktriangleright K⁺ (BK_{Ca}) channels and calcium-spark activated transient K_{Ca} channels in plasma membrane are also targeted by CO [3]. As well known, nitric oxide (NO) also activates BK_{Ca} channels in vascular smooth muscle cells. While both NO and CO open BK_{Ca} channels, CO mainly acts on alpha subunit of BK_{Ca} channels and NO mainly acts on beta subunit of BK_{Ca} channels in vascular smooth muscle cells. Rather than a redundant machinery, CO and NO provide a coordinated regulation of BK_{Ca} channel function by acting on different subunits of the same protein complex. Furthermore, pretreatment of vascular smooth muscle

cells with NO abolished the effect of subsequently applied CO on BK_{Ca} channels. This can be explained by an altered interaction of beta subunit and alpha subunit of BK_{Ca} channels induced by NO, which prevents the interaction of CO with beta subunit of BK_{Ca} channels. It has been shown that in peripheral resistance and cerebral arterioles, activation of K_{Ca} channels by CO is the major molecular mechanism for CO-induced vasorelaxation. In other types of blood vessels, effect of CO on K⁺ channels may become less important in comparison with activation of the cGMP pathway by CO [2].

Drugs

Therapeutic Application of CO

To prepare CO solution for the experimental purpose, it is recommended to bubble 20 ml of stock solution in a sealed glass tube with a stream of pure CO gas. The bubbling process lasts for 20 min under the pressure of 100 kPa at 37°C [3]. One microliter of this CO-saturated solution is estimated to contain 30 ng of the gas based on the solubility of CO at 37°C, the extent of dilution of the CO-saturated solution, and the assumption that the loss of the added CO from the bath solution at the time of experiments is negligible. The stock solution of CO should be freshly prepared before each experiment and then should be diluted immediately to the desired concentration with the bath solution or culture media.

Approaches to Increase CO Levels

Increasing endogenous CO production or directly applying exogenous CO has not been tested on humans. Ample experimental data, however, have been obtained in different animal species and from various types of cultured cells, supporting the idea of using CO as an effective therapeutic agent.

Increased Endogenous CO Production

As CO is the enzymatic product of HO, upregulation of HO expression would increase endogenous CO level. Human *HO-1* gene has been transferred to experimental rats using retroviral vectors to attenuate the development of hypertension, promote somatic growth, and reduce left ventricular myocardial infarction induced by ischemia/reperfusion myocardial injury. Human *HO-1* gene transfer to rat heart also decreases myocardial lipid peroxidation and the abundance of proapoptotic Bax and proinflammatory interleukin-1 β and increase anti-apoptotic Bcl-2 protein levels. Human *HO-1* gene transfer can be potentially applied to and targeted on patients who have history of cardiac attack episodes or at risk of developing coronary ischemic events. The major concern for *HO* gene transfer resides on the issue of safety of vectors. Nonpathogenic, weakly immunogenic, minimal immune and inflammatory reactions by the host are prerequisites for the application of viral or nonviral factors to humans. Furthermore, success in *HO* gene transfer in experimental animals by no means warrants its success on human beings.

HO-1 expression can also be upregulated by various pharmaceutical drugs or compounds. SnCl₂ and CoCl₂ are among HO-1 inducers that were tested in early time. Applications of these compounds have been discontinued due to their excessive toxicity and high index of animal mortality. Heme is also called reduced hematin. The Fe³⁺ oxidation product of heme is termed hemin. Hemin (Fe³⁺) is reduced to heme (Fe²⁺) in vivo prior to oxidation by HO. Hemin is also called hematin chloride. The elevated heme level itself presents a prooxidant threat. The cell copes with this threat by upregulating HO-1 expression. The latter degrades heme to increase the production of CO. Heme derivatives, such as hemin and heme-L-lysinate, are now of choice for pharmacological induction of HO-1 expression. Blood pressure lowering effect of hemin injection to young spontaneously hypertensive rats (SHR) was observed in late 90s'. Short-period administration of hemin (i.p., 15 mg/kg/day for 4 days) to young SHR significantly upregulated HO-1 expression and lowered blood pressure of these hypertensive animals. Application of heme-L-lysinate (45 μ mol/kg i.p.) or heme-L-arginate (45 μ mol/kg i.p.) to SHR, phenylephrine-induced, and DOCA-salt hypertensive rats has been shown to lower blood pressure within 1 h of the bolus

injection. Among the pitfalls for using HO-1 inducers is potential oxidative damage as both the inducers, such as heme, and some of the products of HO, such as iron, are prooxidants. Therefore, dosage and duration as well as administration route of HO-1 inducers should be carefully designed.

Administration of Exogenous CO

In recent years, CO inhalation at 500–1,000 ppm has been tested as a novel therapeutic approach for certain diseases. In one study, myocardial ischemia/reperfusion damage was induced to rats by occluding the left anterior descending coronary artery for 30 min. Inhalation of 1,000 ppm CO for 24 h significantly reduced the ratio of infarct areas to risk areas and suppressed the migration of macrophages and monocytes into infarct areas, and the expression of TNF- α in the heart. In another study, exposing rats for 20 h/day to CO (200 ppm) for 14 consecutive days induced a 21% increase in right ventricular hypertrophy and a 7% increase in left ventricular hypertrophy. It appears that CO inhalation as a therapeutic avenue should only be given for a short period.

CO-releasing compounds have been produced from certain transitional metal carbonyls. The most recently developed tricarbonylchloro(glycinato) ruthenium(II) (CORM-3) slowly liberates CO in vitro, ex vivo, and in vivo. In addition to its advantageous water solubility, CORM-3 also releases CO in a controllable rate at physiological pH. Many laboratories have tested CORM-3 and highly appreciated its usefulness. For example, CORM-3 administration significantly lowered mean blood pressure in vivo, and relaxed pre-contracted aortic rings in vitro [1].

The oxidation of dichloromethane (DCM), also named methylene chloride, yields CO and CO₂ in vivo, constituting a CO prodrug. Six hours after administration of a single oral dose of DCM (6.2 μ mol/kg) to rats led to an elevated mean maximum COHb level of 9.3%. DCM can also be administered by injection (3 μ mol/kg i.p.) or inhalation (100–500 ppm). The quantity of CO produced per mole inhaled DCM in rats was about 0.7–0.8 mol. The half-life of DCM in vivo is about 3 h and CO released from DCM has a half-life of about 13 h. Oral application of DCM immediately after allogeneic aorta transplantation in rats (500 mg/kg/day for 15–30 days) significantly reduced neointima formation of the vessel wall. Prolongation of liver allograft has also been observed with the application of DCM with diminished apoptosis and preservation of hepatic architecture and function. In another study, an oral dose of 6.2 μ mol/kg DCM in corn oil was given 6 h before induction of liver damage. This treatment protected mice from liver damage based on the measurement of plasma enzyme activities of alanine aminotransferase and caspase-3 activation in liver tissues.

Approaches to Decrease CO Levels

Overproduction of CO *in vivo* is accompanied by overloading of iron and accumulation of bilirubin. The former leads to iron intoxication and the latter kernicterus in neonates. Overproduced CO alone stimulates free radical production in mitochondria and becomes poisonous to selective heme proteins. For these considerations, inhibition of endogenous CO production under specific pathological conditions is demanded. Different pharmacological blockers have been tested for their capabilities to selectively inhibit HO activity and the consequent CO production. The most widely studied and used HO blockers are ► **metalloporphyrins**, including chromium mesoporphyrin (CrMP), manganese protoporphyrin, manganese mesoporphyrin, zinc protoporphyrin (ZnPP), tin mesoporphyrin, and tin protoporphyrin (SnPP) [4]. The acute and chronic applications of metalloporphyrins have been reported. For example, daily injection of ZnPP (45 $\mu\text{mol/kg}$ i.p.) or CrMP (4 $\mu\text{mol/kg}$ i.p.) for 4 days resulted in a striking increase in blood pressure in prehypertensive (4-week-old) and young (8-week-old) SHR. By carefully choosing the concentrations, these metalloporphyrins can specifically inhibit HO without interacting with other cellular components. This is specifically relevant to the reported inhibition of NO synthase and sGC activities by metalloporphyrins. The permeability of the blood–brain barrier to different metalloporphyrins varies. SnPP can easily pass the blood–brain barrier, while ZnPP cannot. This property is important in determining administration routes for applying metalloporphyrin *in vivo* to different organs and tissues.

In addition to pharmacological approach, HO expression can also be downregulated by HO antisense treatment. Once the antisense is tagged to a specific cell type, cell type-specific local production of CO can be inhibited, which is more advantageous than general inhibition of HO activity by pharmacological compounds.

Carbon Oxide

► Carbon Monoxide

Carbonic Anhydrase

Carbonic anhydrase (CA) is a zinc-containing enzyme that facilitates the interconversion of CO_2 and HCO_3^- . More than ten carbonic anhydrase isozymes have been identified, some of which are cytoplasmic, such as CA I and CA II, some are membrane bound, such as CA IV, and some are mitochondrial, such as CA V. CA VI is secreted into saliva. CAs have a wide distribution and they participate in all physiological processes that deal with CO_2 and HCO_3^- handling such as cellular pH regulation and acid and ion transport. Highest expression levels are found in red cells (CA I and CA II), but CA activity is also present in lung, endothelial cells, muscle, kidney, ciliary body and lens, pancreatic ducts, salivary gland acini, choroid plexus, osteoclasts, and in other tissues and cells. The observation that sulfanilamide inhibited renal HCO_3^- absorption by inhibition of CA led to the development of the sulfonamide class of diuretics that includes thiazides and loop diuretics. CA II deficiency syndrome is an autosomal recessive disorder characterized by osteopetrosis, renal tubular acidosis, and cerebral calcification and mental retardation while CA VI deficient patients show loss or impairment of taste and smell sensations.

Klinik für Innere Medizin III, , Homburg/Saar,
Germany

Synonyms

Digitalis

Definition

Cardiac glycosides (CG) are potent and highly specific inhibitors of the intrinsic plasma membrane Na^+/K^+ -ATPase, also known as the sodium pump. They modulate electrophysiological properties of the heart and its contractile functions.

Mechanism of Action

The molecular target of cardiac glycosides is the Na^+/K^+ -ATPase (EC 3.1.6.37), which maintains the high sodium and potassium gradients across the plasma membrane, coupled to the hydrolysis of the high-energy phosphate ATP. The gradient is required for the regulation

of cell volume, active transport of molecules or the creation and propagation of the action or resting potential of electrically excitable cells. Such are cardiac cells, with a high density of Na^+/K^+ -ATPase in the ►sarcolemma. While potassium is pumped into the cytoplasm, sodium is transported into the extracellular space in a stoichiometric ratio of $3\text{Na}^+:2\text{K}^+:1\text{ATP}$ (Fig. 1).

Inhibition of the Na^+/K^+ -ATPase leads to a loss of potassium and an increase of sodium within the cell. Secondary intracellular calcium is increased via the $\text{Na}^+/\text{Ca}^{++}$ -exchanger. This results in a positive inotropic effect in the myocardium, with an increase of peak force and a decrease in time to peak tension. Besides this, cardiac glycosides increase vagal activity by effects on the central vagal nuclei, the nodose ganglion and increase in sensitivity of the sinus node to acetylcholine.

Molecular Structure of Cardiac Glycosides

Cardiac glycosides are found in several plants and certain toads. Common to these substances is an aglycone-portion (genine) with a steroid structure, a 17β -unsaturated lactone ring, a glycone-portion (sugar) in 3β -position and an OH-group in position 14 (Fig. 2). Glycosides with a 5-numbered lactone ring are classified as cardenolides, those with a 6-numbered ring bufadienolides. The aglycone portion is essential for pharmacological activity. Its basic structure is a cyclopentanoperhydrophenandrene nucleus in a cis-trans-cis-configuration that makes CG distinct from bile acids, sterol or steroid hormones. Saturation of the lactone ring attenuates activity.

The number of sugar residues linked to the aglycone-portion (1–4) or the hydroxylation of the aglycone markedly influences water and lipid solubility, protein

Cardiac Glycosides. Figure 1 Cardiac glycosides – schematic representation of the Na^+/K^+ -ATPase.

binding, metabolic disposition, duration of action and elimination (Table 1).

Intestinal absorption of digoxin is less complete compared to digitoxin. In order to improve absorption, acetylated- and methylated-digoxin derivatives were developed. Digitoxin is metabolised in hepatic microsomal enzymes and can be cleared independently from renal function. The therapeutic serum level of digoxin is 0.5–2.0 ng/ml and 10–35 ng/ml of digitoxin. Steady state plateau of therapeutic plasma concentrations is reached after 4–5 half-life-times using standard daily doses [5].

Molecular Properties of the Na⁺/K⁺-ATPase

The pharmacological receptor of cardiac glycosides is the sarcolemmal Na⁺/K⁺-ATPase expressed on most eucaryotic membranes. It was characterised biochemically in 1957 by J. Skou, who was awarded with the Nobel Prize in chemistry in 1997. The sodium

pump belongs to a widely distributed class of P-type ATPases forming a phosphorylated aspartyl residue during the catalytic process. Ions migrate through a narrow “access channel”, and are bound, occluded, and transported by cycling between two different cation-dependent conformations.

Structure and Subunit

The sodium pump is an oligomer composed of two major subunit polypeptides: a catalytic α -unit (MW 110 kD) and a glycosylated β -unit (MW 40–60 kD, depending on degree of glycosylation). The α -unit spans the cell membrane 10-times. Both the NH₂- and the COOH-termini face the cytoplasm. It is responsible for the catalytic and transport characteristics of the ATPase. The α -unit contains binding sites for cardiac glycosides, ATP, sodium or potassium and the phosphorylation site. The β -unit is a modulator of the transport characteristics and proper membrane insertion of the Na⁺/K⁺-ATPase and crosses the membrane once. The COOH-terminus is located at the large ectodomain of the β -subunit. The NH₂-terminus is exposed to the cytoplasm. A third protein, termed the γ -subunit, can modify the pump activity, yet its physiological significance is unknown.

Isoforms

Na⁺/K⁺-ATPase is expressed as several isozymes (4 α , 3 β subtypes) that are encoded, on different genes. The degree of identity across different species is <92% for α 1 and α 2- isoforms and <96% for the α 3-isoform. Within one species the homology of α 1-, α 2- and α 3-isoform is <87%. It is 78% between the α 4- and α 1-isoform. The highest structural variability among the isoenzymes occurs at the NH₂-terminus, the ouabain-binding site between transmembrane segments 1 and 2, and the region between amino acids 403 and 503. The greatest similarities exist in the cytoplasmic middle region where the ATP binding and phosphorylation sites are located, in the transmembrane hydrophobic regions and in the carboxy-terminal region. Canine vascular smooth muscle utilises alternative RNA processing of the α 1-isoform gene to express a structurally distinct 65 kD isoform, named α 1-T (truncated) that lacks 40% of the carboxy-terminal sequence, though retains the ATP binding and phosphorylation site. Short variants of the α 1-peptide

Cardiac Glycosides. Figure 2 Cardiac glycosides – molecular structure of digoxin and ouabain. Digoxin contains an additional hydroxy group in position 12 compared to digitoxin.

Cardiac Glycosides. Table 1 Cardiac glycosides

	Ouabain	Digoxin	Digitoxin
Intestinal absorption	3%	60–80%	>98%

Oral daily maintenance dose	–	0.1–0.25 mg	0.07–0.1 mg
Disposition half-time		1.6 days	7–9 days

suggest a cation-selective gate close to the NH₂-terminus. In β -subunits, inhibition of glycosylation by tunicamycin or mutation of the β -subunit renders an active enzyme with catalytically competent sodium pumps and normal affinity for ouabain, yet removal of disulfide bonds abolishes assembly of α/β -subunits. Truncated β -subunits have been described. Different affinities of the isoenzymes for cations and ATP may be essential in adapting cellular Na⁺/K⁺-ATPase activity to specific physiological requirements. Its expression of isoforms is species- and tissue-specific and can be altered during development and by hormones. The $\alpha 1/\beta 1$ -isoenzyme is expressed ubiquitously, whereas the other isoenzymes may play tissue-specific roles. In neuron cells $\alpha 1$ - and $\alpha 2$ -isoforms seem to maintain the basal ionic gradients. The $\alpha 3$ -subunit, because of its low affinity for cations, might serve as a spare pump to help restore the resting membrane potential. The significant role of certain isoforms remains to be established.

The reactivity of the sodium pump isoforms toward ouabain can significantly differ between certain isoenzymes. The $\alpha 1$ -isoform from rat is reported to be 100-fold more resistant to ouabain than $\alpha 2$ - or $\alpha 3$ -isoform. In other species like rabbit, pig, dog or human these differences are not as distinct as in rat, due to a more sensitive $\alpha 1$ -isoform. At least two different types of ouabain binding sites are reported for the Na⁺/K⁺-ATPase [1].

Interactions with the cytoskeleton seem to be responsible for the processing and the targeting of the Na⁺/K⁺-ATPase to the appropriate compartment structures. Protein kinases are considered to play an essential role in modulation of the sodium pump.

Clinical Use

The clinical indications of cardiac glycosides are tachyarrhythmic atrial fibrillation or flutter, as well as

severe heart failure (NYHA III-IV) due to systolic dysfunction. In atrial fibrillation or flutter, the properties of digitalis are the reduction of ventricular heart rate at rest by suppression of the AV-node conduction. By this mechanism digitalis is heart rate limiting, without converting atrial fibrillation into **▶ sinus rhythm**. In heart failure, digitalis leads to a reduction of end diastolic filling pressure and volume, decrease in myocardial wall tension and oxygen consumption, with no evidence of desensitisation or tachyphylaxis. Whereas digitalis enhances vascular tone in healthy subjects by direct action on smooth muscle cells, in heart failure patients baroreflex responsiveness is restored, sympathetic nerve activity is decreased in skeletal muscle and vascular blood flow is increased. Furthermore, cardiac glycosides decrease plasma norepinephrine and renin activity [2].

Clinical Trials

The effect of a digitalis therapy on mortality in patients with chronic heart failure and sinus rhythm receiving diuretics and angiotensin-converting enzyme inhibitors (ACE) has been studied in the DIG (digitalis investigation group) trial. This trial included about 6,800 patients with decreased cardiac ejection fraction (<45%). The follow-up was 37 months. As a result, there was no difference in mortality in both groups, but fewer hospitalisations in the digitalis arm, and a benefit was observed in clinical symptoms in addition to maximum therapeutic regime [3]. Importantly, in a post hoc analysis of the DIG trial a serum digoxin concentration (SDC) of 0.5–0.9 ng/ml was associated with a reduced mortality while there was no effect with SDC ≥ 1 ng/ml [4]. Furthermore, a worsening of heart failure after withdrawal of cardiac glycoside medication in patients with mild to moderate heart failure (NYHA II-III) has been shown in the RADIANCE and PROVE trials.

Cardiac Glycosides. Table 2 Cardiac glycosides

Increased digitalis effects	Mechanism of action	Reduced digitalis effects
Hypocalcemia	Sodium receptor interaction	Hypercalcemia
Hypercalcemia	Sodium receptor interaction	Hypocalcemia
Hypomagnesia	Sodium receptor interaction	Hypermagnesia
Hypothyreosis	Sodium receptor interaction	Hyperthyreosis
Renal failure	Reduced elimination, electrolyte derangements	
Diuretics, laxatives, diarrhoea, emesis	Electrolyte derangements	
	Diminished resorption	Cholestyramine
	Diminished resorption	Neomycin
	Diminished resorption	Sulfasalazine
Erythromycine, tetracycline	Increased resorption	
Quinidine	Diminished renal and nonrenal excretion	
Verapamil, diltiazem, amiodarone	Diminished renal and nonrenal excretion	
	Induction of microsomal enzymes	Phenytoin, rifampin

Interactions and Adverse Effects

Cardiac glycosides have a small ratio of toxic to therapeutic concentration. Possible adverse effects are nausea, vomiting, abdominal pain, diarrhoea, fatigue, headache, drowsiness, colour vision disturbances, sinus bradycardia, premature ventricular complexes, AV-block, bigeminy, atrial tachycardia with AV-Block, ventricular fibrillation. There are several mechanisms relevant for their toxic action (Table 2).

Digoxin is more rapidly eliminated and thereby, possible adverse or toxic effects last for a shorter time.

Cardiac I_{K1}

Definition

Cardiac I_{K1} is the major K⁺ current responsible for stabilizing the resting membrane potential and shaping the late phase of repolarization of the action potential in cardiac myocytes. The name should not be confused with that of an Intermediate conductance calcium-activated K⁺ channel, which sometimes is also called I_{K1}.

► Inward Rectifier K⁺ Channels

Cariporide

An amiloride analog that inhibits Na⁺/H⁺ ion exchangers and is under consideration for the prevention of post-ischemic damage.

► Na⁺/H⁺ Ion Exchangers

Carotinoids

► Retinoids

CART

CART (cocaine- and amphetamine-regulated transcript) is a hypothalamic peptide that inhibits both normal and starvation-induced feeding when injected into cerebral ventricles of rats. CART is co-localized with the anorexigenic peptide α -melanocyte-stimulating hormone in neurons of the arcuate nucleus. Secretion of CART is stimulated by leptin and CART may be an endogenous inhibitor of food intake.

Synonyms

Cysteine endopeptidases; Clan CD; Family C14 (►<http://merops.sanger.ac.uk/>)

Definition

Caspases form an evolutionarily conserved family of cysteine endopeptidases. Like the families of clostripains (C11), legumains (C12), gingipains (C25) and separases (C50), the caspase family (C14) belongs to the protease clan CD, which is a small but important group of proteolytic enzymes with a unique α/β fold (►<http://merops.sanger.ac.uk/>). Features common to all members of the caspase family include the catalytic cysteine residue in the active site, and the ability to cleave substrates on the carboxyl side of aspartate residues, hence the name cysteine aspartate specific proteinases or caspases. Many of the caspase-family members are

activated during ►apoptosis, a specialized form of programmed cell death (PCD). In addition, certain caspases also exert non-apoptotic functions in various processes, including cytokine maturation during innate immunity, cell differentiation, proliferation, and NF- κ B activation. Many diseases can be linked to excessive or insufficient caspase activation. Extensive studies of caspases and natural caspase inhibitors in apoptosis and inflammation during pathologies validated the enzymes as attractive drug targets, the inhibition of which could alleviate a variety of human ailments.

Basic Characteristics

Structure and Activation of Caspases

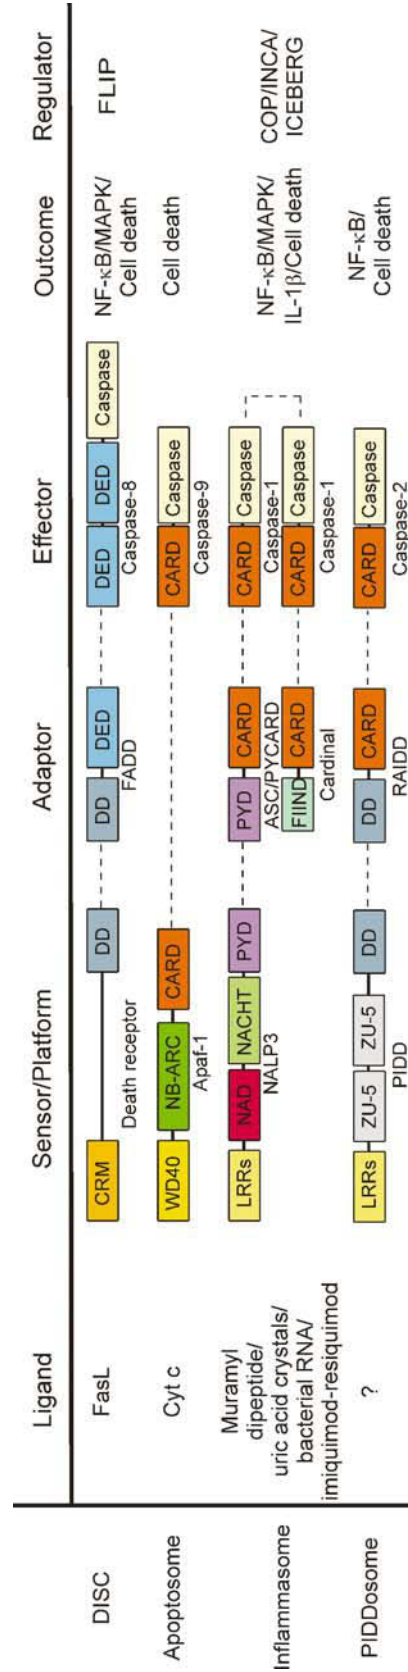

So far ten catalytically active caspases have been reported in mouse (caspase-1, -2, -3, -6, -7, -8, -9, -11, -12, -14) and eleven in human (caspase-1, -2, -3, -4, -5, -6, -7, -8, -9, -10, -14) (Fig. 1). Caspases are expressed as inactive proenzymes that contain an amino-terminal prodomain of variable length followed by two domains with conserved sequences: a large subunit (~20 kDa, p20) and a small carboxy-terminal subunit (~10 kDa, p10). Caspases can be divided according to absence (-3, -6, -7, -14) or presence (-1, -2, -8, -9, -10, -11, -12) of an extended prodomain containing protein-protein interaction motifs belonging to the ►death domain (DD) superfamily, in particular the death effector domains (DED) and the caspase activation and recruitment domains (CARD).

The absence or presence of a prodomain determines the fundamental mechanism by which caspases are activated. The proenzyme forms of caspases lacking a prodomain form homodimers that are activated by proteolytic cleavage at aspartate residues in the hinge region between the p20 and p10 subunits. This cleavage causes a conformational change leading to activation of the dimeric protease. The proenzyme forms of the prodomain-containing caspases exist as monomers and are dimerized by homotypic recruitment on specific adaptor proteins in protein complexes; this leads to a conformational change and activation of the procaspases. This results in autoproteolytic cleavage in the hinge regions between p20 and p10 and between the prodomain and p20. Multiprotein complexes that activate caspase-1, -2, -8 and -9 are, respectively, the inflammasomes, the PIDDosome, the death inducing signaling complex (DISC), and the apoptosome (Fig. 2) [1, 2].

The three dimensional structure of activated dimeric caspases is characterized by the typical caspase fold composed of a central 12-stranded β -sheet plane surrounded by 10 α -helices (Fig. 3). The two dimers align in a head-to-tail configuration, thereby positioning the two active sites at opposite ends of the molecule. The active site spans both the p20 and p10 subunits with His237 and Cys285 (numbering in human procaspase-1), forming a catalytic dyad in the active site of the caspases. Upon substrate binding, the thiolate anion of the catalytic

Caspases. Figure 1 Schematic representation of caspase domain architecture. Illustration of all identified *Homo sapiens* and *Mus musculus* caspases. The prodomain, and the large (p20) and small (p10) subunits are proportionally depicted.

Caspases. Figure 2 Caspase activating complexes. Schematic representation of all described long prodomain caspase activation complexes. Each complex contains essentially three functionally different building blocks: a sensor/platform, an adaptor and an effector in the form of a particular caspase. Some instigating ligands, possible outcomes and regulatory proteins are indicated.

Caspases. Figure 3 Three-dimensional illustration of a caspase. Representation of active caspase-1 adopting the typical caspase fold, consisting of two p20/p10 caspase heteromers folded in a compact cylinder that is dominated by a central six-stranded β -sheet and five α -helices distributed in a three-two configuration on both sides of the plane that is formed by the β -sheet. The subunits of the left heterodimer (dimer 1) are in *gray* (p20) and *purple* (p10). The subunits of the right heterodimer (dimer 2) are in *green* (p20) and *orange* (p10). The catalytic dyad, His237 (*red*) and Cys285 (*blue*), are shown in spacefill.

Cys285 residue participates in a nucleophilic attack on the carbonyl carbon of the scissile amide bond.

Functions of Caspases

Caspases are endopeptidases, meaning that they cleave a substrate very specifically at one or more sites, which results in a loss- or gain-of-function of the substrate. The functionality of the different caspases is thus determined by their substrate spectra (degradome). However, in the case of apoptosis, which is an irreversible cell death process, it is very difficult to distinguish the cleavage events that represent collateral damage and those that contribute to crucial signaling events. From the hundreds of substrates only a few have been shown to contribute to the apoptotic cell death process. However, their proteolytic activity is a central biochemical feature of the apoptotic process during both the initiation and the execution phases. Caspases can be functionally divided into ►**apoptotic initiator caspases** (caspase-2, -8, -9 and -10), which are activated in complexes that sense cellular stress (PIDDosome, DISC, apoptosome), and the ►**apoptotic executioner caspases** (caspase-3, -6, -7), which are activated by the apoptotic initiator caspases and cleave a large number of downstream substrates. Third, the ►**inflammatory caspases** (caspase-1, -4, -5, -11 and -12), with caspase-1 as a prototype, are activated in inflammasome complexes,

and they sense cellular stress, cellular damage and infection. Caspase-1 proteolytically activates inflammatory cytokines, such as pro-IL-1 β and pro-IL-18, and is implicated in their release. In humans, caspase-12 is a catalytically inactive form that is probably involved in dampening the inflammasome-mediated responses by competing for caspase-1 activation. Besides their prominent roles in apoptosis and inflammation, caspases have also been implicated in cell survival, motility, differentiation and proliferation, although it is not clear how these caspases exert their functions without leading to apoptosis. Finally, caspase-14 represents a special case, since it is very specifically expressed in the suprabasal layers of the epidermis and plays a crucial role in water homeostasis of the skin and in protection against UVB radiation.

The different caspases exhibit different substrate specificities for four amino acid stretches ($P_4P_3P_2P_1$) that fit in the substrate-binding cleft of the enzyme. All caspases cleave after an aspartic acid in the P_1 position of the substrate. However, whether a substrate will be recognized and cleaved depends on the accessibility of this cleavage motif on the target protein and on additional interactions between substrate and protease. The use of fluorogenic combinatorial tetrapeptide libraries (acetyl-XXXD-aminomethylcoumarine) led to the identification of the preferential tetrapeptide target sequences. Based on these results, human caspases can be divided into three major groups. Group I caspases (the inflammatory caspases-1, -4 and -5) prefer bulky hydrophobic residues at the P_4 position of the substrate (WEHD). Group II caspases (the downstream apoptotic effector caspases-3 and -7, along with caspase-2) prefer an Asp at the P_4 position (DEXD). Group III caspases (the apoptotic initiator caspases-8, -9, -10 and the apoptotic effector caspase-6) prefer a branched chain aliphatic amino acid residue at the P_4 position (L/VEXD). This specificity formed the basis for the first generation peptide-based synthetic inhibitors of caspases, followed by peptidomimetics (see below).

Regulation of Caspases by Natural Inhibitors

The activation of caspases is tightly controlled by a number of cellular caspase inhibitors [2] [3]. Based on their action mechanisms, natural inhibitors fall in two groups. The first group encompasses some members of the inhibitor of apoptosis protein (IAP) family. Most of the IAP proteins contain BIR motifs and an E3 ligase RING domain. IAPs control caspase expression and activity by a combination of mechanisms involving pseudosubstrate interaction in the catalytic pocket, allosteric inhibition through binding of IAP binding motifs (IBM) on certain caspases, and E3 ligase directed polyubiquitination and degradation of caspases. The most potent and best characterized IAP family member for the inhibition of cell death *in vitro* is XIAP, which mainly targets caspase-3, -7 and -9

with K_i values in the low nanomolar range. Other family members, such as cIAP1, cIAP2 and survivin, cannot directly inhibit caspases in physiological circumstances, because of their high K_i . Caspase inhibitors belonging to the second group prevent caspase activation by competing during the recruitment of inactive procaspases in the caspase activating complexes. Prototypic examples of these caspase-like decoy molecules are the caspase-8 (FLICE) inhibitory proteins (FLIPs) and caspase-1-related CARD-only proteins. Both the short splice variant of cellular FLIP (c-FLIP_s), essentially consisting of a caspase-8-like prodomain, and the long splice variant of cellular FLIP (c-FLIP_L), also containing an inactive caspase-like region, compete with FADD-mediated caspase-8 recruitment and activation in the DISC complex. The three caspase-1-related CARD-only proteins COP, INCA and ICEBERG use a similar mechanism: they compete with ASC/PYCARD-mediated recruitment of procaspase-1 in the inflammasome complex to reduce caspase-1 activation. These CARD-only proteins are the product of recent caspase-1 gene duplications in Hominidae. Remarkably, most of the natural caspase inhibitors were originally identified in viruses, illustrating the importance of these pathways for counteracting pathogens. Caspases are also regulated at the levels of transcription and alternative splicing, by generation of dominant-negative splice-variants that may interfere with heterodimerization of caspases or prevent caspase recruitment in activating complexes.

Involvement of Caspases in Disease

Too strong, too weak, or aberrant activation of one or more caspases is a hallmark of many human ailments. In [Table 1](#) we provide a list of experimental diseases in

which involvement of caspases have been demonstrated using peptide based synthetic caspase substrates, caspase inhibitors or caspase knockout mice.

Drugs

Caspase-1 Inhibitors

Targeting caspases with small-molecule drugs is a very attractive therapeutic strategy for the treatment of several diseases (see overview in [Table 2](#)) [2, 3, 4]. Consequently, several pharmaceutical companies invest in the development of specific or pan-caspase inhibitors (PCI). In collaboration, Vertex Pharmaceuticals Inc. and Aventis Pharma AG were the first to enroll a caspase-targeting drug, pralnacasan (VX-740), in clinical trials. Pralnacasan is a caspase-1 specific peptidomimetic pyridazinodiazepine inhibitor (IC₅₀ 1.3 nM) derived from the YVAD tetrapeptide sequence found in a caspase-1 tetrapeptide substrate screening. Pralnacasan acts as a pseudo-substrate that irreversibly binds to the cysteine of the active site. Administered orally, pralnacasan was shown to inhibit caspase-1 *in vivo* by reducing LPS- and carrageenan-induced IL-1 β production in plasma and peritoneal exudates, respectively. Preclinical data obtained in animal models of rheumatoid arthritis (RA) and osteoarthritis (OA), two malignancies displaying elevated IL-1 β and IL-18 levels in cartilage and synovial fluids, provided additional evidence for the therapeutic potential of pralnacasan. Based on these results, clinical trials for pralnacasan were initiated in RA and OA patients. Phase I trials (completed in 1999) proved that the compound was well tolerated and displayed good oral bioavailability. Phase II clinical trials demonstrated that pralnacasan treatment resulted in significant amelioration of RA but not OA. Although promising, clinical trials for RA and

Caspases. Table 1 Diseases associated with inappropriate caspase activation. Contribution of apoptosis (A) and inflammation (I) are indicated

Disease group	Disorder
Excessive caspase activity	
Liver diseases	Alcoholic hepatitis (A), hepatitis B and C (A), non-alcoholic steatohepatitis (A), liver transplantation (A), Wilson's disease (A)

Compound 34	Sunesis	Caspase-1	ND	ND	Development

OA were aborted in 2003 due to the development of mild to moderate liver fibrosis in dogs treated for 9 months with high doses of pralnacasan. This was in spite of recent evidence demonstrating the effectiveness of pralnacasan treatment in the acute dextran sulfate sodium (DSS)-induced colitis model, which resembles Crohn's disease (CD) characteristics, and in transient ischemia induced brain damage.

Vertex also put in clinical trial VX-765, another caspase-1-specific, YVAD-derived peptidomimetic that is *in vitro* slightly more potent than pralnacasan (IC₅₀ 0.8 nM). Evaluation of VX-765 in a mouse model of oxazolone-induced dermatitis showed a dose-dependent (10–100 mg/kg) inhibition of ear inflammation. Consequently, VX-765 was enrolled in a 4-week phase IIa safety and pharmacokinetic study for psoriasis. However, Vertex has not communicated any results yet.

Pan Caspase-Inhibitors

Apart from these two Vertex compounds, only one other caspase inhibitor, IDN-6556, has been used in clinical trials. This compound belongs to the class of oxamyl dipeptides and was originally developed by Idun Pharmaceuticals (taken over by Pfizer). It is the only pan-caspase inhibitor that has been evaluated in humans. IDN-6556 displays inhibitory activity against all tested human caspases. It is also an irreversible, caspase-specific inhibitor that does not inhibit other major classes of proteases, or other enzymes or receptors. The therapeutic potential of IDN-6556 was first evaluated in several animal models of liver disease because numerous publications suggested that apoptosis contributes substantially to the development of some hepatic diseases, such as alcoholic hepatitis, hepatitis B and C (HBV, HCV), non-alcoholic steatohepatitis (NASH), and ischemia/reperfusion injury associated with liver transplant. Accordingly, IDN-6556 was tested in a phase I study. The drug was safe and

well-tolerated in healthy adults and patients with mild liver impairment. These patients also displayed statistically significant improvements in alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Analysis of the pharmacokinetic profile demonstrated that IDN-6556 is quickly cleared from the venous circulation after infusion. The effect of IDN-6556 was further explored in a phase II study involving 80 patients with chronic HCV and 25 patients with other liver diseases, including NASH and HBV. IDN-6556 significantly reduced ALT and AST levels in HCV patients. In addition, IDN-6556 was also successfully tested in patients experiencing liver transplantation or suffering ischemia-reperfusion injury after lung transplantation. In conclusion, broad-spectrum caspase inhibitors, such as IDN-6556, are promising drugs for the treatment of several disorders.

Pre-Clinical Caspase Inhibitors

Aside from the three above-mentioned compounds that have entered clinical trials, many other compounds are being evaluated in different animal models. Two of the more promising inhibitors, developed by Merck-Frosst, are M826 and M867. These pyrazinone monoamides selectively and reversibly inhibit effector caspases-3 and -7. Both M826 and M867 demonstrated excellent anti-apoptotic activities *in vitro* as well as in several *in vivo* models. For example, M826 displayed a neuronal protective effect in malonate induced ischemic injury in rat a model for Huntington's disease. M867, when given as a continuous infusion, dose-dependently inhibited caspase-3 activity in a rat model of sepsis induced by cecal ligation and perforation. These findings demonstrated for the first time the potential therapeutic benefit of using a selective and reversible caspase-3 and -7 inhibitor to treat acute injuries. Recently, researchers at Sunesis described a different approach, namely targeting a cysteine in the

caspase's allosteric site with a drug that prevents the caspase from adopting the active conformation. In this way they identified their "compound 34," which forms a thiol linkage in the dimeric interface of caspase-1. Sunesis has not provided any information on *in vivo* results so far.

Inhibitors of Natural Caspase Inhibitors as Anti-Cancer Drugs

Chemotherapeutic drugs and radiotherapy kill cancer cells largely by inducing apoptosis [5]. However, most human cancers show considerable resistance to apoptosis. Elevated levels of IAPs (see above), which inhibit caspases, are found in many human cancers and have been associated with poor prognosis. Targeting IAPs presents a promising novel approach to potentiate the effect of chemotherapy and radiotherapy on cancer cells. Recent findings indicate that inhibition of the caspase inhibitor XIAP may prove to be a successful strategy to overcome apoptosis resistance of human cancers. The mitochondrial proteins Smac/DIABLO and Omi/HtrA2 are released from the intermembrane space during apoptosis and contain an amino-terminal IAP binding motif (IBM) that can inhibit the interaction between XIAP and caspase, thereby relieving the inhibitory activity. Peptide inhibitors based on the IBM motif were developed. These inhibitors, when used in combination with chemotherapeutics, γ -irradiation or TRAIL, sensitize several human cancer cell lines and neuroblastoma xenografts for apoptosis. Based on the NMR structure of the IBM motif complexed with XIAP, a novel series of XIAP peptidomimetic antagonists were developed by Idun Pharmaceuticals (now Pfizer Inc). These XIAP small-molecule antagonists "XAntag" were tested both *in vitro* and *in vivo* against a panel of human pancreatic cancer cell lines and showed significant anti-cancer activity, especially in combination therapy with TRAIL or γ -radiation. In conclusion, targeting the caspase inhibitor XIAP by small molecules is a promising new approach to potentiate the efficacy of several anti-cancer therapies.

List of Abbreviations

ALT, alanine aminotransferase
 ASC, apoptosis-associated speck-like protei containing a CARD
 AST, aspartate aminotransferase
 CARD, caspase activation and recruitment domains
 CD, Crohn's disease
 COP, CARD-only protein
 DD, death domain
 DED, death effector domains
 DIABLO, direct IAP-binding protein with low pI

DISC, death inducing signaling complex
 DSS, dextran sulfate sodium
 FLIP, caspase-8 (FLICE) inhibitory protein
 HBV, hepatitis B
 HCV, hepatitis C
 IAP, inhibitor of apoptosis protein
 IBM, IAP binding motifs
 INCA, inhibitory CARD
 NASH, non-alcoholic steatohepatitis
 PCD, programmed cell death
 PCI, pan-caspase inhibitor
 OA, osteoarthritis
 RA, rheumatoid arthritis
 Smac, second mitochondria-derived activator of caspases
 TRAIL, tumor necrosis factor-related apoptosis-inducing ligand.

Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT)

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an inherited heart disorder induced by an intense adrenergic activity (physical or emotional stress), often resulting in syncope or sudden death with no structural abnormalities. The ECGs of patients with CPVT show typical pattern of bidirectional ventricular tachycardia during exertion but are unremarkable at rest. Two genes are currently associated with CPVT: cardiac type ryanodine receptor (RyR2) and calsequestrin (CASQ2).

► Ryanodine Receptor

Catecholamines

Catecholamines are biogenic amines with a catechol (*o*-dihydroxy-benzol) structure. They are synthesized in nerve endings from tyrosine and include dopamine, noradrenaline (norepinephrine) and adrenaline (epinephrine).

COMTase; COMT; EC 2.1.1.6

Definition

Catechol *O*-methyltransferase (COMT) is a widespread enzyme that catalyzes the transfer of the methyl group of ► [S-adenosyl-l-methionine](#) (AdoMet) to one of the phenolic group of the catechol substrate (Fig. 1). High COMT activity is found in the liver, kidney and gut wall

Catechol-O-Methyltransferase. Figure 1 The basic function of COMT. Enzymatic *O*-methylation of the catechol substrate to 3-methoxy (major route) or 4-methoxy (minor route) products in the presence of Mg^{2+} and S-adenosyl-methionine (AdoMet).

[1,2]. A single *COMT* gene codes for two separate enzymes, soluble (S-COMT) and membrane bound (MB-COMT) forms. S-COMT contains 221 amino acids. MB-COMT has an additional amino-terminal extension of 43 (rat) or 50 (man) amino acids. The hydrophobic 17 and 24 amino acid residues in rat and man, respectively, form an α -helical transmembrane domain that serves as a membrane anchor; otherwise the two proteins are similar. MB-COMT is associated with intracellular membranes, not with cell membranes. Also S-COMT is strictly intracellular locating either in cytoplasm or nucleus. Synthesis of recombinant S-COMT in *Escherichia coli* and MB-COMT in insect cells, using baculovirus vectors, has helped to clarify the biochemistry, physiology and pharmacology of COMT [3]. The active site of COMT consists of the AdoMet-binding domain and the catalytic site. S-COMT is abundant in peripheral tissues while MB-COMT prevails in the brain. The catalytic site is formed by a few amino acids that are important for the binding of the substrate, water and Mg^{2+} , and for the catalysis of *O*-methylation. The Mg^{2+} , which is bound to COMT only after AdoMet binding, improves the ionization of the hydroxyl groups. The lysine residue (Lys144), which accepts the proton of one of the hydroxyls, acts as a general catalytic base in the nucleophilic methyl transfer reaction. Mice lacking totally COMT (knock-out mice) or only S-COMT have been developed. These animals behave and breed quite normally suggesting that COMT is not a vital enzyme [3].

Mechanism of Action

COMT *O*-methylates ► [catecholamines](#) and other compounds having a catechol structure including catecholoestrogens (Fig. 2). The two isoforms of

Catechol-O-Methyltransferase. Figure 2 Some substrates of COMT.

COMT may have distinct roles: MB-COMT, a high-affinity isoform of COMT, is supposed to be partially responsible for the termination of dopaminergic and noradrenergic synaptic neurotransmission. S-COMT, on the other hand, is a high capacity enzyme isoform being mainly responsible for the elimination of biologically active or toxic, particularly exogenous, catechols and some hydroxylated metabolites. During the first trimester of pregnancy, COMT present in the placenta protects the developing embryo from hydroxylated compounds. COMT also acts as an enzymatic detoxicating barrier between the blood and other tissues, shielding against the detrimental effects of hydroxylated xenobiotics. COMT may serve some unique or indirect functions in the kidney and intestine tract by modulating the dopaminergic tone. The same may be true in the brain: COMT activity may regulate the amounts of active dopamine particularly in frontal cortical areas of the brain and therefore be associated with mood and other mental processes. COMT has a genetic one-nucleotide polymorphism causing valine amino acid to be changed to methionine leading to thermolability even at $+37^\circ\text{C}$ and a decrease of COMT activity to one third to one fourth. Low COMT activity is connected to improved cognitive functions, probably due to increased dopaminergic activity. However, from population studies there is some evidence that certain psychiatric illnesses (e.g. schizophrenia, rapidly fluctuating depression) and even breast cancer in

postmenopausal women may be slightly increased in people having low COMT activity [3].

Early COMT inhibitors, like gallates, tropolone and U-0521 (3',4'-dihydroxy-2-methyl-propiofenone) have IC_{50} and K_i values in the micromolar range or higher but may still be practical in vitro tools. However, owing to unfavourable pharmacokinetics and toxicity their clinical use is not possible [1].

Second generation COMT inhibitors were developed by three laboratories in the late 1980s. Apart from CGP 28014, nitrocatechol is the key structure of the majority of these molecules (Fig. 3). The current COMT inhibitors can be classified as follows: (i) mainly peripherally acting nitrocatechol-type compounds (entacapone, nitecapone, BIA 3-202), (ii) broad-spectrum nitrocatechols having activity both in peripheral tissues and the brain (tolcapone, Ro 41-0960, dinitrocatechol, vinylphenylketone), and (iii) atypical compounds, pyridine derivatives (CGP 28014, 3-hydroxy-4-pyridone and its derivatives), some of which are not COMT inhibitors in vitro but inhibit catechol *O*-methylation by some other mechanism. The common features of the most new compounds are excellent potency, low toxicity and activity through oral administration. Their biochemical properties have been fairly well characterized. Most of these compounds have an excellent selectivity in that they do not affect any other enzymes studied [2, 3].

Tolcapone and Ro 41-0960 are longer acting than entacapone and nitecapone in in vivo studies in rats. All types of COMT inhibitors prolong the L-dopa-induced turning behaviour of rats having unilateral nigral lesions (Fig. 4). This has generally been used as a reliable rat model of Parkinson's disease. It is noteworthy that the peripherally acting compound entacapone is practically as effective as the broad-spectrum compound tolcapone. This suggests that the majority of the beneficial action is peripheral in origin, evidently through enhanced bioavailability of L-dopa. Statistics: * $P < 0.05$ and ** $P < 0.01$ versus corresponding controls (data from [4]).

Clinical Use (Including Side Effects)

The main clinical use of COMT inhibitors is as adjunct (or additional adjunct) in the therapy of Parkinson's disease. The standard therapy of Parkinson's disease is oral L-dopa (as a drug levodopa) given with a dopa decarboxylase (DDC) inhibitor (e.g. carbidopa and benserazide), which does not reach the brain. When the peripheral DDC is inhibited, the concentration of 3-*O*-methyl-dopa (3-OMD), a product of COMT, in plasma is many times that of L-dopa. Since the half-life of 3-OMD is about 15 h, compared to about 1 h for L-dopa, the concentration of 3-OMD remains particularly high during chronic therapy, especially if new slow release L-dopa preparations are used. A triple therapy (L-dopa plus DDC inhibitor plus COMT-inhibitor) will

Catechol-O-Methyltransferase. Figure 3 Chemical structures of some inhibitors of catechol O-methylation.

evidently substitute the present double therapy in the coming years. A fixed combination preparation containing all three active drugs is indeed getting very popular worldwide.

COMT inhibitors rescue ►L-DOPA and improve the brain entry of L-dopa by decreasing 3-OMD formation in peripheral tissues. The dose of L-dopa could be decreased, compared with the present combination therapy. Dose interval of L-dopa could also be prolonged. Further, COMT inhibitors should decrease fluctuations of dopamine formation in the brain.

Clinical studies, available only for entacapone and tolcapone, support preclinical findings. A dose-dependent (100–800 mg) inhibition of the COMT activity of the erythrocytes can be seen after nitrocatechols. However, effective and sufficient dose levels of both entacapone and tolcapone, given concomitantly with L-dopa and DDC inhibitors to patients with Parkinson's disease, appear to be 100–200 mg. However, the treatment strategies of entacapone and tolcapone differ: entacapone is a short-acting compound that is given with each dose of L-dopa, and COMT activity may even

Catechol-O-Methyltransferase. Figure 4 Rat model of Parkinson's disease. Comparison of entacapone, tolcapone and CGP 28014 in the rat turning model of Parkinson's disease [4].

recover between the doses. Tolcapone, as a longer-acting compound, is given three times a day, and the aim is to keep COMT inhibited most of the time [2, 3].

Since several ►adrenergic drugs, having a catechol structure, are also COMT substrates, it is possible to prolong or even potentiate in some cases their actions by COMT inhibitors. Such drugs include bronchodilating compounds (adrenaline, isoprenaline, rimiterol), dopamine agonists (dobutamide, fenoldopam, apomorphine) and antihypertensive drugs (α -methyl-dopa). It is possible to potentiate interactions with endogenous catecholamines during stress and exercise and adverse drug interactions with, e.g. exogenous ►noradrenaline and the drugs mentioned above. Fortunately, interaction studies in animals and man have not been able to substantiate this threat. Evidently, the capacity of S-COMT in the peripheral tissues is so high that only a minor general COMT inhibition can ever be achieved. Oestrogens are easily hydroxylated to catecholestrogens, which serve as COMT substrates. The consequence of preventing the major metabolic pathway of catecholestrogens by COMT inhibitors requires further studies; it is possible that quinone-forming pathways are activated [2, 3].

In patients having Parkinson's disease, both entacapone and tolcapone potentiate the therapeutic effect of L-dopa and prolong the daily ON time by 1–2 h. In the clinic, COMT inhibitors have been well tolerated, and the number of premature terminations has been low. In general, the incidence of adverse events has been higher in tolcapone-treated patients than in entacapone-treated patients. The main events have comprised of dopaminergic and gastrointestinal problems [2, 3].

Dopaminergic overactivity causes an initial worsening of levodopa-induced ►dyskinesia, nausea, vomiting, orthostatic hypotension, sleep disorders and hallucinations. Tolcapone has been associated with diarrhoea in about 16–18% of cases and entacapone in less than 10% of cases. Diarrhoea has led to discontinuation in 5–6% of patients on tolcapone and in 2.5% of those on entacapone. Urine discolouration to dark yellow or orange is related to the colour of COMT inhibitors and their metabolites. Elevated liver transaminase levels are reported in 1–3% of patients treated with tolcapone but very rarely, if at all, in patients treated with entacapone. Three cases of acute, fatal fulminant ►hepatitis have been described in association of tolcapone where more than 100,000 patients have been treated. In addition, a few potentially fatal neurological adverse reactions, including ►neuroleptic-like malignant syndrome, have been described. Because of these serious adverse drug reactions, tolcapone marketing was temporarily suspended in Europe and Canada in 1999. Now tolcapone is again available in most markets but certain precautions and a regular follow-up of liver function need to be obeyed. So far, no restrictions of the use of entacapone have been proposed [2, 3].

Use of COMT Inhibitors in Positron Emission Tomography

An additional benefit of COMT inhibitors can be found in positron emission tomography (PET) studies. In PET, using 6-[¹⁸F]-fluoro-L-dopa (6-FD) to visualize the brain dopamine metabolism, the peripheral formation of 3-O-methyl-6-[¹⁸F]-fluoro-L-dopa (3-OMFD) by COMT is harmful. 3-OMFD contaminates the brain radioactivity analysed since it is easily transported like 3-OMD to the

brain. COMT inhibition would reduce the formation of 3-OMFD and improve PET analysis. Since 3-OMFD formation continues in the brain, central COMT inhibition may be assumed to offer a further advantage [5].

Cathepsins

Cathepsins are intracellular proteinases that reside within lysosomes or specific intracellular granules. Cathepsins are used to degrade proteins or peptides that are internalised from the extracellular space. Some cathepsins such as cathepsin-G or cathepsin-K may be released from the cell to degrade specific extracellular matrix proteins. All cathepsins except cathepsin-G (serine) and cathepsin-D (aspartyl) are cysteine proteinases.

Cell division cycle; Cell proliferation; Cell multiplication

Definition

The eukaryotic somatic cell cycle is defined by a sequential order of tasks a dividing cell has to complete: it must replicate its DNA, segregate its chromosomes, grow, and divide. The cell cycle can be divided into four discrete phases. ▶ **DNA replication** is restricted to S phase (DNA synthesis phase), which is preceded by a gap phase called G1 and followed by a gap phase called G2. During mitosis (M phase) the sister chromatids are segregated into two new daughter nuclei and mitosis is completed by the division of the cytoplasm termed ▶ **cytokinesis** (Fig. 1).

Basic Mechanisms

Upon mitogenic stimuli, cells can enter the cell cycle, which lasts in the case of a typical dividing human somatic cell for about 24 h. During a single cell cycle, a cell accomplishes four tasks: growth, DNA replication, *chromosome segregation*, and cell division. How a cell regulates the cell cycle and how tumor cells can override these regulatory mechanisms, leading to uncontrolled proliferation, is still insufficiently understood and the subject of intense research. However, it has become clear in recent years that the basic mechanisms of cell cycle

control are remarkably conserved throughout evolution and involve the following mechanisms:

1. reversible protein phosphorylation
2. regulated **ubiquitin-dependent protein degradation**
3. transcriptional control mechanisms
4. regulation by CDK inhibitors
5. **cell cycle checkpoint mechanisms**

Cell Cycle Regulation by Protein Phosphorylation

The discovery of a dominant activity designated as the “mitosis (or maturation) promoting factor” (MPF), which drives interphase cells into mitosis led to the idea that certain oscillating activities are responsible for the initiation of mitosis and for driving the different phases of the cell cycle. Biochemical purification of MPF from sea urchin eggs, frog eggs, and mammalian cells as well as a large number of genetic experiments in *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* using various “cell division cycle (*cdc*) mutants” revealed that MPF represents a heterodimeric protein kinase consisting of a so-called cyclin dependent kinase (CDK1, *cdc2*, or *p34cdc2*) and its regulatory subunit now known as cyclin B. The principle of a heterodimeric kinase consisting of a CDK and a cyclin subunit was subsequently found for multiple CDKs. Different CDKs including CDK1, 2, 4, and 6 and different cyclins including cyclin A, B, E, and D act as key players for the regulation of different cell cycle transitions (Fig. 1).

CDK1–cyclin B kinase represents the key trigger for entry into mitosis. In late G₂, cyclin B binds to CDK1 leading to a preactivated kinase complex. After binding of cyclin B to CDK1, this complex is kept inactive by phosphorylation of the CDK1 protein. First, an activating phosphorylation at threonine-161 is carried

out by a CDK activating kinase (CAK) followed by two inhibitory phosphorylations at residues threonine-14 and tyrosine-15 (in mammals) by the kinases Myt1 and Wee1, respectively. This inactive CDK1–cyclin B complex is called the preMPF and can be activated just prior to mitosis by removing both inhibitory phosphorylation sites by the action of the dual specificity phosphatase Cdc25C (Fig. 2). The inactivating Kinases Myt1 and Wee1 as well as the activating phosphatase Cdc25C are themselves part of a complex regulatory network involving other upstream kinases and phosphatases. Importantly, they are also critical targets for cell cycle checkpoint control mechanisms (see below).

Cell Cycle Control. Figure 1 Cell cycle regulation by Cyclin dependent kinases (CDKs). Different cyclins bound to different CDKs promote the transition from one cell cycle phase into another. CDK-dependent phosphorylation of Rb is required to release active E2F transcription factors, which promotes entry into S phase.

Cell Cycle Control. Figure 2 Regulation of CDK1 activity at the G₂/M transition. The pre-MPF complex consisting of CDK1 and cyclin B is activated by Cdc25C-mediated dephosphorylation at the G₂/M border. Active CDK1 is required for entry into mitosis and progression through mitosis. CDK1 is inactivated at the end of mitosis by ubiquitin-dependent protein degradation of cyclin B.

The activated CDK1–cyclin B kinase finally phosphorylates a large number of proteins most of which are not well characterized, leading to chromosome condensation, nuclear envelope breakdown, spindle assembly, and ► **chromosome segregation**.

Cell Cycle Regulation by Ubiquitin-Mediated Protein Degradation

Cyclins are positive regulatory subunits of CDKs. They represent a family of oscillating proteins that are able to bind to and activate specific CDKs in a cell cycle dependent manner. Each cyclin has certain specificities to activate particular CDKs. Cyclins exhibit cell cycle dependent protein levels, which are the result of transcriptional regulation, stability of their mRNAs, and – maybe most importantly – their protein stability. The cyclin B gene is transcriptionally downregulated during G1 phase and becomes activated during S and G2. Cyclin B protein accumulates continuously throughout S and G2 phase, binds and activates CDK1 in late G2 and during the early stages of mitosis. At the metaphase to anaphase transition cyclin B levels drop dramatically, leading to an irreversible inactivation of CDK1, which is required for exit from mitosis (Fig. 2). The decrease in cyclin B levels after the metaphase to anaphase transition is due to regulated ubiquitin-mediated protein degradation (► **ubiquitin/proteasome**) by the 26S proteasome. The ubiquitination of cyclin B is a prerequisite for its proteasome-dependent degradation and requires three enzymatic activities including a ubiquitin-activating enzyme (E1), a ubiquitin-conjugating enzyme (E2), and a ubiquitin ligase (E3). UbcH5 and UbcH10 are likely the ubiquitin-conjugating enzymes involved in cyclin B ubiquitination while the relevant E3 ligase activity is part of a 1.5 MDa complex known as the *anaphase-promoting complex* or *cyclosome* (APC/C) [1]. During mitosis, the APC/C is specifically activated by coactivator proteins of the Cdc20/Cdh1 family, which also contribute to the recognition of substrate proteins containing a specific sequence motif termed the destruction box (D-box). In addition to mitotic cyclins, the APC/C is involved in the destabilization of various other mitotic target proteins including securin whose degradation at the metaphase to anaphase transition is required for sister chromatid separation. Thus, the APC/C controls the progression and the exit from mitosis. In addition, APC/C-dependent degradation of cyclins during the G1 phase is required to prevent a premature entry into S phase. Moreover, the APC/C controls the degradation of regulators of S phase to regulate replication origin assembly and the APC/C is active in nondividing and differentiated cells suggesting that it has functions beyond the cell cycle [1].

In addition to protein proteolysis during mitosis, ubiquitin-mediated protein degradation (► **ubiquitin/proteasome**) is also required at the G1 to S transition

and during S phase. An ubiquitin ligase complex termed SCF (*Skp1-Cdc53-F-box protein*), which is distinct but related to the APC/C functions to ubiquitinate several substrate proteins including the CDK inhibitor p27Kip1, cyclin E, and the transcription factor E2F-1. SCF mediated ubiquitination is essential for proper G1 to S transition.

Together, it is now well recognized that ubiquitin-mediated protein degradation is an important regulatory mechanism throughout the cell cycle for an irreversible inactivation of various cell cycle regulators, including cyclins, mitotic regulators, CDK inhibitors, and transcription factors.

G1/S Transition and Transcriptional Control

The commitment of cells to enter S phase occurs at the so-called restriction point during late G1 phase. Mitogenic growth factors are required for cells to enter the cell cycle. However, beyond the restriction point, mitogenic growth factors are no longer required to complete the cell cycle. This transition is, at least in part, driven by G1 cyclins activating CDK2, 4, and 6. When cells enter the cell cycle from quiescence (G0), cyclin D (different types: D1, D2, D3), cyclin E, and cyclin A are synthesized sequentially. Cyclins A and E preferentially activate CDK2 whereas D type cyclins activate either CDK4 or CDK6 (Fig. 1). The regulatory principles described for CDK1–cyclin B at G2/M apply similarly to the cyclin–CDK complexes functioning at the G1/S transition. For example, activation of CDK2–cyclin A/E and CDK4/6–cyclin D complexes require an activating and two inhibitory phosphorylations, which are removed at or near G1/S phase by the Cdc25A, a phosphatase related to Cdc25C.

When cells enter the cell cycle, cyclin D dependent CDK4 and CDK6 activity is first detected in mid-G1 phase and increases when cells approach the G1/S transition. The most recognized function of cyclin D containing CDKs is phosphorylation of the retinoblastoma protein (Rb). Rb functions as a transcriptional repressor of the E2F family of DNA-binding transcription factors (E2F). E2F binding sites are found in promoters of many genes that are important for ► **DNA replication** and therefore for initiation of S phase (e.g., *DHFR*, *DNA polymerase α* , *thymidine kinase*, *thymidylate synthase*, *cyclin E*, and others). In early to mid-G1 phase, Rb is hypophosphorylated and bound to E2F repressing its transcriptional activity, thereby inhibiting entry into S phase [2]. When G1 phase progresses, cyclin D dependent CDK activity increases, followed by an increase in cyclin E and cyclin A dependent kinase activity, leading to hyperphosphorylation of Rb. The phosphorylated form of Rb can no longer bind to E2F and its transcriptional activity is restored. This leads to the activation of E2F target genes allowing initiation of S phase (Fig. 1) [2].

During S phase, the genome has to be replicated completely and only once per cell cycle to maintain genomic integrity. ► **Replication** is initiated from multiple origins on the different chromosomes at specific DNA sequences, the autonomously replicating sequences (ARS). According to a current model, a prereplication complex is formed during G1 phase. This complex includes the loading Cdc6, Orc, and Mcm proteins onto the chromatin. G1-Chromatin, “licensed” for replication, is then guided to S phase by phosphorylation of CDKs active at the G1/S transition. Upon entry into S phase, the prereplication complex is then rearranged, accompanied by the recruitment of chain elongation factors, and an establishment of replication forks. DNA replication induces the dissociation of MCM proteins from chromatin and CDK2 activity during S phase prevents its reloading onto chromatin, thereby restricting the initiation of replication to only once per cell cycle.

G1 Control by CDK Inhibitors

CDK activities can be regulated by CDK inhibitors (CKIs). CKIs are small proteins which can be subdivided into two distinct groups: the INK4 proteins (*inhibitors of CDK4*) including p16INK4a, p15INK4b, p18INK4c, and p19INK4d, named by their ability to bind and to inactivate the catalytic subunit of CDK4 and CKD6 [3]. This group is opposed by the Kip/Cip family of CDK inhibitors including p27Kip1, p21Cip1, and p57Kip2, which display a broader range of substrate specificity. The signals that induce synthesis of the INK4 proteins remain unclear. However, p15INK4b is induced by TGF- β signaling where it plays an essential role in mediating the TGF- β triggered G1 arrest. p16INK4a accumulates during ► **senescence**, thereby contributing to the G1 block. p18INK4c and p19INK4d might have roles during terminal differentiation [3].

Kip/Cip proteins are induced upon stress signals (e.g., after genotoxic damage) and function as biological brakes of the cell cycle. The best example investigated is the transcriptional activation of the *p21Cip1* gene by p53 (see below). Accumulated p21Cip1 binds directly to CDK2–cyclin A/E and inhibits the kinase activity. Thus, p21Cip1 prevents entry into S phase in response to cellular damage [3].

CKIs are important tumor suppressor genes. Disruption of *p16INK4a* is a common event in human cancer and low levels of p27Kip1 caused by enhanced protein degradation appear to be associated with tumorigenesis and poor prognosis. This is also underlined by studies in *p27Kip1* heterozygous mice, which show a haploinsufficiency for tumor suppression.

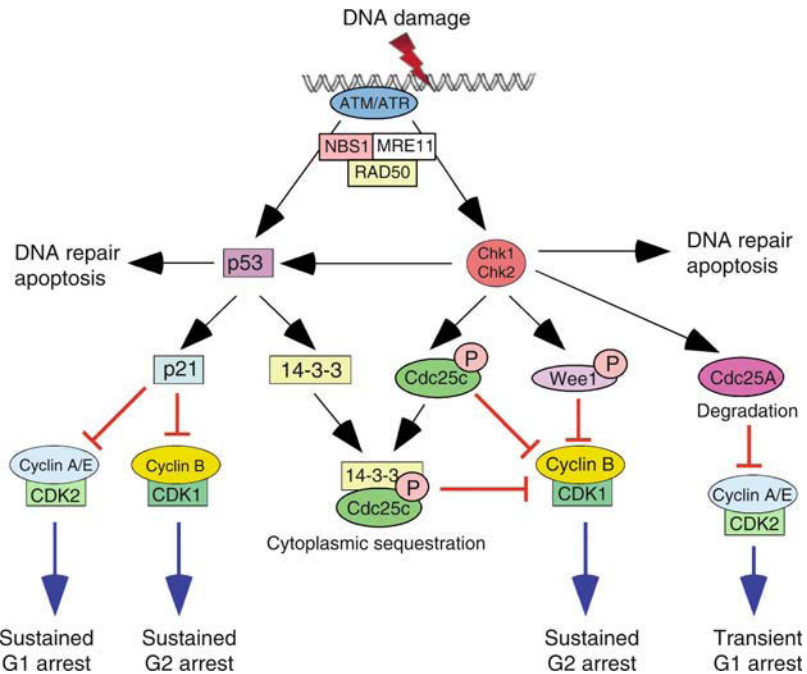

Cell Cycle Checkpoints

The survival of cells depends on their ability to transmit the genetic information properly onto two daughter cells. The faithful transmission depends on proper

DNA replication during S phase, the absence of DNA damage throughout the cell cycle, and the equal distribution of the chromatids during mitosis. Signal transduction pathways referred to as cell cycle checkpoints monitor these requirements. The best example investigated so far is the checkpoint pathway activated upon DNA damage known as the DNA damage checkpoint (Fig. 3) [4]. The DNA damage checkpoint is activated by an initial activation of the Atm or Atr kinases. The Atm kinase seems to be activated in response to DNA damage whereas Atr is primarily activated following arrest of DNA replication forks. How these kinases sense the cellular damage is still not understood, but the Mre11/Rad50/Nbs1 complex might contribute to this initial kinase activation. The alert signal is then transduced to the Chk1 and Chk2 protein kinases. Both, Atm/Atr and Chk1/Chk2 are able to phosphorylate the transcription factor p53 leading to its accumulation and activation. p53 induces a large-number of target genes including *p21Cip1*. The p21 protein accumulates and results in a sustained cell cycle arrest at both, the G1/S and G2/M transition by inactivating CDK2 and CDK1 kinases, respectively. p53 also induces the transcription of DNA repair genes and genes responsible for the induction of ► **apoptosis**. The latter ensures that a damaged cell will rather die than transmitting damaged DNA onto the next generation. Thus, p53 is a central regulator of the DNA damage response. Tumor cells frequently lack functional p53, which can directly contribute to tumorigenesis by promoting the accumulation of DNA damage.

The activation of Atm/Atr and Chk1/Chk2 kinases also results in a p53 independent, but transient G1/S cell cycle arrest by targeting the phosphatase Cdc25A that is required to activate CDK2–Cyclin A/E. Enhanced activity of Atm/Atr–Chk1/Chk2, induces the ubiquitin dependent degradation of Cdc25A, thus preventing CDK2 activation at G1/S. At the G2/M transition, activated Atm/Atr–Chk1/Chk2 phosphorylates the phosphatase Cdc25C leading to its degradation, cytoplasmic sequestration by 14-3-3 sigma proteins and enzymatic inhibition. This results in a sustained p53 independent G2/M arrest upon DNA damage (Fig. 3) [4]. In addition, other upstream regulators of CDK1–cyclin B like Polo-like kinase 1 (Plk1) or Aurora A seem to be part of a DNA damage response and contribute to the cell cycle arrest at G2/M independent of p53.

The mitotic ► **spindle assembly checkpoint** monitors the correct alignment of chromosomes during ► **mitosis**. The spindle checkpoint is activated in the early phases of a normal mitosis and in response to defects that prevent a proper chromosome alignment (e.g., upon drug-induced spindle damage). Progression into anaphase is inhibited as long as all chromosomes are properly attached to the mitotic spindle and aligned at the metaphase plate. This checkpoint involves the function of several checkpoint

Cell Cycle Control. Figure 3 The DNA damage checkpoint. In response to DNA damage cells activate p53 dependent and independent checkpoint pathways leading to cell cycle arrest at G1/S and G2/M allowing DNA repair. If the cellular damage cannot be repaired, cells can initiate apoptosis.

proteins including Mad1, Mad2, Bub1, BubR1, Bub3, Cenp-E that are recruited to kinetochores when the checkpoint is activated. However, the mechanisms leading to checkpoint activation are still not well understood. Spindle checkpoint activation results in an activation of the terminal effector Mad2, which is an inhibitor of the APC/C ubiquitin ligase. Therefore, activation of the spindle checkpoint inhibits the mitotic degradation of securin and cyclin B preventing anaphase onset and mitotic exit.

Pharmacological Intervention

Regulators of the cell cycle are frequently altered in human cancer often resulting in deregulated CDK activities. A promising anticancer therapy is therefore the inactivation of CDK activities using pharmacological CDK inhibitors that lead to a proliferative arrest of cells. Prolonged cell cycle arrest results in induction of ►apoptosis and therefore eliminates tumor cells. In addition, other kinases or regulators of the cell cycle might be suitable targets for anticancer drugs [5].

Cell cycle ►checkpoints also represent potential targets for anticancer drugs. Cells damaged by genotoxic agents or spindle poisons activate the appropriate checkpoint and halt the cell cycle until the damage is repaired. When these checkpoints are abrogated, cells enter mitosis or S phase prior to repair of the genotoxic damage, which promotes cell death. Drugs abrogating cell cycle checkpoints might therefore sensitize cells to chemotherapy [5].

Pharmacological CDK Inhibitors

The rationale behind CDK inhibition during anticancer treatment is to stop hyperactive cell cycles and to inhibit the activity of cyclins that are frequently overexpressed in human cancer.

Currently, many different CDK inhibitors are explored in clinical trials. After the first generation of drugs, which included the natural products flavopiridol, paullone, and indirubin, several purine and pyrimidine analogs are now under investigation. These second generation drugs include olomoucine, purvalanol B, E7070, R-roscovitine, and BMS-387032. Preclinical results show that all these drugs arrest (tumor) cells in G1, S, or G2 and a prolonged cell cycle arrest is followed by the induction of apoptosis. While most of the CDK inhibitors have reasonable toxicity profiles, they do not show a high specificity, which might decrease their tumor cell selectivity [5].

Pharmacological Cell Cycle Inhibitors

Many cell cycle regulatory kinases are overexpressed in human cancer and are therefore prime targets for chemotherapy to be targeted selectively in tumor cells. Several kinases that regulate the progression of mitosis are tested as anticancer drug targets. These kinases include the Aurora kinases and the Plk1. Currently, Aurora inhibitors (e.g., hesperadin, ZM447439, and VX-680) as well as Plk1 inhibitors (e.g., HMN-214) are undergoing clinical trials. However, all kinase inhibitors act by blocking the ATP binding pocket of

the kinases and are therefore expected to be not entirely specific [5].

Also nonkinase molecules might be important targets for anticancer drugs. For instance, the activity of the mitotic kinesin Eg5 (KSP, kinesin-5) can be inhibited by small molecules (e.g., monastrol, KSP-IA) resulting in mitotic defects associated with the induction of apoptosis.

Due to their promising activities in preclinical investigations, the first clinical data for these new generations of anticancer drugs are eagerly awaited.

Pharmacological Cell Cycle Checkpoint Abrogation

The introduction of DNA damage leads to the activation of the DNA damage checkpoint resulting in G1 and G2 cell cycle arrest. Overriding this arrest and inappropriate induction of S phase or mitosis, respectively, results in cell death in most cases. Thus, drugs that facilitate these transitions might sensitize cells to chemotherapy. Prime targets for checkpoint abrogating drugs are the Atm/Atr and the Chk1/Chk2 kinases. Atm can be inhibited by several methylxanthine derivatives (e.g., caffeine and pentoxifylline). However, the cytotoxicity of these drugs limits their use in patients.

In contrast, UCN-01, a staurosporine derivative, acts as a potent inhibitor of the Chk1 kinase and efficiently abrogates the G2 checkpoint upon DNA damage. The forced entry into mitosis in the presence of DNA damage results in a mitotic form of apoptosis. Several clinical trials are currently exploring a combined treatment with UCN-01 and various DNA damaging drugs. In the same vein, inhibitors of Chk2 are developed and tested in clinical trials.

In contrast to the DNA damage checkpoint, the mitotic spindle checkpoint is essential for cell viability. Therefore, targeting kinases of the spindle checkpoint including Bub1, BubR1, and Mps1 might be a valid strategy for anticancer treatment.

Cellular Immunity

In a strict sense the term cellular immunity describes the T-lymphocyte mediated arm of adaptive immunity. T-lymphocytes recognize antigens in form of peptides presented by cells on major histocompatibility antigens (MHC molecules) indicating the phagocytosis of bacteria (presentation of antigen on MHC class II) or infection of a cell by a virus (presentation on MHC class I). T-lymphocytes become activated and clonally expand to become T-helper cells, which can induce an inflammatory response via soluble mediators (cytokines), which can activate the phagocytic system or induce specific antibody production. Alternatively, T-helper cells can activate cytotoxic T-cells, which kill virus infected cells or tumor cells.

- ▶ Immune Defense

Central Core Disease (CCD)

Central core disease (CCD) is an autosomal dominant, non-progressive myopathy characterized by hypotonia and proximal muscle weakness in infancy. CCD is named after detection of characteristic “central cores” that lack both mitochondria and oxidative enzyme

activity within type 1 muscle fibres biopsied from the patients. CCD may be associated with susceptibility to malignant hyperthermia. CCD is linked to a gene for type 1 ryanodine receptor (RyR1).

► Ryanodine Receptor

Central Diabetes Insipidus

In central diabetes insipidus a hypophysial malfunction, caused by different diseases as well as head injuries, neurosurgery, or genetic disorders, leads to AVP hyposecretion. This type of diabetes insipidus can successfully be treated by the exogenous administration of AVP or AVP analogues (e.g. desmopressin).

► Vasopressin/Oxytocin

Central Tolerance

In immunology, tolerance describes the absence of immune reactions against an antigen, mostly against antigens of the own body (self tolerance). Self tolerance can result from eliminating autoreactive lymphocytes when they develop in the central differentiating organs, thymus, or bone marrow (central tolerance), or from keeping lymphocytes, which escaped this central mechanisms into the periphery at rest by active suppressive mechanisms (peripheral tolerance).

► Immune Defense

► Tolerance and Desensitization

Centrosome

Centrosomes, also called the microtubule organizing centre, are protein complexes that contain two centrioles (ringlike structures) and γ -tubulin. They serve as nucleation points for microtubular polymerization and constrain the lattice structure of a microtubule to 13 protofilaments. They are responsible for organizing the mitotic spindle during mitosis.

► Cytoskeleton

Cephalosporins

Like penicillins, cephalosporins are β -lactam antibiotics and interfere with bacterial cell wall synthesis. A very large number of cephalosporins are available for clinical use. They differ in their route of administration and clinical use.

► β -Lactam Antibiotics

CFTR

CFTR, the Cystic fibrosis transmembrane conductance regulator, is the only member of the large ABC transporter gene family that is known to function as an ion channel. Its "ATP Binding Cassettes" are thought to regulate the opening and closing of the pore, rather than provide energy (by ATP hydrolysis) for active transport. Another important mechanism of regulation is provided by cyclic AMP (cAMP)-dependent phosphorylation of residues in the intracellular "R-domain." This renders CFTR into a cAMP-activated chloride channel.

CFTR has a single-channel conductance of about 8 pS. It is present in the apical membranes of many epithelia. Its mutation leads to the potentially lethal disease cystic fibrosis. In addition to acting as a chloride channel, CFTR is also thought to regulate, e.g., the epithelial sodium channel ENaC, a molecularly unknown outwardly-rectifying chloride channel, and possibly also potassium channels and water channels. Some of these potential regulatory processes, however, are controversial. CFTR also acts as a receptor for bacteria.

► Carbon Monoxide

cGMP Kinase

cGMP-dependent protein kinase is encoded by two genes that encode for cGMP kinase I α and I β and cGMP kinase II. cGMP kinase I α and I β are isozymes that differ only at the amino terminus. The amino terminus controls the activity of the enzyme and interacts very specific with different targets.

cGMP-regulated Phosphodiesterases

Phosphodiesterases represent a multi-gene family of enzymes that hydrolyze the second messengers cGMP and cAMP. The hydrolytic activity of several sub-families of these enzymes is regulated in an allosteric manner by the binding of cGMP. The cyclic nucleotide binding site present in cGMP-regulated phosphodiesterases is not homologous to that found in most other cyclic nucleotide-binding proteins.

Channelopathies

“Channelopathies” refer to a class of diseases caused by ion-channel dysfunction. Autoimmune, drug, toxic or genetic mechanisms underlie channelopathies. Mutations in genes encoding ion-channel proteins that alter channel function are common mechanisms underlying the cause of channelopathies. Examples of channelopathies include some forms of Bartter Syndrome (Kir1.1), Andersen’s Syndrome (Kir 2.1), Weaver Mouse Phenotype (Kir 3.2), Persistent Hyperinsulinemic Hypoglycemia of Infancy (PHHI) (Kir 6.2/SUR), Short QT Syndromes (Na and K channels, including Kir 2.1).

Chaperones

RICHARD ZIMMERMANN¹, GREGORY LE BLATCH²
¹Medizinische Biochemie und Molekularbiologie, Universität des Saarlandes, Homburg, Germany
²Department of Biochemistry, Microbiology and Biotechnology, Rhodes University, Grahamstown, South Africa

Synonyms

Molecular chaperones, stress proteins (note: not all stress proteins are molecular chaperones and not all molecular chaperones are stress proteins); Heat shock proteins (Hsp); Polypeptide chain binding proteins

Definition

Chaperones bind to exposed hydrophobic surfaces of polypeptide substrates, and through either ATP-dependent or ATP-independent mechanisms facilitate the folding/assembly, intracellular transport, degradation, and activity of polypeptides.

Basic Mechanisms Molecular Chaperones

The term ▶molecular chaperone was coined by Ron A. Laskey and coworkers in 1978 to describe the

properties of the nuclear protein nucleoplasmin in assisting the assembly of nucleosomes from isolated histones and DNA. Laskey introduced the term molecular chaperone to describe the function of nucleoplasmin because of the analogy with the human chaperone. The role of a human chaperone is to prevent incorrect interactions between pairs of human beings, without either providing a blueprint (or steric information) necessary for their correct interaction or the necessity to be present during their continued interaction. This concept was extended by Hugh R. B. Pelham in 1986. Pelham proposed that members of the Hsp70 and Hsp90 protein families are involved in the assembly and disassembly of proteins in the cytosol, nucleus, and ►endoplasmic reticulum (ER) under nonstress conditions, but are required in increased amounts during cellular stress (such as heat shock-conditions), both to unscramble protein aggregates and to prevent aggregation by binding to hydrophobic surfaces that are exposed as a result of the stress. In addition, Pelham

proposed that all cells contain a variety of proteins that act as molecular chaperones, in preventing incorrect interactions during the operation of several basic cellular processes under normal growth conditions. These cellular processes are protein folding and protein topogenesis in the course of protein biogenesis. Relatively recently, it was appreciated that certain molecular chaperones can also act as modulators/regulators of the activity of folded proteins. Furthermore, these proteins have also been shown to facilitate protein degradation, thereby making them important integration points of the cellular pathways of protein folding and degradation. Therefore, at a broad cellular level, molecular chaperones are some of the key quality control components of the cell.

Today, molecular chaperones are divided into three principle classes, according to their mode of action (Table 1). The one class comprises the chaperonins or Hsp100 protein family members. Chaperonins are oligomeric proteins, composed of two rings placed

back to back, each one enclosing a cavity that allows protein folding in a secluded environment. The term Anfinsen cage was coined by R. John Ellis in 1994 to illustrate this mechanistic principle. They are divided in two groups, those found in eubacteria or endosymbiotic organelles and those found in archaea and the eucaryotic cytosol. The second class includes many of the other Hsp protein families (sHsp, Hsp70, Hsp90, Hsp100) and their respective ►co-chaperones (such as Hsp40 and nucleotide exchange factors, NEF). These chaperones have highly diverse three-dimensional structures but share as a mechanistic principle that they aid protein folding and protein transport by cycles of binding and release of exposed hydrophobic surfaces of polypeptides that, otherwise, would be prone to aggregation. This mode of action is described in detail below in the case of Hsp70. The third class represents polypeptide binding proteins that appear to be more specialized for certain types of substrate polypeptides, such as nascent polypeptide chains (NAC, nascent polypeptide associated complex; SRP, signal recognition particle) or glycoproteins, (Calnexin, Calreticulin) or even single substrate proteins (nucleoplasmin, Hsp47, NDUFAF1, B17.2L).

The Hsp70 chaperone system is the most widely distributed chaperone system in the human cell (Fig. 1). The major molecular chaperone, Hsp70, consists of an N-terminal ATPase domain and a C-terminal substrate binding domain. The affinity of Hsp70 for protein substrates is modulated by ATP binding and hydrolysis. In the ATP bound state, affinity of the substrate binding domain for the substrate protein is low and exchange rates are high. Hydrolysis of ATP to ADP results in high affinity for the substrate and low exchange rates, effectively locking the substrate into the binding pocket. This integral step in assisted protein folding is directly modulated by the binding of Hsp40 proteins. Hsp40s are defined by the presence of an approximately 70 amino acid region known as the J-domain, which is essential for interaction with Hsp70. The J-domain is a highly conserved α -helical structure that interacts with

the Hsp70 ATPase domain and possibly also with the Hsp70 substrate binding domain. Hsp40s are divided into three groups based on their possession of domains in addition to the J-domain. Type I Hsp40s contain four domains: an N-terminal J-domain, a glycine/phenylalanine (GF)-rich region, a zinc finger domain and a C-terminal domain. Type I Hsp40s have been shown to bind protein substrates at their C-terminal domain and to have independent chaperone activity by inhibiting denaturation and aggregation. Type II Hsp40s contain an N-terminal J-domain, a GF-rich region and a C-terminal domain. Type III Hsp40s contain the J-domain, and this may occur at any position within the protein. Other than the J-domain, the type III Hsp40s are highly divergent in size, sequence and structure and tend to serve highly specialized functions.

The various roles of a certain Hsp70 shall be described with respect to Grp78 (also called immunoglobulin heavy-chain binding protein, BiP) (Fig. 2). BiP is the Hsp70 protein family member resident in the ER. It is involved (i) in the import of polypeptides into the ER – working as a structural modulator of the folded Sec61 complex as well as a molecular ratchet on the incoming polypeptide-, (ii) in folding and assembly of proteins in the ER, (iii) in the export of misfolded polypeptides for degradation by the proteasome (►ERAD), and (iv) in the so-called unfolded protein response (►UPR).

RNA Chaperones

As it is the case in polypeptide folding, nonspecific or promiscuous RNA-binding proteins can prevent RNA mis-folding and resolve mis-folded RNAs, thereby ensuring that RNA is accessible for its biological function [1]. Certain DEAD-box proteins as well as some proteins that are involved in the assembly of ribonucleoparticles were shown to act as RNA chaperones.

Chaperone Diseases

There are a number of human diseases associated with mutations in genes encoding chaperones, and the functional failure of certain molecular chaperones has been linked to human diseases [2]. In addition, disease-linked mutations have been found in proteins that regulate the activity of chaperones (i.e., co-chaperones). To name just a few examples and to stay with the Hsp70 chaperone network in the ER (Fig. 2) Marinesco–Sjögren syndrome (MSS; OMIM 248800) and one form of polycystic liver disease (PCLD; OMIM 174050) have been linked to Sil1 and ERj2 (Sec63), a nucleotide exchange factor and Hsp40, respectively, for BiP [3]. In addition, over-expression of various molecular chaperones as well as mutations in certain chaperone genes has been observed in a wide range of tumors [3]. In some cases, the chaperone over-expression was linked to poor prognosis and/or

Chaperones. Figure 1 The functional cycle of Hsp70

Chaperones. Figure 2 The multiple roles of BiP in the biogenesis of the secretory proteins. BiP, immunoglobulin heavy chain binding protein; ER, endoplasmic reticulum; ERAD, ER-associated degradation; ERj, resident ER protein with J-domain; Sec61, core subunit of the protein translocase; UPR, unfolded protein response that involves several signal transduction pathways that are activated in order to increase the biosynthetic capacity and decrease the biosynthetic burden of the ER

resistance to therapy. Furthermore, recent work linked a human infectious disease to inactivation of the ER-resident chaperone BiP [3]. The AB₅ subtilase cytotoxin of certain pathogenic bacteria causes morbidity and mortality among children in developing countries by inactivating BiP.

Pharmacological Intervention

Chemical Chaperones

A number of different low molecular weight compounds are known to stabilize proteins in their native conformation and, therefore, may be effective in correcting of protein folding abnormalities in vivo. Relevant compounds are *N*-acetyl-L-lysine, L-carnitine, taurine, betaine, ectoine, and hydroxy-ectoine [4]. Some of these ►[chemical chaperones](#) and ►[pharmacological chaperones](#) are already used in clinical trials to combat protein folding diseases, such as cystic fibrosis.

Drugs that Target Molecular Chaperones

Several small compounds have been discovered that alter expression or function of Hsp70 and Hsp90,

respectively [5]. The proteasome inhibitor Bortezomib (Velcade[®]) leads to accumulation of mis-folded proteins and, therefore, stress response and subsequent induction of stress proteins, such as Hsp70; the natural compound celastrol as well as geranylgeranylacetone (GGA) were also shown to induce a stress response. Thus, these compounds may some day be used to combat protein folding diseases. Furthermore, small molecules with structural similarity to 15-deoxyspergualin (DSG) or NSC 630668.R/1 were described to inhibit the ATPase activity of Hsp70. Thus, these compounds may be useful in combating certain cancers. Furthermore, based on the discovery of the Hsp70-inhibitors, screening for positive modulators is pursued. The established anti-cancer drug geldanamycin and its less toxic analogue 17-AAG (17-allylaminogeldanamycin), on the other hand, target Hsp90.

Definition

▶ **G-protein-coupled receptors** (GPCRs) play a major role in regulating the overall homeostasis of complex organisms, like mammals, but are also found in primitive species like *Dictyostelium* (slime mold) and yeast [1]. The GPCR superfamily is quite diverse and sequencing has revealed more than 850 genes comprising around 3% of the human genome. The diversity of the GPCRs is equally matched by the variety of ligands that activate them, which include odorants, taste ligands, light, metals, biogenic amines, fatty acids, amino acids, peptides, proteins, nucleotides, lipids, Krebs cycle intermediates, and steroids. Because of their central role in regulating normal physiological responses, GPCRs have attracted considerable attention from the pharmaceutical industry as targets for disease. This large superfamily of proteins remains one of the most druggable targets accounting for more than 40% of all marketed therapeutics. Chemokine receptors are members of the GPCR superfamily and seven CXC, ten

CC, and one CX3C and XC chemokine receptors have been cloned so far [2]. Receptor binding initiates a cascade of intracellular events mediated by the receptor-associated heterotrimeric G-proteins. These G-protein subunits trigger various effector enzymes that lead to the activation not only of ▶chemotaxis but also to a wide range of functions in different leukocytes such as an increase in the respiratory burst, degranulation, ▶phagocytosis, and lipid mediator synthesis.

Basic Characteristics

Chemokines belong to a large family of small, chemotactic cytokines characterized by a distinctive pattern of four conserved cysteine residues [3]. They are divided into two major (CXC and CC) and two minor (C and CX3C) groups dependent on the number and spacing of the first two conserved cysteine residues. Although originally identified on the basis of their ability to regulate the trafficking of immune cells, the biological role of chemokines goes well beyond this simple description of their function as chemoattractants; they have been shown to be involved in a number of biological processes, including growth regulation, hematopoiesis, embryologic development, angiogenesis, and ▶HIV-1 infection (Fig. 1).

Chemokines have been shown to be associated with a number of autoinflammatory diseases including ▶multiple sclerosis, ▶rheumatoid arthritis, atherosclerosis, dermatitis, and organ transplant rejection. Evidence, reviewed below, is mounting that chemokines may play a major role in the pathophysiology of these diseases and thus chemokine receptor ▶antagonists could prove to be useful therapeutics in treating these and other proinflammatory diseases.

Chemokine Receptors

Although leukocytes continue to be the major site of expression of chemokine receptors, several studies have recently demonstrated chemokine receptor expression on neurons in the CNS.

A number of chemokine receptors including CXCR2, CXCR4, CCR1, CCR5, and DARC have been demonstrated in either adult or fetal brain. Not only were these receptors present on the cell surface but they were also functional. Clearly, the role of these receptors on CNS neurons must be very different from their role on immune cells. Given that human astrocytes can be stimulated with cytokines to upregulate the expression of chemokines, it is tempting to speculate that in vivo during CNS development, chemokines

Chemokine Receptors. Figure 1 Biological functions of chemokine receptors as exemplified by the chemokine receptor CXCR4.

secreted by astrocytes might engage specific receptors expressed on neurons and may play a role in the directed migration of specific subsets of neurons to distinctive regions of the brain.

Genetic mutations of receptors, both natural and induced (by targeted gene disruption), can help to unravel their biological roles. Nature has been generous in this regard by providing us with two naturally occurring examples of gene inactivation for chemokine receptors. Humans homozygous for inherited inactivating mutations of the Duffy (*DARC*) gene and the *CCR5* gene have been identified and appear to be phenotypically normal and healthy. Indeed, these gene inactivations appear to be beneficial to their hosts, rendering them resistant to certain infectious diseases. For example, *DARC*-negative individuals are resistant to malaria induced by *Plasmodium vivax*, which utilizes *DARC* to attach to and enter erythrocytes. *CCR5*-negative individuals are resistant to HIV-1, which utilizes this chemokine receptor as a coreceptor for invasion (see section role of receptors in HIV infection).

Analysis of receptor-inactivated individuals can also be useful in clarifying the role of these receptors in disease. For example, it is known that *CCL3* appears to play an important role in multiple sclerosis. This chemokine is a potent ▶agonist for both *CCR1* and *CCR5* receptors, opening the possibility that either of these receptors could be involved in mediating the development of the pathophysiological changes seen in this disease. However, analysis of a large group of individuals, comprising both normal subjects and those suffering from relapsing/remitting multiple sclerosis, showed that there was no significant difference in the allele frequency of the *CCR5* mutation between the groups. These studies indicate that *CCR5* is not an essential component in the expression of multiple sclerosis and implicates *CCR1* in the disease.

Role in Immune Response

Chemokines are potent chemoattractants that provide directional cues to summon leukocytes. Leukocyte recruitment is a three-step process that involves the formation of solid phase chemokine gradients generated by the binding of chemokines to extracellular matrix proteins like glycosaminoglycans, which decorate the cell surface of endothelial cells. These gradients then attract immune cells that first undergo selectin-mediated rolling along the endothelial cells. Chemokine-mediated upregulation of *CD11/18* complexes then results in a much firmer adherence of immune cells to the endothelium and this culminates in diapedesis of leukocytes across the endothelial space into tissues.

By regulating the movement of different subsets of leukocytes from the peripheral blood to extravascular sites such as organs, skin, or connective tissue,

chemokines play a critical role in the maintenance of host defence as well as in the development of the immune response. However, sometimes these molecules can inappropriately target immune cells to attack their own tissues and organs leading to inflammation and cellular destruction. Indeed, strong evidence supports the idea that chemokines play an important role in the pathogenesis of a number of autoimmune diseases such as multiple sclerosis and rheumatoid arthritis.

Rheumatoid arthritis is a chronic inflammatory disease characterized in part by a memory T lymphocyte and monocyte infiltrate. The interaction of the same cell types also play a major role in the demyelinating processes that culminate in multiple sclerosis. Recent studies using neutralizing antibodies have provided strong *in vivo* concept validation for a role of chemokines in animal models of both diseases. For example, in an adjuvant-induced arthritis (AIA) model in the rat, antibodies to *CCL5* were able to abrogate the development of the disease by greatly reducing the infiltration of mononuclear cells into tissue joints. Similarly, antibodies to *CCL3* prevented the development of both initial and relapsing paralytic disease as well as infiltration of mononuclear cells into the central nervous system of a mouse experimental autoimmune encephalomyelitis (EAE) model of multiple sclerosis. These results strongly suggest that chemokines play important roles in T-cell-mediated autoimmune diseases.

In contrast to the role of T-cells and monocytes in chronic inflammation, the primary hallmark of acute inflammatory diseases, such as empyema, acute lung injury, acute respiratory distress syndrome (ARDS), and dermatitis, is tissue infiltration by neutrophils. Thus, neutrophil-activating CXC chemokines-like *CXCL8* are most often associated with these diseases. Clear evidence for a role of *CXCL8* in acute lung injury and pleurisy has been provided by the finding that antibodies to *CXCL8* dramatically increases the survival time of rabbits in models of disease. Not only did the antibodies increase the alveolar–arterial oxygen difference of the animals, increasing the oxygenation of the blood and therefore decreasing breathing difficulties, but they also affected a significant reduction in the infiltration of neutrophils into the lung.

Based on the demonstrated role of chemokines in disease, the generation of small molecule chemokine receptor antagonists have received great interest from pharmaceutical companies as attractive therapeutic approaches. GPCR's like chemokine receptors have in the past been an extremely fertile source of biological targets in the pharmaceutical industry, and compound library screening has proven successful in the discovery of antagonists for a number of these receptors, i.e., CCK and neurotensin antagonists. Using similar approaches

several drug companies have now identified potent small molecule antagonists of a number of chemokine receptors, which should find broad utility in a variety of acute and chronic inflammatory diseases.

Drugs

Insight into the physiological and pathophysiological roles of chemokine receptors have been provided by studies with potent receptor antagonists for CCR1, CCR2, CCR3, CCR4, CCR5, CCR9, CXCR2, CXCR3, and CXCR4, reviewed in Ribeiro and Horuk [4]. A number of these antagonists are in human clinical trials (Table 1). For example, CCR5 antagonists are in phase III clinical trials for the treatment of AIDS and CCR9 antagonists are in phase II clinical trials for inflammatory bowel disease.

Whether these antagonists live up to their initial promise as potent therapeutics for autoimmune disease or not is still open to question. With the exception of the CCR5 antagonist whose target is a viral disease, AIDS, the other antagonists are being used to treat complex human diseases. Just recently three of these clinical trials were reported as failures [4]. The first of these was the Pfizer CCR1 antagonist, CP-481715, which entered Phase II trials in February 2004 for rheumatoid arthritis. Although the compound was well tolerated, data suggested that it did not exhibit efficacy in rheumatoid arthritis patients and the trial was stopped following 6 weeks of treatment. The Berlex/Schering AG oral CCR1 antagonist BX 471 entered phase II clinical trials for multiple sclerosis in early 2004. Again the drug was well-tolerated and showed no safety concerns but its development was stopped after the clinical Phase II study failed to show a reduction in the number of new inflammatory CNS lesions, as detected by Magnetic Resonance Imaging. Finally, a CXCR3 antagonist from Amgen recently entered a Phase II trial

for psoriasis, unfortunately the inhibitor failed to demonstrate any signs of efficacy and the trial was terminated.

What do these failures tell us? These clinical trials could have failed for a variety of reasons for example was sufficient drug on board, was the right target selected, how reliable were the animal efficacy models that preceded the clinical trial, what markers if any were utilized in order that the correct patient population that could respond to the drug was selected? Since we do not know the answers to all of these questions it is difficult to ascribe a reason for the failure of these approaches. One idea that we can however propose is that perhaps targeting complex heterogeneous diseases with a drug that targets a single receptor is not the right approach. Roth et al. have for example advocated a “magic shotgun” rather than a “magic bullet” approach to target complex diseases such as cancer and schizophrenia [5]. In line with this suggestion it is interesting that one of the most successful drugs to target multiple sclerosis recently is the molecule FTY720 which targets four out of the five GPCRs that are activated by sphingosine 1-phosphate. FTY720 is currently entering phase III clinical trials and the phase II data look exciting. Based on the failures of drugs that target a single chemokine receptor (magic bullet) perhaps promiscuous molecules, like FTY720, that target several chemokine receptors (magic shotgun) will be more successful. This is certainly possible for example CCR5 antagonists like TAK 779 and TAK 652 also bind with high affinity to CCR2 and the CCR3 antagonist UCB35625 also binds with high affinity to CCR1.

Chemokine Receptors in Pathogen Infection

A number of viruses, including those in the Herpes and Pox families, express chemokine-like or chemokine receptor-like molecules that presumably help them to

survive immune attack and proliferate. In addition to these strategies, chemoattractant receptors have themselves been targeted as vehicles of cellular invasion by a wide variety of microbes. These range from the Duffy blood group antigen, a promiscuous chemokine receptor on human erythrocytes which serves as a binding protein for the malarial parasite *Plasmodium vivax*, to the fractalkine receptor, CX3CR1, which is a portal of entry for the respiratory syncytial virus, and the HIV-1 virus which utilizes the chemokine receptors CXCR4 and CCR5 as coreceptors for cellular entry. CCR5 is an entry cofactor for M-tropic isolates of HIV-1 and is important in the early proliferative part of the disease, while CXCR4 is a coreceptor for T-tropic isolates of HIV-1 whose emergence in infected individuals usually correlates with accelerated disease progression.

HIV-1 resistance exhibited by some exposed but uninfected individuals is due, in part, to a 32 base pair deletion in the *CCR5* gene (*CCR5D32*) which results in a truncated protein that is not expressed on the cell surface. About 1% of Caucasians are homozygous for the *CCR5D32* allele and appear to be healthy with no untoward signs of disease. In fact, recent findings suggest that homozygosity for the *CCR5D32* alleles confers other selective advantages to these individuals, rendering them less susceptible to rheumatoid arthritis and asthma and prolonging survival of transplanted solid organs.

Chemokines

Chemokines are a family of small cytokines, or proteins secreted by cells. Proteins are classified as chemokines according to shared structural characteristics such as small size (8–10 kDa in size), and the presence of four

cysteine residues in conserved locations that are key to forming their three-dimensional shape. Chemokines have been identified as attractants of different types of blood leukocytes to sites of infection and inflammation. They are produced locally in the affected tissues and act on leukocytes through selective chemokine receptors. Chemokines help to control leukocyte maturation, traffic, and homing of lymphocytes and the development of lymphoid tissues.

Chemoreceptor Trigger Zone

The chemoreceptor trigger zone (CTZ) is a group of neurons in the area postrema of the medulla. Once stimulated, it activates the vomiting center, which is also located in the medulla, thereby causing emesis. The CTZ is sensitive to a variety of chemical stimuli. Syrup of ipecac (synonym ipecacuanha) and apomorphine are direct stimulators of the CTZ. Clinically they are used to provoke emesis after oral ingestion of a poison. The CTZ is also stimulated by other drugs, e.g. cardiac glycosides, morphine (opioid system) and antineoplastic agents.

- ▶ Emesis

Chemotaxis

Chemotaxis is the detection of and coordinated movement toward a chemical compound by a cell or organism, e.g., neutrophils move towards an area of infection because of chemicals released by infected tissues.

Cholera Toxin

Cholera toxin is a protein toxin of *Vibrio cholerae*. Toxin ADP-ribosylates the α -subunit of the G_s heterotrimeric

GTP-binding protein at an arginine residue which is involved in GTP hydrolysis. ADP-ribosylation thus leads to constitutive activation of G_s .

Synonyms

Acetylcholinesterase (EC 3.1.1.7) (AChE): Acetylcholine acetylhydrolase; True ChE; ChE I; ChE; Acetylthiocholinesterase; Acetylcholine hydrolase; Acetyl- β -methylcholinesterase; Erythrocyte ChE

Butyrylcholinesterase (EC 3.1.1.8) (BChE or BuChE): ChE; Pseudocholinesterase; Plasma ChE; Acylcholine acylhydrolase; Non-specific ChE; ChEII; Benzoylcholinesterase; Propionylcholinesterase

Definition

Cholinesterases (ChEs), polymorphic carboxylesterases of broad substrate specificity, terminate neurotransmission at cholinergic synapses and neuromuscular junctions (NMJs). Being sensitive to inhibition by organophosphate (OP) poisons, ChEs belong to the serine hydrolases (B type). ChEs share 65% amino acid sequence homology and have similar molecular forms and active centre structures [1]. Substrate and inhibitor specificities classify ChEs into two subtypes:

1. Acetylcholinesterase (EC 3.1.1.7) (AChE)
Primarily hydrolyses esters with short acyl moiety, such as acetylcholine (ACh). It is the major ChE in human blood, muscle and brain cells. AChE mRNA is 20-fold more abundant than BChE mRNA.
2. Butyrylcholinesterase (EC 3.1.1.8) (BChE or BuChE)
Primarily hydrolyses esters with longer aliphatic (compared to AChE) or aromatic acyl moiety, such as butyrylcholine (BCh) and benzoylcholine (BzCh). BChE is the primary circulating ChE. It is threefold more abundant than AChE in human blood and is found in liver, lungs, muscles, brain and heart.

Basic Characteristics

Cellular Processes

ChEs control the duration of ACh-mediated action on post-synaptic receptors in cholinergic synapses, and have non-hydrolytic roles in nervous systems' development and plasticity.

Catalytic Activity

ChEs hydrolyze choline esters and carboxylic esters (1, 2 respectively):

1. $\text{RCO}_2(\text{CH}_2)_2\text{N}^+(\text{CH}_3)_3 + \text{H}_2\text{O} \rightarrow \text{RCO}_2\text{H} + \text{HO}(\text{CH}_2)_2\text{N}^+(\text{CH}_3)_3$
(R = CH₃ ACh; C₃H₇ BCh; C₆H₅ BzCh)
2. $\text{RCO}_2\text{R}' + \text{H}_2\text{O} \rightarrow \text{RCO}_2\text{H} + \text{HOR}'$

Hydrolysis involves a Glu-His-Ser catalytic triad, similar to other serine hydrolases, through a “charge relay” process. The imidazol ring of His relays electrons from Glu to Ser and the hydroxyl oxygen of Ser becomes a nucleophile and attacks the ester bond of a substrate, yielding an acyl-enzyme intermediate releasing a choline moiety. A water molecule then hydrolyzes the acetylated Ser by nucleophilic attack. Carbamates and OPs chemically modify the active site Ser, slowing down the last hydrolysis step and irreversibly inhibiting hydrolysis.

Cholinergic neurotransmission: ChEs terminate cholinergic transmission in the central nervous system (CNS), in NMJs and in the autonomic system (the parasympathetic system, somatic motor nerves and pre-ganglionic sympathetic nerves). A few sensory cells and the NMJ in nematodes also include ChEs.

Physiological roles: Both enzymes can catalyze ACh hydrolysis into acetic acid and choline, thus maintaining proper transmission of impulses between nerve cells or from neurons to muscles and gland cells. The catalytic mechanism of AChE is extremely efficient, approaching diffusion-controlled rates ($k_{\text{cat}}/K_{\text{M}} = 1.47 \times 10^8 \text{ M}^{-1}\cdot\text{s}^{-1}$), considerably faster than BChE's hydrolysis rate of ACh. BChE deficiency, an uncommon genetic disorder, causes no pathology, but increases carriers' susceptibility to prolonged apnea under muscle relaxant agents, such as succinylcholine or mivacurium, which are naturally destroyed by BChE. When administered under anaesthesia to a susceptible person, these compounds are ineffectively removed, which prolongs muscle relaxation. Likewise, subjects with BChE deficiency are susceptible for adverse reactions to other anti-ChEs.

Both ChEs show arylacylamidase activity, but BChE has a wider range of substrates: it hydrolyzes several choline esters from acetyl to heptanoylcholine, as well as other aliphatic esters. High BChE activity in many first contact tissues (e.g., lungs, skin, blood and placenta) as well as high affinity towards a wide range of orally ingested toxic compounds and xenobiotics (e.g., cocaine, procainamide, acetylsalicylic acid) support the hypothesis that BChE functions as a natural bioscavenger by absorbing and degrading OP poisons (e.g., nerve agents) before these cause neurological damage.

Non-Catalytic Activity

ChEs exist throughout the entire animal kingdom and appear in locations, where no ACh is released, suggesting that these possess additional non-hydrolytic functional properties, designated “non-classical”. These may depend on protein–protein interactions,

compatible with ChE's structural homology with synaptic proteins such as neuroligins, which interact with other synaptic proteins – the neurexins. Also, AChE contains two helix-loop-helix motifs, each forming a calcium-binding site (EF-hand). These do not play a role in its catalytic activity but may participate in protein–protein interactions.

Within the nervous system, ChEs were shown to be involved in membrane conductance and transmission of excitatory amino acids, learning and memory, neurite growth, neuritic translocation and acute stress reactions. Recent findings propose AChE's involvement in apoptosome formation [2].

Reports of ChE abnormalities in tumours, e.g., meningioma, glioma, acoustic neurinomas and lung cancers, megakaryocytopoietic disorders and leukemias, ovarian tumours and neuroblastomas, suggest cell proliferation and differentiation activities.

Structure

ChEs possess the α/β -fold structure, which is shared with other esterases and non-catalytic proteins such as thyroglobulin, glutactin, neurotactin, gliotactin and neuroligins, all of these include a single ChE domain. Both ChEs are ellipsoidal molecules of $\sim 45\cdot 60\cdot 65$ Å³. Their structure consists of a central, highly twisted, 8–12-stranded β -sheet, in which most strands are parallel, flanked on both sides by α -helices. Studies have indicated three major domains within the protein:

The active site is composed of two subsites:

The esteratic subsite contains the catalytic machinery of the enzyme. The catalytic triad residues – Ser 200, His 440 and Glu 327 (the residue numbering in this section refers to *Torpedo californica acetylcholinesterase*, TcAChE) – are identical in both enzymes and basically in the same positions.

The anionic subsite (Trp 84 and Phe 330) lies between the peripheral and acylation sites, half-way down the gorge and accommodates the positively charged quaternary ammonium of the choline moiety. Trp 84 orients the charged part of the substrate to the active centre. This subsite is involved in a “cross-talk” mechanism with the peripheral anionic site (PAS) [3].

The aromatic gorge composed of 14 highly conserved aromatic residues, is placed ~ 20 Å deep, penetrating half-way into the gorge harbouring the active site. In BChE, 6 of the 14 aromatic amino acid residues are replaced by aliphatic ones. Therefore, BChE's gorge is larger in volume and shows a distinct inhibitor sensitivity profile. Other crucial residue changes exist in the acyl-binding pocket, with the replacements of Phe

288 and Phe 290 of TcAChE by Leu 286 and Val 288, respectively; these changes enable the binding of the bulkier butyrate substrate moiety in BChE.

The PAS is located at the rim of the aromatic gorge, on the protein's surface. It spans six AChE residues: Tyr 72, Tyr 124, Glu 285 and Trp 286, on one side of the gorge entrance, and Asp 74 and Tyr 341, on its opposite side. Its core is comprised of Trp 286 and Asp 74, which accommodates many distinct ligands. BChE also has a PAS, but its relatively aromatic content and the response upon ligand-binding differ significantly from those of AChE.

Molecular Mechanisms of Assembly

ChEs present a wide molecular diversity that modulates their function in cholinergic synapses and non-synaptic contexts. This diversity arises at the genetic, post-transcriptional and post-translational levels.

Genetics and Evolution

Genomic comparisons suggest evolutionary gene duplications creating new ChE encoding genes, which initiated before the divergence of nematodes and insects. Subsequent independent duplications lead, for example, to four *ACHE* genes in nematodes. Some families or species may in turn have lost copies of the duplicated genes (e.g. *Drosophila melanogaster*). The duplication that formed *ACHE* and *BCHE* occurred in the tetrapod lineage, thus, amphibians and reptiles but not fish have a *BCHE* homologue resembling *BCHE* of mammals or birds.

The human ACHE gene (7q22) is 7 kb long, encodes all variants of AChE, which share a core domain, spanning the 543 amino acids encoded by exons E2, E3 and E4 of this gene (E1 is a non-coding exon). Post-transcriptional events modify the N²- and the C²-terminus, causing differences in assembly and localization of the AChE multiple forms. A single nucleotide polymorphism (SNP) in position 353 (His353Asn) is responsible for the Yt blood group system; His-353 AChE corresponds to the Yt(a) and the rare Asn-353 AChE variant to Yt(b) blood group antigen.

The human BCHE gene (3q26.1-q26.2) includes four coding exons, yielding a 602 amino acids long protein. More than 40 SNPs have been described for BChE. “Atypical” BChE (the dibucain resistant Asp70Gly) shows reduced activity, because Asp70 facilitates the initial binding of positively charged substrates to the active site gorge. The K (Ala539Thr), J (Glu497Val) and fluoride resistant (Thr247Met or Gly390Val) variants also show reduced BChE activities. Also, ~ 20 different “silent” genotypes have been recognized, with 0–2% of normal activity. Inversely, the Cynthiana and Johannesburg variants show higher activity than “usual” BChE.

Post-Transcriptional Modifications

The *ACHE* gene includes sites for alternative splicing of its pre-mRNA product both at the 5' and the 3' ends. Three different carboxy termini exist: the “synaptic” or S variant also called as “tailed”, the “erythrocytic” or E variant and the “readthrough” or R variant. These join the two different N-termini to yield variants with the common or the “extended” N-terminus.

Post-Translational Modifications

Both ChEs undergo several post-translational modifications, including glycosylation and glycosylphosphatidylinositolation (GPI), phosphorylation and carbamylation.

Glycosylation: AChE and BChE carry 3 and 9, respectively, N-glycosylation consensus sequences attaching carbohydrate residues to the core protein via asparagines. Different molecular forms of the enzymes in various tissues, show different number and composition of carbohydrate residues. N-glycosylation at all sites was shown to be important for effective biosynthesis, secretion and clearance of ChEs from the circulation. Altered patterns of AChE glycosylation have been observed in the brain and cerebrospinal fluid of Alzheimer’s disease (AD) patients, with potential diagnostic value.

Glycosylphosphatidylinositolation: The GlycoPhosphatidyl Inositol moiety anchor of AChE consists exclusively of diacyl molecular species. Over 85% of the molecular species are composed of palmitoyl, stearoyl and oleoyl. The post-translational process of glypiation takes place in the endoplasmic reticulum, after completion of the polypeptide chain; the newly synthesized protein interacts with a transamidase

complex, which cleaves the chain upstream of the hydrophobic region and adds a preformed GPI anchor to the resulting C-terminal residue.

Disulfide bridges formation: ChEs contain 8–10 cysteines; six of these form three internal disulfide bridges. The cysteine that is located four amino acids upstream the carboxyl terminus forms a disulfide bridge with a cysteine of an identical subunit, creating an interchain disulfide bridge, which stabilizes the dimeric structure.

Molecular Forms of ChEs

ChEs present several amphiphilic and soluble homo- and hetero-oligomeric molecular forms in tissues and body fluids, with different tissue distributions (Fig. 1).

BChE and AChE-S (1–4, in green):

1. Amphiphilic monomers and dimers (G1, G2): Abundant in mammalian brain, muscles and intestine for both ChEs.
2. Soluble tetrameric form (G4): Composed of four identical monomers and stabilized by hydrophobic interactions of hydrophobic amino acids at the C terminus of monomers. Abundant for brain AChE and BChE in mammalian body fluids and in the soluble fraction of tissue homogenates.
3. Hydrophobic-tailed tetramers: Abundant form in the mammalian CNS. Anchored to plasma membranes by a hydrophobic, 20 kDalton length polypeptide subunit named PRiMA (Proline-Rich Membrane Anchor).
4. Collagen-like (ColQ) tailed forms or asymmetric multimers: Characterized by triple helical structure of three collagenic subunits Q, each associated with

Cholinesterase. Figure 1 Shown are the seven subgroups of ChEs' Molecular forms: Top, in green: monomeric, dimeric and tetrameric AChE-S forms (G1, G2, G4 and PRiMA). Middle, in green: ColQ tailed AChE-S forms (A4, A8 and A12). Parallel forms exist for BChE. Down: other AChE splicing variants (AChE-R, AChE-E, N-AChE).

one (A4), two (A8) or three (A12) tetramers of ChEs, anchoring to the basal lamina. It is more abundant for AChE than BChE in NMJ.

5. AChE-R (in purple): Naturally rare, stress-induced variant, which lacks a hydrophobic domain and is incapable of binding to ColQ or PRiMA. Therefore, it remains soluble, and its secreted form shows greater mobility than AChE-S. AChE-R can intracellularly interact through its C-terminal tail with the Protein Kinase C Receptor RACK1, a scaffold protein which modifies multiple cellular processes.
6. AChE-E (in blue): GPI-anchored dimers to plasma membranes in mammalian muscles, erythrocytes and lymphocytes.
7. N-AChE (in purple): The N-terminus extension may serve as a transmembrane domain, enabling AChE-R anchorage to the membrane without ColQ/PRiMA. In principle, N-AChE-S, N-AChE-E and N-AChE-R, may exist.

Drugs

Alzheimer's disease (AD) is an age-related neurodegenerative disorder characterized by progressive cognitive impairment, a variety of neuropsychiatric and behavioural disturbances, and restrictions in activities of daily living. Both AChE and BChE are found in human neurons, glia and in AD's plaques and tangles. AChE activity decreases while BChE activity increases with age (>60 years). The Cholinergic Hypothesis attributes to decreased cholinergic transmission a major role in the expression of cognitive, functional, and possibly behavioural symptoms in AD. Correspondingly, cholinesterase inhibitors (ChEI) became the common treatment for dementia symptoms. Male carriers of both *BCHE-K* and the debilitated apolipoprotein E4 variant, when older than 75 years, show high-risk for late-onset AD in some, but not all, studies.

Another pathway of influence in AD is the facilitation of amyloid- β (A β) aggregation through an interaction with the PAS of AChE but not of BChE. Inversely, the "usual" BChE (and more specifically its C-terminus) was shown recently as to attenuate in vitro the formation of amyloid fibrils [4].

Gulf war syndrome (GWS) is the name given to a variety of psychological and physical symptoms suffered by veterans of the 1991 Persian Gulf War. The symptoms have been remarkably wide-ranging, sometimes somewhat ill-defined. These symptoms were interpreted to reflect exposure to centrally acting anti-AChEs.

Cholinesterase Inhibitors

OPs or carbamate esters are potent inhibitors of both AChE and BChE. These include drugs (e.g. for AD or myasthenia gravis, MG), pesticides, insecticides and

chemical warfare agents. Phosphorylation or carbamylation of the serine hydroxyl group in the substrate-binding domain inhibits the enzyme, causing ACh accumulation in synaptic clefts and over-stimulation of cholinergic receptors. This induces various symptoms, including tension, anxiety, headaches, slurred speech, tremor, convulsions, muscle paralysis, seizure and even death by asphyxiation.

Drugs

ChEIs represent the treatment of choice for AD therapy, including physostigmine and tacrine (of the first generation), donepezil, rivastigmine and galantamine (of the second generation). ChEIs vary widely in their pharmacological profiles and affinities for AChE and BChE. Donepezil and galantamine inhibit AChE by 1000- and 50-fold more than BChE, respectively, whereas rivastigmine inhibits both enzymes with similar affinity.

ChEI treatments have been expanded also to include other dementias and CNS disorders, e.g. delirium, traumatic brain injuries and memory impairments, as well as myasthenia gravis, glaucoma and parasite infections.

Dementia with Lewy bodies (DLB) is considered the second most common cause of dementia after AD. The disorder is characterized by progressive fluctuating cognitive impairment, visual hallucinations and motor features of Parkinsonism. Neocortical cholinergic activity is more severely depleted in DLB than in AD, and DLB also affects the caudate nucleus, the thalamus and the brain stem. Tolerability of ChEI in DLB appears similar to AD, with some gastrointestinal effects and muscle cramps.

Parkinson's disease (PD) patients may suffer cognitive and behavioural impairments including apathy, personality changes and visual hallucinations, with no currently recommended treatment. Their significant cholinergic deficits led to recommendation of ChEI therapeutics.

Vascular dementia (VD) accounts for ~20–30% of dementia cases, with clinical and pathological overlap with AD. Reductions in cholinergic markers suggest cholinergic deficits in VD, and ChEIs increase ACh availability and improve their cerebral blood flow.

Down's syndrome (DS) carriers develop early-onset AD, motivating the use of cholinergic therapy in this disorder.

Traumatic brain injury is the most common cause of death in subjects under the age of 40, and an important risk factor for AD. Loss of hippocampal cells and depletion of ACh and of muscarinic receptors can be attenuated in injured experimental animals, improve blood perfusion in ischemic areas and increase cholinergic transmission in cortex and hippocampus; the same mechanism invoked for treatment of VD.

Delirium, e.g. post-narcotic delirium, somnolence or coma, is a common complication involving dementia, with fluctuating attention and consciousness and considerable morbidity. It is not always reversible and there is no specific treatment. Some of the accompanying central cholinergic syndromes can be reversed by ChEIs.

Myasthenia gravis (MG) is an autoimmune disorder characterized by weakness of face, tongue and/or neck, which result in double vision or drooping eyelids, along with difficulty chewing, swallowing and talking. The most commonly used ChEIs in MG are pyridostigmine, neostigmine and huperzine A. An AChE mRNA-targeted agent, Monarsen, is under clinical trials for ameliorating MG symptoms, with significant advantages over ChEIs.

Chemical Warfare Agents, Pesticides and Insecticides

Discovered in the late 1930s in Germany as improved poisonous insecticides, organophosphorus ChEIs were developed as chemical warfare agents (e.g. sarin, soman, and tabun) and were more recently employed in the 1995 terrorist attack in the Tokyo subway system [5].

Therapy against acute nerve gases toxicity includes pre-treatment with pyridostigmine, a reversible carbamate ChEI, capable of inducing AChE over-expression. Post-exposure treatment is continuous with administration of cholinolytic agents such as atropine, the oxime reactivator, pralidoxime chloride and diazepam. Although multi-drug combination therapy is effective in increasing survival, it must be administered immediately and cannot prevent the occurrence of post-exposure toxic symptoms. A recently developing alternative involves the use of highly purified ChEs as therapeutic agents. Recombinant production systems for such proteins include transgenic goats producing human BChE in their milk, or plants production of human AChE.

Cholinesterase Inhibitor

Cholinesterase inhibitor (anti-cholinesterase, ChEI) is a chemical that prevents cholinesterases (ChEs) from breaking down. ACh, which consequently increases the level and duration of action of this neurotransmitter. ChEIs such as organophosphates (esters of phosphoric acid) and carbamates (esters of carbamic acid) – serve as insecticides, pesticides, warfare agents and drugs.

► Cholinesterases

Chorionic Gonadotropin

Chorionic gonadotropin (CG) is produced in the placenta. Together with the pituitary hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), it constitutes the glycoprotein family of gonadotropins. The actions of CG are mediated by the LH receptor, both belonging to the superfamily of G-protein Coupled Receptors.

► G-protein-coupled Receptors
► Contraceptives

Choroideremia

Disorder characterized by atrophy of the choroid (the thin membrane covering most of the posterior of the eye between the retina and sclera) and degeneration of the retinal pigment epithelium resulting in night blindness. The disease is caused by mutations in Rab escort protein Rep1 (component A of Rab geranylgeranyl transferase).

► Protein Trafficking and Quality Control

Chromatin

Chromatin is a noncovalent complex consisting of DNA and dedicated packing proteins, the histones. The name chromatin is derived from the Greek word chroma

(Color) since chromatin can be stained by certain dyes and visualized under a microscope. The main purpose of chromatin is the packaging of DNA and regulation of gene activity. Chromatin can be divided into euchromatin and heterochromatin that differ in microscopic appearance and gene activity. Euchromatin is relatively pale on staining and represents low condensed chromatin with active gene expression. Heterochromatin is intensively stained and strongly condensed without or only low gene activity.

Chromatin is composed of nucleosomes, where each comprise 147 base pairs of DNA wrapped around an octamer of two copies of each histone H2A, H2B, H3, and H4. Nucleosomes are folded into higher-order structures that are stabilized by linker histones. Chromatin structure can be altered by enzymes that posttranslationally modify histones (e.g., through phosphorylation, acetylation, methylation, or ubiquitination) or by ATP-driven chromatin-remodeling complexes that alter nucleosome position and/or composition.

- ▶ Histone Acetylation
- ▶ Transcriptional Regulation

Chromosomal Translocations

The presence of chromosomal translocations is a consistent feature of many leukemia's, lymphomas, and certain solid tumors. At the genetic level, these events can either deregulate an intact gene by disruption or removal and replacement of the adjacent controlling elements, or create a new fusion gene that express the N-terminus of one protein fused to the C-terminus of another protein.

- ▶ RNA Interference (RNAi) – siRNA

Chromosome Segregation

Separation of sister chromatids during anaphase of mitosis. Mitotic chromosomes are first aligned on the metaphase plate before the sister chromatids are separated induced by cleavage of proteins, termed cohesins, holding the chromatids together. The cleavage of cohesins requires the ubiquitin-dependent protein degradation mediated by the APC/C.

- ▶ Cell Cycle Control

Chromosomes

Double helical DNA is organized in all cells into structures generically referred to as chromosomes. Chromosomes contain most of the genetic information of a cell, although bacterial cells may also have plasmids and eukaryotic cells may also have episomes (extrachromosomal elements). In most bacterial cells, the bacterial chromosome is organized as a single circular double-stranded DNA molecule. Most multicellular organisms have several chromosomes that are linear instead of circular. Sexually reproducing organisms have two copies of each chromosome, one from each parent.

Chronic Bronchitis

Chronic productive cough without a medically discernible cause that is present for more than half the time for 2 years.

- ▶ Chronic Obstructive Pulmonary Disease

Chronic Obstructive Pulmonary Disease

Synonyms

Chronic bronchitis; Pulmonary emphysema

Definition

Chronic obstructive pulmonary disease (COPD) affects over 5% of the adult population, is the fourth leading cause of death worldwide and is the only major cause of mortality that is increasing worldwide. It is an inflammatory disorder of the lungs, caused mainly, but not exclusively, by cigarette smoking. 15–20% of smokers develop COPD.

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) has defined COPD as a disease state characterized by airflow limitation that is not fully

reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases (► www.goldcopd.com). The severity of COPD is classified on the basis of chronic symptoms (cough, sputum production) and spirometric lung function tests.

The definition above has replaced older ones that focused to varying degrees on ► **chronic bronchitis** and/or ► **emphysema**. Chronic bronchitis and emphysema frequently represent different consequences of the same insult leading to changes in large airways, small airways and pulmonary parenchyma (Table 1).

Basic Mechanisms

During COPD, the following symptoms occur, usually in the order mucus hypersecretion, ciliary dysfunction, airflow limitation, pulmonary hyperinflation, gas exchange abnormalities, pulmonary hypertension and cor pulmonale. Acute exacerbations appear to be mainly triggered by bacteria, viruses or environmental pollutants. They lead to a worsening of lung functions, wasting and increased mortality; their psychosocial impacts include depression and anxiety that may be associated with the will to die.

COPD is a chronic inflammatory disease that results from prolonged and repeated inhalation of particles and gases, chronic (or latent) infection or an interaction of these factors. In many cases, the inflammation persists even when the exposure (in most cases smoking) is stopped. Prominent among the infiltrating leukocytes are neutrophils, ► **CD8⁺** lymphocytes (Co-receptor for the T-cell receptor. CD8⁺ is specific for the class I MHC protein. It is expressed on the surface of cytotoxic T-cells and natural killer cells.) and ► **CD68⁺** monocytic cells (A lysosomal antigen. All cells that rich in

lysosomes are CD68⁺, e.g. monocytes, macrophages, mast cells.) (Table 1). The particular contribution of these cell types to the pathology of COPD is under intense discussion. However, because COPD develops over so many years, it remains difficult to distinguish cause and correlation.

One intensively investigated feature of the inflammatory process in COPD is the release of proteases from neutrophils and monocytic cells that destroy elastin and other components of the interstitial matrix (Table 1). The best studied protease is neutrophil elastase. Independent of its elastolytic activity, neutrophil elastase is a potent secretagogue. More recently matrix metalloproteases (MMP) have received increasing attention, in particular MMP12 (macrophages elastase). To which extent and how exactly these proteases become activated is not clear at present.

Both elastase and MMPs have physiological antagonists, named α 1-AT (α 1-anti-trypsin is the primary inhibitor of neutrophil elastase) and TIMP (tissue inhibitor of matrix metalloproteases), respectively. Smoke, presumably through oxidative stress may inactivate these anti-proteases. Consequently, it has been suggested that emphysema results from an imbalance of the protease: anti-protease ratio. And in fact, hereditary α 1-AT deficiency is a rare, but well-known cause of emphysema. In experimental animals, TIMP-3 deficiency leads to a combination of developmental airspace enlargement combined with progressive destructive emphysema in adults. Almost certainly, no single protease/anti-protease alone is responsible for the development of COPD.

Oxidative stress has received much attention as a potentially pathogenic factor. It may promote COPD by many factors such as induction of pro-inflammatory genes in many cells including epithelial and endothelial

Chronic Obstructive Pulmonary Disease. Table 1 Pathological changes in chronic obstructive pulmonary disease (COPD)

	Large airways	Small airways (<2 mm ϕ)	Paren-chyma	Products/consequences

^aCorrelates with cough and chronic bronchitis.

^bNumber increases with disease severity.

cells, inactivation of anti-proteases or promotion of histone acetylation. ► **Reactive oxygen species** and other factors such as ceramide or blockade of vascular endothelial growth factor (VEGF) receptors may cause emphysema by induction of apoptosis (in the case of reactive oxygen species also necrosis) in endothelial or epithelial cells. Furthermore, inefficient apoptotic cell clearance (efferocytosis) may also contribute to a probably genetically modulated progressive lung destruction that is accompanied with some fibrous scarring.

Today, COPD is regarded as a systemic disease. The different pathomechanisms do not cause only local lung injury and remodelling, but also alter systemic structure and function. Relatively little is known about the low-grade systemic inflammation present in COPD that is considered the main cause for the systemic effects. These systemic effects of COPD include involuntary weight loss, muscle wasting, impaired bone metabolism, reduced functional capacity and health status, and increased cardiovascular morbidity as an important resource-consuming co-morbidity. Thus COPD is multidimensional disease. To account for the multiple changes in COPD the BODE index was introduced, a 10-point scale combining measures of BMI (B), the degree of airflow obstruction (O) and dyspnea (D), and exercise capacity (E).[1,2]

Pharmacological Interventions

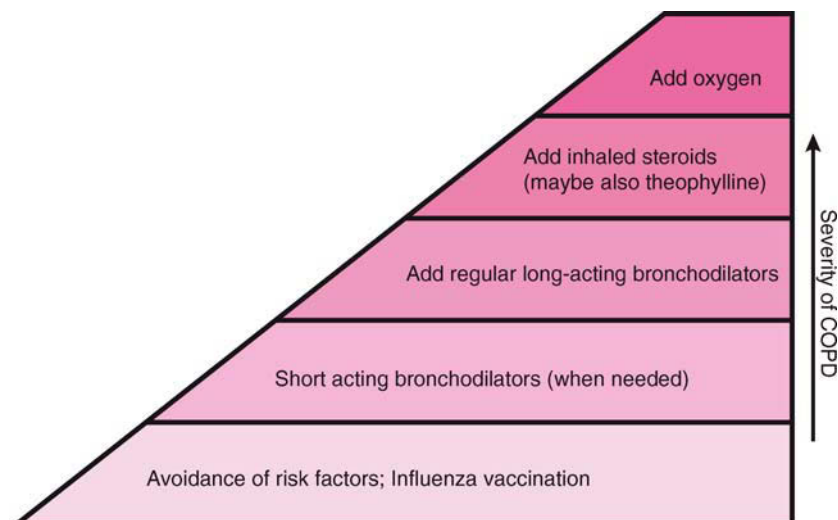

Usually, it takes years of toxin exposure to cause the pathological alterations seen in COPD. In most cases, the disease is already well-progressed when COPD is diagnosed. Reversal of established chronic inflammatory disease is always extremely difficult to achieve and at present healing of COPD is impossible. Smoking cessation is the single most effective and cost-effective

intervention to reduce the risk of developing COPD and to stop its progression. Most of the pharmacological agents that are used in COPD (Fig. 1) have been developed for the treatment of asthma, where their benefit is clearly greater. The comparatively small effect of inhaled β -agonists on airway resistance is even used as a diagnostic criterion to distinguish COPD from asthma. The management of COPD is largely symptom driven, and there is only an imperfect relationship between the degree of airflow limitation and the presence of symptoms. Currently, there is no effective therapy for the irreversible airflow obstruction that results from airway remodelling, fibrosis and emphysema. Available pharmacotherapy can reduce or abolish symptoms, increase exercise capacity, reduce the number and severity of exacerbations, and improve health status. The inhaled route is preferred. Contraindicated for the treatment of stable COPD are anti-tussives and inhaled NO[1,4,5.]

Bronchodilators

The primary aim of the current COPD therapy is to reduce airway resistance by reducing bronchial smooth muscle constriction and mucous plugging. β 2-adrenoreceptor agonists and anti-cholinergics are the mainstay of therapy for symptomatic management. These bronchodilators improve symptoms, exercise tolerance and may reduce exacerbations, but have little effect on inflammation and on the long-term decline in lung functions. β 2-agonists and to some extent also anti-cholinergics may increase the risk of adverse cardiovascular events. The combination of bronchodilators with inhaled steroids is probably more effective than either treatment alone.

β 2-adrenoreceptor agonists: β -agonists increase intracellular cAMP, which in turn leads to bronchodilation and improved lung emptying during breathing.

Chronic Obstructive Pulmonary Disease. Figure 1 Pharmacotherapy of chronic obstructive pulmonary disease (COPD).

Both short- (<6h: salbutamol, terbutaline, orciprenaline, fenoterol) and long-acting (>12h: formoterol, salmeterol) β -agonists are used. Regular treatment with long-acting bronchodilators is more effective and convenient than treatment with short-acting bronchodilators. There is a relatively small and flat dose-response relationship with all β -agonists. Possible side-effects are palpitations and premature ventricular contraction (resulting from stimulation of β_1 -receptors in the heart), tremor and sleep disturbances.

Anti-cholinergics: Tiotropium bromide remains bound to M3-receptors for up to 36 h, and requires only daily intake, whereas other anti-cholinergics (e.g. ipratropium, oxytropium) have to be given up to four-times daily and are often used as maintenance treatment. Possible side-effects are dry mouth, metallic taste after inhalation and very rarely close-angle glaucoma.

Methylxanthines (see also asthma): The best known of these drugs is theophylline. Theophylline is an unspecific phosphodiesterase inhibitor that also possesses some anti-inflammatory effects. Theophylline is generally considered a third-line bronchodilator drug in chronic COPD behind inhaled anti-cholinergics and β_2 -agonists, with slow-release forms of oral theophylline preferred. Methylxanthines have a narrow therapeutic margin. Major side-effects are ventricular and atrial dysrhythmias, and convulsions. Other possible side-effects include headache, nausea, vomiting, diarrhoea and heartburn. More selective phosphodiesterase-4 inhibitors (roflumilast, cilomilast) are under investigation, but have not yet been approved.

Inhaled Corticosteroids

Inhaled steroids (commonly used are beclomethasone, budesonide, triamcinolone, fluticasone, flunisolide) appear to attenuate the inflammatory response, to reduce bronchial hyperreactivity, to decrease exacerbations and to improve health status; they may also reduce the risk of myocardial infarction, but they do not modify the long-term decline in lung function. Whether steroids affect mortality remains unclear. Many patients appear to be resistant to steroids and large, long-term trials have shown only limited effectiveness of inhaled corticosteroid therapy. Certainly, the benefit from steroids is smaller in COPD than in asthma. Topical side-effects of inhaled steroids are oropharyngeal candidiasis and hoarse voice. At the normal doses systemic side-effects of inhaled steroids have not been firmly established. The current recommendation is that the addition of inhaled glucocorticosteroids to bronchodilator treatment is appropriate for patients with severe to very severe COPD.

Mucolytic/Anti-oxidant Therapy

Mucolytic and anti-oxidant drugs include ambroxol, N-acetylcysteine, carbocysteine and iodinated glycerol. These drugs have no proven effect on lung function. At

present, their use is not recommended. N-acetylcysteine may be effective in reducing the number of exacerbations of chronic bronchitis.

Anti-Microbial Therapy

The use of antibiotics is not recommended, except for the treatment of infectious exacerbations of COPD and other bacterial infections. Influenza vaccines decrease illness and death in COPD patients. Pneumococcal vaccination is also recommended.

Psychopharmacological Therapy

Up to 30% of COPD patients suffer from anxiety disorder or depression, and should be treated with conventional pharmacotherapy.

Anti-Trypsin Augmentation Therapy

Approximately 2% of all COPD patients suffer from homozygous α_1 -AT deficiency. Intravenous infusion of replacement protein twice weekly in patients with established α_1 -AT deficiency is approved in the US but not in Europe. The effectiveness of this extremely expensive treatment is not yet known.

Oxygen Therapy

Long-term oxygen therapy (>15 h per day) is introduced in very severe hypoxemic COPD and improves survival, exercise, sleep and cognitive performance. Oxygen therapy is also temporarily used for hospital treatment of hypoxemic COPD exacerbations. In addition to improving oxygenation, oxygen therapy is thought to be effective because it reduces pulmonary hypertension by opposing hypoxic pulmonary vasoconstriction. Hypercapnia is a frequently observed adverse effect after administration of oxygen to COPD patients.

Non-Pharmacological Interventions

Pulmonary rehabilitation as add-on to medication and vaccination has proven to be much more efficient in motivated patients than medication alone. It is aiming at self-management and -training, but also includes nutritional, pharmacological and psychosocial support. Training increases the proportion of type I (minimal fatigable aerobic low-velocity fibres) versus type II fibres (versus the high-velocity anaerobic), stimulates the release of endogenous opioids, provides psychological reinforcement during exercise and improves self-confidence [5].

Lung volume reduction surgery is a rarely performed treatment option for heterogeneous emphysema patients with high hyperinflation. Novel semi-invasive and invasive alternatives are being developed, such as bronchial valves for heterogeneous emphysema treatment, and bronchial stents for homogeneous emphysema to reduce counterproductive collateral ventilation.

Lung transplantation is an ultimate option that has not shown to prolong life, but to improve health status.

Circadian Clock

The phrase circadian clock is used to describe the internal time keeping facilities of an organism, and in animals determines the timing of sleeping and feeding. Most organisms' circadian clocks run to approximately a 24-h cycle, tuned to the light and dark cycle of day and night. Without this light entrainment, for example in conditions of constant darkness, a rhythmic periodicity is still maintained, although the cycle length may deviate from 24-h set-point. In mammals, a brain region called the suprachiasmatic nucleus is responsible for generating the 24-h cycle, with this in turn being regulated by light-generated signals from the retina. The circadian cycle is also modifiable by the relative timing of the availability of food.

Circadian Rhythms

MARINA P. ANTOCH
Department of Molecular and Cancer Biology, Roswell Park Cancer Institute, NY, USA

Synonyms

Daily rhythms; 24-h rhythms

Definition

Many organisms display prominent variations in their behavioral, metabolic, and biochemical activities. Rhythms that have a period close to 24 h (24-h)

are called ►circadian rhythms (from the Latin “circa” meaning “about” and “dien” meaning “day”). Circadian rhythms are governed by an intrinsic molecular mechanism that is able to generate and sustain periodicities even under constant environmental conditions (i.e., in constant darkness). The circadian clock system can respond to various environmental cues (light, food, etc.) to synchronize the periodicities of the internal rhythms with the environment. The circadian clock system is comprised of a number of proteins that, through complex networks of regulation, determine the expression and function of target genes in both the brain and in peripheral tissues [1].

Basic Mechanisms

Organization of the Mammalian Circadian System

In mammals, the circadian system is organized as a hierarchical network of oscillators or “clocks” (schematically presented in Fig. 1). At the top of this hierarchy is the ►suprachiasmatic nucleus (SCN) of the anterior hypothalamus in the brain. The SCN is comprised of ~20,000 neurons that are able of generating and sustaining a 24-h rhythmicity in electrical and metabolic activities. Being directly connected with a photoreceptive tissue via neural projections, it is reset daily by changes in the environmental light–dark (LD) conditions. Upon synchronizing its phase to the LD cycle, the SCN transmits this information to peripheral clocks that are present in almost every tissue of the body. These peripheral clocks are cell-autonomous and self-sustained as they are capable of persistent rhythmicity independent of SCN input. Thus, at the organismal level, the SCN functions as a phase-coordinator of multiple tissue-specific clocks, rather than as a pacemaker driving peripheral oscillations.

It is believed that upon synchronizing its phase to the environmental LD cycle, the SCN transmits this information to peripheral clocks via a combination of neural and humoral signals. Although the molecular nature of such signals is not completely understood, it is known that there are direct neural projections from the SCN to various hypothalamic and thalamic regions that regulate a variety of other organ functions. In addition, two neuropeptides (TGF β and prokineticin 2) have been identified as factors produced by the SCN that affect other regions of the brain and play roles in controlling the rhythmicity of locomotor activity in mice.

Although under normal conditions the SCN plays a dominant role in synchronizing peripheral clocks to the LD cycle, under special circumstances (for example, an artificial feeding schedule with a phase opposite to the normal LD conditions), the phases of molecular oscillations in the SCN and peripheral tissues (for example, in the liver) can become completely uncoupled from one another. This finding suggests the existence of yet unknown synchronization signaling molecules that function in a tissue-specific manner independent of the SCN. Some examples of known signaling molecules that impact the circadian system include dexamethazone, a glucocorticoid receptor agonist that can reset the phase of peripheral oscillators in the liver, protein kinase C and some chemical signals (cAMP, and Ca²⁺) that can induce circadian gene expression in tissue culture cells.

Molecular Mechanism of Circadian Clock Function

In all types of mammalian cells, the molecular mechanism underlying circadian clock function is based upon interconnected transcription/translation feedback loops [2] (Fig. 2). Two proteins that function as transcriptional

Circadian Rhythms. Figure 1 Mammalian circadian system is organized as a hierarchy of multiple clocks that function to synchronize timing of internal processes between each other and with the environment. See details in the text.

Circadian Rhythms. Figure 2 Simplified schematic representation of the mammalian circadian autoregulatory feedback loops. (I – middle panel). Core circadian autoregulatory loop. Positive elements of the loop (CLOCK and BMAL1) dimerize to activate rhythmic transcription of *Per* and *Cry* genes through E-box enhancer elements. The nuclear-localized CRY and PER proteins interact with CLOCK and BMAL1 to negatively regulate CLOCK: BMAL1-mediated transcription; (II – top panel). Positive transcriptional loop. Transcription of nuclear receptor hormones *Rev-erba* and *Rora* is regulated by the same components that control *Per* and *Cry* transcription, and the resulting proteins compete for the RORE site in the promoter of *Bmal1* gene to periodically repress (REV-ERB α) or activate (ROR α) its transcription. (III – lower panel). Molecular basis for clock-controlled processes. CLOCK/BMAL1 complex directly or indirectly regulates transcription of multiple genes via E-box elements in their promoter regions; *Ccg* – clock-controlled genes.

activators, CLOCK and BMAL1, represent the positive elements of the central oscillatory feedback loop. The ►CLOCK/BMAL1 (Major circadian transcription complex) heterodimer binds to E-box elements in the promoters of target genes and drives rhythmic transcription of three *Period* (*Per1*, *Per2*, and *Per3*) and two *Cryptochrome* (*Cry1* and *Cry2*) genes. When PER and CRY proteins are translated, they form PER/CRY complexes that are translocated to the nucleus where they inhibit CLOCK/BMAL1-mediated transcription, forming a negative autoregulatory loop. As a result,

transcription of the *Per* and *Cry* genes is reduced, leading to a decrease in the abundance of the corresponding proteins. This alleviates repression of CLOCK/BMAL1 by PER/CRY and leads to initiation of a new transcriptional cycle. CLOCK/BMAL1 also controls transcription of *Rora* and *Rev-erba*, genes encoding two nuclear receptors that compete for the RORE site in the promoter of the *Bmal1* gene. These transcriptional regulators are responsible for either activation (ROR α) or repression (REV-ERB α) of *Bmal1* transcription, thus forming an additional feedback loop (Fig. 2). Positive and negative

elements of these regulatory loops function to coordinate transcriptional events at appropriate times to provide 24-h periodicities.

The generation of ~24-h periodicities in expression of ►clock genes is further controlled by various posttranslational modifications of clock proteins. Both positive and negative components of the mammalian transcriptional feedback loops are subject to posttranslational modifications that affect their intracellular distribution and/or stability and, consequently, their function in the molecular clock mechanism. Phosphorylation of PER proteins by casein kinases I epsilon (CKIε) or delta (CKIδ) destabilizes the protein, initiates proteasome-dependent degradation and affects its intracellular distribution. Both CRY1 and CRY2 are phosphorylated in vivo in a time-dependent manner. CLOCK and BMAL1 display circadian oscillations in their phosphorylation status and intracellular distribution. Phosphorylation of CLOCK and BMAL1 is triggered by their coexpression and physical interaction and is closely coupled with the nuclear/cytoplasmic distribution, stability, and transcriptional activity of the CLOCK/BMAL1 complex. In addition, BMAL1 undergoes CLOCK-dependent sumoylation that affects the stability of the protein. Altogether, these modifications introduce temporal delays in transcriptional inhibition ensuring circadian rhythms maintain periodicities close to 24-h.

Clock-Controlled Processes

In addition to core components of the circadian oscillatory machinery, such as the *Per*, *Cry*, and *Rev-erba* genes, the CLOCK/BMAL1 complex also drives rhythmic expression of numerous output genes harboring E-boxes in their promoter regions. These genes, which are called clock-controlled genes, encode proteins that are involved in various tissue-specific metabolic and regulatory pathways. Thus, periodic activation/repression of numerous ►clock-controlled genes provides the mechanistic basis for circadian control of output physiology and metabolism. As revealed by several gene expression profiling studies, a significant portion of the genome (~10% of all transcripts) demonstrates 24-h periodicity in its expression pattern. These cycling transcripts are regulated either directly via CLOCK/BMAL1-dependent activation or indirectly by other transcription factors whose expression is under clock control. Importantly, clock-controlled genes are expressed in a tissue-specific manner with very little overlap between different tissues. In many cases, tissue-specific clock-controlled genes have been shown to be involved in rate-limiting steps of processes critical for the function of an organ. For example, some of the genes under circadian regulation in the SCN are involved in protein/neuropeptide synthesis, processing and degradation or in regulation of redox state and

energy utilization. In the liver, the major metabolic organ in mammals, coordinated circadian expression of genes encoding components of sugar, lipid, cholesterol, and xenobiotic metabolic pathways has been reported. These examples demonstrate how oscillations in core clock genes and multiple tissue-specific target genes together account for the circadian rhythmicity of physiological processes and their coordination with the environment [3].

Circadian-Related Disorders

Given the important role that the circadian system plays in timing various physiological processes in concert with daily environmental changes, it is likely that either dysfunction of the internal clock or disruption of its synchronization with the environment could affect an organism's health. This has been most clearly demonstrated by the involvement of clock genes in susceptibility to sleep disorder syndromes. Mutations in the human circadian genes *Per2* and have been linked to Familial Advanced Sleep Phase Syndrome, a disorder in which the major sleep episode is advanced in relation to the desired time of day. Structural polymorphism in another human clock gene, *Per3*, has been related to the pathogenesis of another common sleep disorder, Delayed Sleep Phase Syndrome.

Desynchronization of various tissue-specific rhythms at the level of an organism may also cause serious pathological conditions. Thus, people who work in rotating shifts or at night have been shown to experience a higher incidence of heart disease, back pain, respiratory problems, ulcers, and sleep disorders. These people also have higher rates of error and accident and often experience a significant loss of alertness and ability to make decisions. Another common example of rhythm disruption is induced by travel between time zones, which often results in jet lag, a less serious, but often debilitating and disorienting state. The importance of circadian rhythms in human biology is further supported by numerous observations demonstrating that some widespread pathological conditions display a strong circadian component (for example, the increased occurrence of heart attacks in the morning or asthmatic attacks during the night hours). Finally, both in animal model systems and in human clinical settings, it has been demonstrated that the sensitivity of normal cells and tissues to chemotherapeutic drugs and radiation depends upon the functional status of the circadian clock system.

However, despite its enormous importance to human physiology, no pharmacological compounds targeting the components of the circadian clock system have been identified to date. There are, nevertheless, two therapeutic approaches that are currently used for treatment of circadian-related disorders – full-spectrum and bright light therapy and melatonin therapy. Melatonin is a hormone that is produced by the pineal gland in

circadian fashion. Its secretion peaks in the middle of the night, gradually falls during early morning hours. Applications of both light and melatonin, appropriately timed, have been shown to induce phase-shifts in human circadian rhythms, presumably acting through the SCN. In addition, both treatments have acute physiological and behavioral effects. Depending upon the dose, melatonin (given during the day) can reduce core body temperature and induce sleepiness. Conversely, light exposure during the night increases body temperature and enhances alertness and performance. However, there is currently no melatonin formulation approved for clinical use, nor have consensus protocols for either therapy been developed. Similar to the SCN, which is directly regulated by light exposure, peripheral oscillators in nonphotoreceptive tissues can be reset by a variety of chemical signals. However, all of the presently known circadian modulators (TGF β , glucocorticoids, calcium ionophores, inhibitors and activators of protein kinases, glucose) have an extremely broad spectrum of action, affecting many cellular and physiological processes. This severely restricts their usefulness as specific regulators of circadian behaviors.

Circadian Clocks and Modulation of Therapeutic Responses

In addition to regulating an organism's physiology under normal conditions, circadian proteins play an important role in modulating responses to various stress conditions including those associated with DNA damage induced by anticancer agents such as chemotherapeutic drugs and radiation. Both experimental and clinical studies have conclusively demonstrated that *in vivo* responses to anticancer therapies show significant daily variations and correlate with the functional status of the CLOCK/BMAL1 transcriptional complex [4].

Although the exact mechanism underlying circadian control of genotoxic stress (Cellular response to various DNA-damaging agents that activate multiple pathway leading to cell death or cell survival.) is not completely understood, there are several lines of observation suggesting that it involves complex, multilevel regulation. Indeed, global gene expression analysis of circadian transcriptional output demonstrated that many genes encoding drug-metabolizing enzymes display 24-h periodicities in their expression patterns in the liver and other tissues. Moreover, circadian rhythms have been observed in the proliferation of hematopoietic cells, vascular endothelial cells and intestinal epithelial cells. Since cell sensitivity to genotoxic stress depends strongly upon cell cycle stage, this might also impact time-of-day variations in drug and radiation responses. The CLOCK/BMAL1 complex may also be directly involved in regulating the expression of apoptosis-related genes as indicated by low-amplitude circadian variations in the expression of some pro- and

antiapoptotic genes in mouse bone marrow and tumors. It is also possible that extracellular signaling molecules such as cytokines, growth factors, and hormones might affect cell survival following genotoxic stress. Some of these agents, such as fibroblast growth factor, epidermal growth factor, and transforming growth factor display daily variations in their plasma concentrations. Thus, it is likely that circadian modulation of responses to genotoxic stress *in vivo* reflects the complex superposition of multiple levels of regulation involving a number of factors. An improved understanding of the molecular mechanisms underlying clock-controlled responses to a given treatment may ultimately lead to development of strategies to improve therapeutic efficacy.

Circumventricular Organs

The circumventricular organs are brain structures bordering the third and fourth ventricles and are unique since they lack a blood–brain barrier. Therefore, they are recognized as important sites for communication between the brain and peripheral organs via blood-borne products. They include the median eminence, subfornical organ, area postrema, subcommissural organ, and organum vasculosum.

Cl⁻ Channels and Cl⁻/H⁺ Exchangers

THOMAS J. JENTSCH
Leibniz-Institut für Molekulare Pharmakologie (FMP)
and Max-Delbrück-Centrum für Molekulare Medizin
(MDC), Berlin, Germany

Synonyms

Anion channels

Definition

Chloride channels are membrane proteins that allow for the passive flow of anions across biological membranes. As chloride is the most abundant anion under physiological conditions, these channels are often called chloride channels instead of anion channels, even though other anions (such as iodide or nitrate) may permeate better. As some CLC proteins function as Cl⁻-channels, whereas other perform Cl⁻/H⁺-exchangers are also mentioned here.

Basic Characteristics

Chloride channels are transmembrane proteins with several transmembrane domains, which form a pore that allows for the passive flow of anions along their electrochemical gradient. Like other channels, chloride channels can be opened or closed by a process called gating. Gating can be influenced by several factors, e.g. by the transmembrane voltage in voltage-gated chloride channels, by intracellular Ca in Ca-activated chloride channels, by extracellular ligands such as glycine or GABA as in ligand-gated chloride channels, by cAMP-dependent phosphorylation, or by cell swelling. Chloride channels may be present in the plasma membrane or in the membranes of intracellular organelles. Several intracellular CLC proteins that were previously thought to be Cl⁻ channels recently turned out to rather be electrogenic Cl⁻/H⁺ exchangers. They will be included in this entry.

Classification of Chloride Channels

Chloride channels can be classified by their biophysical characteristics (e.g. single-channel conductance), regulation (e.g. voltage-dependent, ligand-gated, swelling-activated, Ca-activated), or by their sequence (gene families). The latter classification is the most logical one. However, many classes of chloride channels characterized in native tissues have not yet been cloned, raising the possibility that entire gene families of chloride channels remain to be discovered. Therefore, a molecular classification does not yet cover all chloride channels.

Gene Families of Chloride Channels

There are three well established molecular classes of chloride channels: ►CLC chloride channels (several CLC proteins, however, are Cl⁻/H⁺ exchangers), ligand-gated chloride channels (GABA- and glycine-receptors), as well as ►CFTR, the cystic fibrosis transmembrane conductance regulator which belongs to the ABC-transporter family. There is also rather strong evidence that bestrophins are Ca⁺⁺-activated Cl⁻ channels. Other proposed gene families include the CLIC proteins and the CaCC proteins, whose function as chloride channels, however, has not yet been proven [1].

CFTR is the only member of the very large ABC-transporter gene family that is known to function as a

chloride channel. Most other members of this gene family (like *mdr*) probably function as ATP-dependent pumps and not as channels. CFTR is regulated by intracellular ATP and cAMP. cAMP acts through phosphorylation by protein kinase A, resulting in a cAMP-activated chloride channel. CFTR is expressed in many epithelia, e.g. in apical membranes in the lung, pancreas and intestine. Mutations in CFTR underlie cystic fibrosis, a potentially lethal disease with transport defects in the lung, pancreas and colon. In addition to working as a chloride channel, several other important functions (such as the regulation of other ion channels or being a receptor for bacteria) have been attributed to CFTR. CFTR has 12 transmembrane domains and may function as a monomer.

GABA_A- and glycine-receptors are ligand-gated chloride channels that belong to a gene superfamily that also includes cation channels (e.g. nicotinic acetylcholine receptors). These ion channels are involved in synaptic transmission and are mostly inhibitory in the adult due to the direction of the chloride concentration gradient. These ligand-gated channels are important pharmacological targets, but cannot be discussed in detail here. These channels function as pentamers of identical or homologous subunits, with four transmembrane spans each.

CLC chloride channels form a large gene family with members in bacteria, archae and eukaryotes. Many CLCs gate in a voltage-dependent manner. In mammals, there are nine different encoding CLC proteins. CLC channels are present in the plasma membrane and in intracellular organelles. They function as dimers, with each monomer having its own pore (“double-barreled” channels). The structure of a bacterial CLC protein has recently been determined by X-ray crystal structure analysis [2]. Some CLC channels have accessory β-subunits [3]. The CLC protein from *E. coli*, as well as the mammalian endosomal CIC-4 and CIC-5, were recently shown to be Cl⁻/H⁺ exchangers and not channels [4].

The CLC Family of Chloride Channels and Transporters in Mammals

There are nine different CLC isoforms in mammals. Based on homology, they can be classed into three branches. The first branch includes channels that reside predominantly in the plasma membrane. This includes CIC-1, a skeletal muscle chloride channel, CIC-2, a very broadly expressed channel, and CIC-Ka and CIC-Kb, which are expressed predominantly in the kidney but also in the ear.

The physiological roles of these channels are apparent from human diseases or mouse models in which these genes are disrupted.

Mutations in CIC-1 lead to ►myotonia, a muscle stiffness that is associated with a hyperexcitability of the muscle plasma membrane. Thus, the high resting

chloride conductance in muscle is necessary for its electrical stability. CIC-1 shows a distinct voltage-dependence and is activated by depolarization. It is blocked in a voltage-dependent manner by iodide.

The disruption of CIC-2 in mice leads to male infertility, blindness, and leukodystrophy, and was attributed to defective extracellular ion homeostasis in narrow clefts. CIC-2 yields currents that slowly activate upon hyperpolarization. It is also activated by cell swelling and by extracellular acidification. Structural determinants that are essential for these types of activation were identified by mutagenesis. There is a report that CIC-2 might be mutated in human epilepsy, but this has not been confirmed in further studies.

Mutations in CIC-Kb lead to ►**Bartter's syndrome**, a disease associated with severe renal salt loss. This demonstrates that CIC-Kb is essential for the basolateral efflux of chloride from cells of the renal thick ascending limb of Henle. The disruption of CIC-K1 (the species *orthologue* of CIC-Ka) in mice leads to a syndrome resembling nephrogenic diabetes insipidus, and it was shown that it is essential for the establishment of high osmolarity in kidney medulla. CIC-Kb and CIC-Ka need barttin, a protein with two transmembrane domains, as a β -subunit for functional expression. Mutations in barttin lead to Bartter syndrome with deafness. It has been shown that barttin associates with CIC-Ka and CIC-Kb in the basolateral membrane of the stria vascularis of the inner ear. In this tissue, CIC-K/barttin heteromeric channels are necessary for the basolateral recycling of chloride that is taken up by a basolateral NaK2Cl cotransporter. Barttin mutations lead to deafness because K-secretion by the stria into the scala media of the cochlea is impaired. In the kidney, CIC-Ka/barttin channels are present in the thin limb of Henle's loop, while CIC-Kb/barttin is present in the thick ascending limb of Henle's loop and some more distal segments (e.g. acid-secreting intercalated cells). Currents of both CIC-Ka/barttin and CIC-Kb/barttin show a rather linear voltage-dependence, are augmented by raising extracellular Ca, and inhibited by extracellular acidification. Given the important role of CIC-K/barttin in renal salt and fluid reabsorption, they are attractive candidate targets for the development of diuretics. In contrast to diuretics that target channels or transporters of apical membranes of the nephron (such as amiloride or furosemide), drugs inhibiting CIC-K/barttin may also be useful in conditions of renal failure.

All members of this CLC branch have a Cl⁻ > I⁻ permeability and conductance sequence.

CIC-3, -4 and -5 form the second branch of the CLC gene family. These proteins are 80% identical, and with the exception of CIC-5, which is most highly expressed in kidney and intestine, show a broad expression pattern. CIC-3 to CIC-5 reside in intracellular membranes of the endocytotic pathway [4]. Disruption of CIC-5 leads to a defect in endocytosis in mouse

models as well as in human Dent's disease, a disorder associated with proteinuria and kidney stones. CIC-5 currents are necessary to balance the current of the electrogenic proton pump of endosomes. Therefore, the disruption of CIC-5 leads to a defect in endosomal acidification, which impairs endocytosis. The defect in proximal tubular endocytosis leads to secondary changes in calciotropic hormones, leading to tertiary changes such as hyperphosphaturia, hypercalciuria and kidney stones. Recent data show that CIC-4 and CIC-5 are electrogenic Cl⁻/H⁺ exchangers rather than Cl⁻ channels, which is still compatible with a role in acidifying endosomes [4].

Similar to CIC-5, CIC-3 is present in endosomes. It is also found in synaptic vesicles. In both instances, and similar to CIC-5, it is necessary for the efficient intravesicular acidification. The acidification of synaptic vesicles is particularly important as their uptake of neurotransmitters depends on the electrochemical proton gradient. Surprisingly, the disruption of CIC-3 in mice resulted in a drastic degeneration of the hippocampus and the retina. Much less is known about CIC-4, which, however, also appears to be present in endosomal compartments.

All three members of this branch give currents with a NO₃⁻ > Cl⁻ > I⁻ conductance sequence. Currents are very strongly outwardly rectified (opening at voltages more positive than +20 mV), which is enigmatic as this voltage range seems not to be attained in vivo. Their currents can be inhibited by extracellular (intravesicular) acidification. The fact that currents can be observed shows that CIC-3, -4 and -5 are not exclusively present in endosomes, but can also come to the surface upon heterologous expression. It is currently unclear whether this occurs under physiological conditions as well.

CIC-6 and CIC-7 define the third branch of the CLC family. These proteins are only about 45% identical to each other. Whereas CLC-7 is very broadly expressed, the CLC-6 protein seems to be restricted to the nervous system. It proved impossible to obtain plasma membrane chloride currents with either CIC-6 or CIC-7. This is due to the fact that both channels reside in intracellular organelles under most circumstances. Based on structural features, it appears likely that they also mediate Cl⁻/H⁺ exchange.

CIC-6 is a late endosomal chloride transporter. Its disruption in mice led to lysosomal storage disease. CIC-7 is expressed in late endosomes and lysosomes. It needs Ostm1 as β -subunit [3]. The disruption of either CIC-7 or Ostm1 in mice and man leads to severe ►**osteopetrosis**, retinal degeneration, and a severe lysosomal storage disease. CIC-7/Ostm1 is highly expressed in osteoclasts. In these cells, it is inserted together with the proton pump into the specialized plasma membrane ("ruffled border") that faces the reabsorption lacuna. ►**Osteoclasts** are still present in CIC-7 knockout

mice and can still attach to bone. However, they cannot acidify their reabsorption lacuna, resulting in a severe defect of bone resorption. Thus, similar to the roles of other intracellular CLCs, CIC-7 is essential for acidification of certain compartments by electrically balancing the current of the proton pump. CIC-7 may be an interesting target for the treatment of ►osteoporosis as its partial inhibition might increase bone mass. This notion is indirectly supported by the observation that patients that are heterozygous for dominant negative CIC-7 mutations (a situation expected to lead only to a partial inhibition of CIC-7) present with a milder form of osteopetrosis in which retinal degeneration is absent.

Bestrophins

The newest molecular addition to Cl⁻ channels are bestrophins [5]. There are four different bestrophin isoforms in humans. Mutations in Best1 cause Best macular dystrophy, hence their name. All four isoforms induce chloride currents when expressed heterologously. Although they show a dependence on intracellular calcium, their biophysical properties differ from Ca-activated chloride currents typically observed in native cells. Mutagenesis experiments changed the activation of currents and induced slight changes in ion selectivity, lending support to the hypothesis that bestrophins themselves are Cl⁻ channels.

Drugs

Unfortunately, the pharmacology of chloride channels is poorly developed. Specific and highly useful inhibitors or modulators (e.g. strychnine, picrotoxin, diazepam) are only available for ligand-gated chloride channels (but these are covered in a different chapter). There are several “chloride channel inhibitors” such as the stilbene-disulfonates DIDS and SITS, 9-antracene-carboxylic acid (9-AC), arylaminobenzoates such as DPC and NPPB, niflumic acids and derivatives, sulfonyleureas, and zinc and cadmium. All of these inhibitors, however, are not very specific. Several of these inhibitors (e.g. DIDS) inhibit many chloride channels only partially even at millimolar concentrations and have effects on other types of transport proteins.

Tamoxifen and DIDS have been used to inhibit endogenous swelling-activated chloride channels whose molecular identity is still unclear. Glibenclamide has been used to inhibit CFTR, which is quite resistance to DIDS. Endogenous (probably not yet cloned) Ca-activated chloride channels are often sensitive to fenamates such as flufenamic acid and niflumic acid. CLC channels are quite insensitive to DIDS, but can often be inhibited by zinc or cadmium in a submillimolar range. 9-AC is a quite specific inhibitor for the muscle channel CIC-1, and its inhibitor binding site has been mapped recently by mutagenesis. CIC-1 can also be inhibited by clofibrac acid derivatives.

Lubiprostone, a drug used for treating obstipation, has been claimed to be an activator of CIC-2. This is based on a single paper showing activation by lubiprostone of currents thought to represent CIC-2. These currents, however, differ starkly from typical CIC-2 currents. Furthermore, CIC-2 is located in basolateral membranes of the intestine. This localization is incompatible with the hypothesis that its activation increases intestinal chloride and fluid secretion. Thus, the claim that lubiprostone is a Cl⁻ channel activator must be subject to considerable doubt.

Clathrin

Clathrin is a protein complex composed of three heavy and three light chains, which assemble in a so-called triskelion. Clathrin is a major constituent of endocytic vesicles.

►Intracellular Transport

Clathrin-coated Pits

Specialized regions of internalization from the plasma membrane, coated with a polyhedral lattice of the protein clathrin. It is in these regions that the first step of the process of endocytosis takes place, with the formation of clathrin-coated endocytic vesicles.

►Intracellular Transport

Clathrin-coated Vesicle

Clathrin-coated vesicles mediate transport within the late secretory and the endocytic pathways. Their major coat constituents are clathrin and various adaptor complexes.

► Intracellular Transport

CLC

CLC is a gene family of CL-channels. Originally identified by the expression cloning of CLC-0 from the electric organ of the marine ray Torpedo, CLC genes are now known to be present in all kingdoms of life, with nine genes in humans alone. CLC proteins have 17 helices in the membrane plane, several of which, however, do not cross the width of the membrane and therefore do not qualify as transmembrane domains. In CLCs of higher organisms (and also in some, but not all bacteria) CLCs have a large cytoplasmic tail with two conserved CBS domains of largely unknown function. CLC channels function as dimers with two largely independent pores (“double-barreled” channel). Each pore is entirely contained within each monomer, and not at the interface between these. All CLC channels that could be functionally expressed have a Cl⁻ > I⁻ conductance sequence. Gating is often voltage-dependent and depends on anions, resulting in a model in which anions serve as the gating charge.

► Cl⁻ Channels and Cl⁻/H⁺ Exchangers

Clearance

Volume that is cleared from a drug within a defined time interval.

► Pharmacokinetics

Clinical Trials

Clinical trials are usually divided into three phases. In phase I clinical trials, the new drug is tested in a small (20–80) group of healthy volunteers to evaluate its

safety, determine a safe dosage range, and identify side effects. These studies also determine how the compound is absorbed, distributed, metabolized and excreted, as well as the duration of its action. Phase II trials are performed on larger group of people (20–300) to assess clinical efficacy of the therapy, as well as to continue evaluation of the safety and effectiveness of the drug. Phase III studies are randomized controlled trials on large patient groups (300–3,000 or more depending upon the condition) and are aimed at being the definitive assessment of the efficacy of the new therapy.

Clock

Clock gene and transcription factor with histone acetyltransferase (HAT) activity that (in complex with BMAL1) constitutes a positive limb of molecular circadian oscillators.

- Circadian Rhythms
- Orexins

Clonal Selection

T- and B-lymphocytes are the only cells in the body which carry antigen receptors on their plasma membrane. Each individual lymphocyte possesses one type of antigen receptor with specificity for one antigen, which has been created during ontogeny of the cell by irreversible random genetic rearrangement of certain sequences of the DNA. Thus a very large diversity of antigen specificities (possibly > 10⁸) is generated, which allows the specific immune system to cope with all potentially harmful pathogens or substances in the environment. Pathogens invading an organism “select” (are recognized by) one of the millions of lymphocytes which is then activated in a tightly controlled process and starts to proliferate. It clonally expands in order to create enough T- or B-lymphocyte effector cells capable of coping with the pathogen.

► Immune Defense

Clostridial Neurotoxins

Clostridial neurotoxins are bacterial protein toxins that consist of a heavy and a light chain connected by a disulfide bond and non-covalent interactions. They

include tetanus toxin (TeNT) and the seven serotypes of botulinum toxins termed BoNT/A, BoNT/B, BoNT/C1, BoNT/D, BoNT/E, BoNT/F and BoNT/G. The heavy chain binds to the surface of peripheral neurons and mediates cell entry. After endocytotic uptake, the light chain is released into the cytoplasm. The difference between the clinical effects of tetanus and botulinal neurotoxins is due to the fact that tetanus toxin, while being sequestered by peripheral motoneurons in parallel with the BoNTs, is only inefficiently released into the cytoplasm but rather transported retrogradely into the spinal cord. There it is released by the dendrites of the motoneurons and inhibits predominantly presynaptic glycinergic interneurons, causing overexcitation and muscle cramps.

The light chains of the clostridial neurotoxins are metalloproteases with exclusive specificity for neuronal SNAREs. TeNT, BoNTs B,D,F, and G cleave synaptobrevin, BoNTs A and E SNAP-25, and BoNT/C1 syntaxin, and to a lesser extent also SNAP-25. Cleavage of any of the SNAREs causes complete and irreversible block of synaptic transmission.

Synonyms

Blood clotting; Hemostasis; Vessel occlusion

Definition

Coagulation summarizes the mechanisms involved in stopping bleeding due to an injured or defective vessel wall. Coagulation is characterized by procoagulatory and anticoagulatory factors that are in balance under normal conditions. Vessel injuries are occluded by the coagulation system and spontaneous vessel occlusions dissolved by the fibrinolytic cascade.

Thrombosis is an imbalance toward the clotting capacity of the blood that leads to vessel occlusion by a clot. The clot prohibits further blood flow and can so cause pathological sequelae dependent on its localization.

Mechanism of Action

The different pro- and anticoagulatory systems are complex regulated cascades involving blood cells (platelets, monocytes, endothelial cells), enzymes, cofactors, phospholipids, and calcium, which interact with each other

and are further influenced by physical conditions such as blood flow velocity, turbulences, or viscosity.

Coagulation Factors

Coagulation factors are glycoproteins named by roman numbers (the numbers being ascribed at the time of the components' definition, not sequence of activation) (Table 1). Besides von Willebrand factor (vWF), the coagulation factors are synthesized in the liver. They have very different half-lives and different concentrations in the plasma. Several coagulation factors are stored in platelets and endothelial cells and can be released during activation of these cells, which can result in a much higher local concentration of the respective factor (e.g., vWF).

Besides FXIII, all clotting enzymes are serine proteases (FII, FVII, FIX, FX, FXI, FXII). They usually circulate in their inactive form (proenzyme) and become only activated during clotting. In this respect, FVII is an exception as about 1% of FVII circulates in its active form, FVIIa, in plasma without activation of the clotting cascade. Its enzymatic activity is strongly enhanced by binding to its cofactor tissue factor, which under normal conditions is not exposed on cells having direct contact with blood. FV and FVIII are not enzymes but they are required as cofactors to form complexes with activated factors X and IX, respectively.

FVIII circulates in blood complexed to vWF. In the absence of vWF, or in case of impaired binding to vWF, FVIII is degraded.

Activation of the Coagulation Cascade

During activation of the coagulation cascade, coagulation factors form multimolecular (often trimolecular)

complexes. The appropriate sterical orientation of the complex partners is usually provided by a surface of negatively charged phospholipids. The complexes consist of the enzyme, its cofactor, and the respective substrate.

The FVIIa/TF-complex is the main activator of the clotting cascade. Under normal conditions TF is not exposed on the surface of cells being in contact with blood but is expressed in high concentrations by all other cells. When flowing blood comes into contact with TF-bearing cells, TF binds the already circulating FVIIa (Fig. 1). This complex activates the serine proteases FX and FIX, and autocatalyzes activation of FVII (Fig. 2). On the surface of negatively charged phospholipids FXa together with its cofactor Va and the zymogen prothrombin (FII) form the prothrombinase complex, which results in the generation of FIIa (thrombin) (Fig. 3). Within this complex, the activity of FXa to generate FIIa is 300,000× enhanced as compared to the activity of uncomplexed FXa. As activated platelets provide a phospholipid surface rich in negatively charged phospholipids, and as platelets release the reaction determining FV during activation, platelets and clotting factors both contribute to the amplification of the clotting cascade. Activated FIX enhances the initial activation of the clotting cascade by formation of a FX-activating complex together with its cofactor VIII. The importance of this amplifier loop is demonstrated by the bleeding tendency of patients showing inherited FVIII- (hemophilia A) or FIX-deficiencies (hemophilia B). Thrombin by itself contributes to its self-amplifying loop by activating FXI, FVIII, and FV.

Formerly, the clotting cascade had been divided into an extrinsic and intrinsic pathway. Although useful for

Coagulation/Thrombosis. Figure 2 Coagulation/Thrombosis.

Coagulation/Thrombosis. Figure 3 Coagulation/Thrombosis.

didactic purposes, both pathways are not separated but linked by tissue factor/FVIIa activation (Fig. 4).

While the extrinsic pathway starts with FVIIa binding to TF, the intrinsic pathway is characterized by activation through binding of contact factors (Factor XII, Prekallikrein, high molecular weight kininogen) to negatively charged surfaces. This leads to a conformational change and activation to FXIIa and kallikrein.

Factor XIIa is a serine protease that activates FXI to FXIa (Fig. 5). This system is not of physiologic relevance since patients with hereditary deficiencies of factor XII, prekallikrein, and high-molecular weight kininogen do not present with bleeding symptoms.

Vitamin K-dependent Coagulation Factors

Factors VII, IX, X, and II belong to the group of vitamin K-dependent coagulation enzymes. This group of enzymes binds to phospholipid surfaces via Gla-domains, which are generated in the molecule by γ -carboxylation of glutamic acid residues (Fig. 6). This molecular mechanism explains the therapeutic principle of vitamin K-antagonists, such as warfarine or other coumarines. However, the synthesis of the anticoagulant proteins C and S is also vitamin K-dependent (for clinical consequences see paragraph protein-C-pathway).

Generation of Fibrin

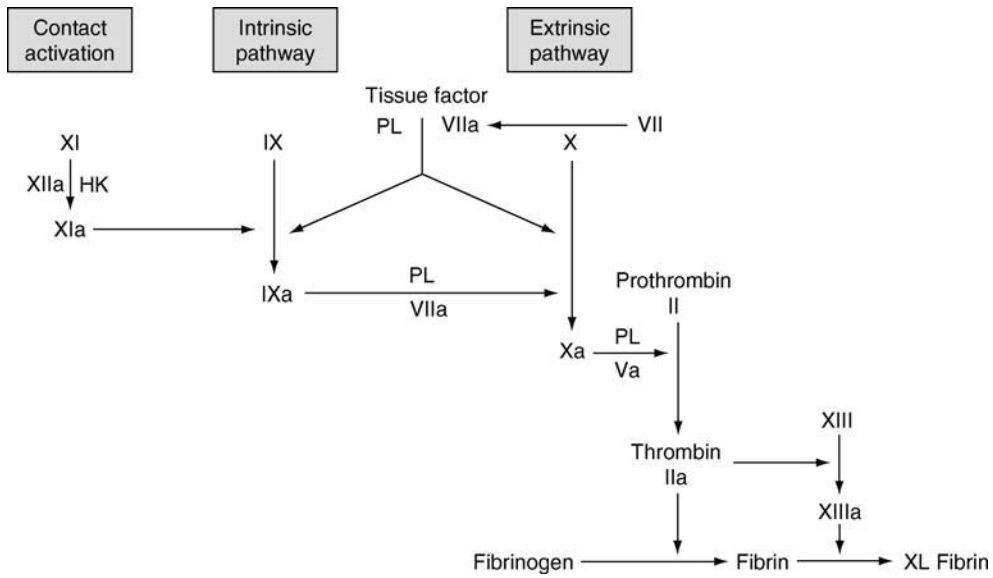

Fibrin is a high molecular polymer. The liver synthesizes its precursor, the protein fibrinogen. It consists of three peptide chains (α -, β -, and γ -chain). Catalyzed by thrombin, the N-terminal fibrinopeptides A and B are cleaved from the α - and β -chain. The remaining peptide chains undergo a conformational change that allows end-to-end polymerization of the fibrin monomers. Stabilization of the fibrin monomers requires cross-linking by the formation of covalent links between the γ - and the α -chains. These links are catalyzed by the transglutaminase factor XIIIa (FXIIIa). FXIIIa is generated from FXIII by thrombin. Fibrin is also linked by FXIIIa to subendothelial proteins like collagen and fibronectin and to adhesive proteins such as vWF and vitronectin. Both, the covalent crosslink within the polymer and the interaction of the fibrinpolymer with the vessel wall provide a stable clot. Noteworthy, patients with a FXIII deficiency present with an intact primary haemostasis but bleeding complications after a time delay of several hours due to instable clot formation.

Regulation of the Clotting Process

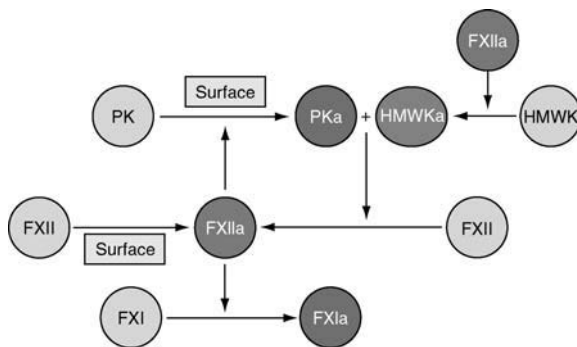

Without effective control mechanisms, the basic principle of self-enhancing amplification loops within the clotting cascade would lead to complete vessel occlusions (thrombosis) once a vessel wall defect occurs, or activated clotting factors would be transported from the side of a vessel injury with the blood stream to other areas causing unwanted clotting there. The anticoagulant mechanisms controlling the clotting process either inactivate clotting factors directly (e.g., FXa, FIIa), or inactivate cofactors (e.g., FVa).

Tissue Factor Pathway Inhibitor

Primarily, tissue factor pathway inhibitor (TFPI) binds to and inactivates FXa. In a second step TFPI/

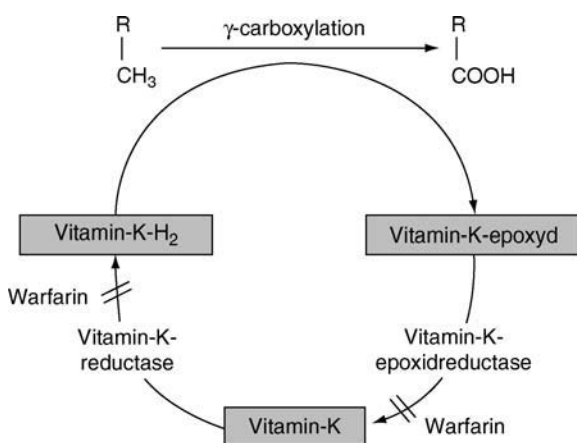

Coagulation/Thrombosis. Figure 4 Coagulation/Thrombosis.

Coagulation/Thrombosis. Figure 5 Coagulation/Thrombosis.

Coagulation/Thrombosis. Figure 7 Coagulation/Thrombosis.

Coagulation/Thrombosis. Figure 6 Coagulation/Thrombosis.

FXa complexes bind to and neutralize tissue factor/FVIIa complexes, the key starting point of the extrinsic clotting cascade (see earlier) (Fig. 7). Heparin is able to enhance this reaction by direct binding to the complex and by releasing TFPI from the unaltered vessel wall, which then can access the TF-exposing surface.

Antithrombin-Heparan Sulfate/Heparin System

Antithrombin (AT) is synthesized by the liver. It forms 1:1 complexes with FXa and FIIa (Fig. 8). Although AT binds to the active centre of the clotting factors FXa and FIIa (thrombin) it is not degraded by these proteases, but forms covalently linked complexes (pseudosubstrate). These AT-clotting factor complexes are degraded in the reticuloendothelial system. Under physiological conditions, AT is catalyzed by endothelial-cell-surface-bound heparansulfate, which binds to AT.

Coagulation/Thrombosis. Figure 8 Coagulation/Thrombosis.

Catalyzation of AT is the major principle of anticoagulatory treatment with heparin. The length of high molecular weight heparins (>18 glucose units) allows formation of a trimolecular complex of AT and FIIa (thrombin) or FXa in which heparin is binding to both molecules, catalyzing thrombin inactivation. Smaller heparin molecules (low molecular weight heparins or the even smaller pentasaccharide) bind only to AT. This still enables inactivation of FXa but no longer inactivation of thrombin.

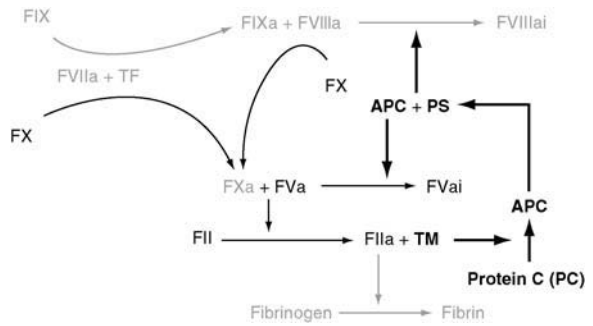

Besides AT, heparin cofactor II (HCII) is an anticoagulatory protein enhanced by heparin. HCII inactivates thrombin and the nonclotting enzymes cathepsin-G and chymotrypsin.

Whereas patients with AT deficiency present clinically with a high risk for thrombosis, HCII-deficient patients do not.

Protein-C Pathway

The protein-C pathway is one of the most important anticoagulant mechanisms. It is activated by thrombin. Thrombin binds to a cofactor in the membrane of endothelial cells, thrombomodulin (TM). TM bound thrombin no longer activates clotting factors or platelets but becomes an effective protein C (PC) activator. Activated PC (APC) forms a complex with Protein S, which inactivates FVIIIa and FVa. Hereby generation of FIIa by the prothrombinase complex is inhibited (Fig. 9). Thus, the PC-pathway controls thrombin generation in a negative feedback manner.

In about 30–40% of patients with suspected inherited thrombophilia the PC-pathway is disturbed by a mutation of FV (FV-Leiden). The FV-Leiden mutation affects one of the APC cleavage sites within the FV molecule. As a consequence, mutated FVa becomes resistant to rapid APC inactivation (APC resistance). About 4–7% of the middle European population carry this polymorphism of FV. Inborn deficiencies of Protein-S or Protein-C are much less frequent (<< 1% and 0.2–0.4%, respectively).

Coagulation/Thrombosis. Figure 9 Coagulation/Thrombosis.

Coagulation/Thrombosis. Figure 10 Coagulation/Thrombosis.

Iatrogenic PC deficiency always occurs at the beginning of oral anticoagulation with vitamin K-antagonists. Due to the short half-life of PC, its plasma concentrations decline within one day, whereas the procoagulatory clotting factors are still present in high concentrations. This makes it mandatory to start vitamin K-antagonist treatment only under parallel parenteral anticoagulation with heparin for about 5 days (Fig. 10).

A new aspect of the PC-pathway is the efficacy of recombinant-APC in reducing mortality in patients with septic shock. Whether this is related to the inhibition of thrombin generation or due to other biological activities of APC is currently under investigation.

Fibrinolysis

Lysis of clots is another system for regulation of the clotting system. Plasmin is the key enzyme of the fibrinolytic system. Its proenzyme plasminogen is synthesized by the liver as a one-chain protein. Tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA) activate plasminogen by cleavage. The remaining two chains are linked by

Coagulation/Thrombolysis. Figure 11 Coagulation/Thrombolysis.

disulfide bonds and undergo autocatalytic cleavage at the N-terminus; thus, plasmin self-enhances its fibrinolytic activity.

Plasmin cleaves fibrin at different positions. Of high clinically practical relevance is the cleavage of the fibrin γ -chain that results in D-Dimers (Fig. 11). D-Dimers are specific for fibrin cleavage by plasmin. They can easily be detected by commercially available assays and are used to exclude thrombolysis. A negative test for D-Dimer has a high negative predictive value for a thrombolysis.

Therapeutically t-PA and urokinase are the most important drugs for fibrinolytic therapy (myocardial infarction, stroke, massive pulmonary embolism). This treatment is associated with an enhanced risk of bleeding complications.

Regulation of the Fibrinolytic System

Generation of plasmin is inhibited by the plasmin-activator inhibitor (PAI). PAI is secreted by endothelial cells. It neutralizes t-PA and u-PA by forming 1:1 complexes.

Nonfibrin bound, free plasmin is inactivated by α_2 -anti-plasmin by an irreversible, covalent 1:1 complex.

Combinatorial Chemistry

JÖRG RADEMANN

Leibniz Institut für Molekulare Pharmakologie (FMP), Berlin, Germany

C

Definition

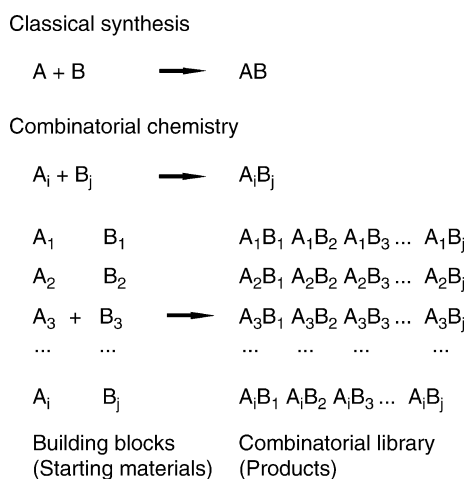

Combinatorial chemistry constitutes a branch of the molecular sciences, providing an array of concepts and methods to solve molecular optimization problems (in drug research and beyond) more rapidly and efficiently than classical synthetic approaches.

Description

Combinatorial chemistry provides an array of concepts and methods to solve molecular optimization problems via the use of chemical libraries. Combinatorial chemistry mimics evolution cycles of synthesis and selection in the chemical laboratory. Since specific molecular interactions between proteins and their ligands have been recognized as the molecular basis of most biological processes including disease, it became possible to study and optimize the interactions between drugs and their target proteins on a molecular level. Thus, drug development has turned into a systematic and rational task of optimization. During the 1990s in the pharmaceutical industry, synthetic chemistry became evident as the major bottleneck in drug development. Combinatorial chemistry was the answer of the synthetic chemistry community. The term “combinatorial” is derived from the mathematical discipline combinatorics dealing with the statistics of element combinations. Combinatorics are employed in chemistry to calculate the number of possible combinations of m chemical building blocks in n synthetic cycles (n^m , see Fig. 1). For example, the 20 native amino acids can be combined to form 20^6 different linear hexapeptides.

Centerpieces of combinatorial concepts include the synthesis of compound libraries instead of the preparation of single target compounds. Library synthesis is supplemented by approaches to optimize the diversity of a compound collection (diversity-oriented synthesis) and by efforts to create powerful interfaces between combinatorial synthesis and bioassays.

These conceptual goals are attained by several combinatorial methods and tools. Characteristic for combinatorial chemistry is the synthesis on solid support or by polymer-supported synthesis, allowing for much higher efficiency in library production. Synthesis can be conducted either in automated parallel synthesis or by ► split-and-recombine synthesis. Centerpieces of combinatorial methods further include specific analytical methods for combinatorial

Combinatorial Chemistry. Figure 1 Whereas in classical chemical synthesis one target molecule was prepared in combinatorial chemistry the systematic combination of building blocks generates chemical libraries.

chemistry and computer-aided methods for combinatorial chemistry.

Chemical Libraries

Precisely defined collections of different chemical compounds are denominated as chemical libraries that can be efficiently prepared by methods of combinatorial chemistry. Each chemical compound owes specific structural, steric, and electronic properties that determine all possible interactions of the small molecule with a given protein or receptor. The molecule's properties are based on the steric arrangement of functional groups, including the conformations that can be attained by a specific structure.

Complex optimization of the ligand-protein interactions require to scan large areas of the chemical space. Thus, the combinatorial chemist aims not at the preparation of single compounds but of chemical libraries. Chemical libraries can be produced as collections of single compounds or as defined mixtures.

Diversity-Oriented Synthesis and the Chemical Space

The challenge in the synthesis of chemical libraries is the vast number of different, potentially drug-like small molecules which is estimated to be as high as 10^{60} . As all of these molecules can never be synthesized and tested, it is essential to define criteria for the composition of libraries spanning the biologically relevant areas of the chemical space most efficiently. An important criterion of a compound library is its chemical diversity, a term describing the similarity or dissimilarity of all library components. Thus, chemical diversity expresses how well a library represents all theoretical possibilities within the chemical property space. A library with low

chemical diversity contains molecules that are relatively similar, thus covering a small area of the accessible property space. On the contrary, a library with a large chemical diversity will contain relatively dissimilar molecules, covering a large volume of the property space. The diversity of a library is a major criterion of its quality and its possible applications. Large diversity is required mainly in the early stages of drug development (lead search), whereas defined small diversity (focussed libraries) is needed for lead optimization. Contrary to classical organic synthesis which was directed at the preparation of a single target compound, diversity-oriented synthesis aims at providing libraries with defined chemical diversity, with the help of combinatorial methods and tools described herein.

Solid Phase Synthesis Versus Polymer-Supported Synthesis in Solution

The evolution of combinatorial methods was closely linked to the development of polymer-supported synthesis, which opened efficient access to diversity-oriented synthesis. In **solid phase synthesis**, forming the backbone of most combinatorial methods, insoluble organic or inorganic matrices are employed as carriers for the construction of product molecules. Using insoluble polymer supports is advantageous, strongly facilitating the isolation of intermediates and products attached to the polymer support. By-products formed in each stage of the synthesis are easily removed by washing the polymer support, thus each isolation step is reduced to simple filtration. By employing reagents in high excess, complete conversion can be attained on the solid phase in reactions that form mixtures in solution. The relative isolation of reactive sites on the polymer supports can be exploited for specific synthetic effects such as favoring cyclization and the reduction of by-products. Finally, the compartmentalized structure of polymer supports allows for split-and-recombine synthesis.

Under certain condition, however, reactions are still preferably conducted in solution. This is the case e.g., for heterogeneous reactions and for conversions, which deliver complex product mixtures. In the latter case, further conversion of this mixture on the solid support is not desirable. In these instances, the combination of solution chemistry with polymer-assisted conversions can be an advantageous solution. Polymer-assisted synthesis in solution employs the polymer matrix either as a scavenger or for polymeric reagents. In both cases the virtues of solution phase and solid supported chemistry are ideally combined allowing for the preparation of pure products by filtration of the reactive resin. If several reactive polymers are used sequentially, multi-step syntheses can be conducted in a polymer-supported manner in solution as well. As a further advantage, many reactive polymers can be recycled for multiple use.

Parallel Synthesis and Automation

If small or medium libraries for lead optimization are demanded and all synthetic products are to be screened individually, most often parallel synthesis is the method of choice. Parallel syntheses can be conducted in solution, on solid phase, with polymer-assisted solution phase syntheses or with a combination of several of these methods. Preferably, parallel syntheses are automated, either employing integrated synthesis robots or by automation of single steps such as washing, isolation, or identification. The latter concept often allows a more flexible and less expensive automation of parallel synthesis.

Split-and-Recombine Synthesis for the Preparation of Large Libraries

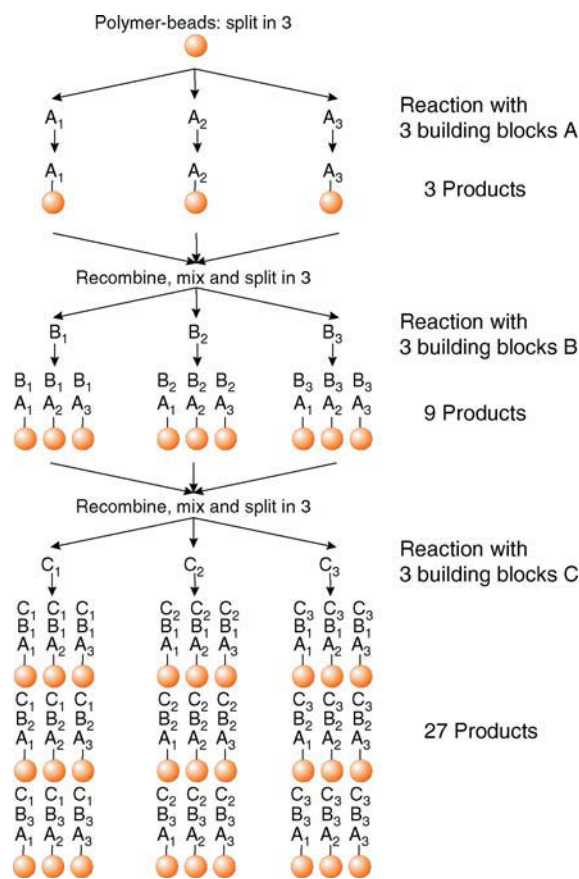

If large or very large libraries are demanded and if a powerful interface to a subsequent bioassay is available, split-and-recombine synthesis can be the method of choice. Split-and-recombine synthesis is mostly conducted on solid phase. During each coupling step the resin is divided into one reactor for each coupled building block (split). Following the coupling reaction with m building blocks, all resin beads are pooled and mixed (recombine) (see Fig. 1). Consequently, after n coupling steps m^n different compounds are obtained in theory, the real number of individual compounds is only limited by the number of available resin beads. As in each coupling step only one building block is coupled per reaction vessel, in the end on every bead only one compound is produced (one bead-one compound) (Fig. 2).

Introduced in the early 1990s, the split-and-recombine concept contributed much to the early success of combinatorial chemistry. Often, all combinatorial methods were identified with this concept. Split-and-recombine synthesis offered easy access to large number of individual compounds in few steps. If conducted on polymer beads, these are easily separated mechanically and can be identified subsequent to a screening step.

Though split-and-recombine techniques make available many compounds in few steps, the concept possesses significant limitations as well. A well-defined synthesis requires employing reliable reactions for all the different starting materials. This requirement is fulfilled only for few reaction types, such as acylations of amines, reductive aminations, substitution of α -halogeno carbonyl compounds. If however, the products of a split-and-recombine synthesis are not obtained purely, it becomes increasingly difficult to ascribe a biological signal unambiguously to an individual compound.

Analytical Methods in Combinatorial Chemistry

Essential prerequisites for the evolution of combinatorial methods were the progress in reaction monitoring and analytics. Of specific importance was the analytics

Combinatorial Chemistry. Figure 2 Chemical libraries are prepared either by parallel synthesis or by the split-and-recombine method. In the latter case, coupling m building blocks in m separated reaction flasks through n synthetic cycles on a beaded polymer carrier generates a combinatorial library with m^n individual compounds and one compound per bead.

of structures attached to a polymeric support (► **on-resin-analysis**) as well as the analytics of cleaved compounds in solution (off-resin-analysis).

For on-bead analysis vibrational spectroscopy (IR-spectroscopy) can be employed; attenuated total reflection is a method allowing fast and nondestructive on-bead analysis of small samples (single bead analysis) without significant sample preparation. Solid phase ► **NMR** is the method of choice if complex structural analysis is intended on the support. Spatially resolved analysis on the resin is possible with microscopic techniques.

For off-bead analysis, coupling between chromatographic separation and mass spectrometric detection has proven especially powerful. The combination between high performance liquid chromatography (HPLC) and ► **electrospray ionisation mass spectrometry** has the advantage that purity of product mixtures can be coupled on-line with the product identification.

Integration of Combinatorial Synthesis and Screening

The potency of combinatorial chemistry is optimally exploited by efficiently integrating combinatorial synthesis with a subsequent bioassay. Chemical libraries are mostly screened in parallel as on microtiter volumes, on spatially addressable molecular arrays, or as complex mixtures as in the case of on-bead assays. The latter approach is especially yielding, as large libraries of synthetic compounds can be screened simultaneously. If the synthetic chemistry is controlled well, it becomes possible through the integration of synthesis and screening to first select the most active compounds, analyze, and resynthesize them for verification. By this method the enormous effort necessary for the parallel screening of large libraries is significantly reduced. This concept was especially successful for the on-bead screening of split-and-recombine libraries. Hits (i.e., the most active compounds) are preferably visualized by fluorescence or color, can be separated by manual or automated selection and subsequently analyzed. Identification of hits is effected by noncovalent binding of fluorophore-labeled proteins, or in the case of polymer-based protease inhibitor assays, by a fluorescent dye that is formed dependent on the inhibitor activity. Identification of hit structures is facilitated by tagging of the beads with easily detectable structures that code for the synthesized molecule on one individual bead.

Bioinformatics and Combinatorial Chemistry

One reason for the initial popularity of combinatorial methods was the dissatisfaction with and the limited success of rational molecular design in the 1980s. Meanwhile, it has been recognized that combinatorial chemistry can profit strongly from computer-aided methods. It became obvious that all possible combinations of building blocks cannot be prepared synthetically due to limited physical resources and for cost reasons. Bioinformatic methods today are used to describe and analyze the diversity of chemical libraries. Moreover, aggregated biological data of chemical compounds are used to determine quantitative structure-activity relationships (QSAR) that deliver criteria for the composition of screening libraries and for systematic hit variation. A prominent example is the Lipinski rules summarizing molecular descriptors to be obeyed by orally available drugs.

If structural information of the protein target is available, e.g., a crystal structure, *in silico* screening of huge virtual compound libraries can be conducted by the use of docking simulations. Based on identified primary hits, structural variations of the ligand can be evaluated by computational modeling of the ligand-protein complex.

Pharmacological Relevance

Combinatorial chemistry is the branch of the molecular sciences providing concepts and methods for solving problems of molecular optimization fast and efficiently.

Since drug development has turned into a systematic and rational task of optimizing molecules and their interactions with proteins, cells, and organisms, combinatorial chemistry has become a significant part of this endeavor. Combinatorial methods are mainly employed in the initial (preclinical) stages of drug development.

Compartment

A compartment is an anatomical space in the body into which a drug or metabolite, or a chemical derivative or metabolite formed from the parent drug may distribute.

- ▶ Pharmacokinetics

Competitive Antagonists

By definition, competitive antagonists compete with the agonist for the same binding domain on the receptor. Therefore, the relative affinities and the relative concentrations of the agonist and antagonist dictate which ligand dominates. Under these circumstances, the concentration of agonist can always be raised to the point where the concomitant receptor occupancy by the antagonist is insignificant. When this occurs, the maximal response to the agonist is observed, i.e., surmountable antagonism results.

- ▶ Drug-Receptor Interaction

Complement System

A cascade of proteins of the immune response that can be triggered by antigen-antibody complexes and by the innate immune system (e.g. exposure to microbial polysaccharides) to raise the immune response. Complement proteins can detect and bind to foreign material or immune complexes and label them for phagocytosis. They can also cause inflammation by directly degranulating mast cells and releasing chemokines to recruit other immune cells into the affected area.

Conditioned Place Preference

The conditioned place preference paradigm is widely used in order to measure the rewarding properties of drugs of abuse (secondary reinforcement). In general individuals are subsequently injected with either the drug or vehicle solution and placed into boxes with

floors with different textures (i.e., either perforated or bar). In this way, the association between the administration of the drug and a particular floor texture (or place) is established. On the final day of the experiment, individuals are left untreated and placed in conditioning boxes that have the two different floor types. To determine the rewarding effects of the drug, the time that each individual stays on the floor type paired with the drug is measured. If the drug has rewarding properties the individual shows a preference to the side that has been paired with drug administration.

► Drug Addiction/Dependence

Conditioned Withdrawal

Individuals experiencing drug withdrawal can become conditioned to environmental situations. Previously neutral stimuli can elicit many of the symptoms of drug withdrawal, and this “conditioned withdrawal” has motivational significance especially in alcohol and opiate addiction. Thus conditioned withdrawal may trigger ► *craving* and relapse in a particular situation.

► Drug Addiction/Dependence

Conditioning

Mechanism through which repeated associations between two stimuli induce a new learned response. In particular, by pairing a neutral stimulus (conditioned stimulus) with an unconditioned stimulus (that induces a physiological response) many times, the neutral stimulus alone will be capable of producing a conditioned physiological response.

► Placebo Effect

Congenital Long QT Syndrome

A disease predisposing those affected to severe cardiac arrhythmia. The term “long QT syndrome” refers to an abnormality found in the electrocardiograms of the patients: a long QT interval caused by a prolonged

repolarisation period of the cardiac myocytes. The disease-causing mutations are located in genes encoding the various subunits of voltage-gated K^+ channels involved in depolarization and repolarization of cardiac myocytes. An example are mutations in the human ether-a-go-go-related protein (HERG).

► Protein Trafficking and Quality Control
 ► Voltage-gated K^+ Channels

Conjugative Plasmids

Plasmids are termed conjugative they have the capacity to transfer themselves from one cell to the other. They can be either self-transmissible or mobilizable (the latter necessitate the presence of a self-transmissible plasmid that supplies missing transfer functions). The *tra* genes encode among other proteins the subunits that form a sex pilus required to mediate the first contact between the donor and the recipient cell (in case of plasmids of gram-negative bacteria). Both cells then come into close contact and form a stable mating pair. The plasmid DNA in the donor cell is then cleaved at an *oriT* site (origin of transfer), unwound and one strand is transferred into the recipient cell. Complementary DNA strands are synthesized and recircularized.

► Microbial Resistance to Drugs

Conjugative Transposon

Conjugative transposons are self-transmissible large DNA elements (up to 150kbp) located in the donor chromosome. After excision a circular intermediate is formed that is unable to replicate autonomously. It is nicked at a origin of transfer site and one strand is then transferred to the recipient cell. After generating a double-stranded circle the transposon integrates into the recipients chromosome.

► Microbial Resistance to Drugs

Conotoxins

Conotoxins are the venoms of the marine cone snails. The >500 *Conus* species produce >10,000 different toxins. All are cysteine-rich peptides of 10–30 amino

acids. Many act on their target molecules with high selectivity. The α -conotoxins are competitive antagonists at nicotinic acetylcholine receptors. The μ -toxins block voltage-sensitive Na^+ channels. The ω -toxins block Ca^{2+} channels. Synthetic ω -conotoxin MVIIA (ziconotide) has been introduced into therapy for spinal administration in chronic pain. Like morphine (but by direct channel blockade rather than through a G protein pathway) it inhibits transmitter release from nociceptive afferents.

Synonyms

Hormonal contraceptives; Oral contraceptives

Definition

Hormonal contraceptives belong to the most widely prescribed and most efficacious drugs that have a profound impact on western societies since their inauguration in the 1960s. In women, oral hormonal contraceptives are used to prevent fertilization or implantation in cases of unplanned pregnancies. Apart from these primary objectives, there are significant additional medical benefits contributing to a substantial improvement of reproductive health in women.

Mechanism of Action

The most frequently used oral contraceptives are composed of varying combinations of ▶estrogens and

▶progestins, which belong to the large family of ▶steroid hormones. Steroids interact with intracellular receptors functioning as ligand-activated transcription factors to control the expression of a wide array of specific genes. The receptors for estrogens and progestins are members of a superfamily of approximately 150 structurally related nuclear receptors that bind ligands such as steroid hormones, retinoids, vitamin D_3 , eicosanoids, and thyroid hormones [1]. Members of this receptor superfamily share a common architecture of mainly four conserved functional domains: The N-terminal transactivation domain (activation function, AF-1) is the most variable in the superfamily of receptors. The subsequent DNA-binding domain also participates in receptor dimerization, whereas nuclear localization is determined by the neighbouring hinge region. The C-terminal hormone-binding domain comprises a ligand-dependent transcriptional activation function (AF-2) and provides the sites for the binding of chaperones like heat shock proteins that prevent dimerization and DNA binding of unliganded receptors.

Upon hormone binding, steroid hormone receptors undergo a conformational change, dissociate from heat shock proteins and translocate into the nucleus where they interact as dimers with specific DNA regulatory sequences of target genes. The transcriptional regulation by steroid hormone receptors is mediated by co-regulatory proteins that either positively (▶co-activators) or negatively (▶co-repressors) influence steroid hormone-induced transcriptional activity. A complementary mode of steroid hormone receptor action relies on direct protein-protein interactions with other transcription factors such as AP-1, Sp-1, and NF- κ B, thus providing an explanation for the well-known observation that steroid hormone receptors are able to regulate genes lacking consensus response elements in their non-coding 5' region [2].

Most nuclear receptors are phosphoproteins, and their function can be influenced by phosphorylation events that are initiated by membranous receptors like receptor tyrosine kinases or G-protein-coupled receptors. Thus, steroid hormone receptors are embedded in complex signalling networks that may give rise to ligand-independent activation of nuclear receptors. In addition to the well-understood nuclear events set in motion by steroid hormones, rapid non-genomic effects have been reported for estrogens and progesterone. These rapid effects of sex-steroids that are often initiated at the plasma membrane, may result from receptor-independent alterations of plasma membrane fluidity or from steroid effects on membranous receptors other than classical steroid hormone receptors. In particular, the rapid engagement of the MAP kinase cascade by estrogen has been studied in great detail, and it is quite likely that cardinal estrogenic effects like cell proliferation and survival are not primarily brought about by

genomic actions of classical nuclear receptors but by rapid, non-genomic mechanisms [3].

At present, two distinct nuclear estrogen receptors, ER α and ER β , are known. The receptors differ in their tissue distribution, ligand binding profile and transcription activation functions in that ER β is devoid of AF-1. In cells, that express both estrogen receptors, ER β appears to oppose the transcriptional activity of ER α . Due to two distinct estrogen-dependent promoters in the single progesterone receptor (PR) gene, two isoforms of the progesterone receptor, PR-B and the N-terminally shortened PR-A, are generated. The biological activities of PR-A and PR-B are distinct and depend on the target tissue in question. In the reproductive system, progesterone acting through its respective nuclear receptors, PR-A and PR-B, serves the role of a physiological negative regulator of estrogen action by causing depletion of estrogen receptors. In addition, the major role of PR-A may be to inhibit transcriptional activity of other steroid receptors like ER α . Although one aspect of the biological relationship between estrogen and progesterone may be called functional antagonism, a concerted, sequential action of estrogen and progesterone is required in reproductive tissues like the endometrium and the breast to yield the desired complex biological response.

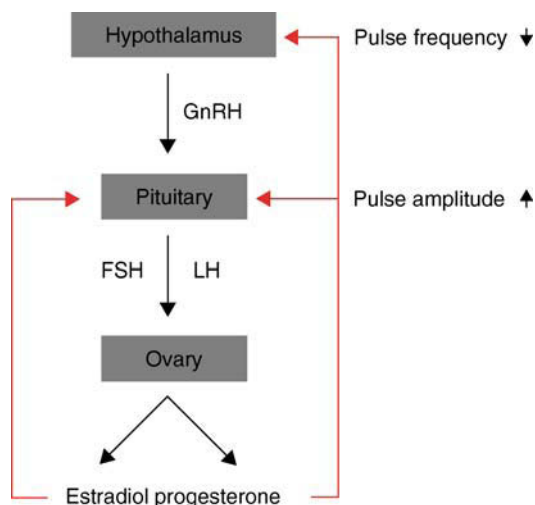

Estrogen and progesterone play a central role in the neuroendocrine control of the female menstrual cycle. In the early follicular phase estrogen exerts an inhibitory effect on the pulsatile secretion of gonadotropins from the pituitary (Fig. 1). Thus, the gradual increase in the peripheral estradiol concentration during the follicular phase is accompanied by a reduced release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the gonadotropes. At midcycle, a different set of regulatory interactions becomes dominant. A sustained

elevation of estradiol (150–200 pg/ml for approximately 36 h) induces a positive feedback on the anterior pituitary to trigger the ovulatory surge of LH. The underlying mechanism is a sensitization of the pituitary gonadotropes towards hypothalamic gonadotropin-releasing hormone (GnRH). Progesterone decreases the frequency of GnRH release from the hypothalamus resulting in a marked decrease of the frequency of gonadotropin pulses in the luteal phase (Fig. 1). At the same time, progesterone increases the amount of LH released per pulse (i.e. the pulse amplitude).

Estrogen exerts a negative feedback on the pituitary and decreases the secretion of FSH and LH during most of the menstrual cycle. Yet, it triggers the LH surge at midcycle by sensitizing the pituitary to hypothalamic GnRH. Progesterone increases the amplitude of gonadotropins released from the pituitary and at the same time decreases the GnRH pulse frequency at the level of the hypothalamus. These feedback controls give rise to fairly frequent LH pulses of low amplitude during the follicular phase of the cycle and less frequent pulses with a higher amplitude in the luteal phase.

The main mechanism of action of a combination oral contraceptive (a combination oral contraceptive contains both an estrogenic and a progestational component to achieve contraception.) is to prevent ovulation by inhibiting gonadotropin secretion via an effect on both pituitary and hypothalamic centres. The progestational component primarily suppresses the surge-like LH release required to induce ovulation, while the estrogenic agent suppresses FSH secretion and thus prevents selection of a dominant follicle. Therefore, both estrogenic and progestational components of an oral contraceptive synergistically contribute to the contraceptive efficacy. However, even if follicular growth were not sufficiently inhibited, the progestational agent alone would suffice to abrogate the ovulatory LH surge. The estrogenic component, however, serves at least two other important purposes. It is responsible for the stability of the endometrium, thus minimizing events of irregular and unwanted breakthrough bleeding. In addition, estrogen action provides for a sufficient concentration of progesterone receptors. In aggregate, a small pharmacologic estrogen level is necessary to maintain the efficacy of the combination oral contraceptive.

As under most circumstances progesterone action will hold primacy over estrogenic effects, the cervical mucus, endometrium, and probably the fallopian tubes reflect progestational stimulation. The cervical mucus becomes thick and viscous and thus impervious to spermatozoa. The endometrium is in a state that is not receptive for implantation of a fertilized egg. Probably, the progestational impact on the secretory activity and peristalsis in the fallopian tubes also assists the general contraceptive effect. It is difficult, however, to assess the relative contribution of the various effects to the

Contraceptives. Figure 1 Regulation of hypothalamic and pituitary function by ovarian steroid hormones.

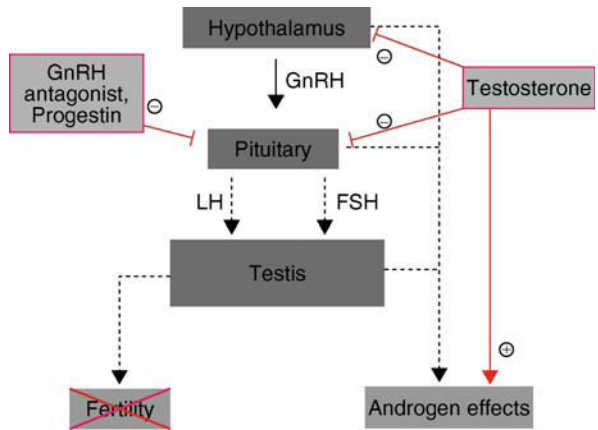

contraceptive efficacy, because combination oral contraceptives suppress ovulation very effectively.

The progestin-only minipill contains a low-dose of a progestational agent which is sufficient to block ovulation in only 60–80% of cycles. The contraceptive effect is largely dependent on endometrial and cervical mucus effects, as gonadotropins are not reliably suppressed. Because of the low-dose of progestins, the minipill must be taken every day at the same time with great accuracy.

Long-acting methods of hormonal contraception are even more effective than oral methods. Two effective systems are available: a sustained-release method of levonorgestrel or etonogestrel using implanted steroid-permeable silastic tubing and depot injections of medroxyprogesterone acetate. The mechanism of action is similar to the progestin-only minipill. However, in addition, the long-acting methods yield progestin plasma levels high enough to prevent ovulation in basically all patients.

High doses of estrogen to prevent implantation were used for emergency postcoital contraception. It was soon appreciated that the extremely large estrogen doses used (25–50 mg/day of diethylstilbestrol or ethinyl estradiol) entailed a high rate of gastrointestinal untoward effects. Clinical trials have ushered the use of combination oral contraceptives for emergency postcoital contraception. In principle, high-dose oral contraceptives can be administered within 72 h of intercourse, followed by a second dose, 12 h later. Such a regimen reduces the risk of pregnancy by approximately 75%. Multiple mechanisms appear to contribute to the treatment efficacy, for instance inhibition of ovulation, endometrial receptivity, cervical mucus composition, and tubular transport of spermatozoa. Alternatively, a high-dose of the progestin levonorgestrel (750 µg) can be used for postcoital emergency contraception. Administration of a total dose of 1,500 µg of levonorgestrel should be started within 12 h of unprotected sexual intercourse to achieve contraceptive protection of approximately 95%. Nausea, lower abdominal and breast pain as well as retarded menstruation have been reported as untoward effects. It is important to note that emergency contraceptives are not used as medical abortifacients to interrupt an established pregnancy defined to begin with implantation.

In recent years strategies for hormonal male contraception have also been devised. Quantitatively and qualitatively normal spermatogenesis critically depends on neatly orchestrated LH and FSH release from the pituitary. In hormonal approaches to male contraception gonadotropin secretion and intratesticular testosterone production needs to be suppressed as efficiently as possible. Because androgens are key determinants of virilization and thus the male phenotype, but also strongly suppress gonadotropin release when applied exogenously, androgen preparations are essential components

Contraceptives. Figure 2 Principles of hormonal male contraception. Testis function is regulated by hypothalamic and pituitary feedback circuits. The application of exogenous testosterone in conjunction with progestins or GnRH antagonists suppresses gonadotropin secretion from the pituitary and intratesticular testosterone production while maintaining extratesticular androgen effects. Such regimen reliably induced azoospermia and infertility.

of all experimental approaches to male contraception (Fig. 2). Notably, the use of long-acting testosterone esters such as testosterone undecanoate causes azoospermia in only 30% of Caucasian men, while androgen-only regimens are highly effective for East Asian men. As additional agents, various combinations of androgens with progestins or GnRH antagonists have been evaluated in clinical trials. Testosterone administered in combination with various progestins such as depot medroxyprogesterone acetate, norethisterone enanthate, desogestrel or etonogestrel has yielded promising efficacy.

Clinical Use (Including Side Effects)

After the seminal observation by Gregory Pincus and colleagues in the 1950s that progestins prevented ovulation in women, initial trials on humans were conducted using progestins like norethynodrel that were contaminated with about 1% mestranol. When subsequent efforts to provide a more pure progestin lowered the estrogenic component but provoked breakthrough bleeding, it was decided to keep the estrogen. Thus, the principles of combined estrogen–progestin oral contraception were established.

A major obstacle to the use of naturally occurring estrogens for the purpose of contraception was extensive first-pass hepatic metabolism and hence inactivation of the compounds when given orally. The addition of an ethinyl group at the 17 position made estradiol orally active. Ethinyl estradiol is a potent oral estrogen and

represents one of the two forms of estrogens used in oral contraceptive pills. The other estrogenic compound is the 3-methyl ether of ethinyl estradiol, mestranol which is converted to ethinyl estradiol in the body.

The progestins used in oral contraceptives are 19-nor compounds of the estrane and gonane series (Fig. 3). Each compound possesses various degrees of androgenic, estrogenic and antiandrogenic activities, thereby determining the scope of side effects. Animal and human studies showed, however, that only norethindrone, norethynodrel, and ethynodiol diacetate have estrogen activity. Replacement of the 13-methyl group of norethindrone with a 13-ethyl moiety gives rise to the gonane norgestrel, which is a potent progestin

with reduced androgenic activity (Fig. 3). More recently developed compounds like desogestrel (Fig. 3), norgestimate and gestoden display the least androgenic characteristics when compared with other 19-nor substances. Although norgestimate is a “newer” progestin, its activity is believed to be largely mediated by levonorgestrel or related metabolites. Therefore, epidemiologists do not generally include combination contraceptives containing norgestimate in the group of third generation compounds.

In epidemiologic studies, all products containing less than 50 μg ethinyl estradiol per pill are summarized as **low-dose oral contraceptives**. The first generation of oral contraceptives includes products with 50 μg

or more of ethinyl estradiol. The second generation of oral contraceptives comprises formulations of norgestrel (0.3–0.5 mg), levonorgestrel (0.1–0.15 mg), norgestimate (0.25 mg), ethynodiol diacetate (1 mg), and other members of the nortethindrone family in conjunction with 30 or 35 µg ethinyl estradiol. Desogestrel (0.15 mg) or gestodene (0.075 mg) are progestins in third generation contraceptives that are combined with 20 or 30 µg ethinyl estradiol. Most notably, the first oral contraceptive available contained 150 µg mestranol and 10 mg norethynodrel. It is nowadays commonly believed that the formulations of third generation oral contraceptives are very close to the lowest hormone levels which can be used without sacrificing contraceptive efficacy.

Combination oral contraceptives are the most frequently used agents and are characterized by a high therapeutic efficacy. Carefully controlled clinical studies with highly motivated subjects achieve an annual failure rate of 0.1%. The typical use effectiveness, however, amounts to 97–98%. Combination oral contraceptives are used as monophasic, biphasic, triphasic, and sequential preparations. In ▶monophasic preparations (Fig. 4), a fixed estrogen/progestin combination is present in each pill which is administered daily for 21 consecutive days followed by a 7-day hormone-free period (usually the pills for the last 7 days of a 28-day pack contain only inert ingredients). In the bi- and triphasic preparations (Fig. 4) varying amounts and ratios of estrogen to

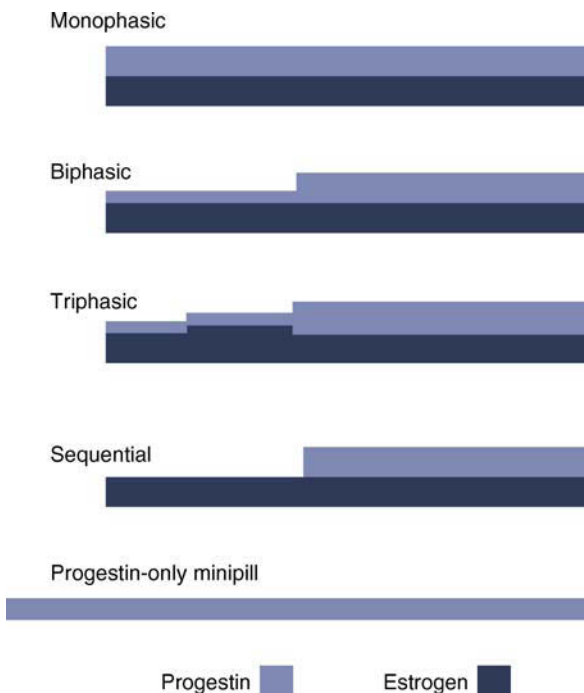

progestin are present in order to mimic most closely the sex-steroid levels throughout a normal menstrual cycle. In addition, the total amount of steroids administered can be reduced when taking multiphasic oral contraceptives. ▶Sequential preparations (Fig. 4) contain only estrogens for the first 7–11 days followed by a fixed estrogen/progestin combination in the remainder of the 21-day hormone application period. Phasic- and sequential-preparations were developed mainly to reduce the amount of progestins due to their untoward effects on the cardiovascular system.

Since a few years, a transdermal system received worldwide approval for hormonal contraception. In addition to ethinyl estradiol it contains norelgestromin as a progestational component. Norelgestromin is the active metabolite of norgestimate and is structurally related to 19-nortestosterone. Norelgestromin has negligible androgenic activity and may thus be suitable for women suffering from symptoms caused by androgen excess. The contraceptive efficacy of the transdermal patch is similar to that of oral contraceptives, but the transdermal system has the additional benefit of a once-weekly administration. In addition, transdermal delivery of hormones abolishes variability in gastrointestinal absorption and circumvents hepatic first-pass metabolism. It should be noted, however, that under steady-state conditions the area under the curve (AUC) describing plasma estrogen concentrations is 60% higher than corresponding levels resulting from a daily oral application of 35 µg ethinyl estradiol. Thus, a potential increase in cardiovascular complications cannot be ruled out with certainty so far.

Another fairly recent development in the field of hormonal contraception are combined contraceptive vaginal rings (NuvaRing) releasing 120 µg etonogestrel and 15 µg ethinyl estradiol daily. The small silastic ring is replaced weekly for 3 weeks followed by a ring-free period of 7 days. NuvaRing is well-tolerated and accepted by women, allows for a good control of the menstrual cycle and has a therapeutic efficacy comparable to oral contraceptives.

Progestin-only contraceptives (Fig. 4) contain low-doses of progestins (e.g. 350 µg norethindrone or 75 µg norgestrel) that have to be administered daily without interruption. The lowest expected failure rate during the first year of use is 0.5%, while the typical failure rate amounts to 3%. Subdermal implants of norgestrel (216 mg) for sustained release provides for long-term (for up to 5 years) contraceptive effects characterized by failure rates of only 0.05%. Reliable contraception for 3 months can be achieved by an intramuscular injection of a crystalline suspension of 150 mg medroxyprogesterone acetate (Fig. 3) (failure rate 0.3%).

The main purpose of healthy women taking oral contraceptives is to prevent unwanted pregnancies. “Primum non nocere” applies particularly to preventive

Contraceptives. Figure 4 Principal composition of various forms of oral contraceptives.

health care measures and therefore, untoward effects of oral contraceptives have to be monitored and assessed with great scrutiny. Shortly after the introduction of oral contraceptives approximately 40 years ago they soon became one of the most widely used drugs throughout the world. Hence, it is not surprising that reports on adverse effects began to appear rather quickly. Most of the untoward effects appeared to be dose-dependent, thus spurring on researchers to develop the current low-dose preparations. The most worrying adverse effects can be summarized in two main categories: the cardiovascular system and cancer.

Synthetic estrogens like ethinyl estradiol have a profound effect on the production of fibrinogen and clotting factors VII, VIII, X, and XII in the liver. In parallel, the concentrations of anticoagulation factors like protein C, S, and antithrombin III are diminished. This procoagulatory effect leads to an increased risk of thromboembolism in healthy women taking oral estrogens. In 1995, several studies reported on a twofold increase in the risk of venous thromboembolism when third generation oral contraceptives containing desogestrel and gestoden were compared with older preparations mostly containing levonorgestrel. This highly contentious issue was finally resolved when further analyses were able to explain the divergent results by confounding variables.

The effects of oral contraceptives on thrombosis can be surmised as follows: All low-dose oral contraceptives, regardless of the type of progestin, have an increased risk of venous thromboembolism. Smoking has no effect on the risk of venous thrombosis. However, smoking and estrogen administration have an additive effect on the risk of arterial thrombosis. Oral contraceptive-induced hypertension was previously observed in users of higher dose pills. An increased risk of clinically significant hypertension, however, has not been reported for low-dose oral contraceptives, including those containing the third generation progestins. Pre-existing hypertension is an important additive risk factor for stroke in oral contraceptive users. Most notably, recent clinical studies fail to find any substantial risk of myocardial infarction or stroke in healthy, non-smoking women, regardless of age, who take low-dose oral contraceptives. The vast majority of myocardial infarctions and strokes in oral contraceptive users occur when women over the age of 35 and cardiovascular risk factors take high-dose products (more than 50 µg ethinyl estradiol per pill). By meticulous screening for the presence of smoking and cardiovascular risk factors, especially hypertension, in older women, the risk of thromboembolic disease associated with low-dose oral contraceptives can virtually be annihilated.

In 1996, a metaanalysis of 54 epidemiologic studies indicated that women had a slightly increased risk of

breast cancer while taking oral contraceptives when compared to non-users (relative risk = 1.24). The increased risk diminished steadily after cessation of medication and was not found elevated 10 years after discontinuation. However, a recent population based case-control study of more than 4,500 women with breast cancer and nearly 4,700 controls showed no association between past and present use of oral contraceptives [4]. Due to the large study, subgroups of women, e.g. those taking a formulation with a high estrogen content, duration of oral contraceptive use, initiation of use during adolescence, history of breast cancer in a first-degree relative, could be analysed. None of these subgroups had a significantly increased risk of breast cancer. In light of these reassuring data, one has to conclude that oral contraceptive use is not associated with an increased risk of breast cancer. Such a conclusion contrasts sharply with the outcome of the Women's Health Initiative (WHI), the first randomised primary prevention trial on the effect of combined estrogen plus progestin (0.625 mg conjugated equine estrogen and 2.5 mg medroxyprogesterone acetate per day) on healthy postmenopausal women. The latter study was terminated early, chiefly because women receiving the active drug had an increased risk of breast cancer and the overall assessment was that the treatment was causing more harm than good [5]. It is therefore important to note that because of differences in doses and specific agents used, it is not justified to extrapolate adverse side effects of hormone replacement therapy to oral contraceptives or vice versa. In 2005, the WHO International Agency for Research on Cancer announced a reassessment of the carcinogenicity of combined estrogen-progestagen contraceptives and menopausal treatment. However, a meaningful discourse about this topic can only take place once the full complement of scientific data is available to the scientific community. Nevertheless, the announcement as such has already instigated vivid public discussions about the safety of hormonal contraceptives.

Thus, our attention should shift from the concern of potential adverse effects to the health benefits imparted by hormonal contraceptives. The use of oral contraceptives for at least 12 months reduces the risk of developing endometrial cancer by 50%. Furthermore, the risk of epithelial ovarian cancer in users of oral contraceptives is reduced by 40% compared with that on nonusers. This kind of protection is already seen after as little as 3–6 months of use. Oral contraceptives also decrease the incidence of ovarian cysts and fibrocystic breast disease. They reduce menstrual blood loss and thus the incidence of iron-deficiency anemia. A decreased incidence of pelvic inflammatory disease and ectopic pregnancies has been reported as well as an ameliorating effect on the clinical course of endometriosis.

Future efforts should be directed at optimizing current formulations to finally come up with an ideal oral contraceptive which would reduce the risk of breast, ovarian and endometrial cancer without any cardiovascular complications.

Contraction/Contracture

Contraction is a general term that refers to the mechanically activated state of myofibrils which is usually caused by action potential(s). Contracture means muscle shortening or tension development, which is not triggered by action potential(s), e.g. K^+ contracture, and caffeine or halothane contracture. The word is also used for deformity or distortion of fingers, hand or limb, such as Dupuytren's or Volkmann's contracture.

Cooperativity Factor

An allosteric ligand has an effect on a receptor protein mediated through the binding of that ligand to the allosteric binding domain. The intensity of that effect, usually a change in the affinity of the receptor for other ligands or the efficacy of a ligand for the receptor, is quantified by the cooperativity factor. Denoted α , a positive value for α defines a potentiation, a fractional value an inhibition. Thus if $\alpha=0.1$, a maximal tenfold decrease in the affinity of a tracer ligand for the receptor would be produced by the allosteric modulator.

COPI Vesicle

COPI vesicles mediate anterograde transport from the intermediate compartment to the Golgi, transport within the Golgi apparatus and retrograde transport back from the Golgi to the ER by the recruitment of soluble

proteins from the cytoplasm, the GTP-binding protein ARF1 and the coat protein complex coatamer that lead to budding of COPI-coated vesicles.

► Intracellular Transport

COPII Vesicle

COPII vesicles are transport intermediates from the endoplasmic reticulum. The process is driven by recruitment of the soluble proteins that form the coat structure called COPII from the cytoplasm to the membrane.

► Intracellular Transport

Coregulators

Macromolecules that associate with nuclear receptors to modulate their transcriptional activity.

► Nuclear Receptors

Co-repressors

The antagonist-induced conformation of nuclear hormone receptors attracts co-repressors like Nco/SMRT (nuclear hormone receptor co-repressor/silencing mediator of retinoid and thyroid receptors) which further recruit other nuclear proteins with histone deacetylase activity. Their action leads to chromatin condensation, thus preventing the general transcription apparatus from binding to promoter regions.

► Nuclear Receptors

Cortico-medullary Solute Gradient

While the osmotic concentration of renal cortical tissue is isotonic, interstitial solute concentration begins to rise at the border between renal cortex and renal medulla to

reach maximum concentrations at the tip of the renal papilla. This rise in tissue osmolarity, the cortico-medullary osmotic gradient, is a consequence of the countercurrent multiplication along the loops of Henle driven by active NaCl retrieval across the water impermeable ascending limb. The interstitial solutes are about half NaCl and half urea. The medullary hypertonicity permits the generation of a hypertonic urine when the collecting duct epithelium is water permeable under the influence of vasopressin.

Co-stimulation

It is an essential step in the induction of adaptive immune responses. Successful T-cell activation requires multiple signals. One signal is provided by presentation of an antigen bound to cell surface MHC molecules on antigen-presenting cells to a specific T-cell receptor. In the absence of further signals, T cells become unresponsive and may ultimately be eliminated through apoptosis. An important co-stimulatory signal is provided by an interaction between members of the B-7 family (either CD80 or 86) on antigen-presenting cells and CD28 on T cells. Other key interactions between antigen-presenting cells and T cells are mediated by binding of ICAM-1 to LFA-1, CD40 to CD40 ligand, LFA-3 to CD2, and so on. After activation, T cells express CTLA-4 which interferes with the B-7–CD28 interaction and helps to return the cells to the quiescent state.

Craving

There are opposing views in the field regarding the term “craving,” whether it describes a physiological, subjective, or behavioral state, if it is necessary at all to explain addictive behavior or is an epiphenomenon, which is not necessary for the production of continued drug use in addicts. The World Health Organization (WHO) agreed on the definition of craving as “the desire to experience the effect(s) of a previously experienced psychoactive substance.” Behavioral researchers conceptualize craving within the framework of incentive motivational theories of behavior and modify the definition of craving as “incentive motivation to self-administer a psychoactive substance.” Such an operational definition of craving has the advantage of making the phenomenon of craving accessible to experimental investigation and making it measurable.

Synonyms

CNG channels and HCN channels

Definition

Cyclic nucleotide-regulated cation channels are ion channels, whose activation is regulated by the direct binding of cyclic AMP or cyclic GMP to the channel protein. Two families of channels regulated by cyclic nucleotides have been identified, the cyclic nucleotide-gated (CNG) channels [1, 2] and the hyperpolarization-activated cyclic nucleotide-gated (HCN) channels [3–5]. CNG channels require the obligatory binding of a cyclic nucleotide in order to be activated. In contrast, HCN channels are activated by membrane

hyperpolarization. Cyclic nucleotides enhance HCN channel activity by affecting the voltage-dependence of channel activation.

Basic Characteristics

Cyclic nucleotides exert their cellular effects by binding to four major classes of cellular receptors: ►cAMP- and cGMP-dependent protein kinases, cGMP-regulated phosphodiesterases, cAMP-binding guanine nucleotide exchange factors (cAMP-GEFs) and cyclic nucleotide-regulated cation (CNG and HCN) channels. Cyclic nucleotide-regulated cation channels are unique among these receptors because their activation is coupled to the influx of extracellular cations into the cytoplasm and to the depolarization of the plasma membrane. CNG channels pass monovalent cations, such as Na^+ and K^+ , but do not discriminate between them. Calcium is also permeable but at the same time acts as a voltage-dependent blocker of monovalent cation permeability. By providing an entry pathway for Ca^{2+} , CNG channels control a variety of cellular processes that are triggered by this cation. HCN channels conduct Na^+ and K^+ with permeability ratios of about 1:4 and are blocked by millimolar concentrations of Cs^+ . Despite this preference for K^+ conductance, HCN channels carry an inward Na^+ current under physiological conditions. HCN channels can also conduct Ca^{2+} , but not as well as CNG channels. At 2.5 mM external Ca^{2+} , the fractional Ca^{2+} current of HCN2 and HCN4 is about 0.5%, whereas for native CNG channels, it is in the range between 10% and 80%.

CNG and HCN channels belong to the superfamily of ►voltage-gated cation channels. The proposed structure of the channels is shown in Fig. 1. The transmembrane channel core consists of six α -helical segments (S1–S6) and an ion-conducting pore loop between the S5 and S6. The amino- and carboxy-termini are localized in the cytosol. CNG and HCN channels contain a positively charged S4 helix carrying 3–9 regularly spaced arginine or lysine residues at every third position. In HCN channels, as in most other members of the channel superfamily, the S4 helix functions as “voltage-sensor,” conferring voltage-dependent ►gating. In CNG channels, which are only slightly voltage-dependent, the specific role of S4 is not known. In the carboxy-terminus, CNG and HCN channels contain a cyclic nucleotide-binding domain (CNBD) that is homologous to CNBDs of cAKs, cGKs, and cAMP-GEFs. In CNG channels, the binding of cGMP or cAMP to the CNBD initiates a sequence of allosteric transitions that lead to the opening of the ion-conducting pore. In HCN channels, the binding of cyclic nucleotides is not required for activation. However, cyclic nucleotides shift the voltage-dependence of channel activation to a more positive membrane potential and

thereby facilitate voltage-dependent channel activation. CNG and HCN channels are tetramers. In native tissue, HCN channel subunits can assemble to form either homo- or heteromeric complexes. By contrast, all known native CNG channels are heterotetramers.

CNG Channels

CNG channels are expressed in retinal photoreceptors and olfactory neurons, and play a key role in visual and olfactory signal transduction. In addition, CNG channels are found at low density in some other cell types and tissues such as brain, testis, and kidney. While the function of CNG channels in sensory neurons has been unequivocally demonstrated, the role of these channels in other cell types, where expression has been observed, remains to be established. Based on their phylogenetic relationship, the six CNG channels

Cyclic Nucleotide-regulated Cation Channels.

Figure 1 Phylogenetic tree and structural model of cyclic nucleotide-regulated cation channels. The CNG channel family comprises six members, which are classified into A subunits (CNGA1–4) and B subunits (CNGB1 and CNGB3). A “CNGB2” subunit does not exist. The HCN channel family comprises four members (HCN1–4). CNG and HCN channels share the same transmembrane topology, consisting of six transmembrane segments (1–6), a pore loop, and a cyclic nucleotide-binding domain (CNBD). CNG channels conduct Ca^{2+} and Na^+ , whereas HCN channels mainly conduct Na^+ and K^+ . CNG channel is activated *in vivo* by binding of either cAMP (cA) or cGMP (cG), depending on the channel type. HCN channels activate on membrane hyperpolarization (ΔV), and are enhanced by binding of cAMP. The positively charged amino acid residues in the S4 segment of HCN channels are indicated by + symbols. CL, C-linker involved in activation gating of CNG and HCN channels.

identified in mammals are divided into two subfamilies, the A-subunits (CNGA1–4) and the B-subunits (CNGB1 and CNGB3). When expressed in **▶heterologous expression systems**, A-subunits, with the exception of CNGA4, form functional homomeric channels. In contrast, B-subunits do not give rise to functional channels when expressed alone. However, together with CNGA1–3 they confer novel properties (e.g., single channel flickering, increased cAMP sensitivity) that are characteristic of native CNG channels. In native tissues, CNG channels are heterotetramers with different heteromers, displaying distinct nucleotide sensitivity, ion selectivity, and modulation by Ca^{2+} . Recent genetic studies in mice indicate that B-subunits play a key role in principal channel formation and channel targeting in native sensory neurons. For example, mice lacking the CNGB1 subunit fail to express substantial amounts of CNG channels in rod outer segments and olfactory cilia, respectively. The physiological role and subunit composition is known for three native channels: the rod and cone photoreceptor channels and the olfactory channel. The CNG channel of rod outer segment consists of the CNGA1 subunit and the CNGB1a subunit (3:1 stoichiometry). The cone photoreceptor channel consists of the CNGA3 and the CNGB3 subunit (2:2 stoichiometry). CNG channels control the membrane potential and the calcium concentration of photoreceptors. In the dark, the channels are maintained in the open state by a high concentration of cGMP. The resulting influx of Na^+ and Ca^{2+} (“dark current”) depolarizes the photoreceptor and promotes synaptic transmission. Light-induced hydrolysis of cGMP leads to the closure of CNG channels. As a result, the photoreceptor hyperpolarizes and shuts off synaptic glutamate release. Mutations in human CNG channel genes have been linked to retinal diseases. Mutations in the CNGA1 and CNGB1 subunits have been identified in the genome of patients suffering from **▶retinitis pigmentosa**. The functional loss of either the CNGA3 or the CNGB3 subunit causes total color blindness (achromatopsia) and degeneration of cone photoreceptors.

The olfactory CNG channel consists of three different subunits: CNGA2, CNGA4, and the CNGB1b subunit (2:1:1 stoichiometry). The channel is activated *in vivo* by cAMP, which is synthesized in response to the binding of odorants to their cognate receptors. The olfactory CNG channel mainly conducts Ca^{2+} under physiological ionic conditions. The increase in cellular Ca^{2+} activates a Ca^{2+} -activated Cl^- channel, which further depolarizes the cell membrane. Ca^{2+} is not only a permeating ion of the olfactory CNG channel, but also an important modulator of this channel. By forming a complex with calmodulin, which binds to the CNGB1b and CNGA4 subunit, Ca^{2+} decreases sensitivity of the CNG channel to cAMP. The resulting inhibition of

channel activity is the principal mechanism, underlying fast odorant adaptation.

HCN Channels

A cation current that is slowly activated by membrane hyperpolarization (termed I_h , I_f or I_q) is found in a variety of excitable cells, including neurons, cardiac pacemaker cells, and photoreceptors. The best understood function of I_h is to control heart rate and rhythm by acting as “pacemaker current” in the sinoatrial (SA) node. I_h is activated during membrane hyperpolarization, following the termination of an action potential, and provides an inward Na^+ current that slowly depolarizes the plasma membrane. Sympathetic stimulation of SA node cells raises cAMP levels and increases I_h by a positive shift of the current activation curve, thus accelerating diastolic depolarization and heart rate. Stimulation of muscarinic receptors slows down heart rate by the opposite action. In neurons, I_h fulfills diverse functions, including generation of pacemaker potentials (“neuronal pacemaking”), control of membrane potential, generation of rebound depolarizations during light-induced hyperpolarizations of photoreceptors, dendritic integration, and synaptic transmission.

HCN channels represent the molecular correlate of the I_h current. In mammals, the HCN channel family comprises four members (HCN1–4) that share about 60% sequence identity to one another and about 25% sequence identity to CNG channels. The highest degree of sequence homology between HCN and CNG channels is found in the CNBD. The crystal structure of this domain has been determined for HCN2 and a bacterial CNG channel. When expressed in heterologous systems, all four HCN channels generate currents displaying, the typical features of native I_h : (i) activation by membrane hyperpolarization, (ii) permeation of Na^+ and K^+ with a permeability ratio $P_{\text{Na}}/P_{\text{K}}$ of about 0.2, (iii) modulation of voltage-dependence of channel activation by direct binding of cAMP, and (iv) channel blockade by extracellular Cs^+ .

HCN1–4 mainly differ from one another with regard to their speed of activation and the extent to which they are modulated by cAMP. HCN1 is the fastest channel, followed by HCN2, HCN3, and HCN4. Unlike HCN2 and HCN4, whose activation curves are shifted by about +15 mV by cAMP, HCN1, and HCN3 are, if at all, only weakly affected by cAMP.

Site-directed mutagenesis experiments have provided insight into the complex mechanism, underlying dual HCN channel activation by voltage and cAMP. Like in other voltage-gated cation channels, activation of HCN channels is initiated by the movement of the positively charged S4 helix in the electric field. The resulting conformational change in the channel protein is allosterically coupled by other channel domains to the opening of the ion-conducting pore. Major determinants affecting

channel activation are the intracellular S4–S5 loop, the S1 segment, and the extracellular S1–S2 loop. The CNBD fulfills the role of an auto-inhibitory channel domain. In the absence of cAMP, the cytoplasmic carboxy-terminus inhibits HCN channel gating by interacting with the channel core and, thereby, shifting the activation curve to more hyperpolarizing voltages. The binding of cAMP to the CNBD relieves this inhibition. Differences in the magnitude of the response to cAMP among the four HCN channel isoforms are largely due to differences in the extent to which the CNBD inhibits basal **gating**. It remains to be determined if the inhibitory effect of the CNBD is conferred by a direct physical interaction with the channel core domain or by some indirect pathway. There is evidence that the so-called C-linker, a peptide of about 80 amino acids that connects the last transmembrane helix (S6) to the CNBD plays an important role in this process. The C-linker was also shown to play a key role in the gating of CNG channels, suggesting that the functional role of this domain has been conserved during channel evolution.

HCN channels are found in neurons and heart cells. In mouse and rat brain, all four HCN isoforms have been detected. The expression levels and the regional distribution of the HCN channel mRNAs vary profoundly between the respective channel types. HCN2 is the most abundant neuronal channel and is found almost ubiquitously in the brain. In contrast, HCN1, HCN3, and HCN4 are enriched in specific regions of the brain such as thalamus (HCN4) hippocampus (HCN1), or olfactory bulb and hypothalamus (HCN3). HCN channels have also been detected in the retina and some peripheral neurons such as dorsal root ganglion neurons. In SA node cells, HCN4 represents the predominantly expressed HCN channel isoform. In addition, minor amounts of HCN2 and HCN1 are also present in these cells. Insights into the (patho)physiological relevance of HCN channels have been gained from the analysis of mouse lines lacking individual HCN channel isoforms. Disruption of HCN1 impairs motor learning but enhances spatial learning and memory. Deletion of HCN2 results in absence epilepsy, ataxia, and sinus node dysfunction. The mice lacking HCN4 die in utero because of the failure to generate mature sinoatrial pacemaker cells. The key role of HCN4 in controlling heart rhythmicity is corroborated by genetic data from human patients. Mutations in the human HCN4 gene, leading to mutated or truncated channel proteins, have been found to be associated with sinus bradycardia (S672R, 573X) and complex cardiac arrhythmia (D552N).

Drugs Acting on CNG Channels

Several drugs have been reported to block CNG channels. The most widely used among these drugs is *L-cis* diltiazem which blocks CNG channels in a voltage-

dependent manner at micromolar concentrations. The *D-cis* enantiomer of diltiazem, which is an important therapeutic blocker of the *L*-type calcium channel, is much less effective than the *L-cis* enantiomer in blocking CNG channels. High affinity binding of *L-cis* diltiazem is only seen in heteromeric CNG channels, containing the CNGB1 subunit. CNG channels are also moderately sensitive to blockage by some other inhibitors of the *L*-type calcium channel (e.g., nifedipine), the local anaesthetic tetracaine, and calmodulin antagonists. Interestingly, LY83583 [6-(phenylamino)-5,8-quinolinedione] blocks both the soluble guanylyl cyclase and some CNG channels at similar concentrations. H-8 [*N*-2-(methylamino)ethyl-5-isoquinolinesulfonamide], which has been widely used as a nonspecific cyclic nucleotide-dependent protein kinase inhibitor, blocks CNG channels, though at significantly higher concentrations than needed to inhibit protein kinases. The most potent blocking agent for CNG channels is pseudochetoxin. This toxin inhibits homomeric CNGA2 channels with a K_i of 5 nM and the homomeric CNGA1 channel with a K_i of 100 nM. The peptide is several orders of magnitude less effective in blocking the heteromeric channels.

Drugs Acting on HCN Channels

Given the key role of HCN channels in cardiac pacemaking, these channels are promising pharmacological targets for the development of drugs, used in the treatment of cardiac arrhythmias and ischemic heart disease. HCN channels are not expressed in vascular and airway smooth muscle. As a consequence, specific HCN channel blockers are expected to have no side effect on the peripheral resistance. Importantly, unlike the well-established β -adrenoceptor blockers, HCN channel blockers would not impair pulmonary function in patients with asthma or obstructive pulmonary disease. Recently, ivabradine (S16257, Procoralan) was approved as the first therapeutic I_h blocker. Ivabradine blocks cardiac I_h at low micromolar concentrations and is used in the treatment of stable angina pectoris. Other known I_h blockers with blocking mechanisms, related to that of ivabradine are ZD7288 [4-(*N*-ethyl-*N*-phenylamino)-1,2-dimethyl-6-(methylamino)pyrimidinium chloride], zatebradine, and cilobradine. These blockers were not introduced into therapy because they either lacked specificity or exerted unacceptable side effects, in particular visual disturbances due to the inhibition of retinal I_h . Interestingly, the well-known α_2 -adrenoceptor agonist clonidine also effectively blocks HCN channels. The block of cardiac I_h (mainly conferred by HCN4) contributes significantly to the bradycardic effect of clonidine. Modulation of I_h may also be a promising approach for the treatment of disease processes in central and peripheral nervous system. For example, I_h is upregulated in dorsal root ganglion neurons in response

to nerve injury, making HCN channels interesting candidates for therapeutic modulation of inflammation and neuropathic pain. Moreover, agents acting on HCN channels may be utilized in the treatment of epilepsies. Finally, HCN1 and HCN2 channels are inhibited by clinically relevant concentrations (≤ 0.5 mM) of the inhalational anesthetics halothane and isoflurane. Similarly, the intravenous anesthetic propofol inhibits and slows the activation of native and expressed HCN channels. Thus, modulation of I_h may contribute to clinical actions of anesthetic agents.

Cyclic Nucleotides

Cyclic nucleotides (cAMP and cGMP) are formed enzymatically from the corresponding triphosphates. As ubiquitous second messengers, they mediate many cellular functions which are initiated by first (extracellular) messengers. Their prime targets in eucaryotic cells are protein kinases (▶ cyclic AMP-dependent protein kinase, ▶ cyclic GMP-dependent protein kinase), ion channels and enzymes.

Cyclooxygenase-2 (Expression in the Kidney)

Cyclooxygenase (COX) activity is responsible for the formation of prostaglandins from their arachidonic acid precursor. Two COX isoforms have been identified, COX-1 and COX-2. While COX-1 is constitutively expressed in most tissues, COX-2 is typically only found after induction by proinflammatory stimuli. However, a constitutively expressed and highly regulated COX-2 is found in the kidney, both in the renal medulla and in the renal cortex. Renal cortical COX-2 is located in the area of the juxtaglomerular apparatus, and prostaglandins formed by COX-2 regulate the expression and secretion of renin in response to a reduction in NaCl concentration at the macula densa.

Synonyms

Prostaglandin H₂ synthase (PGHS); EC 1.14.99.1; COX-1; COX-2

Definition

Cyclooxygenase (COX) is the enzyme that catalyses the conversion of arachidonic acid to the highly active group of lipid mediators, the prostaglandins and thromboxane. These end products are involved in a multitude of diverse pathophysiological processes, ranging from the induction of the vascular inflammatory response to tissue damage or infection, fever, pain perception, haemostasis, cytoprotection of the gastric mucosa from the erosive effects of gastric acid, the induction of labour and the regulation of kidney function. Thus, the inhibition of COX can result in alleviation of the symptoms of many diseases, particularly inflammatory joint disease such as ►**rheumatoid arthritis**. However, this often occurs with the generation of severe side effects, such as gastrototoxicity, due to the inhibition of physiological functions.

In 1971 inhibition of COX was established as the mode of action of the archetypal non-steroid anti-inflammatory drug (NSAID) aspirin, thus resolving an enigma that had puzzled researchers since the synthesis of salicylate in the mid nineteenth century. The realisation that inhibition of COX was the general mode of action of the large number of marketed NSAIDs also explained why the common toxic effects of these drugs, such as gastro- and nephrotoxicity, prolongation of bleeding time and delayed labour, could not be divorced from their beneficial analgesic, antipyretic and anti-inflammatory actions.

Basic Characteristics

COX possesses two catalytic sites. The cyclooxygenase active site converts arachidonic acid substrate, mobilised from membrane phospholipid by a phospholipase, to the prostaglandin endoperoxide, PGG₂. The endoperoxide is then converted by a peroxidase-active site on COX to form prostaglandin H₂ (PGH₂). PGH₂ is then acted upon by various synthases to form the active prostanoids, the most important of which are prostaglandin E₂ (PGE₂), thromboxane A₂ (TXA₂), prostacyclin (PGI₂), prostaglandin D₂ (PGD₂) and prostaglandin F_{2α} (PGF_{2α}). COX is widely distributed in tissues, indeed, prostanoids can be synthesised and released by any mammalian cells except erythrocytes. The stages in the production of the prostanoids are summarised in Fig. 1. The main actions of these mediators are listed in Table 1.

By the late 1980s, it became clear that there were two forms of COX, one that was constitutive, i.e. permanently present in many tissues, and the other that could be induced over time by mitogens or pro-inflammatory agents, this induction being inhibited by

anti-inflammatory steroids such as dexamethasone. In 1991, it was established that there were, in fact, two distinct COX enzymes, encoded by two distinct genes. The constitutive enzyme was designated COX-1 and the inducible enzyme COX-2. In general, COX-1 is responsible for the synthesis of PGs, which serve physiological or so-called “house-keeping” functions, whereas COX-2 synthesises PGs, involved in pathological processes, which are responsible for symptoms such as the swelling and pain of inflammatory conditions.

The two isozymes are both homodimers, composed of approximately 600 amino acids and possess approximately 60% homology. The three-dimensional structures of COX-1 and COX-2 are very similar. Each one consists of three independent units: an epidermal growth factor-like domain, a membrane-binding section and an enzymic domain. The catalytic sites and the residues immediately adjacent are identical but for two small but crucial variations that result in an increase in the volume of the COX-2-active site, enabling it to accept inhibitor-molecules larger than those that could be accommodated in the COX-1 molecule.

The identification of the two COX isozymes explained why some NSAIDs had the same efficacy as other drugs, but apparently, were marginally less likely to produce the common side effect of gastrotoxicity, manifested by perforations, ulcers or bleeding from the gastric mucosa. It is of greater significance that the establishment of differences in the volume of the active site of COX-2 also raised the possibility of the synthesis of inhibitors, tailor-made to fit the COX-2 site, without the capacity to inhibit COX-1. Such drugs would prevent the formation of PGs responsible for pain, fever and inflammatory reactions, with minimal or no action on the synthesis of the beneficial or “housekeeping” PGs (Fig. 2).

Since COX-2 is overexpressed in tumour cells, such as those of colorectal cancer, it was anticipated that selective COX-2 inhibitors may inhibit tumour growth.

Drugs

Aspirin has been remarkably successful in the treatment of the pain and swelling of inflammatory disease and in fact, an estimated 45,000 tons of aspirin are still consumed each year. This success resulted in the syntheses of many other “aspirin-like drugs”, now referred to as NSAIDs. Aspirin, however, continues to have a unique use in the prevention of thrombosis. Since it produces irreversible inhibition of COX-1 by acetylation of serine at position 530 in the active site, a daily low dose of aspirin will cause a cumulative inhibition of COX-1 in platelets, in the portal circulation. A gradual inhibition of platelet aggregation occurs, reducing the possibility of occlusion of coronary or cerebral vessels by platelet thrombi. However, there are no systemic

Cyclooxygenases. Figure 1 Pathways for the formation of prostanoids from arachidonic acid. Arachidonic acid is converted by cyclooxygenase to endoperoxides, which are acted upon by various synthesases to form the prostanoids. Prostacyclin and thromboxane are relatively unstable and break down rapidly to form the inactive metabolites 6-oxo-PGF_{1α} and thromboxane B₂, respectively.

Cyclooxygenases. Table 1 Actions of the common prostanoids

Actions of the common prostanoids	
PGE ₂	Vasodilatation (decrease in blood pressure); inhibits platelet aggregation; decreased gastric secretion; bronchodilatation; hyperalgesia; fever; contraction of intestinal and uterine smooth muscle. (Mediates inflammation, fever, pain, protects gastric mucosa)
PGI ₂	Vasodilatation (decrease in blood pressure); inhibits platelet aggregation; decreased gastric secretion; bronchodilatation; hyperalgesia. (Mediates pain, protects gastric mucosa, antithrombogenic)
PGF _{2α}	Vasodilatation/vasoconstriction; bronchoconstriction; contraction of intestinal and uterine smooth muscle. (Important functions in ovulation and parturition)
PGD ₂	Vasodilatation; inhibits platelet aggregation; decreases fever; relaxes intestinal smooth muscle. (Released mainly in brain and mast cells, induces sleep)
TXA ₂	Increases blood pressure; platelet aggregation; vasoconstriction; bronchoconstriction. (Important in haemostasis)

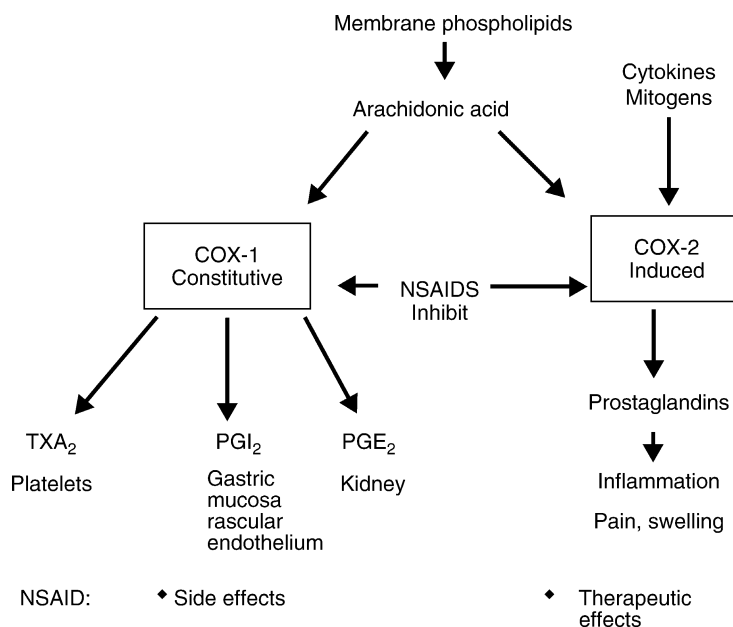

Putative pathophysiological functions placed in parenthesis.

toxic effects since the small dose of aspirin administered is destroyed by hepatic metabolism.

NSAIDs are used as the first-line treatment of rheumatoid arthritis, ▶osteoarthritis, systemic lupus erythematosus and other inflammatory diseases, and are thus amongst the most widely used drugs in the developed world. This widespread use inevitably entailed a considerable associated morbidity, in particular a high incidence of gastric toxicity. In the USA alone, perforations, ulcers and bleeds lead to the hospitalisation of 100,000 patients per year, and about 15% of these die while under intensive care.

NSAIDs are of diverse chemical structures: salicylates (aspirin, sulphasalazine), indole acetic acids (indomethacin, etodolac), heteroaryl acetic acids (diclofenac), arylpropionic acids (ibuprofen, naproxen), anthranilic acids (mefenamic acid) and enolic acids (piroxicam, meloxicam).

The identification of COX-2 as the enzyme, responsible for the synthesis of PGs involved in pathology, led to the examination of the relative activities of the established NSAIDs on COX-1 and COX-2. Various test systems have been used for this purpose and it is now generally accepted that the whole

Cyclooxygenases. Figure 2 Mechanism of the therapeutic and toxic actions of NSAIDs. The induced cyclooxygenase (COX-2) produces the pro-inflammatory prostaglandins responsible for the swelling and pain associated with inflammation. COX-1 produces the prostanoids responsible for protective physiological actions: thromboxane A₂ (TX)A₂ causes platelet aggregation, PGI₂ prevents intravascular aggregation and is protective for the gastric mucosa, and PGE₂ maintains renal blood flow (from Botting, 1999, with permission) [1].

blood assay of Patrignani et al. is the preferred method since it uses the human enzymes in platelets (COX-1) and activated mononuclear cells (COX-2) in the presence of the plasma proteins, thus allowing for the participation of protein binding which is significant for some NSAIDs [2].

Three established NSAIDs were found to inhibit COX-2 in lower concentrations than those required to inhibit the constitutive enzyme. These were nimesulide, etodolac and meloxicam. Epidemiological studies showed that at therapeutic doses these drugs induced less gastrointestinal toxicity than NSAIDs, such as indomethacin, naproxen and ketorolac, which were more potent at inhibiting COX-1 compared with COX-2. The proof that selective inhibitors of COX-2 are efficacious anti-inflammatory agents with minimal or no toxic side effects, stimulated several commercial groups to develop, through knowledge of the differences in the shape of the catalytic sites of the isozymes, highly selective inhibitors of COX-2, some of which are 1000-fold more potent against COX-2 than COX-1.

The first two selective COX-2 inhibitors to be marketed and subjected to in depth clinical trials were celecoxib and rofecoxib. Both compounds are as effective as standard NSAIDs in rheumatoid arthritis, osteoarthritis and for pain following orthopaedic or dental surgery. Gastrointestinal side effects were far fewer than with comparator drugs and in fact were no

more common with the ►coxibs than with placebo treatment.

However, already in an early clinical trial, rofecoxib was found to produce four times the number of ►myocardial infarctions than its comparator drug, naproxen. A subsequent trial of rofecoxib compared to placebo in colorectal cancer prevention demonstrated, after 18 months of study, that a greater number of myocardial infarctions occurred in the rofecoxib group. In 2004 the manufacturers of rofecoxib withdrew the drug from the market. A similar study of celecoxib compared to placebo in cancer prevention, showed that celecoxib also increased the risk of cardiovascular embolisms [3].

The Future of Selective COX-2 Inhibitors

Celecoxib, which has a low selectivity for COX-2 compared to COX-1, is still available, although its more selective successor, valdecoxib has been withdrawn. Etoricoxib, the successor to rofecoxib, is marketed in Europe but not in the USA. In a large multinational clinical trial, etoricoxib caused no more thromboembolic events than diclofenac, but after 18 months the incidence of gastrointestinal ulcers and bleeding was the same for both drugs [4].

Lumiracoxib, which has been approved in the UK but not by the FDA, has a phenyl acetic acid structure resembling diclofenac rather than the other coxibs

which are sulphonamide or sulphone derivatives. It is highly selective for COX-2 and studies show a similar incidence of thromboembolism and lower incidence of gastrointestinal damage than comparator NSAIDs.

COX-2 synthesises PGI₂ (prostacyclin) and the high incidence of myocardial infarctions with selective COX-2 inhibitors has been attributed to inhibition of COX-2 in vascular tissues. Prostacyclin, made by blood vessel walls, inhibits aggregation of platelets and maintains a balance with thromboxane. Thromboxane, which is released by platelets, promotes clotting. Prostacyclin is synthesised mostly by COX-1, but in humans selective COX-2 inhibition reduces its biosynthesis *in vivo*. This reduced synthesis may lead to an overactive thromboxane system and increased risk of thromboembolism.

Current studies indicate that prolonged use of selective COX-2 inhibitors, which would be required to treat cancer, may lead to an increase in myocardial infarctions and ultimately, gastric damage. The indications are that selective COX-2 inhibitors relieve the pain of rheumatoid arthritis, osteoarthritis and acute pain, but they should not be administered continuously for long periods. They should not be given to patients for pain originating in the cardiovascular system, for example, pain following cardiac arterial bypass surgery.

The possibility still exists that selective COX-2 inhibitors may be used to treat cancer if the beneficial effect outweighs the side effects. They may also have a therapeutic role in treating premature labour, since labour is induced partly through the uterotonic effect of PGs synthesised by COX-2. Non-selective NSAIDs such as indomethacin will also delay premature labour but they are contraindicated for this condition since they also cause early closure of the ductus arteriosus through inhibition of COX-1, which synthesises PGs maintaining patency of the ductus [5].

Cyclosporin A

A secondary metabolite produced by *Tolypocladium inflatum*. This fungus was initially isolated in a soil sample collected in Norway. Cyclosporin A is a cyclic undecapeptide. Inside cells, cyclosporine A binds its immunophilin receptor known as cyclophilin. Like the FK506-FKBP12 complex, cyclosporin A-cyclophilin binds and inhibits the protein phosphatase calcineurin.

Cystic Fibrosis

Cystic fibrosis is a common autosomal recessive disorder caused by mutations in the gene encoding the cystic fibrosis transmembrane conductance regulator (CFTR) protein. The CFTR protein is a cAMP-regulated Cl^- channel belonging to the ABC transporter family. The main symptoms of cystic fibrosis are a progressive obstructive lung disease and pancreatic insufficiency. Patients suffer from the increased production of viscous mucus which leads to impaired function and severe infections of the lung. About 70% of the patients carry the $\Delta F508$ mutation which leads to an intracellularly-retained CFTR protein. Cystic fibrosis is one of the most common hereditary diseases of children that reduce life expectancy.

Cytochalasins

Cytochalasins B and D are used as tools to study F-actin. Cytochalasins bind to the barbed end of F-actin and block the addition as well as dissociation of G-actin at that end. When applied to cultured cells micromolar concentrations of cytochalasins remove stress fibres and other F-actin structures.

Cytokeratin

Cytokeratins are members of the intermediate filament class of cytoskeletal proteins. Cytokeratins are a large protein family comprising two subfamilies of polypeptides, i.e. acidic (type I) and basic (type II) ones. Cytokeratin form tetramers, consisting of two type I and two type II polypeptides arranged in pairs of laterally aligned coiled coils. The distribution of the different type I and II cytokeratins in normal epithelia and in carcinomas is differentiation-related and can be used for cell typing and identification.

Cytokine Receptors

Cytokine receptors are a group of structurally related receptors, which couple to the JAK-STAT pathway. Cytokine receptors function as homodimers or hetero-oligomers. They are divided into two main subclasses, class I, which contains receptors for a variety of hematopoietic growth factors and interleukins and class II, which contains receptors for interferons and interleukins 10, 20/24 and 22.

Cytokines

MICHAEL KRACHT, HELMUT HOLTSMANN
Rudolf-Buchheim-Institut für Pharmakologie,
Frankfurter Straße 107, D-35392 Gießen

Synonyms

No true synonyms. Related terms/subgroups: Lymphokines; Monokines; Interleukins; Chemokines; Interferons; Growth factors (Table 1).

Definition

Cytokines are a large and heterogenous group of small polypeptides, most of them with a Mr between 8 and 30 kDa. They are mostly soluble extracellular mediators (some exist in membrane-associated form) and function through high-affinity cell surface receptors. Released by cells of hematopoietic origin (reflected in the terms “lymphokines” and “monokines”) as well as by a wide variety of nonhematopoietic cells, cytokines are critical for the normal functioning of the immune defense, which they coordinate by communicating between participating cells.

“My private metaphor was that of a zoo of factors in a jungle of interactions surrounded by deep morasses of acronyms and bleak deserts of synonyms” [1].

Basic Characteristics

Historically, many cytokines were discovered by means of their immunoregulatory properties, hence, the term interleukins. However, cytokines regulate not only functions of the specific immune system, but also many

Cytokines. Table 1 Structural/functional groups of cytokines (examples)

Interferons	IFN- α , β , γ
Hematopoietic cytokines/colony-stimulating factors	IL-3, IL-5, IL-6, IL-7, erythropoietin, GM-CSF, G-CSF, M-CSF, thrombopoietin
IL-1 family	IL-1 α , IL-1 β , IL-18, IL-1RA
TNF family	TNF- α , TNF- β , CD40 ligand, CD95 ligand, TRAIL
Chemokines	IL-8, MIP-1- α , RANTES
Immunoregulatory cytokines	IL-2, IL-4, IL-10, IL-12

aspects of infection and inflammation. At the cellular level they control proliferation, differentiation, functional activity, and apoptosis. As a whole, they are synthesized by a broad variety of different cell types. This also holds true for many cytokines individually (e.g., IL-6, IL-8, IFN- β , for further information on individual cytokines see [1]), whereas synthesis of others is restricted to one or few cell types (e.g., IL-2, IL-4, IFN- γ). In general, their biosynthesis is rapidly and highly inducible by changes in the cell microenvironment. Cytokines often have a short half-life and production is restricted to potentially pathological conditions. Uncontrolled synthesis results in chronic inflammatory or other diseases. All cytokines act locally in an autocrine or paracrine manner, but some may also act systemically. Examples for the latter are the induction of fever by IL-1 and \blacktriangleright TNF, and the induction of acute phase proteins in the liver by IL-6. Cytokines can therefore also be regarded as hormones. Cytokines are pleiotropic, that is, they control multiple biological responses. There is considerable functional overlap between certain cytokines (e.g., \blacktriangleright TNF and IL-1). In general, activation of a cell by a cytokine results in reprogramming of the cell's gene expression profile.

Mechanism of Action

Most cytokines – in particular the ones that are in clinical use – bind to high-affinity receptors on the plasma membrane. These receptors fall into different classes, those with enzymatic tyrosine kinase activity (e.g., the receptors of certain hematopoietic growth factors (M-CSF, SCF), G-protein coupled receptors (chemokine receptors), and several groups that bind to other intracellular adaptor proteins (IL-1-, TNF-, interferon- and hematopoietic cytokine receptor families). Ligand-dependent receptor clustering activates several intracellular signaling pathways. These pathways consist of consecutive interactions between protein components that in part involve enzymatic activities. The activity of many proteins in a given cytokine-activated pathway is regulated by reversible phosphorylation. The \blacktriangleright MAP kinase cascades and the \blacktriangleright JAK/STAT pathways are intensively studied exam-

ples. Certain receptors (of the TNF-R family) can activate caspases; a family of proteases that executes programmed cell death. Other protein synthesis independent effects of cytokines include cytoskeletal changes and modulation of cell surface receptors and adhesion molecules.

Most cytokine-activated intracellular pathways ultimately turn on expression of genes whose products change the biological function of the same or a neighboring cell. These include cytokines (hence the term “cytokine network”), cell surface receptors and adhesion molecules, enzymes involved in degradative processes (e.g., collagenases) and in formation of small molecular weight mediators (e.g., cyclooxygenase II, inducible NO-synthase).

Cytokines and Therapy

Knowledge on cytokines has been exploited to improve the therapy of many diseases, basically in two ways:

1. Application of cytokines as drugs. Several examples will be given below. In general, treatment with cytokines turned out to be problematic due to their pleiotropic nature of function. Thus tumor necrosis factor, apart from its antitumoral effect, has severe systemic side effects as manifestations of its activity, which largely precludes its use as anticancer drug. Similar toxicity has been observed for several other inflammatory cytokines. Recombinant cytokines can be used to boost immune reactions during infection and cancer (interleukin-2, interferons) or to substitute cytokine deficiencies (hematopoietic growth factors, erythropoietin).
2. Interference with cytokine action. Inhibition of cytokine synthesis has turned out to be a major component of the activity of anti-inflammatory drugs, glucocorticoids being a prominent example. Because for many cytokines the molecular mechanisms of their actions have been worked out in detail, rational strategies for interfering with their biological activities have been or are being developed. The action of cytokines can be suppressed pharmacologically by different means: (i) Inhibition of their synthesis by drugs (cyclosporin-IL-2 synthesis); (ii) Prevention of their interaction with cell

surface receptors by soluble receptors (TNF-RI extracellular domain), anticytokine, or anticytokine receptor antibodies (anti-TNF, anti-IL-2R antibodies), or natural antagonists (IL-1R antagonist); (iii) Blockade of specific events in the intracellular signaling pathways (protein kinase inhibitors). Clinically used cytokines or cytokine antagonists are proteins. Repeated application, especially for those of nonhuman origin, bears the risk of recognition by the immune system and antibody production against them with subsequent loss of efficacy. Therefore, the proteins are often genetically engineered, that is, humanized (see Humanized Monoclonal Antibodies) to be as homologous as possible to human proteins.

Clinical Use (Including Side Effects)

Examples of Recombinant Cytokines Currently in Use

Interferons

Interferon alfacon-1 (Inferax®), interferon alfa-2b (IntronA®), and interferon alfa-2a (Roferon®-A) are applied in the treatment of chronic hepatitis B and C and some malignancies, especially hairy cell leukemia. IFN- α proteins induce the expression of antiviral, antiproliferative and immunomodulatory genes.

Interferon beta-1a (AVONEX®, Rebif®), interferon beta-1b (Betaferon®), and interferon beta (Fiblaferon®) are applied in multiple sclerosis to reduce both frequency and severity of disease incidents and for the treatment of severe viral infections. In multiple sclerosis, IFN- β proteins modulate the destruction of myelin in the cause of the autoimmune reaction.

Interferon gamma-1b (Imukin®) is used to reduce the incidence of infections in the treatment of chronic granulomatosis.

Common side effects of interferons are flu-like symptoms, fever, myelosuppression, and skin-reactions.

Human Recombinant Colony-Stimulating Factors

Molgramostim (rhu GM-CSF, Leucomax®), Filgrastim (r-metHuG-CSF, Neupogen®), and Lenograstim (rHuG-CSF, Granocyte®) promote the differentiation of pluripotent bone marrow stem cells to leukocytes. GM-CSF induces proliferation in cells of the macrophage, neutrophil, and eosinophil lineages, while G-CSF acts primarily on neutrophil precursors. They are effective in treatment of congenital and acquired neutropenias during chemotherapy of cancer or bone marrow transplantation. G-CSF is also applied to donors to increase peripheral blood progenitor cells for allogeneic bone marrow transplantation. Side effects include bone pain, fever, and myalgia.

Interleukin 2 (Aldesleukin, Proleukin®) is a major growth factor and activator of cytotoxic and other T-lymphocytes. It is applied in the therapy of metastasizing renal carcinoma and melanoma. Side effects include

hypotension, arrhythmias, edema, pruritus, erythema, central nervous symptoms, fever, and many others.

Erythropoietin (Eprex®) is physiologically produced in the kidney and regulates proliferation of committed progenitors of red blood cells. It is used to substitute erythropoietin in severe anemias due to end stage renal disease or treatment of cancer with cytostatic agents. Side effects include hypertension and increased risk of thrombosis.

Inhibitors of Cytokine Action

Inhibition of hematopoietic growth factors: Imatinib (Glivec®) is applied to treat chronic myeloid leukemia in Philadelphia-chromosome positive patients. In these patients, translocation of parts of chromosomes 9 and 22 results in the expression of a fusion protein with increased tyrosine kinase activity, called Bcr-Abl. Imatinib is a small Mw inhibitor selective for the tyrosine kinase activity of Bcr-Abl. Thereby, it inhibits the Bcr-Abl induced cell cycle progression and the uncontrolled proliferation of tumor cells.

Inhibition of immunomodulatory cytokines (Fig. 1): Anti-T-cell receptor antibodies: Muromonab (OKT3, Orthoclone®) binds to the CD3 complex of the T-cell receptor and induces depletion of T-lymphocytes. It is applied to prevent acute rejection of kidney, liver, and heart allografts. Rapid side effects (within 30–60 min) include a cytokine release syndrome with fever, flu-like symptoms, and shock. Late side effects include an increased risk of viral and bacterial infections and an increased incidence of lymphoproliferative diseases due to immunosuppression.

Humanized recombinant anti-IL-2 receptor antibodies (Basiliximab, Simulect®, and Daclizumab Zenapax®). These antibodies bind with high affinity to the IL-2 receptor on T-lymphocytes and prevent activation and clonal expansion of anti-allograft T-lymphocytes by endogenous IL-2. They are used to prevent kidney allograft rejection. The main side effect is immunosuppression.

Intracellular inhibition of interleukin-2 production and activity: The immunosuppressants Cyclosporin (Sandimmune®), Tacrolimus (Prograf®), and Sirolimus (Rapamune®) are used for the prophylaxis of allograft rejection. Cyclosporin binds to the intracellular protein cyclophilin, and Sirolimus binds to the intracellular protein FKBP12. The resulting complexes inhibit a serine-threonine phosphatase, calcineurin, which is required for T-lymphocyte activation and for IL-2 gene expression. Sirolimus also binds to FKBP12. However, the complex inhibits a different enzyme, the protein kinase mTOR (mammalian target of rapamycin); thereby, it inhibits IL-2-dependent progression of activated T-lymphocytes through the cell cycle. All three drugs suppress clonal expansion of antigen-activated T-lymphocytes. Cyclosporin and Tacrolimus

Cytokines. Figure 1 Inhibition of cytokine synthesis during activation of the specific immune system. The monoclonal antibodies Muromonab and Basiliximab are specific for the CD3 complex of the T-cell receptor, and for the IL-2 receptor on lymphocytes, respectively. Cyclosporin and Tacrolimus inhibit activation of cytoplasmic NF-AT, a transcription factor essential for activation of the IL-2 gene (►NFAT Family of Transcription Factors). Sirolimus interferes with mTOR signaling and inhibits IL-2 dependent proliferation. Red: pharmaka, blue: target proteins.

are nephrotoxic, and Sirolimus causes hyperlipidemia. For further details see ►Immunosuppressive Agents.

Inhibition of inflammatory cytokines (Fig. 2): Humanized monoclonal anti-TNF antibodies (Infliximab (Remicade®), Adalimumab (Humira®)) bind with high selectivity to human TNF- α and neutralize its activity. Thereby, infliximab decreases the effects of enhanced TNF levels during inflammatory disease such as production of proteases, chemokines, adhesion molecules, cyclooxygenase products (prostaglandins), and proinflammatory molecules such as interleukin-1 and -6. The antibodies may also recognize membrane-bound TNF- α on lymphocytes and other immune cells. These cells may subsequently become apoptotic or are eliminated via Fc-receptor-mediated phagocytosis.

The antibodies are used to treat Crohn's disease, Psoriasis (including Psoriasis arthritis), Spondylitis ankylosans, and rheumatoid arthritis. Side effects

include immunosuppression and increased risk of infections.

Recombinant soluble TNF-RI-IgG1 fusion protein Etanercept, Enbrel® is a chimeric molecule consisting of the extracellular domain of the TNF receptor I (TNF-RI) and the Fc portion of human IgG1. Two Fc domains are bound to each other via disulfide bonds, thereby yielding dimers with two binding sites for the TNF trimer. Etanercept binds with high affinity to extracellular TNF and reduces TNF activity. Etanercept is not effective in Crohn's disease, possibly because it does not lead to destruction of membrane TNF- α expressing cells. Indications and side effects are similar to those of Infliximab and Adalimumab.

Recombinant human IL-1 receptor antagonist (Anakinra, Kineret®) blocks the biological activity of interleukin-1 by competitively inhibiting IL-1 binding to the interleukin-1 type I receptor (IL-1RI), which is expressed in a wide variety of tissues and organs. Thereby it reduces the pro-inflammatory activities of IL-1 including cartilage destruction and bone resorption. Side effects include an increased risk of infections and neutropenia.

Outlook: The anti TNF and anti IL-1 therapies are being improved by modifications such as addition of polyethylene glycol (PEG) to optimize pharmacokinetic parameters or by the development of inhibitors that can be administered orally. The concept of genetically engineered antibodies or cytokine traps is currently being expanded to include many more cytokines (e.g., IL-6 and IL-4). Many different protein kinase inhibitors that target central effector molecules in the intracellular signaling pathways downstream of cytokine receptors are in different phases of clinical testing. It can be expected that some of them – like the inhibitors of IL-2 signaling described above – will be approved soon to treat human inflammatory disease.

Definition

► **Microtubules**, ► **F-actin** (microfilaments) and ► **intermediate filaments** form the cytoskeleton. These polymeric structures are highly dynamic and respond to extracellular signals. Thus, they mediate the adaptation of the cellular architecture to functional changes. They are essential for cell attachment, motility and proliferation, and organize the intracellular transport and compartments. In addition, cytoskeletal elements anchor receptors and ion channels in the cell membrane and organize the subsequent signal transduction pathways. Several drugs are known that specifically affect microtubules and microfilaments. In contrast, the specific pharmacological manipulation of intermediate filaments is presently not possible. Therefore, the present chapter will not deal with intermediate filaments.

Basic Characteristics

Organization of Microtubules

The globular polypeptides α - and β -**tubulin** have molecular weights of about 50 kDa. In mammals 6 known α -tubulin and 7 known β -tubulin genes are expressed in a cell-type specific manner. Whereas α - as well as β -tubulins bind GTP, only the GTP bound by β -tubulin is exchangeable. α - and β -tubulins associate to heterodimers that polymerize head-to-tail to form protofilaments, 13 of which make up a hollow tube of 25 nm diameter, a microtubule (MT) (Figure 1a). These polarized structures have GTP-binding β -tubulins at the plus ends and α -tubulins at the minus ends. β -tubulins within the protofilament are in the GDP-binding state. Heterodimers can be added or released during processes called “dynamic instability” and “treadmill-

ing.” Dynamic instability of MTs is characterized by abrupt stochastic transitions among phases of growing, shortening and pause. In most cells, the plus end grows and shrinks, while the unstable minus end shrinks, if it is not stabilized by capping proteins. Treadmilling is a net addition of tubulin heterodimers at the plus end and the balanced net loss from the minus end.

MT-associated proteins (MAPs) are attached to MTs in vivo and play a role in their nucleation, growth, shrinkage, stabilization and motion. Of the MAPs, the tau family proteins have received special attention as they are involved in the pathophysiology of Alzheimer’s disease.

MTs are stabilized at their minus ends by the ► **centrosome** (also called microtubule organizing center, MTOC). Centrosomes are protein complexes containing among other proteins two centrioles (ring-like structures) and α -tubulin. Centrosomes serve as nucleation points for microtubular polymerization and constrain the lattice structure of an MT to 13 protofila-

Cytoskeleton. Figure 1 Cytoskeleton – see text for further explanation.

ments. Centrosome-independent nucleation is possible and may be induced by DNA or proteins such as cadherin. At the plus end, capping proteins such as mDIA can stabilize MTs. Stable MTs often are acetylated at lysine-40 of α -tubulin and detyrosinated at the C-terminal of the β -tubulin.

► **Motor proteins** move along MTs in an ATP-dependent manner. Members of the superfamily of kinesin motors move only to the plus ends and dynein motors only to the minus ends. The respective motor domains are linked via adaptor proteins to their cargoes. The binding activity of the motors to MTs is regulated by kinases and phosphatases. When motors are immobilized at their cargo-binding area, they can move MTs.

MTs extend from the centrosome throughout the cytoplasm to the plasma membrane, where they are stabilized by caps. Sliding along the MTs, kinesin and dynein motors transport their cargoes between the center and the periphery of the cell. MTs present in the axons of neurons are extended not only by addition of heterodimers to the plus ends but also by use of short MTs that initiate in the centrosome. Their axonal transport is mediated by dynein motors that are passively moved along actin filaments. Once formed in the axon, MTs serve as tracks for the fast axonal transport, i.e. the movement of membranous organelles and membrane proteins to the nerve ending.

Functions of MTs

Some specialized eukaryotic cells have cilia that show a whiplike motion. Sperm cells move with one flagella, which is much longer than a cilium but has a nearly identical internal structure called axoneme. It is composed of nine doublet MTs that form a ring around a pair of single MTs. Numerous proteins bind to the MTs. Ciliary dynein motors generate the force by which MTs slide along each other to cause the bending of the axoneme necessary for motion.

The membrane tubules and lamellae of the endoplasmic reticulum (ER) are extended in the cell with the use of MTs and actin filaments. Kinesin motors are required for stretching out the ER, whereas depolymerization of microtubules causes the retraction of the ER to the cell centre in an actin-dependent manner. Newly synthesized proteins in the ER are moved by dynein motors along MTs to the Golgi complex (GC), where they are modified and packaged. The resulting vesicles move along the MTs to the cell periphery transported by kinesin motors. MTs determine the shape and the position also of the GC. Their depolymerization causes the fragmentation and dispersal of the GC. Dynein motors are required to rebuild the GC.

When cells enter mitosis, the interphase array of MTs is dismantled. The centrosome duplicates, and the daughters move to opposite poles of the nucleus. After disassembly of the nuclear envelope, MTs emanat-

ing from both centrosomes show pronounced dynamic instability. They grow and shorten and thus probe the cytoplasm until they find attachment sites at the condensed chromosomes, the ► **kinetochores**. Dynein motors are involved in the attachment and in the subsequent segregation of the two sets of chromosomes. In some cells, spindles are formed in the absence of centrosomes. Here, microtubular nucleation is initiated at the kinetochores by DNA itself with the help of the GTPase Ran and/or the microtubule-destabilizing factor stathmin. Kinesin and dynein motors then bundle and focus the MTs at their minus ends [1].

Organization of Actin Filaments (F-actin)

Globular actin (► **G-actin**) has a molecular weight of about 42 kDa. In higher vertebrates, the 6 isotypes are expressed in a cell-specific manner, which contain 374/375 residues. They are present in striated muscle cells (skeletal and cardiac isotypes), smooth muscle cells (vascular and visceral isotypes) and in non-muscle cells such as neurons and glial cells (2 isotypes). All isotypes are N-terminally acetylated and bind ATP/ADP. F-actin is a double-stranded, right-handed helix with 14 actin molecules per strand and turn. F-actin has a diameter of 8 nm and is polarized with a pointed (minus) and a barbed (plus) end. The length of F-actin is regulated by dynamic instability and treadmilling (Figure 1b). Within the F-actin polymer the ATP of an actin protomer is hydrolyzed to ADP. Once the inorganic phosphate is dissociated from the actin-ADP complex, the actin molecule will ultimately dissociate from the pointed end. After exchange of ADP to ATP, G-actin binds to the protein profilin and is ready for the next cycle (Fig. 1c).

Numerous ► **actin binding proteins** (ABPs) influence the turnover of F-actin. They are regulated in their activity via membrane receptors and thus transmit extracellular stimuli to the actin cytoskeleton. The ► **small GTPases** of the Rho family RhoA, Rac1 and Cdc42 are important mediators in the signal transduction pathway (Fig. 1c). Upon stimulation they activate proteins of the WASP/Scar family that bind to and activate the Arp2/3 complex. Subsequently ATP-G-actins bound to profilin are nucleated, i.e. two ATP-binding G-actins self-assemble side by side and further G-actins are added in a head-to-tail fashion (Fig. 1c). Alternatively, branches may be formed on existing actin filaments. Capping proteins that bind to the barbed end can block further elongation. Proteins of the ADF/cofilin family can sever and depolymerize ADP actin filaments.

Functions of F-actin

The interaction with myosin motors enables F-actin to transport molecules as well as to change or maintain the shape of the cell by exerting tension. Thus, myosin-I motors move to the barbed end and can transport cargoes such as vesicles. When immobilized at the cargo site

they can move actin filaments. Two myosin-II motors can assemble in an antiparallel manner. Attached to antiparallel F-actin, they can slide the actin filaments over each other and thus cause contractions. Such actomyosin interactions are essential for skeletal muscle contraction. Moreover, the contractile ring formed in the telophase of the cell cycle is an actomyosin structure that separates the filial cells during cytokinesis. In addition, actomyosin interactions play critical roles in the regulation of the morphology, adhesion and migration of non-muscle cells. Obviously, drugs that destroy F-actin have profound effects on cell shape and proliferation. In addition, F-actin plays an important role in cell adherence and motility.

Drugs

Drugs with Actions on MTs

Numerous drugs bind to β -tubulin and thus affect the function of MTs. The alkaloids vinblastine and vincristine extracted from the plant *Catharantus roseus* (also called *Vinca rosea*) and the semisynthetic derivatives vindesine, vinorelbine, and vinflunine can block mitosis and are clinically used for cancer treatment. When used at micromolar concentrations, the alkaloids bind with 1:1 stoichiometry to β -tubulin in a region between residues 175 and 213. The bound disassembled tubulin heterodimers can no longer polymerize to MTs and form paracrystalline tubulin-*Vinca* alkaloid arrays. Pre-existent MTs are subsequently depolymerized. Chromosomes are no longer separated but dispersed or clumped in the cytoplasm. The cells undergo apoptosis. When used at nanomolar concentrations, *Vinca* alkaloids may block mitosis at the metaphase–anaphase transition by inhibiting the dynamic instability and treadmilling of MTs, without affecting microtubular mass [2]. The cytostatic agent estramustin has similar effects. It blocks heterodimer polymerization at micromolar concentrations and inhibits dynamic instability at nanomolar concentrations.

In contrast, paclitaxel (isolated from the bark of the yew tree *Taxus brevifolia*) and its more potent analogue docetaxel (from *Taxus bacca*) bind to microtubules when used at nanomolar concentrations. By attaching to β -tubulin between amino acids 239 and 254, the agents block the release of heterodimers from MTs and prevent the dynamic instability necessary for the capturing of chromosomes without affecting microtubular mass. Both taxols are used for cancer treatment. There is evidence that the β -tubulin isotypes differ in their sensitivity to taxols. Thus, the upregulation of β -tubulin III expression in glioma as well as in lung and prostate cancer cells corellates with the resistance to taxols [3]. Their severe side effects include neurotoxicity, neutropenia, cardiac effects and immunosuppression. Taxols can lose their cellular activity due to the multi-drug resistance P-glycoprotein transporter. In addition, their aqueous insolubility makes

their application difficult. Therefore, several new compounds are currently under investigation [4].

The epothilones A and B are produced by the myxobacterium *Sorangia cellulorum*. They compete with taxols for microtubular binding sites, but in contrast to taxols are not substrates of the P-glycoprotein transporter. Discodermolide produced by the sponge *Discodermia dissoluta* competes with taxols for microtubular binding sites but has different properties. Unlike taxols and epothilones, it is active in cells with β -tubulin mutations. In addition, it has pronounced synergistic effects with taxols. It is active in cells that express the P-glycoprotein transporter. Further products investigated for their taxol-like effects are laulimalide and isolaulimalide from the sponge *Cacospongia mycofijiensis* and eleutherobin from the soft coral *Eleutherobia* [4].

In addition, the alkaloid colchicine (from *Colchicum autumnale*) blocks tubulin polymerization by binding to heterodimeric β -tubulin between amino acids 239 and 254. Since it inhibits the MT-dependent migration of granulocytes into areas of inflammation and their MT-dependent release of proinflammatory agents, it is used to treat attacks of gout. Its antimitotic effect in the gastrointestinal system induces diarrhoea. Nocodazole competes for the binding site of colchicine and has similar effects on heterodimeric β -tubulin.

In view of the importance of the motor dynein for microtubular function, this protein is currently considered as a new target for the development of cytostatic agents.

Drugs with Actions on F-actin

Several agents affect the turnover of F-actin. They are not used therapeutically but serve as experimental tools to study the role of F-actin in cell function.

The ►cytochalasins A, B, C, D, E, and H are found in various species of mould. Mainly cytochalasin B and D are used as experimental tools. Cytochalasin D is 10 times more potent, acting at concentrations between 2 and 35 nM in cell-free systems. Cytochalasins bind to the barbed end of F-actin and block the addition as well as dissociation of G-actin at that end. At micromolar concentrations, cytochalasin D can bind to G-actin and actin dimers and thus block additional polymerization. When applied to cultured cells, micromolar concentrations of cytochalasins remove stress fibres and other F-actin structures.

Swinholide A, isolated from the marine sponge *Theonella swinhoei*, sequesters actin dimers and induces their formation. One molecule of swinholide A binds to one dimer. In addition, swinholide A can sever F-actin by binding to the neighbouring protomers. Increased depolymerization of F-actin has also been reported.

Several toxins produced by marine sponges cause the destabilization of F-actin. They contain a macrocyclic ring and an aliphatic chain, by which they bind to actin protomers. The toxins that include reidispongioides,

sphingolides, aplyronins, mycalolides, ulapualides, halichondramides and kabiramides are currently investigated for their potential use in cancer treatment [5].

Latrunculins A and B are macrolides from the sponge *Latrunculia magnifica*. Latrunculin A (≥ 50 nM) binds close to the nucleotide binding site of G-actin and blocks the assembly with F-actin without promoting disassembly.

Phalloidin and phalloidin are cyclic peptides from the mushroom *Amanita phalloides* that stabilize F-actin. Phalloidin binds to residues 114–118 of an actin protomere and blocks nucleotide exchange without interfering with nucleotide hydrolysis. It enhances the rate of nucleation as well as that of elongation. It slowly penetrates the cell membrane and is used for immunocytochemical localization of F-actin.

In contrast, jasplakinolide, a cyclodepsipeptide from the marine sponge *Jaspis johnstoni*, rapidly penetrates the cell membrane. It competes with phalloidin for F-actin binding and has a dissociation constant of approximately 15 nM. It induces actin polymerization and stabilizes pre-existing actin filaments. Dolastatin 11, a depsipeptide from the mollusk *Dolabella auricularia*, induces F-actin polymerization. Its binding site differs from that of phalloidin or jasplakinolide.

Cytotoxic Agents

► Antineoplastic Agents

Cytotoxic T-cells

Cytotoxic T-cells, or cytolytic T-cells (CTLs), are effector cells of the immune system that carry the CD8⁺ surface marker. These cells are able to recognize autologous cells expressing foreign antigens (e.g., virus infected cells). Recognition is depending on the recognition of the MHC-I molecule by the T-cell receptor present on CTLs. This interaction of CTLs and target cells can lead to the lysis of the target cell.

Databank

In the biosciences, a databank (or data bank) is a structured set of raw data, most notably DNA sequences from sequencing projects (e.g. the EMBL and GenBank databases).

► Bioinformatics

Database

A database (or data base) is a collection of data that is organised so that its contents can easily be accessed, managed, and modified by a computer. The most prevalent type of database is the relational database which organises the data in tables; multiple relations can be mathematically defined between the rows and columns of each table to yield the desired information. An object-oriented database stores data in the form of objects which are organised in hierarchical classes that may inherit properties from classes higher in the tree structure.

In the biosciences, a database is a curated repository of raw data containing annotations, further analysis, and links to other databases. Examples of databases are the SWISSPROT database for annotated protein sequences or the FlyBase database of genetic and molecular data for *Drosophila melanogaster*.

Death Domain and Death Receptors

Extrinsic apoptosis signaling is mediated by so-called *death receptors*. Besides Tumor Necrosis Factor receptor type I (TNFR1) the group of death receptors comprises seven additional members (Fas, DR3 [death receptor 3], DR4 [TRAIL-R1 {TNF-related apoptosis-inducing ligand receptor 1}], DR5 [TRAIL-R2], DR6, p75-NGFR [p75-nerve growth factor receptor], and EDAR [ectodermal dysplasia receptor]). Death receptors belong to the tumor necrosis factor receptor gene superfamily. Signaling of these death receptors is mediated by their cytoplasmic part containing a conserved sequence of approximately 90 amino acids length termed *death domain* (DD) (► [Death Domain Superfamily](#)). Adapter molecules, also possessing a DD, like FADD or TRADD, can be recruited to these receptors by homophilic DD/DD interactions, thereby initiating caspase activation and apoptotic signals.

► Tumor Necrosis Factor (TNF)

► Apoptosis

► Caspases

Death Domain Superfamily

Death domain (DD) superfamily consists of structurally related homotypic interaction motifs of approximately 90 amino acids. The motifs are organized in six antiparallel amphipathic α -helices, the so-called DD fold. The four members of the superfamily are the death domain (DD), the death effector domain (DED), the caspase activation and recruitment domain (CARD), and the Pyrin domain. All are important mediators for the assembly of caspase activating complexes.

Defensins

Definition

Defensins are a group of antimicrobial and cytotoxic peptides made by immune cells. There are seven defensins in humans, six alpha-defensins and one beta-defensin, which are involved in the innate immune defense at the surface of epithelia from the respiratory tract, the intestinal tract or the urinary tract.

- ▶ Immune Defense
- ▶ Nuclear Factor Kappa B

Delayed-rectifier K⁺ Channels

Delayed-rectifier K⁺ channels activate with a delay and mediate outwardly-rectifying K⁺ currents. These channels may make a significant contribution to the repolarizing phase of nervous action potentials.

- ▶ K⁺ Channels

Delayed Type Hypersensitivity Reaction

Delayed type hypersensitivity (DTH) reactions (synonym type IV allergic reactions) are exaggerated, T-lymphocyte mediated, cellular immune reactions to foreign substances, which require one to two days to manifest clinical symptoms.

- ▶ Allergy

Dendritic Cells

Dendritic cells (DC) are important antigen-presenting cells mostly derived from the bone marrow. Microscopically they show characteristic long cytoplasmic extensions called “dendrites.” There are several types of specialized DC present in all lymphoid tissues and major

organs, in particular in the skin where they are also called Langerhans Cells. Another specialized population called plasmacytoid DC is found in the marginal zone of the spleen and represents the major IFN- α producing cell type in the organism. DC are constantly sensing their environment for antigenic material derived from pathogenic microorganisms or allergens with the help of DC-specific pattern recognition receptors such as Toll-like receptors. Following antigen uptake and activation, DC migrate to lymphoid organs to present processed antigen to T- and B-lymphocytes.

- ▶ Immue Defense

Dependence

Dependence is a somatic state which develops after chronic administration of certain drugs. This condition is characterized by the necessity to continue administration of the drug to avoid the appearance of withdrawal symptoms. Withdrawal symptoms are relieved by the administration of the drug upon which the body was “dependent”. Psychological dependence is due to (e.g., social) reinforcement processes in the maintenance of drug-seeking behavior.

- ▶ Drug Addiction/Dependence

Depolarisation

A reduction in charge separation across the plasma membrane resulting in a less negative membrane potential. For example, a change from a resting potential of -60 to -40 mV. The membrane potential is always measured as the charge on the inside of the cell relative to outside, and has a negative value at rest reflecting the unequal distribution of charged species (small ions and charged molecules including proteins) across the membrane. The summation of temporally and spatially related depolarisations can reach a ‘threshold’ value that triggers the opening of voltage-dependent ion channels, producing a rapid, large ‘all or none’ depolarisation called an action potential. In skeletal muscle cells this results in muscle contraction.

Descending Inhibitory Pathway

The descending inhibitory pathway is an endogenous pain-suppressing system, which becomes activated especially under pathological conditions, when stress is present. A key part of this system is an area of the midbrain, called the “▶periaqueductal grey” (PAG). The PAG is rich in enkephalin-containing neurons. It receives inputs from many other brain regions, including the hypothalamus, cortex and thalamus. These connections may represent the mechanism whereby cortical and other inputs control pain perception. Activation of PAG neurons leads to the activation

of neurons in the rostroventral medulla, which includes the nucleus raphe magnus. From the nucleus raphe magnus, serotonin- and enkephalin-containing neurons project to the substantia gelatinosa of the dorsal horn of the spinal cord and exert their inhibitory influences on nociceptive transmission. There is also a noradrenergic pathway, which originates from the locus ceruleus, which also has an inhibitory effect on the nociceptive transmission in the dorsal horn. The PAG and the substantia gelatinosa are especially rich in enkephalin-containing neurons, suggesting that opioid peptides function as transmitters in this system. The antinociceptive effects of opioids are believed to be at least partly mediated by effects on the descending inhibitory pathway.

- ▶ Nociception

Desensitised State

A condition in which a receptor is unresponsive despite the presence of agonist; also referred to as a ‘refractory state’. Typically this state is the consequence of prolonged exposure to agonist, and occurs after receptor activation; it is a built in mechanism to limit a receptor’s effects. Mechanistically the desensitised state differs from the resting, closed state of a receptor because in the latter state, a receptor *can* respond to agonist. This difference predicts that these states are structurally distinct. The desensitised state may also be stabilised by very low concentrations of agonist, such that no measurable activation of the receptor precedes it. Desensitisation is an intrinsic property of many receptors but can also be influenced by other interactions or modifications, such as phosphorylation.

- ▶ Ionotropic Glutamate Receptors
- ▶ Nicotinic Receptors
- ▶ Neurotransmitter Transporters

Desensitization

Desensitization is the rapid attenuation of receptor activation as a result of stimulation of cells and occurs in seconds to minutes. Receptor phosphorylation

by G-protein-coupled receptor kinases and second-messenger-regulated kinases as well as receptor/G-protein uncoupling contribute to this process. In the continued presence or at high concentrations of agonistic ligands, ligand gated ion channels may undergo desensitization by entering a permanently closed state. While the ligand binding domain is occupied by the agonist, the desensitized channel is unable to re-open. For ligand-gated ion channels, the structural basis of desensitization is not understood. For voltage-gated K^+ channels, the 'ball and chain' model suggests a mechanism of ion channel desensitization.

Desmoplakin

Desmoplakin is the most abundant desmosomal component that plays a critical role in linking intermediate filament networks to the desmosomal plaque. Desmoplakin forms rod-like dimers that bind to intermediate filaments and to the cadherin-associated proteins plakoglobin and plakophilin. Gene knock-out experiments have revealed an essential role of desmoplakin in establishing cell-cell contacts in early mouse embryos.

Deubiquitinating Enzymes (DUBs)

The human genome contains more than 90 different DUBs. Besides cleaving ubiquitin from distinct substrates, DUBs are also responsible for the recycling of free ubiquitin from ubiquitin chains and processing of ubiquitin- or ubiquitin like precursor proteins. Certain DUBs are also associated with the proteasome in order to detach ubiquitin chains before proteolysis.

- ▶ Ubiquitin/Proteasome

Dexamethasone

Synthetic steroid with strong glucocorticoid-agonistic activity. Dexamethasone is over 10 times more potent than cortisol due to a higher binding affinity for glucocorticoid receptor and a decreased clearance rate of the compound. Due to its potency, dexamethasone is widely used in the clinics for the treatment of inflammatory diseases.

Synonyms

Diabetes mellitus

Definition

Diabetes mellitus is defined as hyperglycaemia (fasting > 7 mM and/or 2 h postprandial > 11.1 mM) due to absolute or relative lack of insulin. The most common forms are type 1 diabetes (prevalence 0.25%), with absolute lack of insulin, and type 2 diabetes (prevalence 4–6%) which is due to the combination of insulin resistance and insufficient insulin secretion.

Basic Mechanisms

Type 1 Diabetes (Previously Insulin-Dependent Diabetes Mellitus, IDDM, or Juvenile Diabetes)

Progradient destruction of insulin-secreting β -cells by an autoimmune mechanism during a period of several years [1]. The diagnosis is confirmed by detection of antibodies against β -cell proteins (glutamic acid decarboxylase, tyrosine phosphatase IA-2, insulin). Islet cell destruction is probably mediated by activated T lymphocytes. There is a genetic susceptibility to type 1 diabetes, and several predisposing loci (e.g. the MHC locus) and alleles of genes associated with the disease risk (the insulin gene, PTPN22, CTLA-4) have been identified [1]. In addition, genetic and epidemiological data indicate a strong environmental factor in the pathogenesis.

Type 2 Diabetes (Previously non-Insulin-Dependent Diabetes Mellitus, NIDDM)

Type 2 diabetes is a frequent consequence of the ►metabolic syndrome (obesity, insulin resistance, dyslipidemia, hypertension). Obesity causes insulin resistance which is initially compensated by hyperinsulinemia. In the course of insulin resistance, the β -cell function deteriorates and insulin secretion is reduced, leading to relative insulinopenia. In particular, the initial response (first phase) of the pancreas to a glucose load is impaired during the first stages of the disease. Fasting hyperglycaemia is preceded by a variable period of impaired glucose tolerance (IGT) during which secondary complications (micro- and macrovascular) start to develop. Thus, in many type 2 diabetics, secondary complication can be diagnosed at the time of the detection of hyperglycaemia; these are accelerated and aggravated by other components of the metabolic syndrome (dyslipidemia, hypertension).

Obesity and insulin resistance appear to be due to a heterogenous combination of genes involved in the control of appetite and thermogenesis. Several genes have been identified that are involved in the regulation of food intake and of body weight (e.g. leptin, the leptin receptor, melanocortin receptors; see chapter on appetite control). However, the genes responsible for the polygenic obesity are largely unknown. Data obtained from rodent models indicate that islet cell failure is produced by a different set of genes; obesity is a necessary condition for their effects on the pancreas. This interaction of two different genetic constellations (obesity and diabetes genes) explains the heterogeneity of the type 2 diabetes with regard to its association with body weight.

The molecular pathology of the β -cell destruction in the course of insulin resistance is largely unknown. It has been suggested that the constant hyperstimulation of the β -cell by glucose ('glucose toxicity') or elevated fatty acids ('lipotoxicity') may lead to cell damage.

Pharmacological Intervention

Type 1 diabetes always requires treatment with insulin. The preferred therapeutic regimen is the 'intensified conventional therapy' (ICT) which combines 1–2 daily injections of a retarded insulin (usually NPH insulin) with 3–4 injections of a short-acting insulin (e.g. regular insulin) at mealtimes. ICT requires 4–5 daily blood sugar determinations and adjustment of the dose to (preprandial) blood sugar and (estimated) carbohydrate content of meals. If the complicated ICT regimen is not feasible, a conventional regimen (CT) may be employed which comprises two daily injections of a combination of NPH with regular insulin (two thirds of the daily dose before breakfast, one third before dinner). CT usually applies constant doses of insulin and requires a stricter adherence to the diet than ICT, i.e. meals that contain a controlled carbohydrate content and are timed according to the profile of the insulin injections.

Insulin preparations (Table 1): Recombinant human insulin obtained from genetically engineered *E. coli* or yeast is used predominantly. Retarded preparations are generated by addition of protamine (*NPH insulin*, neutral protamine Hagedorn) which may provide the 'basal' supply in both ICT and CT. Five insulin analogs with altered amino acid sequence and different pharmacokinetic characteristics are available: *insulin lispro* (swap of B28 proline and B29 lysine), *insulin aspart* (exchange of aspartate for B28 proline), and *insulin glulisine* (exchange of lysine for asparagine B3 and glutamate for lysine B29) exhibit a more rapid onset and a shorter duration of action because of a faster dissociation of the hexameric insulin–zinc–phenol complex. *Insulin glargine* is a long-acting analogue which is soluble at low pH because of two additional arginines

Diabetes Mellitus. Table 1 Pharmacokinetic characteristics of the most commonly used insulin preparations and analogs

	onset of action	maximum	duration of action
<i>short acting insulins:</i>			
insulin lispro	15 min	½–1 h	2–5 h
insulin aspart	15 min	½–1 h	2–5 h
insulin glulisine	15 min	½–1 h	2–5 h
regular insulin	30 min	1–2 h	5–8 h
<i>long acting insulins:</i>			
NPH insulin	30–60 min	2 h	11–20 h
insulin glargine	60 min	4 h	12–30 h
insulin detemir	60 min	5–8 h	12–22 h

at the C terminus of the B chain. After injection, the analogue precipitates from its solution and forms a long-acting depot with a steady absorption kinetic. *Insulin detemir* lacks threonine B30 and is myristoylated at lysine B29. Binding of the analogue to serum albumin is responsible for its longer duration of action which is comparable to that of *insulin glargine*.

Type 2 diabetes: After clinical diagnosis, weight normalization by hypocaloric, low-fat diet and exercise may normalize glucose homeostasis for a period of several years. Accordingly, this intervention markedly delays the onset of overt hyperglycaemia when employed at the stage of IGT. Because the ‘lifestyle changes’ are difficult to maintain, and because of the progression of the islet cell failure, pharmacological intervention will usually become inevitable and has to be intensified throughout the course of the disease. Initially, normalization of blood sugar can be accomplished with oral antidiabetics. Later on, a combination of oral antidiabetics with insulin or insulin alone (preferably ICT) will be required.

β-Cytotropic agents: These agents enhance the effect of glucose on the secretion of insulin [2]. Commonly used drugs are sulfonylurea derivatives and the more recently introduced benzoic acid derivatives ► [repaglinide](#) and [nateglinide](#). Their receptor is a membrane protein (SUR, ► [sulfonylurea receptor](#)) which regulates the activity of the ATP-dependent potassium channel of the pancreatic β-cell (Kir 6.2). Binding of ATP, or of a sulfonylurea, to SUR reduces the potassium current and causes membrane depolarization, subsequently opening of voltage-gated calcium channels, and calcium-stimulated exocytosis of insulin-containing granules (Fig. 1). Lack-of-function mutants of SUR are characterized by an increased secretion of insulin (congenital hypoglycaemia). The effect of the β-cytotropic agents on the channel is antagonized by the ‘potassium channel openers’ diazoxide and minoxidil.

Two isotypes of SUR have been cloned, SUR1 and SUR2. In addition, two splicing variants of SUR2, distinguished by 42 C-terminal amino acids, have been

identified. SUR1 is mainly expressed in β-cells. SUR2B is expressed in vascular smooth muscle, heart, skeletal muscle and brain, whereas expression of SUR2A is restricted to heart and skeletal muscle. Sulfonylureas exhibit a higher affinity for the SUR1. Block of SUR2 by minoxidil or diazoxide produces vasodilation; stimulation of SUR2 by high, non-therapeutic concentrations of glibenclamide produces vasoconstriction. A potential effect of sulfonylureas on the cardiac SUR2, producing cardiac arrhythmia in particular under ischemic conditions, is a matter of ongoing debate.

To date, the commonly used sulfonylureas are the long-acting derivatives glibenclamide (US synonym: glyburide) and glimepiride. Glimepiride is believed to have a somewhat longer duration of action than glibenclamide, and to exert additional extrapancreatic effects. The mechanism of these potential extrapancreatic effects is not defined, and their clinical relevance is unclear. The non-sulfonylurea potassium channel blockers repaglinide and nateglinide have been shown to act by the same mechanism of action as the sulfonylureas. The duration of action of repaglinide and nateglinide is short because of their rapid metabolism and/or excretion. These pharmacokinetic parameters are thought to allow a specific reduction of postprandial glucose excursions. However, because the effects of the potassium channel openers largely depend on plasma glucose levels, both long- and short-acting agents mainly stimulate a postprandial insulin secretion. A potential advantage of the short-acting derivatives might be a reduced risk of hypoglycaemia.

Exenatide: ► [Exenatide](#) is a peptide which mimics the effect of glucagon-like peptide 1 (GLP-1) in stimulating glucose-dependent insulin secretion from β-cells and inhibiting glucagon secretion from α-cells [3]. Exenatide is injected subcutaneously and improves glycaemic control in type 2 diabetics and causes a significant reduction of body weight.

DPP-IV inhibitors: Inhibition of the dipeptidyl peptidase IV (by ► [sitagliptin](#) or ► [vildagliptin](#)) prolongs the duration of action of endogenous GLP-1 and thereby

Diabetes Mellitus. Figure 1 Mechanism of insulin secretion and its stimulation by β -cytotropic agents. Glucose enters the β -cell via GLUT2, is phosphorylated by glucokinase, and generates ATP. Rise in the ATP-ADP ratio results in closure of ATP-dependent K^+ channels, membrane depolarization and opening of voltage-gated Ca^{2+} channels. Ca^{2+} influx activates the exocytosis of insulin-containing secretory granules. The ATP-dependent K^+ channel consists of Kir6.2 (a K^+ inward rectifier) and SUR (sulfonylurea receptor). Sulfonylureas block the ATP-dependent K^+ channels by enhancing the effect of ATP.

improves glycaemic control, either alone or in combination with other antidiabetic agents [4].

Metformin: The biguanide ►metformin lowers blood sugar mainly by inhibition of glucose output from the liver. It is generally accepted that this effect reflects a marked inhibition of gluconeogenesis and lipogenesis, presumably mediated by a stimulation of the AMP-dependent kinase [5]. Other effects of metformin (stimulation of glucose transport in muscle, inhibition of intestinal glucose absorption) require higher concentrations and appear to contribute little to the in-vivo effect.

Under certain circumstances, and very rarely, the inhibition of gluconeogenesis by metformin may suppress lactic acid metabolism and precipitate a potentially fatal lactic acidosis. Impairment of renal function, liver disease, alcoholism, conditions that give rise to increased lactate production (e.g. congestive heart failure, infections) are therefore contraindications for the application of metformin.

Oral formulations of metformin are rapidly and completely absorbed. The agent is poorly bound to plasma proteins; its duration of action is determined exclusively by renal elimination. Higher concentrations of metformin than in most tissues are found in the intestinal mucosa, giving rise to common side effects (irritation, diarrhoea etc.).

Acarbose and Miglitol: These agents are specific inhibitors of intestinal glucosidases and reduce the conversion of sucrose and starch to glucose. Their main effect is a delay, not a complete inhibition, of the absorption of carbohydrates. Postprandial blood sugar excursions are effectively reduced. Because a small portion of the carbohydrates enters the colon, their microbial degradation frequently causes flatulence or

meteorism. Acarbose produces a somewhat lower reduction of HbA_{1c} levels than glibenclamide and metformin, but may enhance the effect of these agents. When given to patients with IGT, acarbose reduces the progression of the disease to overt hyperglycaemia by 30%.

Thiazolidinediones (PPAR γ -agonists): Thiazolidinediones (►pioglitazone, ►rosiglitazone) lower blood glucose levels in animal models of insulin resistance and also in insulin resistant patients. They are agonists of the ►peroxisome proliferator-activated receptor γ (PPAR γ). Because they enhance the effect of insulin and reduce serum insulin levels in insulin resistant patients, thiazolidinediones are usually referred to as 'insulin sensitizers'.

PPAR γ is a transcription factor which controls the expression of enzymes and proteins involved in fat and glucose metabolism. More importantly, stimulation of this receptor induces differentiation of preadipocytes to adipose cells. It is believed that the formation of additional, small fat cells lowers free fatty acids and hepatic triglycerides, thereby correcting insulin resistance.

ryanodine receptor (RyR1), resulting in Ca^{2+} release through RyR1. Ca^{2+} -induced Ca^{2+} release (CICR) in the skeletal muscle is too slow to make a significant contribution to DICR. In cardiac muscle, in contrast, Ca^{2+} influx through the α 1C subunit of DHPR triggers CICR. Consistently, contraction of skeletal muscle is independent of the external Ca^{2+} , whereas cardiac muscle contraction is dependent on it.

Dicer

Dicer represents the key enzyme in the RNAi pathway. Dicer is also known as Helicase with RNase motif, heRNA, Helicase-moi, K12H4.8-like, or KIAA0928. Dicer produces cleaves long double-stranded RNA into small pieces of about 21–23 nucleotides. These so-called siRNA duplexes produced by the action of Dicer contain 5'-phosphates and free 3' -hydroxyl groups

- ▶ RNA Interference (RNAi) – siRNA

DICR

DICR (depolarization-induced Ca^{2+} release) is Ca^{2+} release triggered by depolarization of the sarcolemma. In skeletal muscle, conformational change in the voltage sensor (α 1S subunit of the dihydropyridine receptor) in the T-tubule is directly transmitted to the

Differential Display

Differential display is a method for identifying differentially expressed genes, using anchored oligo-dT, random oligonucleotide primers and polymerase chain reaction on reverse-transcribed RNA from different cell populations. The amplified complementary DNAs are displayed and comparisons are drawn between the different cell populations.

Dimeric Transcription Factors

Sequence-specific transcription factors often bind as multimers especially as dimers to DNA. This allows binding of mirror-imaged sequences (palindromes) in the DNA that are separated by a few spacer nucleotides. The dimerization is stabilized by hydrophobic motifs within dimerization motifs of each transcription factor molecule. Dependent on the nature of the dimerization domain and the abundance of individual transcription factors homo- or heterodimers can form and bind to palindromes with differential activity.

- ▶ Transcriptional Regulation

Dioxins

Dioxins are prominent members of the class of polychlorinated hydrocarbons that also includes dibenzofuran, biphenyls and others. Dioxins are highly toxic environmental contaminants. Like others small planar xenobiotics, some dioxins bind with high affinity to the arylhydrocarbon (Ah) receptor. Dioxins activate the receptor over a long time period, but are themselves poor substrates for the enzymes which are induced via the Ah-receptor. These properties of the dioxins and related xenobiotics may be important for the toxicity of these compounds. Dioxins like 2,3,7,8-tetrachloro-p-dibenzodioxin can cause persistent dermatosis, like chloracne and may have other neurotoxic, immunotoxic and carcinogenic effects.

Discharge of Neurons

Discharge is the electrical signal of an activated neuron or a group of neurons. During a discharge or 'action potential', neurons lose their negative intracellular potential and become positively charged for a fraction of a second (1–4 milliseconds). This excitation is conducted to the nerve terminals which form synapses with other cells and can thereby facilitate action potential generation in these target cells (at excitatory synapses) or impede action potential generation (inhibitory synapses).

Disease-modifying Anti-rheumatic Drugs (DMARDs)

The term disease-modifying anti-rheumatic drug or DMARD refers to a category of pharmacological agent that has some ability to retard the rate of structural joint damage. This property distinguishes DMARDs from non-steroidal anti-inflammatory drugs which improve certain features of inflammation but have no capability to modify the rate of structural damage to joints in human disease, although they may do so in animal models. The term DMARD has also been applied to drugs that result in sustained improvement in physical function or a decrease in inflammatory synovitis.

Diuretics

JURGEN SCHNERMANN

National Institutes of Health, Bethesda, MD, USA

Synonyms

Natriuretics; Antinatriferics

Definition

Diuretics promote the urinary excretion of sodium and water by inhibiting the absorption of filtered fluid across the renal tubular epithelium. The ensuing reduction in Na reabsorption reduces the Na content of the body, the critical determinant of extracellular and plasma fluid volumes. Thus, the use of diuretics is primarily indicated in the treatment of edematous diseases and of arterial hypertension.

Mechanisms of Action

The mammalian kidney generates its excretory product, the urine, in a two-step process where filtration of a large volume of plasma-like fluid across the glomerular blood capillaries is followed by the reabsorption and secretion of solutes and water across the tubular epithelial cell layer. Transcellular reabsorption of filtered Na is achieved by apical Na uptake along a favorable electrochemical gradient and by basolateral Na extrusion through the energy consuming action of Na, K-ATPase. The renal tubule is cytologically heterogeneous along its longitudinal axis, and one expression of this heterogeneity is the type of transport protein responsible for apical Na uptake. As a general rule, currently available diuretics inhibit a specific apical Na transporter, and their action therefore displays tubule segment specificity.

Na uptake in the proximal tubule, a segment in which about 2/3 of the filtered Na is reabsorbed, is mediated by a **▶Na⁺/H⁺ exchanger** (NHE3) and a number of other transporters that typically carry a second solute in a Na-dependent cotransport mode. Along the thick ascending limb of the loop of Henle, Na uptake occurs mostly through the electroneutral **▶Na⁺,K⁺,2Cl⁻ cotransporters** (NKCC2) in a process that accounts for roughly 25% of total renal Na reabsorption. Na uptake in the distal convoluted tubule is mediated by a **▶NaCl cotransporter** (NCC), and this segment accounts for about 5% of Na reabsorption. Finally, electrogenic Na reabsorption through the **▶epithelial Na⁺ channel** (ENaC) is the uptake mode across the cortical collecting duct, a process that may be responsible for 2–3% of Na reabsorption. Na transport through ENaC is regulated by the adrenal gland steroid aldosterone.

As a general rule, increases of renal blood flow and/or **▶glomerular filtration rate** (GFR) correlate rather well with increased urinary excretion of solutes and water. The underlying causes for this correlation are not fully understood, but they reflect incomplete adjustments of tubular reabsorption to an increase of tubular electrolyte load.

Proximal Tubule Diuretics

Inhibition of **▶carbonic anhydrase** (CA) causes inhibition of NaHCO₃ reabsorption in the proximal tubule (Fig. 1). Apical Na uptake through NHE3 requires the delivery of H ions to the intracellular binding site of the transporter and of HCO₃ to the basolateral 3Na/HCO₃ cotransporter. The generation of H and HCO₃ at appropriate rates from H₂O and CO₂ is dependent upon catalysis by intracellular carbonic anhydrase (type II CA). In addition, carbonic acid dehydration in the tubular lumen is catalyzed by a CA located in the luminal membrane of proximal tubules (type IV CA). Both enzymes must be functional for reabsorption of Na HCO₃ in the proximal tubule to proceed at normal rates. CA inhibitors (acetazolamide, benzolamide, methazolamide, and others) cause NaHCO₃ reabsorption to decrease by about 40–80% and urinary Na HCO₃ excretion to increase by about 25–30%. Efficacy of CA inhibitors is diminished by a consistent reduction of GFR.

Activation of dopamine 1 receptors (fenoldopam) or inhibition of A1 adenosine receptors (CVT 124, KW-3902) are additional approaches that cause increased NaCl excretion at least in part by inhibition of proximal reabsorption.

Loop of Henle Diuretics

The so-called loop diuretics (sulfonamide derivatives like furosemide, bumetanide, torsemide, and others, and phenoxyacetic acid derivatives like ethacrynic acid) augment the excretion of NaCl through inhibition of the electroneutral NKCC2 cotransporter in the apical membrane of the thick ascending limb (TAL) of the loop of Henle. Loop diuretics directly interact with the transport protein, presumably by binding to a region that is also critical for binding of a chloride ion. By collapsing the normally lumen positive transepithelial potential difference loop diuretics abolish the electrical driving force that is responsible for the paracellular absorption of Na and other cations such as Ca and Mg. Since NaCl transport across the TAL causes the accumulation of medullary solutes, loop diuretics lead to a dissipation of the **▶cortico-medullary solute gradient**, and thereby disable the urinary concentrating mechanism. Renal blood flow and glomerular filtration rate are usually not affected by loop diuretics. While some of the natriuretic action of loop diuretics is due to direct inhibition of NKCC2, another part is the secondary

Diuretics. Figure 1 Schematic representation of four cells representative for the proximal tubule, the thick ascending limb of the loop of Henle, the distal convoluted tubule, and the collecting duct. The upper diagrams show the normal functional state of these cells whereas the lower diagrams show the effect of the segment-specific diuretics. Circles indicate transport proteins, and double lines represent channels. Arrows indicate the normal direction of net transport, and the boldness of the arrows is a qualitative index of transport rate. Only those cellular features are shown that are relevant to understanding the action of the diuretic agents. CA, carbonic anhydrase; MR Aldo, mineralocorticoid receptor aldosterone complex.

consequence of simultaneous stimulation of PGE₂ production. Blockade of cyclooxygenases, particularly of ▶**cyclooxygenase-2**, has been shown to reduce loop diuretic-induced natriuresis by about 50% through mechanisms that are not fully understood. Since PGE₂ generated by cyclooxygenase-2 under conditions of reduced NaCl transport is also a main factor in macula densa stimulation of renin secretion, loop diuretics are typically associated with an increase in renin secretion and greatly elevated plasma renin levels. Loop diuretics act from the luminal aspect of the tubule. Because of their intense protein binding these agents are not filtered effectively, and they gain access to the tubule lumen by secretion. Loss of function mutations in the NKCC2 gene are the cause of ▶**Barter syndrome** type I, and the symptoms of this disease are comparable to those caused by loop diuretics including salt and water loss, calciuria, magnesiuria, hypokalemia, metabolic alkalosis, hyperreninemia, and hyperprostaglandinuria.

Distal Convolved Tubule Diuretics

Electroneutral NaCl transport in the distal convoluted tubule is inhibited by the class of thiazide diuretics (chlorothiazide, hydrochlorothiazide, metolazone, chlorthalidone, and others). Thiazides interfere with the Cl binding site of NCC, and cause a relatively small

increase in Na excretion. Inhibition of NCC is not associated with persistent and marked changes in renal hemodynamics. Like the loop diuretics, thiazides act from the luminal side and gain access to it by tubular secretion. Loss of function mutations in the NCC gene have been identified as the cause of ▶**Gitelman's syndrome**, an electrolyte disorder characterized by hypokalemic metabolic alkalosis, magnesium wasting, and hypercalcemia.

Collecting Duct Diuretics

Na uptake through ENaC in cortical and probably also in inner medullary collecting ducts is inhibited by the so-called K-sparing diuretics (amiloride and triamterene). The natriuretic effect of this class of diuretics is small, commensurate with the small fraction of filtered Na normally absorbed along the collecting duct. Clinically perhaps more important than their natriuretic effect is the inhibition of K secretion that results from a reduced Na flux through ENaC. Inhibition of electrogenic Na absorption causes a hyperpolarization of the apical membrane and therefore a reduction in the electrochemical driving force for K secretion. The result is a reduction in K secretion and excretion since the tubular site of ENaC expression overlaps with that of the K channel responsible for the secretory cell to lumen K flux. Loss of function mutations in the ENaC gene

are the cause of ►**pseudohypoaldosteronism** type I, a salt losing nephropathy, and gain of function mutations cause ►**Liddle's syndrome**, a salt retaining state with severe hypertension.

A second diuretic acting along the collecting duct is spironolactone, a steroid that antagonizes the action of aldosterone. Eplerenone is a derivative of spironolactone with a shorter half-life and lower affinity for androgen and progesterone receptors and therefore reduced hormonal side effects. Spironolactone or eplerenone compete with aldosterone for the mineralocorticoid receptor and prevent the nuclear translocation of the receptor–ligand complex that is required for its genomic actions. Like amiloride, spironolactone causes a mild natriuresis and a reduction in K secretion.

Inhibition of V2 vasopressin receptors causes an increase in urine volume primarily by reducing the reabsorption of water along the collecting duct, an aquaretic effect that is fundamentally different from the natriuretic actions discussed so far. Nevertheless, some of the conditions calling for the use of natriuretic intervention are identical to those in which the administration of a new class of orally active nonpeptide V2 antagonists may be useful (tolvaptan, lixivaptan, and others).

Vasodilator Diuretics

Because renal vasodilatation and hyperfiltration are often associated with a natriuretic response, a number of activators or inhibitors of endogenous vasoactive systems can cause increased NaCl excretion, and some of these may be developed into compounds of clinical interest in special situations. Such agents include natriuretic peptides most notably B-type natriuretic peptide (nesiritide), neutral endopeptidase (NEP) inhibitors (thiorphan, phosphoramidon), mixed NEP and ACE inhibitors (omapatrilat), guanylin and uroguanylin, kinins, prostaglandins of the E series, adrenomedullin, relaxin, prolactin, and others.

Clinical Use

CA Inhibitors

The use of CA inhibitors as diuretics is limited by their propensity to cause metabolic acidosis and hypokalemia. Their use can be indicated in patients with metabolic alkalosis and secondary hyperaldosteronism resulting for example from aggressive use of loop diuretics. Furthermore, CA inhibitors are effective drugs to produce a relatively alkaline urine for the treatment of cysteine and uric acid stones as well as for the accelerated excretion of salicylates. Perhaps the most common use of CA inhibitors is in the treatment of glaucoma.

Loop Diuretics

Loop diuretics are the drugs of choice for the treatment of edematous patients with congestive heart failure, cirrhosis of the liver, and nephrotic syndrome. Excretion of Na is helpful only to the extent that some of the

excess interstitial fluid is mobilized and shifted into the intravascular space. Aggressive diuretic therapy is only necessary in pulmonary ►**edema** resulting from left ventricular heart failure. In all edematous conditions, the diuretic treatment addresses a symptom, not the cause of the disease, and it is therefore not the therapeutic mainstay. Other clinical situations where loop diuretics are indicated include hypercalcemia, hyperkalemia, and hypermagnesemia. Loop diuretics have also been found to be advantageous in the treatment of asthma.

Adverse side effects of loop diuretics are mainly the consequence of the altered absorptive function along the loop of Henle. The most common side effect of diuretic treatment is the loss of potassium that may result in ►**hypokalemia**. K loss is a consequence of (i) reduced K reabsorption along the TAL due to the direct inhibition of NKCC2, (ii) increased K secretion caused by the combined effects of increased tubular fluid flow along the K secreting cortical collecting duct, and (iii) increased plasma aldosterone resulting from diuretic-induced hypovolemia. Furthermore, loop diuretics can cause metabolic alkalosis and the urinary loss of calcium and magnesium. NKCC1, a more widely expressed isoform of the cotransporter, is found in the inner ear, and it is involved in maintaining the unusual ionic composition of the endolymph. By interfering with this process loop diuretics at high doses, especially ethacrynic acid, can cause hearing impairment that is typically reversible, but can also lead to permanent deafness.

Thiazide Diuretics

Interference with Na absorption in the distal convoluted tubule by thiazide-like diuretics is effective in the therapy of arterial hypertension. On average, about half of patients with essential hypertension respond to thiazide monotherapy with a blood pressure reduction of more than 10%. While the initial reduction in blood pressure appears to be a consequence of a reduced plasma volume, venous return, and cardiac output, the prolonged effect of thiazides to reduce blood pressure is related to a reduction in total peripheral resistance. The cause for this long-term adjustment is multifactorial. The hypotensive effect of thiazides is enhanced by a low NaCl diet and by combination with other blood pressure lowering drugs. Often in combination with loop diuretics thiazides are also used in the treatment of edematous diseases. Like loop diuretics thiazides can cause K loss and hypokalemia, hyponatremia, and urinary magnesium wasting while they usually reduce the excretion of calcium. This characteristic feature to stimulate Ca reabsorption makes thiazides a useful drug in the prevention of calcium stone formation in ►**idiopathic hypercalciuria**. Thiazides have also been described to diminish the occurrence of bone loss, hip fractures, and osteoporosis.

K-Sparing Drugs

Amiloride, triamterene, or spironolactone are typically not used to augment the excretion of Na, but to counteract the kaliuretic effect of loop diuretics and thiazides as an alternative to dietary K supplements. Thus, K-sparing drugs often accompany treatment with loop diuretics and are useful in other K-wasting states such as primary hyperaldosteronism or Bartter's syndrome. Another beneficial effect of amiloride is a stimulation of calcium and magnesium reabsorption along distal tubules and collecting ducts, an action that counteracts the Ca and Mg wasting of loop diuretics and the Mg wasting of thiazides. Spironolactone requires functional adrenal glands and is most effective in patients with elevated plasma aldosterone levels such as those with cirrhosis of the liver and ascites. Interestingly, spironolactone or eplerenone have been found to exert beneficial cardioprotective effects as an adjuvant therapy in the treatment of heart failure.

Vasopressin Antagonists

The use of V2 antagonists is promising in the treatment of the hyponatremia that usually accompanies congestive heart failure and cirrhosis, two edematous conditions in which the use of diuretics is indicated. In addition, V2 antagonists may be beneficial in the treatment of polycystic kidney disease.

DNA Fragmentation

DNA fragmentation occurs in two stages. Firstly, endonucleolytic activity cleaves the DNA into high molecular weight fragments leading to the morphological picture of chromatin condensation characteristic

of apoptosis. The second stage involves a calcium-magnesium endonuclease which catalyses the further fragmentation of the DNA into oligonucleosomal fragments, which give rise to the pattern of DNA base pairing which shows up as the classical DNA ladder pattern by electrophoresis. In several populations of lymphocytes, namely B lymphocyte populations in the germinal centre of lymph nodes, immature thymocytes, and cytotoxic T lymphocytes, it has been noted that only the first stage of DNA fragmentation is occurring.

- ▶ Apoptosis

DNA Methylation

In higher eukaryotes, most of the chromosomal DNA carries 5-methyl-cytidine residues located in CpG sequence motifs. There is a close correlation between transcriptional inactivation and methylation. On the other hand, considerable evidence shows that regions of DNA that are actively engaged in transcription lack 5-methyl-cytidine nucleotides in CpG motifs. Hence DNA methylation is a means how cells regulate gene expression. DNA methylation which is catalyzed by DNA methyltransferases is the best characterized epigenetic mechanism.

- ▶ Epigenetics
- ▶ Cell cycle Control

DNA Replication

DNA synthesis during S phase of the cell cycle resulting in a doubling of the genomic DNA. Replication can be subdivided into three distinct phases: initiation, elongation, and termination.

- ▶ Cell Cycle Control

DNA Response Elements

DNA response elements are generally found a short distance upstream of promoters in selected genes. They are specific for selective transcription factors and

thereby control the expression of genes regulated by these factors. The response elements often consist of small sequence repeats (or inverted repeats) separated by a variable number of DNA base pairs.

DNA Vaccination and Genetic Vaccination

NICO MICHEL¹, MARTIN MÜLLER²

¹Universitätsklinikum Heidelberg, Heidelberg, Germany

Definition

The administration of purified antigen-encoding plasmid DNA to a human being or laboratory animal with the aim of inducing cellular and/or humoral immune responses against the antigen is called genetic vaccination or DNA vaccination. Although less common, plasmid DNA can be replaced by a protein-encoding mRNA with the benefit of meeting high safety standards as this strategy completely eliminates the risk of integration of the plasmid DNA into the host chromosomes. In a more extended view, genetic vaccination also includes the use of recombinant viral vector systems in order to improve the delivery of the genetic information (for a more comprehensive overview see [1]).

Basic Mechanism

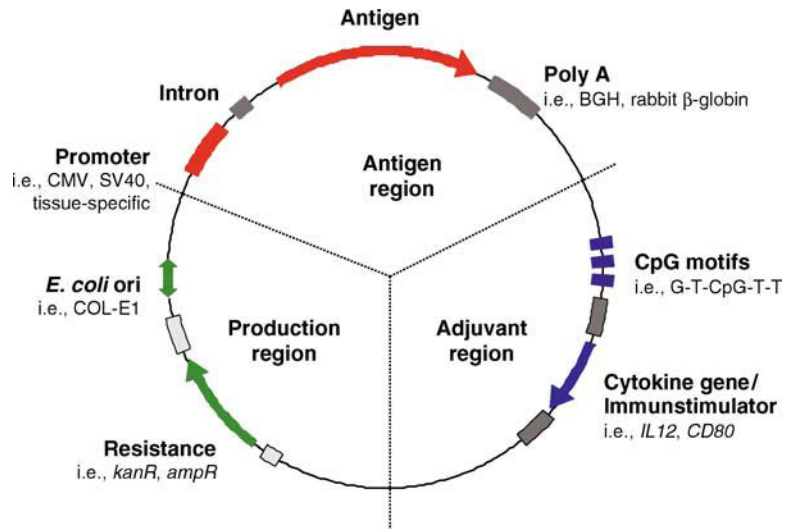

In contrast to conventional vaccines, the antigen against which an immune response is to be evoked is not delivered as a protein but as an antigen-encoding gene embedded in a eukaryotic expression vector (▶ eukaryotic expression cassette, see Figure 1). Compared with other vaccines (e.g., purified recombinant proteins, attenuated or inactivated live virus), DNA vaccines are of great simplicity and therefore can be produced easily and are cost-effective under standardized conditions even for an intentional use in human clinical trials. Several different application routes for the DNA currently exist. The DNA is administered either via simple injection of a buffered solution into the muscle or intradermally or with the aid of delivery vehicles (gold particles in combination with a ▶ gene gun, needle-injection devices, liposome-formulations). The route of application strongly affects both strength

and nature of the induced immune response (humoral vs. cellular immune response). A major advantage of DNA vaccines is that they have the potency to induce cytotoxic T-cell responses against the viral antigen that are otherwise difficult to achieve using conventional vaccines, with the exception of live attenuated vaccines. DNA vaccines have been successfully used as a powerful tool for the vaccination of laboratory animals against various different antigens. Because of its success under laboratory conditions, DNA vaccines meanwhile have been analyzed in numerous studies involving human subjects under clinical settings. However, at this time there is yet no DNA vaccine licensed for use in humans mainly because of difficulties of translating the promising findings from studies with small laboratory animals to human or nonhuman primates. Although DNA vaccination was proven to be safe and well-tolerated by the human study subjects in a number of phase I clinical trials, its efficacy in eliciting an antigen-specific immune-response was in most instances rather disappointing. Therefore, research is currently focusing on methods to improve the DNA-vaccine efficacy in humans. It should be noted that the application of nucleic acids to patients may also be performed for reasons other than vaccination: delivery of naked DNA/RNA could be used, e.g., for gene therapy or gene silencing.

Principles of DNA Vaccines, Mechanisms of Action

The field of DNA vaccination started when eukaryotic expression vectors were injected into the muscle of laboratory animals [2]. The authors observed protein expression for more than 2 months after injection and noted that no special delivery system was required to obtain this expression. Subsequently, it was demonstrated that antibodies can be induced simply by injecting plasmid DNA into the muscle of mice [3]. Subsequent studies found that the injection of expression plasmids also leads to the induction of a cytotoxic T-cell response. After injection, the DNA enters cells of the vaccinated host and the encoded gene becomes expressed. This eventually leads to the induction of a cellular cytotoxic T-cell, T-helper, and/or humoral (antibody) immune response.

Although a humoral immune response is the primary protection against most viral and some bacterial diseases, protective defense against other pathogens such as HIV, *Plasmodium* and *Mycobacterium tuberculosis* requires a cytotoxic response mediated by CD8⁺ T-cells (CTL response). Since the introduction of the vaccination concept by Jenner almost 200 years ago, only few vaccines have been developed that are able to induce a CTL response. These vaccines are usually attenuated live vaccines that are accompanied by certain risks and are not readily available for most pathogens. The immense appeal of DNA vaccines can be attributed to a considerable part to the fact that they are able to induce

DNA Vaccination and Genetic Vaccination. Figure 1 Plasmid vector for DNA vaccination. Three functionally distinct regions can be distinguished in a typical vaccination vector: (i) *Antigen region* contains the gene encoding the antigen of interest under the control of either a strong viral, a tissue type-specific cellular or even a synthetic promoter. Nuclear export and stability of mRNA require the presence of polyadenylation (poly A) sequences. In many instances, expression can be enhanced by insertion of a small intron upstream of the gene of interest. (ii) *Adjuvant region* CpG DNA motifs (cytosine-phosphate-guanosine as part of the sequence GTCpGTT for humans or GACpGTT for mice) of prokaryotic origin stimulate cytokine production in vivo [4]. Optionally, genes for cytokines or co-stimulatory molecules (e.g., IL-4, IL-12, IL-18, GM-CSF, B7.1), can be co-delivered with the antigen gene to improve the immune response, these elements could also be encoded by a co-administered second plasmid. (iii) *Production unit* contains elements for the production of the plasmid in bacteria. This unit includes an origin of replication, antibiotic resistance gene or other selectable marker. Note that the *ampicillin* resistance gene cannot be used in clinical trials involving human subjects. Instead, there are now nonantibiotic based selectable markers for plasmid maintenance in *Escherichia coli* available, which function by repressor titration strategies.

long-lasting CTL responses, next to the ease of their production. Additionally, since antigen expression occurs in an authentic intracellular environment, antigens have a high probability to fold into their native conformation as well as acquire relevant posttranslational modifications and thus have a great potential to induce effective antibody responses. Other advantages of DNA vaccines include (i) their low production costs as generic manufacturing procedures can be applied, (ii) clinically proven safety as compared with live attenuated vaccines, and (iii) high physical stability not requiring intact cold chains. Standardized production protocols, which are independent on the encoded antigen, would allow shorter response times to provide protection against, e.g., Influenza pandemics; however, this head start is consumed by the requirement for three successive immunizations to achieve protective antibody titers using a DNA-based flu vaccine.

Pharmacological Relevance

There are various protocols of administering eukaryotic expression vectors aiming to deliver (i.e. transfect) the DNA into the cytoplasm of the host cells (see Figure 2). The DNA is subsequently imported into the nucleus of the transfected cells allowing expression of the

encoded antigen. To induce antigen-specific, CD8⁺ cytotoxic T-cells, the antigen has to be presented by professional antigen-presenting cells (APCs). It is still under discussion whether DNA vaccination requires direct transfection of APCs (see Fig. 2A) or whether delivery of the DNA into nonimmune cells (e.g., muscle cells; Fig. 2B) is sufficient. In the latter scenario, there are a number of pathways that allow transfer of the antigen from nonimmune cells to APCs, a process that is called cross-priming.

The resulting immune response shows qualitative differences based on the method used for DNA vaccination. Injection of naked plasmid DNA predominantly leads to the induction of a strong cytotoxic T-cell response. In contrast, if the DNA is delivered via gold-particle bombardment using a gene gun, the immune response is biased towards a humoral response. The reason for these differences is based on the fact that gold particle bombardment is thought to deliver the DNA directly into the cytoplasm of the host cells. This bypasses the interaction of the bacterially derived vector DNA with specialized “toll-like”-receptors (TLR) present on the surface of many cells.

TLRs are the basis for the fact that plasmid DNA of prokaryotic origin, as is used in all DNA vaccination

DNA Vaccination and Genetic Vaccination. Figure 2 Mechanisms of DNA vaccination. Via needle injection or with the aid of specific devices (gene gun, needle injector, tattoo device), the expression construct is delivered indirectly or directly into the cytoplasm and subsequently the nucleus of cells in vivo. Alternatively, noninvasive methods, such as aerosols and viral vectors are employed in order to improve DNA delivery. Following uptake of the DNA, the antigen-encoding gene becomes expressed by the transfected cell. Two major hypotheses have been proposed for the induction of a cellular immune response. (A) In this scenario the DNA is delivered directly to specialized immune cells, the professional antigen-presenting cells (APCs). These cells have the ability to process the expressed antigen and present it to both CD8⁺ T-cells of the immune system in the context of the major histocompatibility complex class I (MHC I) and CD4⁺ T-cells in context of MHC II. The T-cells become efficiently activated since the professional APCs provide the required co-stimulatory signals (i.e. CD80 or CD86 of APCs binding to the CD28 receptor on T-cells). (B) Alternative mechanism for the induction of a cellular response (called cross-priming). In this setting, the antigen becomes expressed and presented by somatic, nonimmune cells. Since these cells lack the co-stimulatory signals, this presentation does not lead to the activation of CD8⁺ effector cells. It has been shown, however, that the expressed antigen can be released from the somatic cells and thereby enables the activation of both arms of the adaptive immune system (i) the released antigen can be recognized by circulating B-cells, which initiate the production of antigen-specific antibodies. This humoral immune response is further stimulated by CD4⁺ T-helper cells that become activated by APCs presenting the antigen through the MHC class II pathway. (ii) CD8⁺ cytotoxic T-cell responses can be induced by a specialized subset of bone-marrow derived APCs, which allow MHC-I presentation of exogenous antigens in the context of co-stimulatory molecules – a process termed cross-presentation or cross-priming. In addition to the two scenarios above, it has been found that there is an alternative co-stimulatory molecule (BB-1) expressed by myocytes in muscles upon induction of inflammation. However, there is strong evidence that bone marrow-derived APCs are essential for the induction of CTL responses during the course of DNA vaccination.

protocols, not only exhibits an inherent adjuvant effect on the stimulation of immune responses against the vector-encoded antigen but also against other antigens if they are co-administered with the DNA. The reason of this adjuvant effect lies in the presence of so-called CpG (5'-Cytosine-phosphate-Guanosine-3') motifs in

the vector backbones [5]. These motifs are, in comparison with prokaryotes, underrepresented and usually methylated in mammalian genomes. Contact with a significant amount of unmethylated CpG motifs during the course of bacterial infection or following vaccination with plasmid DNA of prokaryotic origin, leads to the activation

of immune cells expressing the TLR9. Consequently, these cells secrete immune stimulatory ► **cytokines** that can boost the induced immune response.

Potential Risks

In general, currently available preclinical and clinical data indicate that DNA vaccination is safe and well-tolerated [5]. Available data show that there is no indication of integration of the injected DNA into the host genome and therefore the risk of causing cancer by insertional mutagenesis is generally thought to be negligible. Additionally, in none of the clinical or preclinical studies there have been indications for the induction of anti-DNA antibodies believed to be key factors in certain autoimmune diseases. Anyway, even without DNA vaccination, humans are frequently exposed to bacterial DNA without evidence for adverse consequences. However, several safety concerns remain unanswered at present and have to be evaluated in the future. Immuno-regulatory cytokines induced by the CpG motifs present on the DNA vaccine may interfere with the host immune response either leading to autoimmune diseases or inducing tolerance to human pathogens that are present at the time of vaccination. Additional concerns are raised when, in addition to the antigen of interest, genes encoding immuno-stimulatory proteins such as cytokines are co-administered. It has been demonstrated that plasmid DNA can persist for weeks or even years post-vaccination. The consequences of such long-term exposure to foreign antigens, especially in respect to tolerance and long-lasting memory responses, are still not clear. These consequences of DNA vaccination have to be evaluated carefully, especially since most vaccine applications that are currently in evaluation target newborns or young children.

Clinical Use

A large and rapidly growing number of clinical trials (phase I and phase II) evaluating the potential of DNA vaccines to treat and prevent a variety of human diseases are currently being performed (► <http://clinicaltrials.gov>); however, there is yet no licensed DNA vaccine product available for use in humans. The clinical trials include the treatment of various types of cancers (e.g., melanoma, breast, renal, lymphoma, prostate, and pancreas) and also the prevention and therapy of infectious diseases (e.g., HIV/AIDS, malaria, Hepatitis B virus, Influenza virus, and Dengue virus). So far, no principally adverse effects have been reported from these trials. The main challenge for the development of DNA vaccines for use in humans is to improve the rather weak potency. DNA vaccines are already commercially available for veterinary medicine for prevention of West Nile Virus infections in horses and Infectious Hematopoietic Necrosis Virus in Salmon.

Routes of Administration/Vehicles for Administration/Formulation

Since, upon injection of naked plasmid DNA, the vast majority of DNA becomes readily degraded by cellular nucleases, efforts have been undertaken to increase the number of DNA molecules reaching the nucleus of cells. DNA molecules can be introduced into the cytoplasm of cells by the use of gold particle bombardment via a gene gun. This reduces the amount of DNA required for induction of an immune response to 1/10th compared with the injection of plasmid DNA and pressure-powered delivery devices licensed for use in humans are available (e.g., PowderMed™). In addition, a number of routes for DNA injection (intramuscular, intradermal, intraperitoneal, epidermal, intranasal, and intravenous) have been investigated. In most protocols, a dose of 1–100 µg of DNA per administration is used for small laboratory animals and 100–4000 µg for humans. However, only a minute fraction of the DNA molecules actually arrive in the nucleus and lead to the production of protein in the pico-to-nanogram range over a time period of weeks to several months. Recently, several alternative methods have been applied for DNA delivery. First, the use of a tattooing device for genetic vaccination of laboratory animals was shown to strongly improve the vaccine efficacy. Second, a growing number of trials involving animal and human subjects have used a method called ‘*in vivo* electroporation’ in order to deliver the DNA. Here, a brief electronic pulse is applied to the site of DNA injection. This method proved to be highly efficient in DNA delivery, however, it is accompanied by a (short-lived) moderate-to-serious discomfort for the vaccinee, acceptable only under therapeutic settings. In addition, it has been reported that electroporation leads to an increased frequency of integration of plasmids into the host genome. Finally, it has been demonstrated that oral delivery of a DNA vaccine can be significantly improved by the use of nasal sprays in combination with viral vector systems that are able to target these tissues. In addition to the incorporation of immune-modulatory genes as ‘genetic adjuvants’, a number of other formulations have been investigated in order to improve DNA vaccination. DNA molecules can be delivered by liposome formulation using commercial reagents such as Lipofectamine, Transfectam, and Bupivacaine, which allow a more efficient cellular uptake of the DNA and possibly also provide some degree of an adjuvant effect. For protection against degradation and to allow deposit effects, DNA vaccines can be microencapsulated by the use of polymers such as Poly-lactide-co-glycolide or chitosan. QS21, a saponin that is derived from the bark of the *Quillaja saponaria* tree was shown to function as adjuvant in DNA vaccination.

Docking Protein

► Adaptor Proteins

Domain

A domain is a part of a larger protein which has distinctive structural or functional properties.

L-DOPA/Levodopa

The immediate metabolic precursor to dopamine, L-DOPA (L-dihydroxyphenylalanine) is converted to the active neurotransmitter dopamine by the action of the enzyme aromatic amine acid decarboxylase (AADC). L-DOPA (INN name Levodopa) is the main drug used to treat Parkinson's disease.

- Dopamine System
- Catechol-O-Methyltransferase and its Inhibitors
- Anti-Parkinson Drugs

Dopa Decarboxylase

Dopa decarboxylase is an enzyme catalyzing the synthesis of dopamine from L-DOPA or of serotonin (= 5-hydroxytryptamine) from L-tryptophan. Inhibitors of this enzyme, which do not pass through the

blood–brain barrier (e.g. carbidopa), reduce the toxicity and peripheral side-effects of L-DOPA during treatment of Parkinson's disease.

Synonyms

Dopamine: 3,4-dihydroxyphenylethylamine

Definition

The dopamine system constitutes the cellular and biochemical network that is involved in the synthesis, release, and response to dopamine. In general, this involves cells that express significant levels of ► tyrosine hydroxylase (TH) and limited amounts of dopamine β -hydroxylase [1]. Dopamine-responsive cells express receptors specifically activated by this neurotransmitter, which are known as dopamine D1, D2, D3, D4, and D5 receptors [2, 3].

Characteristics and Basic Mechanisms

Anatomy and Function

Dopamine is one of the main neurotransmitters in the central nervous system (CNS), but has also been reported to play a role in the periphery. In the CNS, dopamine-synthesizing neurons have been found in a number of discreet cell groups in the mid- and forebrain, designated as A8-A10 (midbrain areas), A11-A15 (hypothalamic areas), A16 (olfactory bulb), and A17 (retina). The main dopaminergic neurons are found in the substantia nigra pars compacta and in the ventral tegmental area, which are also designated as the A9 and A10 cell groups and constitute the nigrostriatal and mesocortical/mesolimbic systems, respectively (Fig. 1).

The nigrostriatal system is predominantly involved in motor control, which is particularly evident in ► Parkinson's disease (PD), where a progressive loss of these neurons results in loss of motor function. In the early stages of the disorder, the motor impairment can be reversed by the administration of the dopamine precursor ► L-DOPA (L-3,4-dihydroxyphenylalanine), which bypasses the need for TH in dopamine

Dopamine System. Figure 1 Dopamine synthesis and metabolism in humans. The enzyme tyrosine hydroxylase (TH) catalyzes the formation of L-DOPA from tyrosine in presynaptic catecholaminergic neurons. L-DOPA (L-3,4-dihydroxyphenylalanine) is converted to dopamine by AADC (aromatic amino acid decarboxylase) and taken up by vesicles through the vesicular monoamine transporter (VMAT). After the release of vesicular dopamine into the synapse, signaling is terminated by the reuptake of dopamine into the presynaptic terminal by the dopamine transporter (DAT). Dopamine that leaves the synapse is primarily inactivated by the sequential action of monoamine oxidase (MAO) B and catecholamine-O-methyl transferase (COMT), which catalyzes the formation of DOPAC (3,4-dihydroxyphenylacetic acid) and HVA (homovanillic acid), respectively. MAO B also catalyzes the formation of the neurotoxin MPP⁺ from MPTP. Although MAO A can also oxidize dopamine, it does not appear to carry out this role in humans. In the periphery, dietary dopamine is primarily inactivated by the action of the phenyl sulfotransferase SULT1A3. Dopamine sulfate (DA-SO₄) is the predominant form of dopamine in human plasma. In Parkinson's disease patients, L-DOPA treatment results in a large increase in peripheral dopamine metabolites such as DA-SO₄ and 3-OMD (3-O-methyldopa). Drugs such as carbidopa, benserazide, tolcapone, and entacapone are used clinically to increase the brain availability of L-DOPA. The selective MAO B inhibitor deprenyl is used to delay the progression of PD symptoms and enhance the effectiveness of L-DOPA therapy.

synthesis [1]. The mesocortical and mesolimbic systems play important roles in reward, emotion, and cognition. This is exemplified by the addictive properties of dopamine stimulants, such as cocaine and amphetamine, as well as the therapeutic properties of drugs that block the D2 class of dopamine receptors, which control the psychotic symptoms of **schizophrenia** (see below). Dopaminergic hypothalamic neurons in the arcuate nucleus (A12) and A14 cell groups form the

tuberoinfundibular system. These neurons project to the median eminence and control the release of prolactin through the hypophysial portal system. More dorsally located dopamine neurons in the hypothalamus (A11, A13) project to autonomic areas of the lower brain stem and preganglionic sympathetic neurons of the spinal cord. Dopamine in the retina has been found in the amacrine and interplexiform cells and is involved in light and dark adaptation.

In the periphery, potential physiological roles of dopamine are less well established. The main roles for peripheral dopamine appear in the control of blood pressure. Dopamine affects vasodilation by sympathetic and renal mechanisms involving hemodynamic and direct effects on the nephron as well as effects on renin secretion. Furthermore, dopamine can modulate the secretion of aldosterone from the adrenals. Peripheral dopamine is also postulated to function in the gastrointestinal system. In this respect, it is important to note the antiemetic effects of the peripheral D2 class blockers, such as domperidone. These drugs presumably act via interaction with receptors in the chemoreceptor trigger zone. The origin of peripheral dopamine is not entirely resolved. Most of the dopamine in the circulation is in an inactivated form conjugated to sulphate or glucuronide. Origins of peripheral dopamine are thought to be from the sympathetic neurons, mesenteric organs, and adrenals.

Genetic disruption of dopamine synthesis in mice lacking TH shows that dopamine is not essential for development. However, dopamine deficient mice do not survive long after weaning unless treated with L-DOPA. These mice display severe aphagia and adipsia and loss of motor function. While these mice have a major reduction in dopamine levels some residual dopamine can be detected that is generated through the action of tyrosinases.

Dopamine Synthesis and Metabolism

The rate-limiting step in dopamine biosynthesis is the conversion of L-tyrosine to L-DOPA by the enzyme tyrosine hydroxylase (TH) [1]. TH is expressed in catecholaminergic neurons in the brain, sympathetic ganglia, and adrenal medulla. The monooxygenase activity of TH is dependent on the cofactor tetrahydropterin (BH4), and nigrostriatal neurons are particularly sensitive to BH4 levels. Genetic mutation in GTP cyclohydrolase I, which regulates production of BH4, is the cause of HPD (hereditary progressive dystonia). In catecholaminergic neurons, the enzyme aromatic amino acid decarboxylase (AADC) (also known as dopamine decarboxylase) catalyzes the formation of dopamine from L-DOPA. Dopamine is taken up into vesicles by the vesicular monoamine transporter (VMAT). In humans, peripheral dopamine formed from L-DOPA or absorbed intestinally is rapidly converted to inactive dopamine sulfate by the phenol sulfotransferase SULT1A3. In some species such as rats, the major form of dopamine in plasma is glucuronide conjugated [4].

The principal mechanism for terminating dopamine signaling is reuptake by the presynaptic neuron via the dopamine transporter (DAT). Dopamine that is not taken up is metabolized by the enzymes ►monoamine oxidase (MAO) and ►catechol-*O*-methyl transferase

(COMT) [5, 6]. MAO is an FAD (flavin adenine dinucleotide)-dependent enzyme with two distinct forms, MAO A and MAO B. Both occur on the outer mitochondrial membrane, but they have distinct localization and substrate specificity. MAOs are involved in inactivating neuroactive amines in the brain and periphery as well as detoxification of xenobiotics. Low levels of MAO A have been observed in dopaminergic neurons. However, dopamine oxidation in humans occurs primarily through MAO B, which is located in serotonergic neurons and glial cells. The distinction between the sites of dopamine biosynthesis and MAO B expression suggests that its role is to prevent dopamine from affecting nondopaminergic neurons. MAO A is selectively inhibited by clorgyline and moclobemide while MAO B is blocked by the reversible inhibitor deprenyl. Deprenyl also protects nigrostriatal neurons from the PD-like effect of the drug MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine). MAO B activity is required to catalyze the formation of neurotoxic MPP⁺ (1-methyl-4-phenylpyridinium ion), which is selectively taken up by nigrostriatal neurons resulting in Parkinsonism. MAO B activity increases with aging, and deprenyl has been shown to delay the progression of PD, although its precise mechanism of action is currently unknown.

MAO converts dopamine to DOPAC (3,4-dihydroxyphenylacetic acid), which can be further metabolized by COMT to form homovanillic acid (HVA). HVA is the main product of dopamine metabolism and the principal dopamine metabolite in urine. Increased neuronal dopaminergic activity is associated with increases in plasma concentrations of DOPAC and HVA. COMT preferentially methylates dopamine at the 3'-hydroxyl position and utilizes *S*-adenosyl-L-methionine as a methyl group donor. COMT is expressed widely in the periphery and in glial cells. In PD, COMT has been targeted since it can convert L-DOPA to inactive 3-OMD (3-*O*-methyl-dopa). In the presence of an AADC inhibitor such as carbidopa, 3-OMD is the major metabolite of L-DOPA treatment.

Dopamine Receptors

To date, five different dopamine receptors have been identified in and cloned from mammalian organisms [2, 3]. These are classified as dopamine D1 (D1a), D5 (D1b), D2, D3, and D4 receptors. The genes for the D1 and D5 receptors have two exons and are intronless in the coding sequence, while the D2, D3, and D4 receptors have eight, six, and four exons, respectively. Through alternative splicing of the sixth exon (fifth in coding sequence), the human D2 receptor gene can generate two forms of the receptor, which are called D2long (D2L, D2(443)) and D2short (D2S, D2(414)). The dopamine receptors belong to the superfamily of ►G protein-coupled receptors (GPCR). Most structural

data on dopamine receptors have been derived from mutagenesis studies, by analogy with the structure of other catecholamine receptors and from structural information on the protoypic class I GPCR, rhodopsin. Critical amino acid residues for dopamine binding and receptor activation are an aspartate in transmembrane domain three, which serves as counterion for the primary amine of dopamine, and the two serine residues in transmembrane domain five, which are involved in hydrogen bonding with the hydroxyl groups of the catechol ring. Dopamine has access to these residues through a hydrophilic pocket that is presumably formed through the counter-clockwise orientation of the transmembrane domains. To date there are no crystallographic data on the dopamine receptors. As with other GPCR, it has been shown that dopamine receptors, particularly D2 receptors, can form homo- and hetero-oligomeric structures. Whether the receptor exists as monomeric or oligomeric form *in vivo* or is regulated in a functionally dynamic fashion is still unknown.

Functionally, the D1-like receptors (D1, D5) are coupled to the G protein $G\alpha_s$ and thus can stimulate adenylyl cyclase. The D2-like receptors (D2, D3, and D4) couple to pertussis toxin sensitive \blacktriangleright G proteins ($G\alpha_{i/o}$), and consequently inhibit adenylyl cyclase activity. While the D1-like receptors almost exclusively signal through $G\alpha_s$ -mediated activation of adenylyl cyclase, the D2-like receptors have been reported to modulate the activity of a plethora of signaling molecules and pathways. Many of these actions are mediated through the $G\beta\gamma$ subunit. Some of these molecules and pathways include the calcium channels, potassium channels, sodium-hydrogen exchanger, arachidonic acid release, and mitogen-activated protein kinase pathways.

Direct interactions of dopamine receptors with signaling, regulatory, and structural molecules have also been reported. This includes the interaction of D1 receptors with calycon, D5 receptors with GABA_A channel subunits, D2 receptors with spinophilin and actin-binding protein (ABP-280), and D2-like receptors with SH3 domain-containing proteins. Dopamine receptors may be substrates for GPCR kinases (GRK) and arrestins, regulating the activity of the receptors through GRK-mediated phosphorylation and subsequent increased affinity for arrestins. Repeated and/or extended activation of many GPCRs, including dopamine receptors, results in reduced responsiveness. This desensitization process is mediated by the association of arrestin to GPCR. Regulation of dopamine receptors by GRK and arrestins is shown for D1 and D2 receptors, but not yet extensively studied. Most of the functional activities have been examined *in vitro* and in heterologous expression systems using recombinant receptors. The particular use of any signaling

pathway/molecule *in vivo* is largely dependent on the cellular phenotype of these cells.

Dopamine receptors are widely expressed in the brain. The main areas of D1 receptor expression are the caudate nucleus, putamen, and accumbens, with lower levels in the neocortex, hippocampus, and amygdala. The D5 receptor is expressed at very low levels in the brain, predominantly in limbic areas. The D2 receptor is also expressed highly in the caudate nucleus, putamen, accumbens, and islands of Calleja. D2 receptor levels in the neocortex, amygdala, and hippocampus are in the same order of magnitude as D1 receptor levels. Expression of the D2 receptor in the dopamine neurons of the substantia nigra and ventral tegmental indicate that it serves as a so-called dopamine autoreceptor. Unlike the D1 receptor, the D2 receptor is expressed in the pituitary gland, most notably in the mammotrophic cells of the anterior pituitary. It has been reported that the alternatively spliced short form (D2S) is preferentially expressed in the dopaminergic neurons of the substantia nigra, while the long isoform (D2L) is expressed in postsynaptic areas. The D3 receptor is expressed at intermediate levels in brain, most notably in the shell region of the accumbens and Islands of Calleja and at lower levels in dopaminergic neurons. The D4 receptors are widely expressed through the brain at intermediate to low levels. D4 receptor expression has been observed in the retina, neocortex, hippocampus, and amygdala.

Clearly, the highest levels of expression of D1 and D2 receptors are seen in the striatum. The levels of expression are at least one order of magnitude higher than in any other brain region or for any of the other receptors. The D1 and D2 receptors are expressed in the medium spiny neurons of this region. The majority of these receptors are not colocalized in this region and form, respectively, the so-called direct and indirect pathways to the output neurons of the basal ganglia. In cortical areas, dopamine receptors are found in the pyramidal neurons and interneurons. D2 receptors have also been found in cortical astroglia. The dopamine receptors are found in the terminal fields of dopaminergic projections and a significant proportion of dopamine-mediated modulation is via "volume-control."

In the periphery, dopamine receptor levels are generally lower than those observed in brain, particularly in comparison to striatal dopamine receptor levels. Due to these low levels, knowledge of receptor distribution in the periphery is not yet comprehensive. Nevertheless, D1-like receptors have been reported in the parathyroid gland and in the tubular cells of the kidney. D2-like dopamine receptors have also been observed in the kidney. In addition, dopamine D2 and D4 receptors have been found in the adrenal cortex, where they modulate aldosterone secretion. The

dopamine D4 receptor has been detected at relatively high levels in the cardiac atrium. Furthermore, D1- and D2-like receptors have been reported in various arterial beds (including renal, coronary, pulmonary, and cerebral arteries), the carotid body, sympathetic neurons, and the gastrointestinal tract.

The physiological roles of the different dopamine receptors in the CNS have been investigated by pharmacologic and genetic means. Pharmacologically, D1 and D5 receptors cannot be distinguished. However, D1-like receptor blockade can induce catalepsy, while mice in which the D1 receptors are genetically ablated display only minor motor control problems. However, pharmacological and genetic evidence suggest a role for D1 receptors in mediating the action of psychostimulants. D5-deficient mice have only been generated recently and no major phenotypes have yet been reported.

Drugs that block D2 receptors and D2 receptor-deficient mice have both demonstrated that these receptors have a major role in motor control, reward mechanisms, and endocrine control. Clinical pharmacological evidence indicates that the majority of antipsychotic medications mediate their effects through this receptor. While there are several D3 receptor preferring ligands, no truly selective ligands for this receptor have been identified to date. Nevertheless, pharmacological and genetic studies do not indicate a major role for this receptor in motor control, although a possible role in the response to psychostimulants is emerging. Similarly, the D4 receptor appears to play no major role in motor control. However, pharmacological evidence combined with the use of mice deficient for D4 receptors indicate that D4 receptors are involved in the response to psychostimulants and novel stimuli. Human genetic studies have provided evidence that the D3 receptor gene is a factor in the development of neuroleptic-induced tardive dyskinesia, while D4 receptors may be a genetic factor contributing to the development attention deficit hyperactivity disorder (ADHD). D1 and D3-deficient mice develop hypertension, indicating a role for dopamine receptors in blood pressure control.

Pharmacology, Drugs, and Clinical Uses

The dopamine D1-like receptor family has preferential affinity for ligands of the benzazepine class. Currently, there are no ▶antagonists or agonists that can distinguish between D1 and D5 receptors. However, the antagonist SCH23390 and agonist SKF38393 are selective for the D1-class of receptors, although no major clinical applications for D1 receptor-selective ligands have been identified.

The antipsychotic activity of ▶neuroleptics (D2-like receptor antagonists) has led to the development of many different ligands for the D2 receptor. These drugs

are used to control the psychosis that is seen in schizophrenia, as well as Huntington's disease and Alzheimer's disease. The major drug classes are the phenothiazines, butyrophenones, and benzamides, of which chlorpromazine, haloperidol, and sulpiride are examples frequently used in the clinic. Many of the so-called classic neuroleptics display an increased propensity for motor side effects (Parkinsonian-like effects), particularly when used at too high doses (over 80% D2 receptor occupancy). Atypical ▶antipsychotics, like clozapine, risperidone, and olanzapine, display a limited propensity for motor side effects. These drugs have a more complex pharmacological profile that includes antagonism of 5HT, muscarinic, and α -adrenergic receptors, as well as D2 receptor block. Most of the common antipsychotics also block the D3 and D4 receptors, but the antipsychotics raclopride and sulpiride have a poor affinity for D4 receptors. Selective ligands for D3 and D4 receptors have been developed, but have no clinical use thus far. D2-like receptor blockers that cannot cross the blood-brain barrier, like domperidone, are frequently used as antiemetic/prokinetic to combat nausea and dyspepsia.

Dopamine D2-like receptor ▶agonists include quinpirole, bromocryptine, and pergolide. Selective agonists, like bromocryptine, are used in the control of prolactinomas and its associated hyperprolactinaemia. Dopamine agonists like pergolide are used in the treatment of PD. Because of their vasodilatory and renal effects, dopamine receptor agonists, including dopamine itself, have been used in the treatment of heart failure.

The dopamine precursor L-DOPA (levodopa) is commonly used in TH treatment of the symptoms of PD. L-DOPA can be absorbed in the intestinal tract and transported across the blood-brain barrier by the large neutral amino acid (LNAA) transport system, where it taken up by dopaminergic neurons and converted into dopamine by the activity of TH. In PD treatment, peripheral AADC can be blocked by carbidopa or benserazide to increase the amount of L-DOPA reaching the brain. Selective MAO B inhibitors like deprenyl (selegiline) have also been effectively used with L-DOPA therapy to reduce the metabolism of dopamine. Recently, potent and selective nitrocatechol-type COMT inhibitors such as entacapone and tolcapone have been shown to be clinically effective in improving the bioavailability of L-DOPA and potentiating its effectiveness in the treatment of PD.

Definition

Drug addiction is defined as a syndrome in which drug use (e.g., psychostimulants, opiates, alcohol) pervades all life activities of the user. Life becomes governed by the drug and the addicted patient can lose social compatibility (e.g., loss of partner and friends, loss of job, crime). Behavioral characteristics of this syndrome are compulsive drug use, ►**craving**, and chronic relapses that can occur even after years of abstinence.

Drug addiction is a pathological behavioral syndrome that has to be strictly separated from ►**physical dependence**. An individual can be physically dependent on a drug without being addicted to it and vice versa. Transient neuroadaptive processes underlie physical dependence and ►**tolerance** to a drug, whereas persistent changes within specific neuronal systems underlie addictive behavior.

Basic Mechanisms

Acute Drug Action/Drug Reinforcement and the Mesolimbic Dopamine System

The dopaminergic ►**mesolimbic system** is thought to serve as a final common neural pathway for mediating drug reinforcement [1]. Drugs of abuse have different primary pharmacological targets (e.g., monoamine transporters, opioid receptors, cannabinoid receptors, nicotinic receptors) but ultimately, they all activate dopamine neurons. Although drug-induced activation of mesolimbic dopamine neurons has an important function in the acquisition of behavior reinforced by drug stimuli, the subjective rewarding actions of drugs of abuse are more likely to be mediated via activation of opioidergic systems. Thus a variety of drugs of abuse including alcohol and psychostimulants stimulate endorphin release in the nucleus accumbens [2]. The endocannabinoid system is also involved in mediating brain reward functions as it has been shown that activation or blockade of the endogenous cannabinoid system modulate the rewarding effects of drugs of abuse.

Psychostimulants

Both ►**psychostimulants** D-amphetamine and cocaine elevate extracellular dopamine concentrations in the terminal region of midbrain dopamine neurons,

especially in the nucleus accumbens. Microdialysis experiments examining the dopaminergic response to cocaine in self-administering rats with high-time resolution demonstrate that responses to cocaine are regulated by changes in extracellular dopamine levels in the nucleus accumbens. Since cocaine-induced increases in extracellular dopamine concentrations are due to the blockade of presynaptic dopamine transporters (DAT), disruption of DAT should attenuate the reinforcing effects of cocaine; however, DAT knockout mice acquire self-administration of cocaine. Thus, the reinforcing actions of cocaine do not depend solely on cocaine-induced increases in synaptic dopamine. It has been found that serotonin transporters (SERT) are also involved in acute reinforcement processes of cocaine.

Opioids

In vivo microdialysis data demonstrate that acute systemic or intracerebroventricular administration of μ - or δ -opioid receptor agonists increase dopamine release in the nucleus accumbens. Opioid agonists increase extracellular dopamine levels within the nucleus accumbens by disinhibiting GABA interneurons in the ventral tegmental area. Activation of μ -opioid receptors on GABAergic interneurons hyperpolarizes these interneurons and concomitantly disinhibits dopamine cell firing. These disinhibitory actions of opioid receptor agonists are restricted to the ventral tegmental area since direct application of μ -opioid receptor agonists into the midbrain increases mesolimbic dopamine activity whereas intra-nucleus accumbens infusions do not alter extracellular dopamine levels in this structure. Opiate reward as measured by the ►**conditioned place preference** method depends on midbrain dopamine mechanisms. Microinjections of opioid receptor agonists into the ventral tegmental area, but not nucleus accumbens, induce conditioned place preference.

Alcohol

Alcohol has a complex pharmacology. Primary targets of ethanol are GABA_A, NMDA, nACh, and 5-HT₃ receptors and potassium channels as well. Alcohol increases firing of dopamine neurons in the ventral tegmental area, enhances release of dopamine from the nucleus accumbens shell region. Similar to opioid-induced stimulation of dopamine release alcohol is thought to decrease the activity of GABAergic neurons in the ventral tegmental area, which leads to a disinhibition of mesolimbic dopamine neurons. Importantly, rats will self-administer ethanol directly into the ventral tegmental cell body region of mesolimbic dopamine neurons, and both dopamine D1 and D2 antagonists administered either systemically or locally into the nucleus accumbens decrease home cage drinking and operant responding for alcohol showing that alcohol reinforcement depends on the mesolimbic system.

Molecular Mechanisms of Physical Dependence

Chronic administration of opiates and alcohol leads to physical dependence; a phenomenon, which is only weakly expressed following chronic administration of psychostimulants or other drugs of abuse. Physical dependence results from neuroadaptive intracellular changes to an altered pharmacological state. Abstinence from chronic opiate or alcohol use leads to a variety of physiological and psychological withdrawal symptoms based on these adaptations of the neuronal system.

Opioids

The opiate withdrawal symptoms in humans and experimental animals are generally the same: Elevation of temperature and blood pressure, alteration of pulse rate, restlessness, diarrhea, weight loss, anxiety and depression. Most of the physiological aspects of opiate withdrawal are based upon an over-excitability of the noradrenergic system. The locus coeruleus is the major noradrenergic nucleus in the brain and is thought to be involved in physical dependence. Chronic opiate exposure results in an up-regulation of the cAMP system. This up-regulated or “hypertrophied” cAMP system in the locus coeruleus and other brain stem nuclei is a compensatory, homeostatic response to the inhibition from chronic opiate treatment. cAMP up-regulation results in the activation of the transcription factor cAMP response binding element (►CREB). The up-regulated cAMP system has been shown to contribute to the increase in the electrical excitability of locus coeruleus neurones associated with opiate withdrawal, and transgenic mice deficient in CREB exhibit attenuated withdrawal signs compared to wild-type mice.

Alcohol

Chronic administration of ethanol leads to a variety of adaptive responses within the central nervous system that become uncovered during withdrawal. Especially, hyperexcitability and susceptibility to seizures during withdrawal are thought to be due to adaptive responses within the glutamatergic system in the hippocampus. Assuming that acute ethanol induces a reduction in glutamate release, adaptive responses such as changes in the number and affinity of synaptic glutamate receptors and glutamate transporters occur in order to keep physiological homeostasis of the glutamatergic system [3]. During withdrawal these adaptive responses become visible. Indeed, microdialysis studies within the nucleus accumbens and the hippocampus, which were performed in alcohol-dependent rats after withdrawal, show that glutamate levels increase 2–3 fold approximately 6h after withdrawal, which is the time associated with the commencement of seizures and hyperexcitability, and reach a peak at 12 h then decline to baseline values at 24–36 h from the interruption of the chronic

alcohol treatment. It is important to note that these changes in glutamate are observed in occurrence with overt physical withdrawal signs.

Molecular Mechanisms of Addictive Behavior

Chronic drug use and abuse leads to ►sensitization processes within the mesolimbic system. In the case of psychostimulants and opioids, *in vivo* measurements of extracellular dopamine levels provide direct evidence that these drugs, when administered under an intermittent injection schedule, can lead to a more pronounced increase in dopamine levels as compared to acute administration of these drugs. A major hypothesis postulates that the activation of a sensitized dopaminergic system (►Dopamine System) by conditioned stimuli is directly involved in drug craving [4]. Changes within the mesolimbic dopaminergic system and behavioral abnormalities that characterize drug addiction are long-lasting, and it is thought that regulation of neural gene expression is involved in the process by which drugs of abuse cause a state of addiction. The transcription factor Δ FosB represents one mechanism by which drugs of abuse can produce relatively stable changes in the brain that contribute to drug-induced sensitization processes and ►reinstatement of drug-seeking behavior in mice and rats. Δ FosB, a member of the Fos family of transcription factors, is induced in brain, in a region- and cell-type-specific manner by drugs of abuse. Thus, Δ FosB can be seen as a “molecular switch” that gradually converts acute drug responses into relatively stable adaptations that may contribute to the long-term neural and behavioral changes underlying addiction. However, Δ FosB plays also a role in long-term adaptive changes in the brain associated with other conditions, such as Parkinson’s disease, depression, and antidepressant treatment. Other transcription factors such as Period2 (Per2), are also induced by drugs of abuse but again various stressors and antidepressants can also induce a long-lasting up-regulation of Per2.

Following chronic drug intake long-term neuroplastic changes do not only occur in the brain reward system but also in brain stress systems that provide a negative motivational state that drives addictive behavior. This leads to further drug intake motivated by relief of negative emotionality. The changes in the reward and stress systems maintain hedonic stability in an ►allostatic state and one key mechanism in the transition to negative reinforcement is a recruitment of corticotropin-releasing factor (CRF) signaling within the ►extended amygdala. Thus long-term up-regulation of CRF1 receptors is observed in the amygdala following excessive chronic drug intake, and CRF1 receptor antagonists selectively block emotionality, excessive drug intake, and stress-induced reinstatement of drug-seeking behavior [5].

Psychostimulants and Opioids

Long-lasting alterations within the glutamatergic system seem to be critically involved in cocaine addiction. In particular, glutamatergic projections onto dopaminergic neurons (Fig. 1) within the ventral tegmental area undergo synaptic changes following cocaine administration. In the dopaminergic cells, cocaine and other psychostimulants influence at least two forms of synaptic plasticity linked to glutamatergic transmission, namely LTP and LTD. Thus, by increasing synaptic strength, facilitating LTP and/or reverting LTD processes these drugs augment glutamatergic input onto dopaminergic neurons and finally promote enhanced dopamine release in brain areas such as the nucleus accumbens and the prefrontal cortex. Along with those synaptic changes locomotor sensitization, reinforcement, and cocaine-seeking behavior occur— all phenomena that are considered as landmarks of addictive behavior in rodents. These behavioral phenomena may indeed be linked to the glutamatergic synapses. Thus, intra-VTA administered glutamate antagonists reduce locomotor sensitization, reduce cocaine, and opioid reinforcement

measured by conditioned place preference, and suppress drug-seeking behavior. The fact that *in vivo* cocaine administration enhances AMPA-synaptic transmission and increases the AMPAR:NMDAR ratio in dopaminergic cells led further to the conclusion that AMPA receptors located on these neurons could play a role in these and other manifestations of cocaine addiction.

Alcohol

Preclinical as well as clinical data strongly imply that craving and relapse for alcohol can be induced through different mechanisms. A first pathway may induce alcohol craving and relapse due to the mood enhancing, positive reinforcing effects of alcohol consumption. This pathway seems to involve opioidergic and dopaminergic systems in the ventral striatum. The role of the dopaminergic system may lie in the direction of attention toward reward-indicating stimuli, while the induction of euphoria and positive mood states may be mediated by opioidergic systems. Associative learning may, in turn, transform positive mood states and previously neutral environmental stimuli into

Drug Addiction/Dependence. Figure 1 Actions of drugs of abuse on dopaminergic neurons. Acute and long-lasting effects of alcohol, opioids, and psychostimulants on mesolimbic dopaminergic neurons. Nicotine, cannabinoids, and other drugs of abuse also affect these neurons in order to produce their reinforcing and long-lasting effects. Note that all drugs of abuse enhance either directly or indirectly dopamine release in the nucleus accumbens. Activation of neurons within the nucleus accumbens by chronic drug use leads to long-lasting changes in gene expression (e.g., prodynorphine gene) as indicated by accumulated Δ FosB isoforms (small inset).

alcohol-associated cues that acquire positive motivational salience and induce reward craving. A second and potentially independent pathway may induce alcohol craving and relapse by negative motivational states, including conditioned withdrawal and stress. This pathway seems to involve the glutamatergic system and the CRF-system. Chronic alcohol intake leads to compensatory changes within these systems. During withdrawal and abstinence increased glutamatergic excitatory neurotransmission as well as increased CRF release leads to a state of hyperexcitability that becomes manifest as craving, anxiety, and autonomic dysregulation [5]. Moreover, cues associated with prior alcohol intake that are not followed by actual drug consumption may induce ► **conditioned withdrawal**.

Pharmacological Relevance

Treatment of drug addicts can be separated into two phases: detoxification and relapse prevention. Detoxification programs and treatment of physical withdrawal symptoms, respectively, is clinically routine for most drugs of abuse. However, pharmacological intervention programs for relapse prevention are still not very efficient.

Detoxification

Alcohol

Cessation of prolonged heavy alcohol abuse may be followed by alcohol withdrawal or life-threatening alcohol withdrawal delirium. Typical withdrawal symptoms are autonomic hyperactivity, increased hand tremor, insomnia and anxiety, and are treated with benzodiazepines and thiamine. Alcoholism is the most common cause of thiamine deficiency and can lead in its extreme form to the ► **Wernicke's syndrome** that can be effectively treated by high doses of thiamine.

Opioids

Opiate overdose is a medical emergency that can result in respiratory and CNS depression. The opioid receptor antagonist naloxone immediately reverses cardiorespiratory depression. However, repeated naloxone administration is required, since the effects of naloxone last for 30 min, while opioid agonists can remain at potentially lethal blood levels for several hours.

Relapse Prevention

Alcohol

Anti-relapse compounds have recently been registered for relapse prophylaxis in weaned alcoholics in various European countries and in the United States. Acamprosate, the Ca^{2+} salt of *N*-acetyl-homotaurinate, interacts with the glutamatergic system in various brain regions and reduces Ca^{2+} fluxes through voltage-dependent ion channels. The opioid receptor antagonist naltrexone interferes with alcohol-induced reinforcement via blockade of opioid receptors. Although the dopaminergic

system has been in the focus of alcohol research for many years, clinical trials interfering with several components of this system displayed rather disappointing results. This situation, however, could change in light of the discovery that dopamine D3 receptor antagonism produces very consistent and robust results in preclinical studies. CRF1 receptor signaling and the endocannabinoid system integrate stress-related events and thereby mediate relapse behavior. Beside CRF1 receptor and CB1 receptors many new targets have been identified and several new compounds are currently undergoing clinical testing. However, given the heterogeneity in treatment response, genetic and protein markers as well as endophenotypes are currently characterized for individualized pharmacotherapy.

Opioids

Substitution therapy with methadone or buprenorphine has been very successful in terms of harm reduction. Some opiate addicts might also benefit from naltrexone treatment. One idea is that patients should undergo rapid opiate detoxification with naltrexone under anaesthesia, which then allows further naltrexone treatment to reduce the likelihood of relapse. However, the mode of action of rapid opiate detoxification is obscure. Moreover, it can be a dangerous procedure and some studies now indicate that this procedure can induce even more severe and long-lasting withdrawal symptoms as well as no improvement in relapse rates than a regular detoxification and psychosocial relapse prevention program.

Drug–Drug Interaction

- ▶ Drug Interaction

Drug Efficacy

Drug efficacy refers to the capacity of a drug to produce an alteration in a target cell/organ after binding to its receptor. A competitive antagonist, that occupies a binding site without producing any alteration in the receptor, is considered to have an efficacy of zero. The efficacy is generally independent of potency/affinity, and is related to the maximum effect that a particular drug is capable of producing.

²Department of Molecular Pharmacokinetics, Graduate School of Pharmaceutical Sciences, The University of Tokyo, Tokyo, Japan

Synonyms

Drug–drug interactions; Pharmacokinetic and/or pharmacodynamic interactions; Pharmacokinetic and/or pharmacodynamic consequence of multiple drug therapy

Definition

Drug interactions can occur when two drugs are administered together, one affecting the pharmacological and/or adverse effects of the other. One or both of the drugs could be affected leading to either clinically beneficial interactions (e.g. increased pharmacological effects or reduced adverse effects) or harmful interactions (e.g. reduced pharmacological effects or increased adverse effects).

Basic Mechanisms

Pharmacokinetic Interactions

Interactions resulting from a change in the amount of drug reaching the site of action are called pharmacokinetic interactions (Fig. 1). A co-administered drug can affect any of the processes of absorption, distribution, metabolism, and excretion of the original drug, which are determinants of its pharmacokinetic profile [1–3].

Drug Interactions During Absorption

Changes in Gastrointestinal pH

Following oral administration, drug molecules in their lipophilic non-ionic form are more easily absorbed by ▶ simple diffusion through the gastrointestinal mucosa. Therefore, the alteration in the fraction of non-ionic form caused by gastrointestinal pH change due to co-administered drugs, such as antacids, can lead to a change in drug absorption.

Absorption, Chelation, and Complex Formation

Charcoal, which is used as a detoxicant in overdose, etc., is able to adsorb drugs, thereby causing a reduction in drug absorption. Absorption of new quinolone antibiotics is reduced by forming an insoluble chelate with secondary or tertiary cations, such as Mg^{2+} or Al^{3+} ,

Drug Interactions. Figure 1 Increase in drug concentration caused by pharmacokinetic interactions. Shadow represents the therapeutic range.

found in many antiacids. The cholesterol-lowering agent, cholestyramine, which is an anion-exchange resin, reduces the absorption of drugs like warfarin by binding to them.

Changes in Gastrointestinal Motility

Because the majority of orally administered drugs are absorbed mainly from the upper part of the small intestine, an alteration in gastric emptying rate (The rate of orally administered drug reaching the small intestine from the stomach. This can be affected by various factors such as food, body position, and certain drugs.) caused by co-administered drugs can lead to alterations in drug absorption. For example, anticholinergic drugs, such as propantheline, delay gastric emptying by reducing gastrointestinal motility, causing the reduced absorption rate of acetaminophen, etc., while metoclopramide has the opposite effect.

Effects on Transporters such as P-Glycoprotein

P-glycoprotein (P-gp) works as a transporter at the intestinal mucosa pumping drugs out into the lumen. Absorption of P-gp substrates, such as digoxin, cyclosporine, etc., can be increased by inhibitors of P-gp and reduced by inducers.

Drug Interactions During Distribution

Displacement from Plasma Protein Binding Sites

In general, only the free molecules which are not bound to plasma proteins, such as albumin and α_1 -acid glycoprotein, cross biological membranes and exhibit pharmacological effects. Therefore, displacement from plasma protein binding sites by co-administered drugs can cause an increase in the unbound fraction of the original drug in plasma, possibly leading to increased pharmacological effects.

Effects on Transporters

The tissue distribution of substrates of transporters involved in the **active transport** into or out of tissues

such as liver, kidney, brain, tumour cells, etc., can be affected by the co-administration of inhibitors and/or inducers of such transporters. For example, cyclosporin A inhibits the hepatic uptake of cerivastatin via OATP-C/OATP2, a transporter localized on the sinusoidal membrane of the liver. Quinidine inhibits the brain efflux of loperamide via P-gp, thereby enhancing its distribution into the brain.

Drug Interactions During Metabolism

Enzyme Inhibition

Following concurrent administration of two drugs, especially when they are metabolized by the same enzyme in the liver or small intestine, the metabolism of one or both drugs can be inhibited, which may lead to elevated plasma concentrations of the drug(s), and increased pharmacological effects. The types of enzyme inhibition include reversible inhibition, such as **competitive** or **non-competitive inhibition**, and irreversible inhibition, such as **mechanism-based inhibition**. The clinically important examples of drug interactions involving the inhibition of metabolic enzymes are listed in [Table 1](#) [1, 4].

Enzyme Induction

The co-administration of drugs which induce the metabolic enzymes in the liver or small intestine can reduce the plasma concentrations of drugs which are substrates of the enzyme, leading to reduced drug effects. For example, the plasma concentrations of many drugs which are substrates of the enzyme CYP3A4, such as cyclosporine, are decreased by co-administration of rifampicin, which is an inducer of CYP3A4.

Drug Interactions During Excretion

Changes in Urinary pH

As in gastrointestinal absorption, the lipophilic non-ionic form of a drug is more susceptible to reabsorption from the renal tubules by simple diffusion. Therefore,

Drug Interactions. Table 1 Examples of clinically important drug interactions due to enzyme inhibition

Substrate	Inhibitor	Inhibited enzyme	Possible clinical outcome
Theophylline	Ciprofloxacin, fluvoxamine, etc.	CYP1A2	Theophylline toxicity
Phenytoin	Chloramphenicol, isoniazid, etc.	CYP2C9, CYP2C19	Phenytoin intoxication
Tolbutamide	Sulfaphenazole	CYP2C9	Hypoglycaemia
Warfarin	Fluconazole, metronidazole, etc.	CYP2C9	Haemorrhage
Astemizole, terfenadine	Ketoconazole, erythromycin, etc.	CYP3A4	Ventricular, arrhythmia
Cyclosporine, tacrolimus	Ketoconazole, erythromycin, etc.	CYP3A4	Cyclosporine/tacrolimus toxicity
Lovastatin, simvastatin	Ketoconazole, erythromycin, etc.	CYP3A4	Rhabdomyolysis
Azathiopurine, mercaptopurine	Allopurinol	Xanthine oxidase	Azathiopurine/mercaptopurine toxicity

reabsorption of weakly acidic drugs can be enhanced (or inhibited) by co-administration of drugs which reduce (or elevate) the urinary pH, leading to elevated (or reduced) plasma concentrations. The opposite effects are observed for the weakly basic drugs.

Effects on Renal Tubular Secretion

The co-administration of drugs which inhibit the transporters involved in renal tubular secretion can reduce the urinary excretion of drugs which are substrates of the transporter, leading to elevated plasma concentrations of the drugs. For example, probenecid increases the plasma concentration and the duration of effect of penicillin by inhibiting its renal tubular secretion. It also elevates the plasma concentration of methotrexate by the same mechanism, provoking its toxic effects.

Effects on Biliary Excretion

The co-administration of drugs which inhibit the transporters involved in biliary excretion can reduce the biliary excretion of drugs which are substrates of the transporter, leading to elevated plasma concentrations of the drugs. For example, biliary and urinary excretion of digoxin, both mediated by P-gp, are inhibited by quinidine which is an inhibitor of P-gp.

Pharmacodynamic Interactions

Pharmacodynamic interactions are drug interactions involving alterations in drug effects following co-administration of drugs, without alterations in the drug concentrations at the site of action. They include direct interactions, such as two drugs exhibiting their pharmacological effects via binding to the same receptor, and indirect interactions, in which the drug effects are affected by biochemical or physiological changes due to the co-administered drug.

Additive or Synergistic Interactions

When two drugs with similar pharmacological and/or adverse effects are administered simultaneously, an additive or synergistic increase in their effects can be observed. These include the increased sedative effects seen in the central nervous system following co-administration of alcohol and benzodiazepine hypnotics/anxiolytics and the increased risk of bleeding following co-administration of the anticoagulant, warfarin, and the non-steroidal anti-inflammatory drug, aspirin.

Antagonistic Interactions

The pharmacological and/or adverse effects of a drug can be reversed by co-administration of drugs which compete for the same receptor. For example, an opioid receptor antagonist naloxone is used to reverse the effects of opiates. Drugs acting at the same site with opposite effects also can affect each other, e.g. the reduction in the anticoagulant effect of warfarin by vitamin K.

Pharmacological Relevance

Drug interactions can cause serious problems in clinical practice especially when the affected drug has the potential to be highly toxic. Furthermore, pharmacokinetic interactions are clinically important if the affected drug has a narrow therapeutic range (i.e. small difference between the minimum effective concentration and the toxic concentration; Fig. 1) and a steep concentration–response curve (i.e. significant alterations in pharmacological and/or adverse effects caused by small changes in blood concentration).

Although drug interactions involving plasma protein binding and drug metabolism are often evaluated in *in vitro* studies, the interactions observed *in vitro* are not necessarily observed *in vivo* or clinically relevant. For example, even when the plasma unbound fraction of a drug is increased by protein binding displacement, kinetic theory (clearance concept) indicates that the steady-state plasma unbound concentration may not change because the unbound drug is subject to metabolism and excretion. Therefore, this type of drug interaction is unlikely to be clinically significant unless a high clearance drug is administered intravenously. However, a transient increase in the plasma unbound concentration can be observed under non-steady-state conditions, especially for drugs with small volumes of distribution. It should be taken into account that such a transient increase may cause some side effect of drugs.

In the case of drug interactions involving metabolic inhibition, little increase in the substrate concentration is expected when the inhibition constant (K_i) determined in *in vitro* studies using human liver samples is larger than the inhibitor concentration *in vivo*. Various approaches have been adopted using mathematical models in attempts to quantitatively predict *in vivo* drug interactions from *in vitro* data [5].

Drug Metabolism

The metabolism of foreign compounds (xenobiotics) often takes place in two consecutive reactions, classically referred to as phases one and two. Phase I is a functionalization of the lipophilic compound that can be used to attach a conjugate in Phase II. The conjugated product is usually sufficiently water-soluble to be excretable into the urine. The most important biotransformations of Phase I are aromatic and aliphatic hydroxylations catalyzed by cytochromes P450. Other Phase I enzymes are for example epoxide hydrolases or carboxylesterases. Typical Phase II enzymes are UDP-glucuronosyltransferases, sulfotransferases, N-acetyltransferases and methyltransferases e.g. thiopurin S-methyltransferase.

Drug receptor theory; Quantification of drug effect

Definition

Mathematical models of the interaction between drugs and ▶receptors, based on ▶Michaelis–Menten kinetics, are utilized to create the quantitative tools currently used in receptor pharmacology to quantify drug effect in biological systems. Such tools are necessary since drugs almost always are tested in surrogate systems until they are known to be sufficiently active and safe for therapeutic use. The aim of receptor pharmacology is to define the molecular properties of ▶affinity and ▶intrinsic efficacy of drugs; these can be used to predict drug effect across different biological systems. It will be seen that the properties of affinity and efficacy are sufficient to describe the case of the interaction of a single molecule, target receptor, and cell. For an extended system of two interacting molecules (e.g., agonist and antagonist), target receptor and cell, it is useful to know additional information, namely knowledge as to whether the interaction is orthosteric or allosteric, and (optionally) the kinetics of interaction of the molecules with the target (target residence time) in order to fully characterize drug activity.

Basic Mechanisms

A basic premise in receptor pharmacology is that all drugs have affinity for receptors (the chemical property that unites the drug with the receptor), and some drugs have efficacy, the chemical property that causes the receptor to change its behavior toward its host cell. Drugs that have efficacy can produce concentration-dependent responses in physiological systems, characterized by a concentration–response curve (also often referred to as a dose–response curve).

Drugs that produce pharmacological activation of a system are called *agonists*, those that inhibit activation of a receptor system are called *antagonists*, and those that reverse spontaneously active receptor systems (▶constitutive receptor activity) are called *inverse agonists* (Fig. 1). This latter class of drugs reduce elevated basal responses. Agonism is the observed effect of a ligand producing stimulus to a receptor. The host cellular system processes that stimulus and yields an observable response.

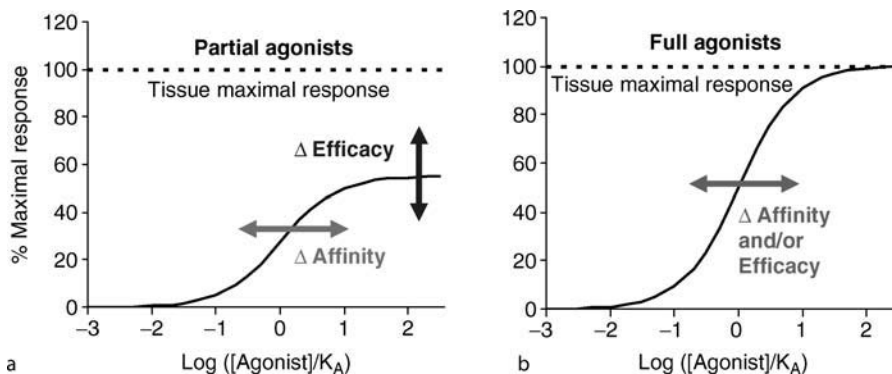

The common currency of drug receptor pharmacology is the dose–response curve, as it defines the relationship between concentrations of drug and the resulting effect. Dose–response curves have three basic properties with which they can be described: threshold abscissal value, slope, and maximum asymptote. The location parameter of the dose–response characterizes drug potency; most often this is quantified as the EC_{50} or the molar concentration of drug producing half the maximal effect. Given tissue systems have maximal capabilities to return drug response. When an agonist produces a maximal response that is equal to the system maximal response it is referred to as a *full agonist*

(Fig. 1). If an agonist produces a submaximal system response it is called a *partial agonist* (Fig. 1). While the potency of an agonist is quantified by the location parameter of the dose-response curve (EC_{50}), a reflection of (but not a direct measure of) the intrinsic efficacy of an agonist is given by its maximal response.

It is important to note that both the quality and quantity of biological response obtained with a given drug depends very much on the assay system used to make the measurement. If the assay does not have the means to detect a given efficacy, then none will be observed; this should not be taken to mean that the drug does not have that particular efficacy. A common case in point

Drug-Receptor Interaction. Figure 1 Dose-response curves to drugs that have direct effects on physiological systems. A drug that produces the maximal effect capable from the system is a *full agonist*. A submaximal effect is produced by a *partial agonist*. Drugs may not produce directly observable effects but may be present on the receptor to produce antagonism (see Fig. 3). If a system is constitutively active and shows an actively elevated basal response, then a drug that reduces this is termed an *inverse agonist*.

Drug-Receptor Interaction. Figure 2 Relationships between affinity and efficacy with different agonist response patterns. (a) For partial agonists, differences in maximal responses between agonists relate to differences in efficacy. Differences in the location parameter of the concentration-response curve (potency) indicate differences in affinity. (b) For full agonists, differences in potency indicate differences in either affinity, efficacy or both.

is the failure of nonconstitutive receptor systems to detect negative efficacy (inverse agonism). For this particular efficacy to be detected, an especially engineered assay must be used. Similar effects are observed in the receptor-mediated signaling effects. While most agonist-bound receptor activates G-proteins, some initiate the binding of intracellular proteins such as beta-arrestin to induce kinase signaling. There are cases, such as for the β -adrenoceptor antagonist ICI 118,551, where the same drug will have a negative efficacy for one response system (i.e., G-proteins) and positive efficacy for another (beta-arrestin kinase stimulation).

In general, if a drug generates a direct response in a system, and if that response is lower in magnitude than the system maximal response (i.e., it is a partial agonist, see Fig. 1), then the location of the concentration-response curve along the concentration axis is determined by the affinity of the agonist and the maximal response is determined by the magnitude of the efficacy (Fig. 2a). If the agonist produces the full system maximal response (it is a full agonist), then it is not possible to assess efficacy (since the maximal response is constant) and the location of the concentration-response curve is determined by a complex function of both affinity and efficacy (Fig. 2b).

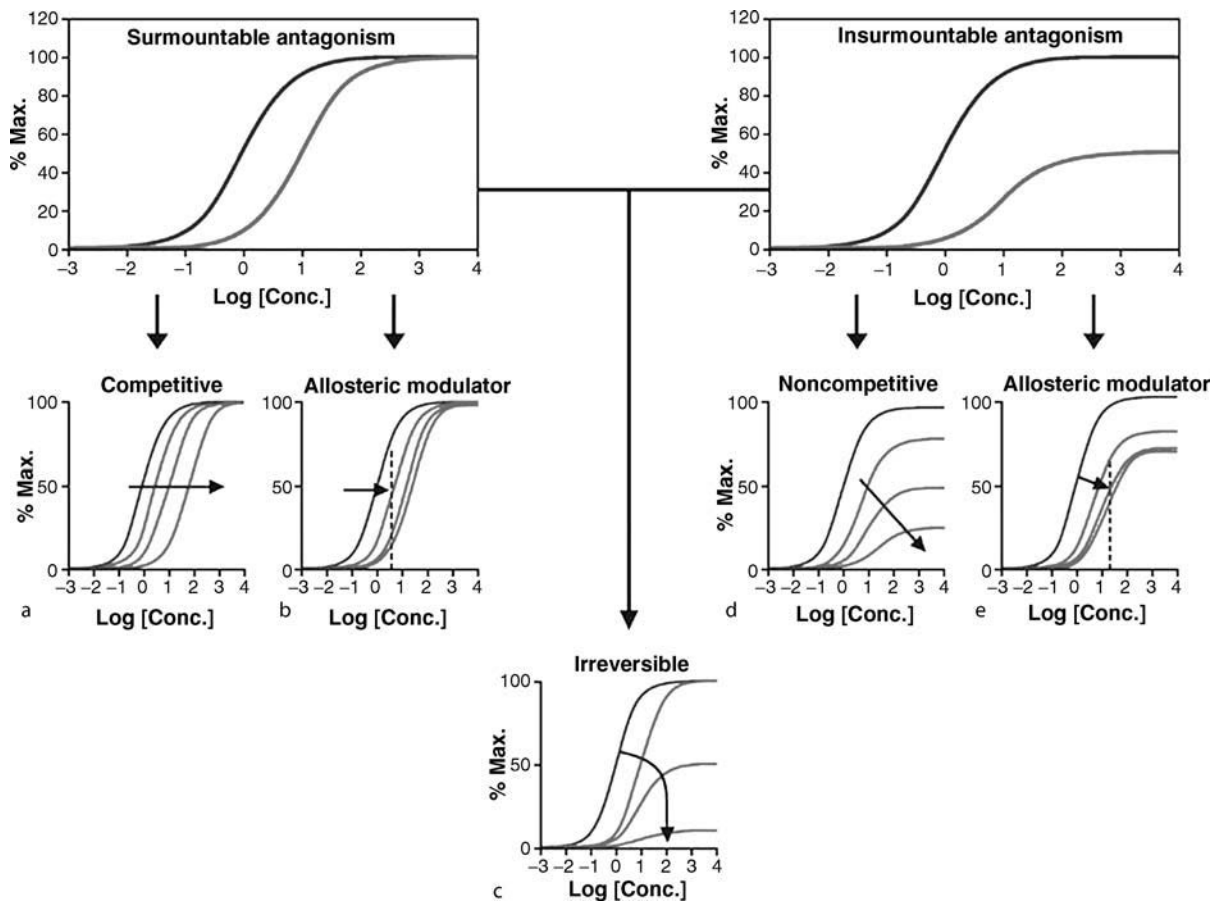

The inhibition of agonist response is termed antagonism. The effect that a given antagonist has on the dose-response curve to an agonist can be a clue to the mechanism of action of that antagonists' interaction with the receptor. In the presence of an antagonist, more agonist must be present in the receptor compartment to produce a response than would be necessary in the absence of the antagonist. A singular characteristic of an antagonist is its effect on the maximal capability of an agonist to overcome the presence of the antagonist and produce the system maximal response. If enough agonist can be added to produce the agonist maximal response in the presence of the antagonist, the

antagonism is referred to as surmountable antagonism (see Fig. 3). If no amount of agonist will produce the maximal response, the antagonism is referred to as insurmountable (see Fig. 3).

A basic concept in receptor pharmacology is the idea of orthosteric and allosteric interaction. Orthosteric interaction occurs when two molecules compete for a single binding domain on the receptor. With allosteric interactions two molecules each have their own binding domain on the receptor and the two interact through effects on the protein (conformational change). Thus, with orthosteric interactions only one molecule may occupy the receptor at any one instant whereas with allosteric interactions both molecules can bind to the receptor at the same time. There are implications for

pharmacological activity, especially for antagonists, that arise from these two molecular mechanisms (*vide infra*).

There are certain molecular mechanisms of antagonism associated with these observed patterns on dose–response curves. Thus, ►**competitive antagonists** produce parallel shifts to the right of agonist dose–response curves with no diminution of maximal response through an orthosteric interaction of antagonist and agonist (Fig. 3a). Theoretically, there is no limit to the degree of dextral displacement a given competitive antagonist can produce on a dose–response curve. ►**Schild analysis** is used to measure the affinity of competitive antagonists. This same pattern of response also can occur with ►**allosteric modulators** (Fig. 3b) but in this case the shift of the agonist dose–response curve

Drug–Receptor Interaction. Figure 3 Various patterns of antagonism of drug effect. Antagonism is classified according to effects on the dose–response curve to the agonist (blue lines). Two general classifications are surmountable antagonism (maximal response to the agonist retained – top left panel) or nonsurmountable antagonism (depressed maximal response to the agonist – top right panel). These general patterns can be the result of different molecular mechanisms. (a) Orthosteric competition between the agonist and antagonist for the same binding site on the receptor. (b) Binding of an allosteric modulator to its own binding site to modify the affinity or efficacy of the agonist in a saturable manner. (c) Irreversible blockade of receptors in a system with *receptor reserve* (parallel shift to the right followed by depression of the maximal response at higher concentrations of antagonist). (d) Blockade of receptor function or access of agonist to the receptor either orthostericly or allosterically in a system with little receptor reserve for the agonist. (e) Saturable allosteric modulation of receptor function by an antagonist in a system with little receptor reserve for the agonist.

is limited to a maximal value defined by the molecular ►**co-operativity factor** of the antagonist. Thus, a hallmark of allosteric inhibition is that it is saturable and reaches a maximal asymptotic value. In some cases, ►**irreversible antagonists** can produce parallel shifts to the right of dose–response curves if there is a ►**receptor reserve** for the agonist (Fig. 3c). This latter mechanism can be detected with increasing concentrations of irreversible antagonist since these eventually cause depression of the maximal response.

In cases where insurmountable antagonism is observed, this can be evidence of ►**non-competitive antagonism**. This can result from an inhibition of receptor function (either orthosteric or allosteric) or be due to antagonist-mediated modification of receptor reactivity to the agonist (Fig. 3e). The *method of ►Gaddum* is used to measure the affinity of noncompetitive antagonists for receptors. Parenthetically, similar effects on dose–response curves are produced by irreversible antagonists when there is no receptor reserve for the agonist.

While antagonist potency (quantified as the equilibrium dissociation constant of the antagonist–receptor complex, specifically the rate of offset of the antagonist away from the receptor divided by the rate of onset toward the receptor) usually is used as a measure of the therapeutic utility of an antagonist (i.e., high potency leads to the use of low dose with the concomitant avoidance of high concentrations that may produce side effects), the kinetics of receptor antagonism also are important. Thus, if antagonist negation of receptor function is the desired effect, then for two antagonists of equal potency, the one with the most persistent binding (slowest rate of offset from the receptor) is preferred. This is referred to as target residence time.

Pharmacological Relevance

An important tenet of receptor pharmacology states that the molecular properties of a drug, namely affinity and intrinsic efficacy, are interpreted and reflected by physiological systems and that this process *controls* what is observed as drug effect. For example, a physiological system requires a certain sensitivity to return response from stimulation by a weak agonist, i.e., the receptor coupling of that system must be of sufficient efficiency to amplify the stimulus into an observable response. When the same weak agonist is tested in a physiological system of lower sensitivity, it might be an antagonist. Thus, it can be seen that the monikers of agonist and antagonist can be system dependent and unreliable as molecular labels for drugs. In the same manner that a system must be of sufficient sensitivity to detect efficacy and return response, it also can be overloaded by a strong stimulus. When this occurs, the system returns the system maximal response and the agonist demonstrates full agonism. A series of agonists of differing intrinsic efficacy may all overload

a given system and all return the same (system) maximal response (all be full agonists); this does not imply that these agonists are of equal efficacy but only that the system was unable to discern different efficacies beyond a certain level. For this reason, the labels of full and partial agonist are also system dependent and not useful for molecular characterization of drugs.

Since drugs are tested in many surrogate systems, it is necessary to develop methods to quantify drug effect in a system-independent manner. Absolute scales are not practical, or in some cases, even possible, in this process. As discussed previously, while an absolute potency for an agonist can be determined by the EC_{50} , the magnitude of this value depends on the sensitivity of the particular measuring system and thus it cannot be extrapolated to other systems. Rather, the relative potency of agonists (ratios of EC_{50} values) is used to quantify agonist power to induce response. This process utilizes the null method and isolates only the intrinsic ability of the agonists to produce response at the receptor level. This allows for the resulting potency ratios to be a measure of relative agonist activity that is comparatively independent of the system in which the measurement is made. This ratio transcends the particular system in which it is measured and is applicable to all systems in which the agonists produce maximal response. Under optimal conditions, the therapeutic profile of the standard agonist will be known in humans, therefore the agonist potency ratio can be used to gauge the expected activity of the experimental agonist in the therapeutic arena.

In the case of antagonists, absolute measures of potency are theoretically possible since these are chemical terms describing the affinity of the drugs for receptor protein. However, physiological systems can also control the observed antagonism. For example, a noncompetitive antagonist will produce a diminution of the maximal response to an agonist in a system where the response is linearly related to the receptor occupancy (Fig. 3d). However, if the receptors in a system are coupled with high efficiency and the agonist has high efficacy, then maximal responses may be achieved with less than maximal agonist receptor occupancy, i.e., there may be a ►**receptor reserve** for the agonist. Under these circumstances the agonist may still produce the maximal response even when the antagonist completely inactivates a portion of the receptors. When this occurs the antagonism resembles competitive antagonism at low concentrations and noncompetitive antagonism at higher concentrations (resembling the profile in Fig. 3c). This would be system dependent and not necessarily indicative of the molecular mechanism of the antagonist.

Another example of where the setpoint of the physiological system can change the observed behavior of drugs is the absence of direct effects of inverse agonists in nonconstitutively active receptor systems.

A receptor system must be constitutively active (elevated basal response) to detect inverse agonism (Fig. 1). In nonconstitutively active receptor systems, inverse agonists behave as simple competitive antagonists.

In general, receptor theory uses indirect mathematical models to estimate descriptors of drug effect. These descriptors still must be used with the proviso that biological systems may still modify drug effect in a system-dependent manner and thus predictions of therapeutic effect must be made with caution across different systems.

Dubin–Johnson Syndrome

The Dubin–Johnson Syndrome is a rare hereditary disease, which is associated with hyperbilirubinemia (high bilirubin and bilirubin-glucuronide plasma concentrations). The disease is caused by *loss of function* mutations in the *ABCC2* gene, which is coding for the ABC-transporter MRP2 (also termed as *multispecific organic anion transporter* (MOAT)). Normally, this transporter is localized in the canalicular membrane of hepatocytes, where it eliminates bilirubin-glucuronide and other organic anions into the bile.

Dynamic Programming

In general, dynamic programming is an algorithmic scheme for solving discrete optimisation problems that have overlapping subproblems. In a dynamic

programming algorithm, the definition of the function that is optimised is extended as the computation proceeds. The solution is constructed by progressing from simpler to more complex cases, thereby solving each subproblem before it is needed by any other subproblem. In particular, the algorithm for finding optimal alignments is an example of dynamic programming.

Dyslipidemia

Dyslipidemia is change in the normal lipid concentrations in the blood. In particular, hypercholesterolemia is a major cause of increased atherogenic risk, leading to atherosclerosis and atherosclerosis-associated conditions, such as coronary heart disease, ischemic cerebrovascular disease and peripheral vascular disease. Both genetic disorders and diets enriched in saturated fat and cholesterol contribute to the elevated lipid levels in a considerable part of the population of developed countries. Hypertriglyceridemia, when severe, may cause pancreatitis. Moderately elevated levels of triglycerides are often associated with a syndrome distinguished by insulin resistance, obesity, hypertension and substantially increased risk of coronary heart disease. Hypercholesterolemia, especially, requires treatment either by diet and/or with lipid-lowering drugs (e.g. statins, anion exchange resins).

E3 Ligase

E3 ligases are enzymes that together with E1 and E2 ligases catalyse the transfer of the ubiquitin polypeptide onto proteins destined for degradation. E1 ligase activates ubiquitin, E2 ligase performs the actual transfer of ubiquitin to the target protein, and E3 ligases are involved in substrate recognition and determining the specificity. Poly-ubiquitinated proteins are degraded in proteasomes.

Ectodermin

A Ring-type ubiquitin ligase for Smad4, serving as a vital regulator of the transforming growth factor-beta (TGF-beta)/BMP signaling pathway in early embryonic development and cancer. As Smad4 is the Comediator Smad and facilitates the translocation of the R-Smads into the nucleus, ectodermin forces Smad4 out of the nucleus and promotes its degradation. Through this regulation of the TGF-beta signaling, ectodermin keeps ectoderm cells pluripotent until gastrulation and ensures that ectoderm cells do not undertake mesoderm fate. Ectodermin is also important in reducing TGF-beta/Smad4 induced cytostasis as it is expressed in the stem cells of colorectal cancer and intestinal crypts.

Edema

Edema refers to an accumulation of interstitial fluid to a point where it is palpable or visible. In general this point is reached with a fluid volume of 2–3 L. Edema formation is the result of a shift of fluid into the interstitial space due to primary disturbances in the hydraulic forces governing transcapillary fluid transport, and of subsequent excessive fluid reabsorption by the kidneys. Deranged capillary hydraulic pressures initiate edema formation in congestive heart failure and liver cirrhosis, whereas a deranged plasma oncotic pressure is leading to edema in nephrotic syndrome and malnutrition. Increased capillary permeability is responsible for edema in inflammation and burns.

Electrochemical Driving Force

The net electrochemical driving force is determined by two factors, the electrical potential difference across the cell membrane and the concentration gradient of the permeant ion across the membrane. Changing either one can change the net driving force. The membrane potential of a cell is defined as the inside potential minus the outside, i.e. the potential difference across the cell membrane. It results from the separation of charge across the cell membrane.

- ▶ Depolarisation

Electroencephalogram (EEG)

A measurement of the brains electrical activity, usually measured by means of electrodes placed on the individual's scalp. The EEG is used clinically to differentiate arousal states and to diagnose epileptic phenomena. It can also be used for more advanced applications such as mapping areas of cognitive activity. By employing mathematical analysis (Fourier transform) of the EEG, a power spectrum can be generated. This yields a portrayal of the relative proportion of the various frequency components present in the signal, which are commonly divided into the followings bands: DELTA less than 4 Hz; THETA 4–8 Hz; ALPHA 8–12 Hz; BETA 13–30Hz; GAMMA greater than 30Hz.

Electromyogram (EMG)

Measurement of muscle activity, usually measured by electrodes placed on the skin. The EMG is used in sleep research to aid in the discrimination of sleep stages, and also as part of diagnosis of sleep disorders such as periodic limb movements and restless legs syndrome.

- ▶ Sleep

Electro-oculogram (EOG)

Measurement of movement of the eyeballs by means of electrodes placed adjacent to the eye sockets. The EOG parameter is important in defining ▶REM sleep. Indeed, in animals sleep experiments where EOG data are not collected, the corresponding sleep state is most correctly termed paradoxical sleep.

- ▶ Sleep

Electrophilic

An electrophile or electrophilic compound is a reagent attracted to electrons that participates in a chemical reaction by accepting an electron pair in order to bond to a nucleophile. Because electrophiles accept electrons, they are Lewis acids. Most electrophiles are positively charged, have an atom which carries a partial positive charge, or have an atom which does not have an octet of electrons. The electrophiles attack the most electron-populated part of a ►nucleophile.

Electrospray Ionization Mass Spectrometry (ESI-MS)

Electrospray ionization mass spectrometry (ESI-MS) is an analytical method for mass determination of ionized molecules. It is a commonly used method for “soft” ionization of peptides and proteins in quadrupole, ion-trap, or time-of-flight mass spectrometers. The ionization is performed by application of a high voltage to a stream of liquid emitted from a capillary. The highly charged droplets are shrunk and the resulting peptide or protein ions are sampled and separated by the mass spectrometer.

Emesis

FREDERICK JOHN MITCHELSON
Department of Pharmacology, University of
Melbourne, Melbourne, VIC Australia

Synonyms

Vomiting

Definition

Emesis is the forceful involuntary expulsion of the stomach contents through the mouth. It is a reflex response that may be initiated by a number of stimuli.

Nausea is an unpleasant sensation of a desire to vomit or of an impending vomiting episode. When prolonged, it may occur in waves and may not always be followed by vomiting.

Retching is the process of emesis but without the actual expulsion of any of the stomach contents.

Basic Mechanisms

The vomiting reflex is controlled by the vomiting centre, a diffuse area in the medullary region of the brainstem. There are a number of ways to initiate the reflex (Fig. 1), including stimulation of sensory receptors in the alimentary canal, activation of the chemoreceptor trigger zone (CTZ) in the ▶area postrema, and excessive motion or other disturbances of the ▶labyrinth. Pregnancy, exposure to radiation, psychological or visual stimuli and various disease states such as migraine, diabetes or uraemia may also cause vomiting.

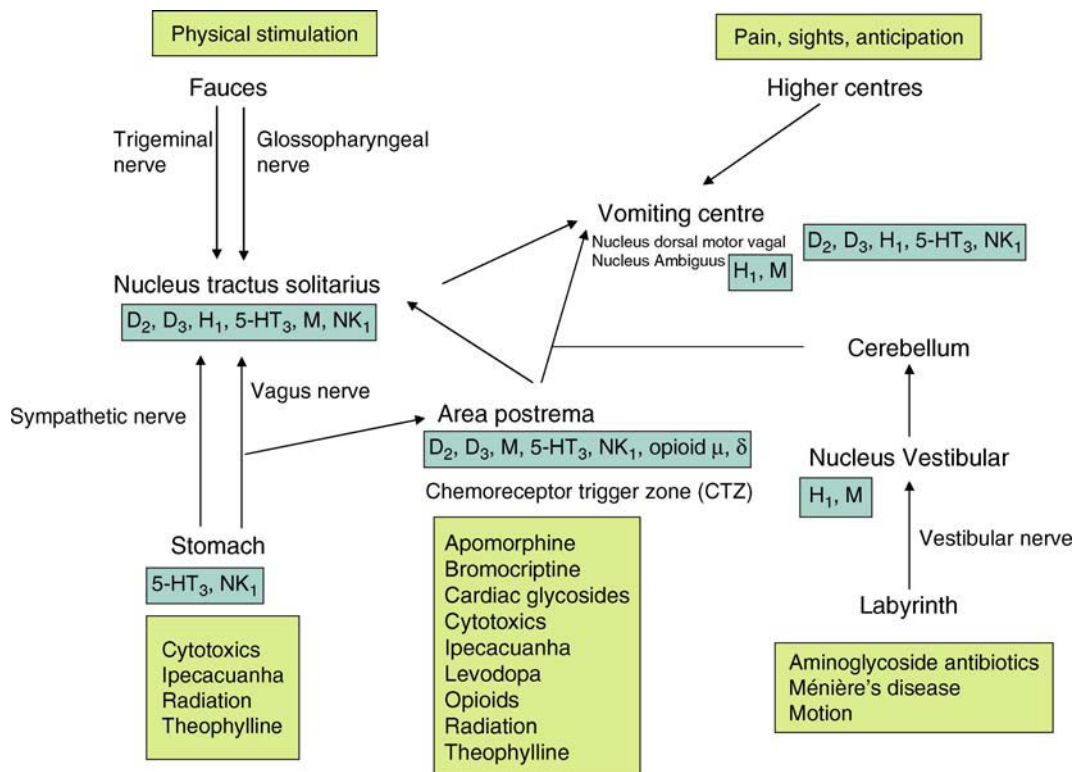

In the gastrointestinal tract, drugs or toxins, as well as mechanical stimulation, induce emesis by activation of sensory receptors on afferent neurons in the vagus and sympathetic nerves. Information is relayed to the vomiting centre via the nucleus tractus solitarius

(NTS) in the medulla. The area postrema lacks a ▶blood–brain barrier and is accessible to emetogens in the bloodstream. Neurons pass from the CTZ to the NTS and the vomiting centre.

Impulses from the vestibular apparatus in the labyrinth are conducted via the vestibular nucleus and cerebellum to the vomiting centre. Abnormal stimulation of the vestibular apparatus is involved in motion sickness and emesis, associated with ▶Ménière's disease.

Nausea and vomiting may also be induced by stimuli affecting higher centres of the brain, presumably the cortex, from unpleasant sights and smells as well as pain. Anticipatory vomiting also may occur during cancer chemotherapy. The ▶act of vomiting involves contraction of the diaphragm and abdominal muscles, to increase intragastric pressure. Also, retroperistaltic contractions of the intestine move the contents back into the stomach. Relaxation of the oesophagus and the cardiac sphincter at its lower end then allows the stomach contents to be vomited. The role of the stomach is passive, as active contraction is inhibited preceding emesis.

Nausea is often assumed to be a low level stimulation of the vomiting reflex. However, vomiting occurs without nausea in intestinal obstruction and in space

Emesis. Figure 1 Afferent pathways involved in vomiting. Some stimuli for initiation of vomiting from the various locations are shown in the boxes. The presence of receptors at a particular location does not imply that they are necessarily involved in normal transmission of the vomiting reflex.

motion sickness. Elevated plasma levels of ►**vasopressin** as well as tachygastric may play a role in nausea development.

Several neurotransmitters and ►**autacoids** are involved in initiating and conducting the vomiting reflex, including ►**acetylcholine**, **dopamine**, **histamine**, **serotonin**, **substance P (SP)** and possibly ►**prostaglandins**. Receptors for the neurotransmitters are known to occur in many central areas associated with pathways for initiating emesis (Fig. 1). However, the presence of receptors may not be always indicative of their involvement. For example, muscarinic receptors in the area postrema are probably not involved in motion sickness since all muscarinic receptor antagonists that are active as antiemetics have a non-quaternary structure, suggesting that they must be capable of crossing the blood–brain barrier.

Dopamine D₂ receptors are involved in some emetic responses but studies have also suggested that activation of D₃ receptors in the area postrema may either produce vomiting or enhance that elicited by D₂ receptor activation.

Release of serotonin from enterochromaffin cells in the gastrointestinal tract with activation of serotonin 5-HT₃ receptors on vagal afferents has an important role in the initiation of vomiting by anticancer drugs, exposure to radiation and in postoperative vomiting after abdominal surgery and may cause the vomiting seen on oral ingestion of hyperosmolar solutions of sodium chloride or after intravenous injection of erythromycin.

The neurokinin, substance P (SP), may be involved as a sensory transmitter in afferent vagal nerves involved in the vomiting reflex. Both SP and its receptors (NK₁ receptors) have been detected in several areas of the brain associated with vomiting, including the AP, NTS and dorsal motor vagal nucleus. The neurokinin can activate neurons in the AP and NTS. SP is present also in sensory nerves in the gut as well as being co-localised with serotonin in some enterochromaffin cells.

Clinical Aspects

Drug-Induced Emesis

Emetogenic drugs may be of value in treating cases of acute poisoning but usually nausea and vomiting induced by a drug are unwanted effects occurring in addition to its therapeutic action.

Emetics for Poisoning – Ipecacuanha

The most widely used emetic is syrup of ipecac, containing the alkaloids, emetine and cephaeline. Emetine induces vomiting by activation of sensory neurons in the vagus and sympathetic nerves to the stomach and centrally in the medulla, possibly at the CTZ. The release of serotonin and SP may be involved as 5-HT₃ and NK₁ receptor antagonists prevent emesis induced

by ipecacuanha. The use of syrup of ipecac in the treatment of poisoning is declining as activated charcoal is equally or more effective with fewer complications.

Cytotoxics

The incidence of vomiting in cancer chemotherapy is variable; the highly emetogenic cisplatin affects >90% of patients but some with low emetogenic potential such as vincristine, affect <10%. The time course of emesis also varies; cyclophosphamide induces a single phase that persists for 24 h whereas cisplatin produces a biphasic pattern; an acute phase, peaking at 6 h and a less intense second phase, peaking at day 2–3. Patients on repeated courses of chemotherapy often develop anticipatory vomiting and nausea, commencing several hours before treatment is given, subsequent to the initial course. This appears to be due to associative learning together with psychological stress from the drug regimen.

Cytotoxics cause an elevation of dopamine levels in the area postrema in animal studies and may release prostaglandins and inhibit enzymes such as enkephalinases to allow increased levels of enkephalins to activate opioid receptors on dopaminergic nerves.

Cytotoxics also cause cellular damage and the release of serotonin and other mediators from enterochromaffin cells. There is conflicting evidence regarding whether 5-HT₃ receptors in the medulla are activated also during chemotherapy and contribute to production of emesis. Currently, the weight of evidence favours peripheral 5-HT₃ receptors, with minor involvement of central receptors.

Release of SP from neurons in the AP, NTS and dorsal vagal motor nucleus may play a role in vomiting induced by cytotoxics. Based on the relative effectiveness of selective antagonists of 5-HT₃ receptors and NK₁ receptors against acute and delayed phases of cisplatin-induced vomiting, it has been suggested that serotonin has a greater role in the acute phase whereas SP has the major role in the delayed phase.

Dopamine Receptor Agonists

Parkinsonian patients receiving the dopamine precursor, levodopa or dopamine receptor agonists, such as bromocriptine and apomorphine may experience nausea and vomiting due to stimulation of dopamine D₂ receptors in the CTZ.

Opioids

Opioids act on the area postrema and/or the NTS via μ or δ receptors to produce emesis. Also, ambulatory patients receiving opioids are more affected than those confined to bed, suggesting a vestibular component in the effect. The emetic action of opioids is complicated by an antiemetic action, possibly involving two receptors at the NTS or the vomiting centre.

Morning Sickness and Hyperemesis Gravidarum

Morning sickness is experienced by many expectant mothers, during the first 3 months of gestation. Symptoms usually consist of nausea and retching rather than vomiting but a few women experience protracted vomiting (hyperemesis gravidarum). The basis for morning sickness is not known but has been variously considered to involve psychosomatic, endocrine, allergic and metabolic aspects. It may be a protective mechanism against ingestion of toxins or harmful chemicals in foodstuffs. Endocrine studies show hyperemesis gravidarum is associated with elevated serum levels of human chorionic gonadotrophin.

Motion Sickness

Motion sickness arises in the vestibular apparatus. Stimulation of the semicircular canals or the utricles by unfamiliar accelerating movement may cause a mismatch between the sensory information reaching the brain centres controlling balance and posture, with that anticipated. Motion sickness may be avoided by reducing 'sensory conflict'; fixing vision on a stable reference point, such as the horizon may be effective. Cortical centres may also contribute; memories of previous travel or the sight, and sounds of others being affected often increases susceptibility.

Postoperative Vomiting

The incidence of postoperative nausea and vomiting is variable, depending on a number of factors. These include the type of operations as well as the sex and age of the patient; women and children being more prone. Also, the type of anaesthetic and whether other drugs are used; opioids for example increase the incidence. Intraabdominal operations, neurosurgery and breast, eye, ear, nose or throat surgery have a high likelihood of nausea and vomiting. Overall incidence has been estimated at ca. 20–30%.

Pharmacological Intervention

Cannabinoids

Dronabinol (tetrahydrocannabinol), the active principle from cannabis and synthetic cannabinoids, nabilone and levonantradol are effective in treating nausea and vomiting in cancer chemotherapy. The mode of action is unclear but appears to involve cannabinoid CB₁ receptors. Cannabinoids have been shown to reduce acetylcholine release in the cortex and hippocampus, and have been suggested to inhibit medullary activity by a cortical action. Inhibition of prostaglandin synthesis and release of endorphins may also be involved in the antiemetic effect. A review of trials of dronabinol, nabilone or levonantradol concluded that while the cannabinoids were superior to placebo or dopamine receptor antagonists in controlling emesis

due to moderate emetogenic cancer chemotherapy, they produced harmful adverse effects more frequently.

Corticosteroids

Dexamethasone and methylprednisolone are useful antiemetics in chemotherapy, radiotherapy and postoperative vomiting, possibly acting by inhibiting central prostaglandin formation. They are used either alone for low emetogenic risk chemotherapy or in combination with 5-HT₃ receptor antagonists and aprepitant to improve control for moderate to highly emetogenic chemotherapy. Steroids have been found useful in the delayed, as well as acute phase of cisplatin-induced emesis. They can also be combined with metoclopramide and other dopamine receptor antagonists to enhance control of cytotoxic-induced vomiting. Used alone before induction of anaesthesia or in combination with 5-HT₃ receptor antagonists or high dose metoclopramide has improved control of postoperative vomiting.

Dopamine D₂-Like Receptor Antagonists

Several D₂-like receptor antagonists are used as antiemetics. They include phenothiazines (metopimazine, perphenazine, prochlorperazine, thiethylperazine), butyrophenones (droperidol, haloperidol), metoclopramide and domperidone. Metoclopramide also raises tone in the lower oesophagus and increases gastrointestinal motility and in high concentrations causes blockade of serotonin 5-HT₃ receptors. Domperidone does not readily cross the blood–brain barrier. It is particularly useful in controlling emesis associated with levodopa and dopamine receptor agonists used in Parkinsonism as it will not affect their beneficial action in the basal ganglia. The D₂-like receptor antagonists are useful in emesis occurring postoperatively and for cancer chemotherapy or radiotherapy but are not effective in motion sickness.

Metoclopramide, used in high doses, is more effective than other D₂ receptor antagonists in emesis due to cancer chemotherapy but its usefulness is limited by ▶extrapyramidal effects. Early clinical studies suggested variable effectiveness in postoperative nausea and vomiting but a recent multicentre-study has shown that a high dose administered intraoperatively, in combination with dexamethasone, produced effective control with minimal extrapyramidal effects. Metoclopramide is also effective in vomiting associated with migraine or uraemia and both metoclopramide and domperidone reduce nausea and vomiting associated with diabetic gastroparesis.

Histamine H₁ Receptor Antagonists (Histamine and Emesis)

Several histamine H₁ receptor antagonists are effective in treating motion sickness, Ménière's disease, morning sickness, uraemia and postoperative vomiting. They are not effective against cytotoxics. Antagonists with

piperazine-based structures (chlorcyclizine, cinnarazine, cyclizine, meclozine) or ethanolamine-based (dimenhydrinate, diphenhydramine, doxylamine) as well as promethazine are effective and appear to depend on central inhibition of histamine H₁ receptors and possibly also on an ability to inhibit muscarinic receptors. The non-sedating H₁ receptor antagonist, astemizole, is not effective in motion sickness. There has been considerable controversy regarding whether H₁ receptor antagonists pose a teratogenic risk when used to treat morning sickness but a meta-analysis has concluded that they can be used safely in pregnancy if nausea and retching cannot be controlled adequately by dietary modification.

Lorazepam

The benzodiazepine, lorazepam, acts allosterically on GABA_A receptors to facilitate the actions of GABA. Lorazepam has some antiemetic activity in cancer chemotherapy. When used in combination therapy, it does not appear to add to antiemetic control but may contribute to a reduction in anxiety.

Muscarinic Receptor Antagonists

These include atropine, scopolamine (hyoscine), trihexyphenidyl (benzhexol) and benztropine. They block central muscarinic receptors involved in various afferent pathways of the vomiting reflex (Fig. 1). They have been used to control motion sickness, emesis in Ménière's disease and postoperative vomiting. Currently, hyoscine is largely restricted to the treatment of motion sickness where it has a fast onset of action but a short duration (4–6 h). Administration of hyoscine by transdermal patch produces a prolonged, low-level release of the drug with minimal side effects. To control postoperative vomiting, it should be applied >8 h before emesis is anticipated.

Neurokinin NK₁ Receptor Antagonists

Aprepitant [MK-869, L-754030] is the only member of this class currently licensed for general clinical use. Animal studies have shown that several non-peptide NK₁ receptor antagonists inhibit emesis produced by the neurokinin, substance P and other emetogens such as apomorphine, morphine, ipecacuanha, cytotoxics and radiation. Clinical trials with non-peptide antagonists have relieved nausea and vomiting after gynaecological surgery and after cisplatin, and other chemotherapy. There is international consensus that combination of aprepitant with a 5-HT₃ receptor antagonist and dexamethasone produces the most effective control of vomiting after cyclophosphamide plus an anthracycline, as well as both acute and delayed emesis after cisplatin. Effectiveness of the combination against cisplatin is maintained over at least six cycles of therapy.

Aprepitant, which inhibits the cytochrome P450 isoform, CYP3A4, is metabolised by it. As a result,

aprepitant inhibits the metabolism of dexamethasone and methylprednisolone.

Pyridoxine

▶Pyridoxine is used in morning sickness. Its mechanism of action remains unclear and several reviews of the use of pyridoxine have failed to find conclusive evidence of effectiveness. A recent double blind trial found pyridoxine to be of benefit in reducing nausea only. Some clinicians use pyridoxine as the first drug on the basis that it is the least likely to be toxic to the foetus.

Serotonin 5-HT₃ Receptor Antagonists

Those developed for clinical use as antiemetics include dolasetron, granisetron, ondansetron, palonosetron and tropisetron. They are effective against vomiting occurring postoperatively and that induced by cytotoxics or radiation. There is international consensus that these compounds are used first if vomiting occurs postoperatively in patients with no preoperative prophylaxis and that they are the preferred treatment in combination with dexamethasone for prevention of acute emesis induced by chemotherapy of moderate risk. For low to moderate risk radiation-induced emesis, there is consensus that they are the preferred antiemetic and for high risk, that they should be used in combination with dexamethasone. Preliminary evidence suggests they may also limit binge-vomiting in bulimics and ondansetron has been shown to reduce nausea, following intraduodenal infusion of lipids. The 5-HT₃ receptor antagonists are ineffective against motion sickness.

Endocannabinoids

VINCENZO DI MARZO

Endocannabinoid Research Group, Institute of Biomolecular Chemistry, Pozzuoli, (NA), Italy

Synonyms

Endogenous cannabinoids; Endogenous agonists of cannabinoid receptors

Definition

Endocannabinoids are endogenous mediators acting via the binding to, and activation of, ►cannabinoid receptors, CB₁ and CB₂ [1]. *N*-arachidonoyl-ethanolamine (AEA, anandamide) and 2-arachidonoyl-glycerol (2-AG) (Fig. 1) are the two most studied endocannabinoids. In the nervous system, endocannabinoids act as

►neuromodulators. In peripheral non-nervous tissues, they act as autocrine or paracrine regulators of the homeostasis of other chemical mediators.

Basic Characteristics

Endocannabinoid Biosynthesis

Both AEA and 2-AG are biosynthesized “on demand” and released from cells immediately after their production. These events are triggered by the enhancement of intracellular Ca²⁺ concentrations that follows cell depolarization or the mobilization of intracellular Ca²⁺ stores subsequent to stimulation of G_{q/11} protein-coupled receptors [2]. However, in many cases, the levels of the two main endocannabinoids are modulated in different and sometimes even opposing ways via the modulation of the activity and/or expression of either biosynthetic or degrading enzymes or both. AEA is produced from the processing of *N*-arachidonoyl-phosphatidylethanolamine (NArPE), which in turn is obtained from the enzymatic transfer of arachidonic acid esterified on the *sn*-1 position of phospholipids to the nitrogen atom of phosphatidylethanolamine, via an as-yet unidentified *N*-acyltransferase. The enzyme catalyzing the one-step conversion of NArPEs and other *N*-acylphosphatidylethanolamines (NAPEs) into AEA and other *N*-acyl-ethanolamines is the same and is termed NAPE-selective phospholipase D (NAPE-PLD). It is: (i) enzymatically distinct from other PLD enzymes, (ii) stimulated by Ca²⁺, and (iii) a member of the β -lactamase fold of the zinc-metallo-hydrolase family of enzymes. Its over-expression in cells leads to higher cellular levels of AEA and correspondingly lower levels of NArPE, thus supporting its role in the biosynthesis of this endocannabinoid. However, three more pathways have been identified that can transform NArPE into AEA. In macrophages, a phospholipase C (PLC) converts NArPE into AEA via phospho-AEA. PTPN22, a protein tyrosine phosphatase, is the enzyme catalyzing phospho-AEA hydrolysis to AEA. In brain homogenates, NArPE can be converted into 2-lyso-NArPE, via the action of a groupIB soluble phospholipase A₂, or into glycerophospho-AEA, via alpha/beta-hydrolase 4. AEA is then formed via the hydrolysis of 2-lyso-NArPE by a selective lysophospholipase D, or of glycerophospho-AEA by a phosphodiesterase, respectively (Fig. 2).

2-Arachidonate-containing DAGs are the most frequent biosynthetic precursors of 2-AG. They are produced from the hydrolysis of phosphoinositol-bis-phosphate (PIP₂), catalysed by the PIP₂-selective PLC, or, in some cases, from the hydrolysis of phosphatidic acid, catalysed by a phosphohydrolase. DAGs are then converted into 2-AG by the action of two plasma membrane *sn*-1-selective DAG lipases, DAGL α and DAGL β (Fig. 2). These two enzymes: (i) contain the typical lipase-3 and Ser-lipase signature sequences, in which two highly conserved amino acid residues, Ser443 and Asp495, are

Endocannabinoids. Figure 1 Chemical structures of the two most studied endocannabinoids, anandamide and 2-arachidonoylglycerol, of *Cannabis sativa* psychoactive principle, Δ⁹-tetrahydrocannabinol, and of the CB₁ receptor antagonist/inverse agonist, rimonabant.

necessary for enzymatic activity, (ii) exhibit also four hydrophobic, possibly *trans*-membrane, domains near their N terminus, (iii) are stimulated by Ca²⁺ and (iv) do not prefer DAGs with any particular fatty acyl chain in the *sn*-2 or *sn*-1 position, although they exhibit strong selectivity for DAGs over phospholipids, monoacylglycerides, triacylglycerols and fatty acid amides. DAGLα is more abundant in the adult brain, and DAGLβ in the developing brain. Both enzymes are co-localized with CB₁ receptors in neuronal axons of the perinatal nervous system, and “move” to post-synaptic neurons in the adult brain. DAGLα is found in post-synaptic dendritic spines establishing synapses with CB₁ expressing axons, thus supporting the proposed roles for 2-AG as a ►retrograde messenger of ►synaptic plasticity in the adult brain.

Endocannabinoid Action

Once released from cells, endocannabinoids bind to cannabinoid receptors and elicit typical CB₁- and CB₂-mediated intracellular signalling events, thereby leading to biological responses typical of cannabinoid receptor agonists [1, 2]. However, the functional role of endocannabinoids cannot be inferred only from the knowledge of the pharmacological effects of Δ⁹-►tetrahydrocannabinol (THC) and synthetic cannabinoids for several reasons: (i) because of the mechanisms underlying their biosynthesis and because of their rapid metabolism, endocannabinoids appear to be produced only “when and where” needed. Thus, for example, if endocannabinoids are being made and released to protect a neuron from glutamate-induced excitotoxicity, they will be released only from the post-synaptic neuron undergoing excessive stimulation

by glutamate, to inhibit only glutamate release from the pre-synaptic glutamatergic neuron, without inhibiting the activity of GABA-ergic interneurons, which, by releasing GABA, also tone down excitotoxicity. This specificity of endocannabinoid action is not always maintained when CB₁ receptors are activated by exogenous agonists, (ii) in some cases endocannabinoids are biosynthesized together with congeners that are inactive per se at cannabinoid receptors, but can nevertheless modulate the activity of AEA and 2-AG or even act at different receptors, (iii) endocannabinoids, and AEA in particular, can act also at non-cannabinoid receptors, including ion channels and receptors for neurotransmitters or other neuromodulators and (iv) arachidonic acid produced from the degradation of exogenously administered endocannabinoids (see below) can be used to generate other mediators, which in turn may act on other targets. Therefore, to understand endocannabinoid action, pharmacological studies using cannabinoid CB₁ and CB₂ receptor agonists and ►antagonists/inverse agonists, and inhibitors of endocannabinoid metabolism, must be accompanied by observations on the phenotype of CB₁, CB₂ and FAAH “knock-out” mice, and by the quantification of anandamide and 2-AG levels in various tissues under physiological and pathological conditions (see below). It was established that, in the brain, endocannabinoids act as retrograde messengers acting on pre-synaptic CB₁ receptors in both short-term and long-term forms of synaptic plasticity. These retrograde actions underlie at least part of CB₁-mediated regulation of cognitive and emotional functions in the brain, reinforcement of substances of abuse in the mesolimbic system,

induction of appetite or reduction of satiety in the hypothalamus and brainstem, and control of movement and posture in the basal ganglia and cerebellum. Neuromodulatory, CB₁-mediated actions of endocannabinoids in the sensory and autonomic nervous systems result in the regulation of circulatory and gastrointestinal functions and the hypothalamic-pituitary-adrenal axis. Direct autocrine or paracrine actions in non-neuronal cells underlie the several CB₁- and CB₂-mediated effects of these compounds on female and male reproduction, bone formation, immune response and adipocyte, and β -cell function.

Endocannabinoid Inactivation

AEA is inactivated through intracellular enzymatic hydrolysis to arachidonic acid and ethanolamine (Fig. 2). The enzyme catalyzing this reaction was named “fatty acid amide hydrolase” (FAAH) as it recognizes as substrates also other long chain fatty acid amides, including *N*-acylethanolamines, primary amides, *N*-acyl-aminoacids and *N*-acyl-taurines. FAAH catalyses efficiently also the hydrolysis of long chain fatty acid esters, including 2-AG. The physiopathological role of FAAH as a major endocannabinoid-inactivating enzyme has been assessed through: (i) the study of the phenotype of transgenic mice lacking the enzyme, i.e. the “FAAH knockout mice”, (ii) the design and pharmacological testing in vivo of specific FAAH inhibitors, (iii) immunohistochemical studies describing the tissue and cellular distribution of the enzyme and its relationship with cannabinoid receptor distribution and (iv) the identification of *Faah* gene polymorphisms associated with disorders such as obesity, propensity to drug addiction and schizophrenia.

In addition, Monoacylglycerol lipase (MAGL) enzymatic activities inactivate 2-AG (Fig. 2). A MAGL was cloned recently from the rat and evidence for its role in 2-AG degradation in isolated cells was provided by the use of “silencing RNA” techniques. The cloned MAGL seems to account for only 50% of the total 2-AG-hydrolyzing activity in soluble fractions of rat brain, and pharmacological evidence for the existence of other MAGL isoforms has been provided. The cloned MAGL recognizes as substrates both *sn*-1 and -2-acylglycerols with almost any unsaturated long chain fatty acid esterified to the glycerol backbone, but is inactive with fatty acid amides. It is distributed in the CNS in the same brain regions as CB₁ receptors and is a pre-synaptic enzyme, in agreement with the necessity of inactivating 2-AG acting as a retrograde signal. However, our current knowledge of the role of MAGL is still limited due to the lack of a “knockout” mouse for this enzyme and of selective inhibitors. Whether FAAH degrades 2-AG constitutively is still controversial. Selective FAAH inhibitor does produce a significant

elevation of 2-AG tissue levels under certain conditions of administration and in certain tissues.

In cell free systems or isolated cells, some enzymes of the arachidonate cascade can also recognize AEA and 2-AG as substrates, thereby producing the corresponding lipoxygenase and cyclooxygenase-2 derivatives. However, these metabolites have not yet been isolated from tissues and their biological relevance is still unknown.

Endocannabinoid Membrane Transport

AEA and 2-AG need to be transported across the membrane in order to interact with either cannabinoid receptors or intracellular hydrolyzing enzymes (Fig. 2) [3]. It is still being debated whether or not endocannabinoid uptake by, and release from, cells occurs via a membrane transporter, and not via simple **passive diffusion**. Intracellular degradation of AEA by FAAH was suggested to be the only drive behind its cellular uptake. However, strong indirect evidence exists for specific proteins facilitating the membrane transport of both AEA and 2-AG. Experiments carried out using cells from FAAH knockout mice, confocal microscopy to assess the spatial and functional separation between anandamide uptake and hydrolysis, and synthetic inhibitors capable to distinguish between FAAH and proteins responsible for the cell membrane binding/cellular uptake of AEA, favour the existence of one or more specific proteins for AEA transport. Nevertheless, no such protein has been cloned or identified to date.

Drugs

Pathological Conditions in Which Endocannabinoids are Involved

Endocannabinoid levels often undergo dramatic tissue-specific changes in both animal models of disorders and in human diseases (Table 1) [4]. During some acute pathological states or transient near-physiological perturbations of the normal homeostasis of the organism, the levels of at least one endocannabinoid are elevated only in the tissues specifically involved in the disorder to help re-establishing the levels of other endogenous mediators. This occurs, for example, following insults or stressful stimuli ranging from brief food deprivation, restriction-induced stress, and retrieving of aversive memories to administration of acute painful stimuli, head injury, and ischemia. In the case of progressive/chronic disorders, endocannabinoid levels can become permanently elevated, although again in a tissue-selective way. This might lead again to homeostatic (e.g. anti-inflammatory or cell protective) effects in ways mediated by CB₁- or CB₂ receptors (or also by non-cannabinoid receptors), as in the case of some types of cancer (breast and colorectal carcinoma, glioma, etc.) or inflammatory gastrointestinal disorders (colitis,

Endocannabinoids. Table 1 Changes of endocannabinoid levels during pathological conditions and subsequent possible pharmacological interventions

Disorder	Effects on endocannabinoid levels	Potential drugs
<i>Neurodegenerative/neuromotor disorders:</i>		
1. Parkinson's disease (PD)	1. In a non-human primate model of PD endocannabinoid levels are elevated in the basal ganglia and may contribute to the generation of parkinsonian symptoms and/or to expression of levodopa-induced dyskinesia. The cerebrospinal fluid of untreated PD patients contains elevated levels of AEA	1. CB ₁ antagonists or biosynthesis inhibitors
2. Alzheimer's disease (AD)	2. In the hippocampus of β -amyloid-treated rats, an animal model of AD, 2-AG levels are elevated and exert neuroprotection but also participate in memory retention loss	2. Inhibitors of cellular re-uptake or CB ₁ antagonists, possibly depending on the phase of the disorder
3. Amyotrophic lateral sclerosis (ALS)	3. AEA and 2-AG increase in the spinal cord of SOD1 transgenic mice, a model of ALS, to inhibit disease progress	3. CB ₂ receptor agonists or inhibitors of degradation
4. Multiple sclerosis (MS)	4. In rats with EAE, an animal model of multiple sclerosis, AEA and 2-AG levels are decreased in the striatum and midbrain. This might be associated with motor impairment	4. Inhibitors of degradation (both FAAH and cellular re-uptake)
<i>Neuronal excitotoxicity</i>	AEA levels are elevated in the hippocampus of mice treated with kainic acid. 2-AG levels are elevated in rats treated with pilocarpine. These are two animal models of epileptic seizures, where the endocannabinoids play an anti-convulsant and protective function	Inhibitors of cellular re-uptake
<i>Neuropathic pain</i>	Endocannabinoid levels are elevated in periaqueductal grey, rostral ventral medulla and spinal cord during chronic constriction injury of the sciatic nerve in the rat, probably to inhibit pain	<ul style="list-style-type: none"> • FAAH inhibitors • Cannabis extracts (e.g. Sativex)
<i>Gastrointestinal disorders:</i>		
1. Colon inflammation	1. AEA levels are elevated in the colon of DNBS-treated mice and in the colon submucosa of TNBS-treated rats, two animal models of inflammatory bowel diseases, and in the biopsies of patients with ulcerative colitis, to control inflammation	1. Inhibitors of degradation (both FAAH and cellular re-uptake)
2. Cholera toxin-induced diarrhoea	2. Increased AEA levels after administration of cholera toxin to mice, a model of diarrhoea, exert anti-secretory action in the small intestine	2. Inhibitors of cellular reuptake
3. Diverticular disease	3. Increased AEA levels in colon strips from patients with diverticular disease participate in alterations of neural control of colon motility	3. None tested
4. Paralytic ileus	4. Increased AEA levels participate in inhibition of small intestine motility	4. CB ₁ antagonists
<i>Eating and metabolic disorders:</i>		
1. Anorexia nervosa (AN) and Binge-eating disorder (BED)	1. Increased blood levels of AEA in patients with AN and BED may participate in reward aspects of aberrant eating behaviours	1. None tested

Endocannabinoids. Table 1 Changes of endocannabinoid levels during pathological conditions and subsequent possible pharmacological interventions (Continued)

Disorder	Effects on endocannabinoid levels	Potential drugs
2. Obesity and hyperglycemia	2. 2-AG levels are elevated in mouse adipocytes and epididymal of mice with DIO. AEA and 2-AG levels are elevated in rat insulinoma β -cells, in pancreas of mice with DIO, and in obese women. Patients with obesity or hyperglycaemia caused by type 2 diabetes exhibit elevated levels of 2-AG or of both endocannabinoids in visceral fat or blood, respectively. AEA levels are elevated in the liver of DIO mice	2. CB ₁ antagonists
Cancer	Elevated levels of AEA in glioblastomas, increased levels of 2-AG in meningiomas, elevated levels of both AEA and 2-AG in colorectal carcinoma, with possible anti-tumour action	Inhibitors of degradation (both FAAH and cellular re-uptake)

Recent data are shown on those pathological conditions in which endocannabinoid levels are found to be altered in the tissues or organs affected by the disorder. Depending on the possible functional significance of these changes, pharmacological intervention with degradation inhibitors/agonists or with biosynthesis inhibitors/antagonists is suggested as a possible therapeutic strategy

AEA, anandamide; 2-AG, 2-arachidonoyl glycerol; EAE, experimental autoimmune encephalomyelitis; DIO, diet-induced obesity

diverticular disease, celiac disease) [4, 5]. However, a chronic over-activity of CB₁ receptors might eventually contribute to the development of also some of the symptoms typical of the disorder. This situation has been described for some experimental models of Parkinson's disease (PD) and Alzheimer's disease (AD), of genetic and diet-induced obesity, and of hepatic fibrosis, osteoporosis, ►paralytic ileus and ►noxious hypotension [3, 5]. In the female reproductive system, a critical balance between anandamide synthesis and degradation in mouse embryos and oviducts creates the appropriate conditions for normal development of embryos and their oviductal transport, the malfunctioning of which possibly explains the association observed between lower FAAH/higher AEA levels in the blood of pregnant women and pre-term abortion. Finally, a reduction of endocannabinoid levels is found in the brain of mice with experimental allergic encephalomyelitis, a mouse model of multiple sclerosis, in animal models of Huntington's chorea, and in patients with migraine. The subsequent impaired CB₁ signalling might explain some of the clinical hallmarks of these disorders (Table 1).

Endocannabinoid-Based Drugs

Based on the role of endocannabinoids and cannabinoid receptors in several pathological conditions, the pharmacological manipulation of their levels or action is being developed as a therapeutic strategy. Enhancement of endocannabinoid signalling when this plays uniquely a protective role can be effected in a safer way using: (i) cannabis extracts in which the presence of non-psychotropic cannabinoids with therapeutic activity per

se mitigates the unwanted CB₁-mediated effects of THC and potentiates those of more therapeutic value, (ii) synthetic compounds specific for CB₂ receptors and (iii) inhibitors of endocannabinoid degradation, which are likely to act only in those tissues where there is an ongoing turnover of endocannabinoids. Inhibitors of endocannabinoid action or biosynthesis will be of benefit, instead, in those conditions where endocannabinoids contribute to the symptoms or progress of disease. The marketing in Europe of a CB₁ receptor antagonist/inverse agonist (rimonabant, Acomplia[®]) (Fig. 1) against obesity and the ►metabolic syndrome, and in Canada of Sativex[®], a cannabis extract, against neuropathic pain in multiple sclerosis, demonstrate that it is possible to interact safely with the endocannabinoid system, and open the way to future studies in disorders ranging from neuronal damage, anxiety and depression to chronic pain, hypertension, cancer and gastrointestinal disorders [4, 5].

Endocytosis

A process in which a substance gains entry into a cell. Endocytic mechanisms are crucial for a variety of cellular functions such as the uptake of nutrients, regulation of cell surface expression of receptors, maintenance of cell polarity, and more. Receptor-mediated endocytosis via clathrin-coated pits is the most studied endocytic process, which is important for regulation of the time and magnitude of signals generated by a variety of cell-surface receptors.

Endogenous Antipyresis

The inherent mechanism that prevents the height of fever from reaching a potentially dangerous level. It is mediated by substances liberated both systemically and within the brain during fever that counter the formation or action of endogenous pyrogens, or inhibit the activity of neural circuits that modulate febrigenesis.

Endogenous antipyretics include certain cytokines, neuropeptides, glucocorticoids, hormones, nitric oxide, and others.

- ▶ Fever

Endogenous Opioid Peptides

Endogenous opioid peptide released both in the central nervous system and in other apparatuses of the body that have many regulatory functions, including inhibition of pain transmission.

Endogenous opioid peptides are the wide variety of endogenous peptides isolated since 1975 which are the natural ligands for the opioid receptors. The peptides

derive from three precursor molecules (proopiomelanocortin, proenkephalin, prodynorphin); each encoded by a separate gene. The discovery of the endomorphins, two amidated tetrapeptides which do not derive from the three precursor molecules, indicate the existence of additional opioid peptide genes which, however, have not yet been identified.

Endopeptidase

A peptidase that can cleave peptide bonds within a protein or peptide. Endopeptidases are classified in Enzyme Nomenclature according to catalytic type and are included in sub-subclasses 3.4.21–3.4.24.

- ▶ Non-viral Peptidases

Endoplasmic Reticulum (ER)

A system of membrane enclosed cisternae in the cytoplasm. The ER is continuous with the outer membrane of the nuclear envelope. The part of the ER coated with ribosomes is called rough ER, the other part is called smooth-surfaced ER. The rough ER is the first compartment of the secretory pathway. Here, membrane proteins are integrated into and secretory proteins translocated across the ER membrane. Furthermore,

protein folding is established and checked by a quality control system. From the ER, proteins are delivered in vesicles to the ERGIC.

Endothelins

ALEXANDER OKSCHE

Mundipharma Research GmbH, Limburg, Germany

Definition

Endothelins comprise a family of three vasoactive isopeptides of 21 amino acids that have an essential role in the regulation of the vascular and bronchiolar tone and the control of natriuresis in the kidney. Endothelin peptides are also involved in nociception and have a critical role in the progression of prostate and ovarian cancer.

Basic Characteristics

Endothelin and Endothelin-converting Enzymes

In 1985, a peptide was described in the supernatants of endothelial cells that mediated vasoconstriction [1]. This peptide was isolated and sequenced, and the cDNA was cloned. According to its origin from endothelial cells it was named endothelin.

To date, three endothelin isoforms are known (ET-1, ET-2, ET-3), encoded by different genes [2]. Endothelins are synthesized as prepolypeptides of approximately 200 amino acids (Table 1). The biological active endothelins are generated in a two-step proteolytic process (Fig. 1). In the first step, ►**furin-like proteases** generate big-endothelins (big-ETs) of 38–41 amino acids that are biologically inactive. In a second step, specific ►**endothelin-converting enzymes** (ECEs) specifically cleave big-ETs between tryptophan 21 and valine/isoleucine 22, thereby producing the mature endothelins. Big-ET-1 was also found to be cleaved by mast cell ►**chymase** resulting in ET-1(1–31). Whilst ET-1(1–31) is not a substrate of ECEs, it is further processed by neutral

endopeptidase (NEP) to the biological active ET-1. ►**Matrix metalloproteinase 2** (gelatinase A) also cleaves big-ET-1 and yields ET-1(1–32). Whether ET-1(1–32) is also a substrate of NEP remains to be shown.

ECEs are ►**metalloproteinases** that are homologous to the ►**neutral endopeptidase** (NEP, E-24.11, neprilysin); unlike NEP, however, they form disulfide-bonded homodimers. In man, with ECE-1 and ECE-2, two isoforms are known, which are encoded by two separate genes. For ECE-1 four different variants have been identified (ECE-1a–d), which are generated by the use of alternative promoters (Table 2). The ECE-1 isoforms only differ in their N-terminal amino acid sequence. For ECE-2, a single gene product has been described in

Endothelins. Table 1 Human endothelin isoforms

	Number of amino acids in		Chromosome	Diseases
	Prepro-ET-1	Big-ET-1		
hET1	212	38	6p23–24	
hET2	178	38	1p34	
hET3	238	41	20q13.2–13.3	Hirschsprung's disease, Waardenberg syndrome, type 4

Endothelins. Figure 1 Processing of prepro-ET-1. ET-1 is generated as a preprohormone consisting of 212 amino acids. Amino acids 53–90 represent big-ET-1, amino acids 53–73 mature ET-1. Amino acids that vary between the three endothelin isoforms are depicted by hatched circles (only variant amino acids of the mature ET-1 moiety and of the ECE-cleavage site are indicated). The amino acids present in ET-2 and ET-3 are depicted by light or dark grey circles, respectively. The signal peptide (grey cylinder) is cleaved off in the endoplasmic reticulum by the signal peptidase. Big-ET-1 is generated by proteolytical processing (furin-like proteases), which recognize dibasic amino acids motifs. Mature ET-1 is formed after processing through the endothelin converting enzyme. Mast cell chymase generates ET-1(1–31), which is further processed by NEP to yield ET-1.

Endothelins. Table 2 Properties of the different isoforms of endothelin-converting enzymes

	Subcellular localization	pH Optimum	Amino acids (in human)	Species
ECE1a	Pm	6.8–7.2	758	Human, bovine, rat
ECE1b	i.c.	6.8–7.2	770	Human, bovine, rat
ECE1c	Pm late endosomes/multivesicular bodies	6.8–7.2	754	Human
ECE1d	i.c. recycling endosomes	6.8	767	Human, rat
ECE2a	i.c.	5.5	787	Human, mouse, bovine
ECE2b	?	?	765	Human, mouse, bovine
ECE3	?	6.6	-	Bovine

pm: plasma membrane, *i.c.*: intracellular.

man, whereas in mouse and calf two splice variants have been identified. In calf, an ECE-3 isoform has been isolated from iris microsomes and the choroid plexus, which is specifically involved in the conversion of big-ET-3 to ET-3. A human homologue of bovine ECE-3 has not yet been identified.

The ECE isoforms show different subcellular distributions and enzymatic characteristics (Table 2). ECE-1a and ECE-1c are mainly expressed at the cell surface, whereas ECE-1b, ECE-1d and ECE-2 are expressed intracellularly. Plasma membrane-bound ECE cleaves big-ET-1 circulating in the blood, whereas intracellular ECE isoforms are involved in the generation of mature endothelins. In addition, ECEs (as well as NEP and the insulin-degrading enzyme) contribute to the degradation of amyloid β ($A\beta$) peptide.

Human umbilical vein endothelial cells (HUVEC) express the isoforms ECE-1a, -1b, -1d and ECE-2. In these cells, ET-1 is secreted *via* both a constitutive and a regulated pathway. The ratio of released ET-1:big-ET-1 is 4:1. About 80% of the ET-1 is secreted at the abluminal cell surface of endothelial cells. ECE-isoforms are abundantly expressed on the cell surface of endothelial cells and to a lower level also on vascular smooth muscle cells. In atherosclerotic lesions of vessels, however, ECE expression in smooth muscle cells is upregulated. ECE isoforms expressed in smooth muscle cells contribute significantly to the generation of mature ET in normal and in particular atherosclerotic vessels.

Endothelial cells are the major source of ET-1-synthesis. ET-1 is also produced by astrocytes, neurons, hepatocytes, bronchial epithelial cells, renal epithelial and mesangial cells. Physiological stimuli of ET-1-synthesis in endothelial cells are angiotensin II, catecholamines, thrombin, growth factors, insulin, hypoxia and shear stress. Inhibitors of ET-1 synthesis are atrial natriuretic peptide, prostaglandin E2 and prostacyclin. ET-2 is mainly synthesized in kidney, intestine, myocardium and placenta and ET-3 is predominantly produced by neurons, astrocytes and renal epithelial cells.

Endothelin Receptors

Endothelins exert their diverse actions *via* two G protein-coupled receptors named endothelin A (ET_A) and endothelin B (ET_B) receptor, which share an identity of about 64% in their amino acid sequences. Both receptors display a signal peptide that is required for the correct biogenesis. After the N terminus is accessible in the ER lumen, the signal peptide is cleaved off (comprising 20 and 26 amino acids in ET_A and ET_B receptors, respectively). Further post-translational modifications are ► **Asn-linked glycosylation** of the extracellular N terminus (h ET_A : Asn29, Asn 62; h ET_B Asn 59) and ► **palmitoylation** of cysteine residues in the intracellular C terminus. Mass spectrometry of the bovine ET_B receptor revealed that cysteine residues 402 and 404 are palmitoylated. The palmitoylation of endothelin receptors is essential for the activation of G proteins, since palmitoylation-deficient ET_A and ET_B receptors fail to stimulate $G_{q/11}$ and G_i proteins, respectively. Disulfide bonds between the highly conserved cysteine residues of the first (ET_A : Cys158, ET_B : Cys174) and the second extracellular loop (ET_A : Cys239, ET_B : Cys255) are also likely. Whether cysteine residues in the extracellular N terminus (ET_A : Cys69, ET_B : Cys90) and the third extracellular loop (ET_A : Cys341, ET_B : Cys359) also form disulfide bonds has not been clarified. The extracellular N terminus of the ET_B receptor undergoes agonist-induced limited proteolysis. Upon binding of ET-1 the N terminal 38 amino acids are cleaved off by a metalloprotease. The cleavage involves the single Asn-linked glycosylation site, resulting in a non-glycosylated receptor. The functional role for the N-terminal cleavage is not known, yet. However, genetic deletion of the N terminus or proteolytic removal results in an ET_B receptor with an altered signal transduction.

The endothelin receptor subtypes show differences in their signal transduction, ligand binding and tissue distribution. The ET_A receptor is isopeptide-selective and binds ET-1 and ET-2 with the same and ET-3 with 70–100-fold lower affinity. The ET_B receptor binds all three isoforms with the same affinity.

Pharmacological studies provided evidence for two subtypes of ET_A (ET_{A1} , ET_{A2}) and ET_B receptors (ET_{B1} , ET_{B2}), although genetic studies revealed only two different genes. Thus, the additional receptor subtypes may be derived from (i) alternative splicing, (ii) differences in post-translational processing or (iii) protein-protein interactions. Splice variants have been described for the ET_B receptor. However, these isoforms most likely do not account for the postulated second receptor subtype. One splice variant harbours ten additional amino acids in the third intracellular loop and has normal binding characteristics and functional activity (IP and cAMP formation). The second splice variant, which carries a completely altered intracellular C terminus, has normal binding properties but lacks functional activity. In vitro, homo- and heterodimerization of endothelin receptor subtypes has been demonstrated, but these receptor-receptor interactions are unlikely to account for the observed subtypes of ET_A

and ET_B receptors: Pharmacological binding profiles of ET_A/ET_B receptor heterodimers were essentially similar to those of individually expressed ET_A and ET_B receptors.

The ET_A receptor activates G proteins of the $G_{q/11}$ and $G_{12/13}$ family. The ET_B receptor stimulates G proteins of the G_i and $G_{q/11}$ family. In endothelial cells, activation of the ET_B receptor stimulates the release of NO and prostacyclin (PGI_2) via pertussis toxin-sensitive G proteins. In smooth muscle cells, the activation of ET_A receptors leads to an increase of intracellular calcium via pertussis toxin-insensitive G proteins of the $G_{q/11}$ family and to an activation of Rho proteins most likely via G proteins of the $G_{12/13}$ family. Increase of intracellular calcium results in a calmodulin-dependent activation of the myosin light chain kinase (MLCK, Fig. 2). MLCK phosphorylates the 20 kDa myosin light chain (MLC-20), which then stimulates actin-myosin interaction of vascular smooth muscle cells resulting in vasoconstriction. Since activated Rho

E

Endothelins. Figure 2 Summary of short-term signalling events mediated by endothelin. In endothelial cells (EC) the activation of the ET_B receptor leads to the formation of prostacyclin (PGI_2) and NO, thereby eliciting vasodilation. In vascular smooth muscle cells activation of the ET_A receptor results in a robust vasoconstriction by a dual regulation of the 20 kDa myosin light chain (MLC-20). AA: arachidonic acid, AC: adenylyl cyclase, ATP: adenosine triphosphate, CaM: Calmodulin, cAMP: cyclic adenosine monophosphate, DAG, diacyl glycerol, eNOS: endothelial NO synthase, IP₃: inositol-3,4,5-phosphate, MLC-20: 20 kDa myosin light chain, MLCP: myosin light chain phosphatase, Rho-GEF: Rho-guanine nucleotide exchange factor, SER: smooth endoplasmic reticulum, IP₃R: IP₃ receptor, PKA: protein kinase A, PKC: protein kinase C, PLA: phospholipase A, PLC: phospholipase C, PLD: phospholipase D.

inhibits the myosin light chain phosphatase *via* Rho-kinase, the dephosphorylation of the MLC-20 is blocked. The dual action of the ET_A receptor signalling on MLC-20 results in a robust vasoconstriction of vessels. Beside the short-term effects, such as vasodilation and vasoconstriction, endothelin receptors also stimulate long-term events (cell growth and differentiation). Whilst stimulation of the ET_A receptor results in a transient, monophasic activation of ERK1/2 *via* a G_{q/11}-proteins, activation of the ET_B receptor elicits a long-lasting, biphasic ERK1/2 activation involving a G_{q/11}- and a G_i-mediated pathway (Fig. 3).

ET-1 also stimulates anti-apoptotic signal cascades in fibroblasts, vascular smooth muscles and endothelial cells (*via* phosphatidylinositol-3-kinase and Akt/protein kinase B). In prostate and ovarian cancer, upregulation of endothelin synthesis and ET_A receptors has been associated with a progression of the disease. The inhibition of ET_A receptors results in a reduced tumour growth. In malignant melanoma, ET_B receptors are associated with tumour progression. Endothelins can also stimulate apoptosis in stretch-activated vessels *via* the ET_B receptor, which contrasts the above-mentioned effects. The molecular basis for these differential anti- and pro-apoptotic reactions mediated by endothelins remains elusive.

Activation of matrix metalloproteinases (MMP) is also involved in vascular and cardiac remodelling. For example, the fibrillar collagen matrix of the heart

maintains the shape of the left ventricle. If the delicate balance between matrix deposition and degradation is altered, cardiac fibrosis (increase of collagen synthesis) or left ventricular remodelling (increase of degradation) occurs. Activation of ET_A receptors leads to a stimulation of MMP-1,-2 and -9 in isolated myocytes and in the myocardium and thereby contributes to ventricular remodelling after myocardial infarction.

Sites of endothelin-receptor expression. ET_A receptors are expressed in the smooth muscle cells of the vascular medial layer and the airways, in cardiac myocytes, lung parenchyma, bronchiolar epithelial cells and prostate epithelial cells. ET_B receptors are expressed in endothelial cells, in bronchiolar smooth muscle cells, vascular smooth muscle cells of certain vessels (e.g. saphenous vein, internal mammary artery), in the renal proximal and distal tubule, the renal collecting duct and in the cells of the atrioventricular conducting system.

In addition, ET_B receptors are upregulated in vessels with atherosclerotic lesions and in pulmonary vessels of patients with severe pulmonary hypertension. The upregulation can be attributed to increased ET_B receptor expression in smooth muscle cells and to ET_B receptors expressed on infiltrating macrophages.

In the vascular system, endothelial ET_B receptors mediate a transient vasodilation, whereas ET_A receptors cause a long-lasting vasoconstriction. The role of ET_B receptors expressed on smooth muscle cells

Endothelins. Figure 3 Diagram of ET_A and ET_B receptor-mediated ERK1/2 activation. ET_A and ET_B receptor stimulate a transient ERK1/2 activation *via* G proteins of the G_{q/11}/PLCβ/Ca²⁺/c-Src-dependent pathway. In addition, the ET_B receptor stimulates a second, long-lasting phase of ERK1/2 activation *via* a G_i protein/metalloprotease/HB-EGF/EGF receptor-dependent pathway. ERK2: extracellular signal-regulated kinase; HB-EGF: heparin-binding epidermal growth factor; Nuc: nucleus; PM: plasma membrane.

remains elusive. In some vessels, ET_B receptor stimulation causes vasoconstriction which is, however, only of transient nature and quantitatively much lower than that following ET_A receptor activation. In the kidney, ET_A receptors, which are almost exclusively expressed in vessels, regulate renal circulation, whereas ET_B receptors expressed in the proximal and distal tubule and in the collecting duct are involved in natriuresis and diuresis. The main natriuretic action occurs most likely *via* the inhibition of the ▶**amiloride-sensitive Na⁺ channel** (ENaC). In the lung, endothelin causes long-lasting vaso- and bronchoconstriction. The contribution of each receptor subtype to the endothelin-evoked pulmonary responses is still controversial. The current data suggest that in the healthy lung ET_A receptors are involved primarily in pulmonary vasoconstriction and ET_B receptors in bronchoconstriction. In the central nervous system, ET_A receptors are expressed on smooth muscle cells of large- and small-cerebral arteries. In addition, ET_A receptors were also found to be expressed on endothelial cells isolated from capillaries and larger microvessels of the brain, but the physiological role of ET_A receptor expression in endothelial cells in the brain remains elusive. Further, ET_A receptors are expressed in small sensory C fibres. Activation of ET_A receptors in C fibres causes a sensitization of the tetrodotoxin-insensitive sodium channel as well as of the polymodal receptor TRPV1. Interestingly, stimulation of ET_B receptors expressed in keratinocytes leads to the release of β-endorphins, thereby counteracting ET_A receptor-mediated [3]. Neurons, particularly those of the level III and IV of the cortex predominately express ET_B receptors. In isolated astrocytes, both receptor subtypes were found to be expressed at the cell surface.

Genetic Studies and Human Diseases

Mice homozygous for an ET_A receptor gene disruption show craniofacial malformations, such as cleft palate, micrognathia, microtia and microglossia. ET_A (−/−) mice die shortly after birth due to respiratory failure. Mice with an ET-1-null mutation show the same craniofacial malformations and, in addition, cardiovascular disorders (e.g. septal defects, abnormal cardiac outflow tract, aortic arch and subclavian arteries).

Mice with a disruption of the ET-3 or the ET_B receptor gene display pigment disorder and a megacolon. The former resembles the congenital megacolon associated with pigment disorders and cochlear hearing problems (Waardenberg syndrome) or the isolated congenital megacolon (Hirschsprung's disease) observed in man. Hirschsprung's disease and Waardenberg syndrome can be caused by several different gene mutations, among others inactivating mutations in the ET-3 and the ET_B receptor gene (about 5% of the patients with

Hirschsprung's disease have ET_B receptor mutations). The lack of ET-3/ET_B receptor results in the absence of parasympathic ganglionic neurons in the myenteric plexus (Auerbach). Mice with an ET-3/ET_B receptor disruption die within 2 weeks after birth. In transgenic mice, in which the expression of the ET_B receptor is driven by the dopamine β-hydroxylase promoter, normal myenteric plexus are present and no enteric disorder develops. These mice, however, show a salt-sensitive hypertension, which can be efficiently treated with amiloride, indicating that ET_B receptors are involved in the regulation of natriuresis *via* the amilorid-sensitive sodium channel ENaC.

The genetically engineered disruption of the ECE1 gene causes craniofacial and cardiovascular malformations (ET-1/ET_A receptor phenotype), congenital megacolon and pigment disorders (ET-3/ET_B receptor phenotype). The ECE-2 (−/−) mice do not display any abnormality, indicating that ECE-1 is of crucial importance in embryonic development. Strikingly, ECE-1 (−/−) mice and ECE-1 (−/−)/ECE-2 (−/−) mice still have about 60% of wild-type ET-1 levels [4]. This result indicates that alternative pathways in the generation of mature ET-1 exist (e.g. NEP). This alternatively generated ET-1, however, cannot compensate for the embryogenic defects.

ECE isoforms are also involved in the degradation of Aβ peptide. A genetic variant of ECE-1 with an increased transcriptional activity is associated with a decreased risk for AD. Thus, the inhibition of ECE in the CNS may increase the risk for the development of Alzheimer's disease (AD).

In malignant prostate epithelial cells, auto- and paracrine release of ET-1 is a critical factor in ET_A receptor-mediated proliferation [5]. In addition, the ET-1/ET_A receptor axis has emerged as a potential target in prostate cancer bone metastasis

Drugs

Clinical Use

As endothelins mediate potent vasoconstrictor effects, ECE inhibitors and endothelin receptor antagonists were developed for the treatment of cardiovascular diseases, such as acute and chronic heart failure, pulmonary hypertension and subarachnoid haemorrhage. As ET_A receptors have potent mitogenic responses and may promote progression of ovarian and prostate cancer and bone metastases ET_A receptors are also considered as a potential targets for anti-tumour activity.

A great number of ECE-inhibitors and mixed and selective ET_A and ET_B receptor antagonists have been developed in the past. For specific inhibitors of ECE, however, only very limited effects on the endothelin system were found. The limited potency of ECE inhibition might be due to the generation of mature

Endothelins. Table 3 Summary of clinical trials with endothelin receptor antagonists or ECE-inhibitors

Drug	Company	Antagonist/ Inhibitor	Approval/clinical study
Bosentan (Tracleer®)	Actelion, Switzerland	ET _A /ET _B re- ceptor	Grade III and IV PAH and chronic thromboembolic pulmonary hypertension (European approval in 2002 as orphan medicine) Program for CHF was terminated in phase III
TBC11251 (Sitaxsentan)	Texas Biotech- nology, USA	ET _A receptor	Grade III PAH (designated orphan medicine in 2004)
Ambrisentan (Letairis)	Gilead, USA	ET _A receptor	Grade II and III PAH (designated orphan medicine in 2005, US approval in 2007)
ABT-627 (Atrasentan)	Abbott Labora- tories, USA	ET _A receptor	Hormone-refractory prostate cancer, stage IV (phase III)
S-0139	Shionogi/GSK, Japan	ET _A receptor	Hemorrhagic and ischemic stroke (phase II, Japan)
SLV306	Solvay, Germany	NEP/ECE (dual inhibitor)	Hypertension and diabetic nephropathy (phase II)
Ro-61-0612 (Tezosentan)	Actelion, Switzerland	ET _A /ET _B re- ceptor	AHF (phase III, discontinued)
LU135252 (Darusentan)	Aventis, Germany	ET _A receptor	CHF (phase III, discontinued)
ZD4054	AstraZeneca, UK	ET _A receptor	Hormone-refractory prostate cancer (phase II)

AHF: acute heart failure, CHF: chronic heart failure, CRF: chronic renal failure, NEP: neutral endopeptidase, ECE: endothelin converting enzyme, PAH: pulmonary arterial hypertension.

ET-1 from big-ET-1 by other proteases such as neutral endopeptidase or other currently unidentified proteases. Therefore, dual inhibition of ECE and NEP might inhibit ET-1 generation more efficiently, than that seen for selective ECE inhibitors. However, dual inhibition of ECE and NEP could also increase the risk for the development of AD, as both enzyme classes are involved in the degradation of A β peptide.

In the case of receptor antagonists, it is still unknown whether mixed antagonism of endothelin receptors or selective blockade of ET_A receptors is of greater benefit in the treatment of diseases. Several clinical trials have been launched involving the treatment of heart and renal failure, pulmonary hypertension, subarachnoid haemorrhage and prostate cancer (Table 3). The majority of the studies is performed with selective ET_A receptor antagonists. Recently, the petidic ET_B receptor agonist SPI-1620 (Spectrum Pharmaceuticals) has entered clinical development as an adjunct for chemotherapy (increasing tumour blood flow and delivery of anti-cancer drugs). At present, however, only the mixed endothelin receptor antagonist Tracleer (Bosentan) and the ET_A receptor-selective antagonist Letairis (Ambrisentan) are approved for treatment (pulmonary hypertension).

Entamoeba Histolytica

Entamoeba histolytica is an anaerobic rhizopod that occurs in tropical and subtropical areas. It can cause intestinal and extraintestinal manifestations. It is transmitted orally by ingestion of cysts that develop into trophozoites in the large intestine. Amebic trophozoites release several cytolytic factors, e.g. amoebapore, which enable the parasite to invade tissue. In intestinal amoebiasis, *E. histolytica* trophozoites invade the intestinal mucosa, causing a form of ulcerative colitis with bloody and mucous diarrhoea. Extraintestinal manifestation of amoebiasis results in abscess formation, usually in the liver but sometimes in the brain.

Epinephrine

► Adrenaline

Episodic Ataxia/Myokymia

Episodic ataxia (EA) is an autosomal dominant disorder that brief episodes of ataxia can be triggered by physical or emotional stress. The symptom can occur several times during the day, last for seconds to minutes, and be associated with dysarthria and motor neuron activity, which causes muscle rippling (myokymia) between and during attacks. It is caused by a mutation in a neuronal voltage dependent Ca²⁺ channel.

► Voltage-dependent Ca²⁺ Channels

Episome

An episome is nuclear DNA that is maintained without integrating into chromosomes.

► Gene Therapy

Epithelial Ca²⁺ Channel

Epithelial calcium channel 1 (ECaC1), synonym TRPV5, is a member of the TRP family of ion channels, implicated in vitamin D-dependent transcellular Ca²⁺ transport in epithelial cells of the kidney, placenta and the intestine.

► TRP Channels

Epithelial Mesenchymal Transition (EMT)

A process by which epithelial cells lose cell–cell adhesion and become more migratory and acquire mesenchymal properties. The process is associated with

drastic changes in gene expression, leading to the downregulation of epithelial marker genes such as E-cadherin, claudins, and keratin, and the upregulation of mesenchymal markers such as vimentin. EMT occurs during embryonic development, e.g. during gastrulation, and neural crest formation, and carcinoma invasion. The reverse of EMT, mesenchymal-to-epithelia transition is observed for instance during formation of kidney tubules from mesenchymal precursor cells, but frequently also when carcinoma cells form a metastasis in the target organ.

Epithelial Na⁺ Channel

LAURENT SCHILD, STEPHAN KELLENBERGER
BERNARD C. ROSSIER

l'Université, Lausanne, Switzerland

Definition

The epithelial Na⁺ channel (ENaC) is the highly selective Na⁺ channel expressed in epithelia. The ENaC channel is a heteromeric channel made of homologous α β γ ENaC subunits. The human genes encoding the α β γ ENaC named *SCNN1A*, *SCNN1B*, and *SCNN1G* are located in chromosome 12 (α) and 16 (β γ), respectively. The mouse genes encoding the α β γ ENaC named *Scnn1a*, *Scnn1b*, and *Scnn1g* are located on chromosomes 6 (α) and 7 (β γ), respectively [1].

Basic Characteristics

ENaC belongs to a recently discovered family of ► **ionic channels** that include in mammals the neuronal acid-sensing ion channels (ASICs) and in the worm *C.elegans* the degenerin channel family (Mec4, Mec10) involved in mechanosensation [2]. The homologous α β γ subunits of ENaC consist of a large extracellular loop, two transmembrane domains, and short intracellular N- and C-termini, and are arranged pseudosymmetrically around the channel pore.

ENaC is located in the apical membrane of polarized epithelial cells where it mediates Na⁺ transport across tight epithelia [3]. The most important tight epithelia expressing ENaC include the distal nephron of the kidney, the respiratory epithelium, and the distal colon. The basic function of ENaC in polarized epithelial cells is to allow vectorial transcellular transport of Na⁺ ions. This transepithelial Na⁺ transport through a cell involves

Epithelial Na⁺ Channel. Figure 1 Transepithelial ion transport in a principal cell of the aldosterone-sensitive distal nephron (ASDN).

basically two steps, as illustrated in the Fig. 1. The large electrochemical gradient for Na⁺ ions existing across the apical membrane provides the driving force for the entry of Na⁺ into the cell. Active Na⁺ transport across the basolateral membrane is accomplished by the ►Na⁺/K⁺-ATPase.

ENaC mediates Na⁺ entry from the tubule lumen at the apical membrane and the Na⁺/K⁺ ATPase extrudes Na⁺ at the basolateral side. K⁺ channels are present on the basolateral and apical membrane. K⁺ channels at the apical membrane mediate K⁺ secretion into the tubular lumen.

In the *aldosterone-sensitive distal nephron* (ASDN), ENaC-mediated Na⁺ absorption under the control of aldosterone is critical to balance urinary Na⁺ excretion with the daily intake. ENaC allows Na⁺ entry from the tubule lumen at the apical membrane, and the Na⁺/K⁺ ATPase extrudes Na⁺ at the basolateral side. The Na⁺ absorption in the distal nephron is coupled to K⁺ secretion via K⁺ channels (ROMK2) located at the apical membrane.

Three successive tubule portions contribute to the ASDN: the late portion of the distal convoluted tubule, the connecting tubule, and the collecting duct. The recent observation that collecting duct-specific inactivation of α ENaC in the mouse kidney does not impair sodium and potassium balance, suggests that the more proximal nephron segments (late distal convoluted tubule, connecting tubule) are mainly important for achieving sodium and potassium balance.

ENaC activity is under the control of ►aldosterone and ►vasopressin that are secreted in response to stimuli

such as extracellular volume contraction, dehydration, or hyperkalemia. Aldosterone binds to intracellular mineralocorticoid receptors (MR receptors); the ligand–receptor complex is translocated to the nucleus and induces the expression of ENaC and the Na⁺/K⁺-ATPase proteins via aldosterone-induced transcripts (AITs) and/or aldosterone-repressed transcripts (ARTs). Vasopressin binds to the G-protein coupled V2 receptor and activates ENaC via the c-AMP-dependent pathway.

The role of ENaC is crucial for the maintenance of the extracellular fluid volume and blood pressure [4]. The recent identification of mutations in genes encoding the ENaC, the mineralocorticoid receptor (MR) and the ►11 β -hydroxysteroid dehydrogenase type 2 (11 β -HSD-2) that cause monogenic forms of hypertension, strongly supports this notion. Mutations of ENaC associated with an increased Na⁺ absorption in the distal nephron leading to a low aldosterone and low plasma renin hypertension (►Liddle syndrome or pseudoaldosteronism), are activating mutations that remove a conserved proline-rich motif in the intracytoplasmic region of ENaC, important for channel endocytosis and degradation. Conversely, loss of function mutations cause Na⁺ salt losing nephropathy with dehydration, hyperkalemia, elevated plasma renin, and aldosterone levels characteristic of the recessive form of pseudohypoaldosteronism Type 1 (recessive PHA-1).

In *the lung*, ENaC is important for the ionic composition and the clearance of the ►airway surface liquid (ASL) [5]. The activity of ENaC is inversely coupled to that of CFTR (Cystic fibrosis transmembrane regulator), responsible for chloride secretion at the apical membrane or airway epithelium. In cystic fibrosis, CFTR activity is lost and ENaC activity enhanced, causing an increased fluid reabsorption of ASL and increased mucous viscosity, preventing a normal mucociliary clearance. In mice, airway-specific overexpression of ENaC results in an increased Na⁺ absorption and in a severe spontaneous lung disease sharing features with cystic fibrosis. Conversely, loss of function mutations of ENaC, as observed in recessive PHA-1, cause an increase of mucociliary clearance and a decrease in mucous viscosity. ENaC activity in the lung is developmentally regulated and plays a critical role at birth for a rapid and normal fluid reabsorption from the lung which turns from a secretory (fetal) to a reabsorptive (adult) mode. Respiratory distress syndrome (RDS) observed in premature newborn can be, in part, due to ENaC immaturity. In the fetal lung, ENaC maturation is controlled by glucocorticoids and, at birth, by sympathetic mimetics and pO₂. In the adult distal lung, ENaC activity is primarily controlled by ► β adrenergic agonist and pO₂. It plays an important role in the pathophysiology of high altitude pulmonary

edema (HAPE), which can be greatly prevented by administration of β adrenergic drugs.

In the skin, ENaC is expressed in keratinocytes of the epidermis and in hair follicles. It could play a role in terminal differentiation by modulating keratinocyte calcium signaling. The skin expresses MR, GR, and 11β HSD2, but the role of aldosterone and glucocorticoids on ENaC activity and keratinocyte differentiation is not yet understood.

In the tongue, ENaC is expressed in taste bud epithelial cells. The expression of α , β and γ subunits at the apical membrane of taste buds is observed under low salt diet, known to greatly increase plasma aldosterone. This observation suggests that ENaC could play a significant role in the transduction of salt sensation.

In the inner ear, ENaC is expressed in supporting cells surrounding hair cells and is postulated to play a role in the low sodium concentration of endolymph, critical for proper mechanotransduction and hearing.

Drugs

ENaC is blocked from the tubular lumen of the distal nephron by amiloride at submicromolar concentrations. By blocking ENaC activity at the apical membrane of the target cell of the distal nephron, the electrochemical gradient favoring the passive secretion of potassium through ROMK2 (or other apically located K channels) is dissipated and potassium secretion blocked. Unlike loop diuretics (►furosemide and analogs) or distal convoluted diuretics (i.e., thiazide diuretics), which cause potassium secretion and ►hypokalemia, amiloride and analogs cause potassium retention (and ultimately ►hyperkalemia) and are currently used as K^+ -sparing diuretics. Spironolactone, a competitive antagonist of aldosterone for the mineralocorticoid receptor, inhibits epithelial sodium transport and potassium secretion and belongs to the same class of diuretic. Obviously, it is mostly effective when plasma aldosterone is elevated (►primary or secondary aldosteronism), whereas amiloride is effective even in the presence of low circulating aldosterone. The biophysical characteristics of the block of ENaC by amiloride including voltage-dependence, competitive interaction with permeant cations, such as Na^+ or Li^+ ions, strongly suggest that amiloride is a pore blocker which, upon binding to its receptor on the channel, physically occludes the ion permeation pathway. The binding site for amiloride is located in the extracellular vestibule of the channel pore close to the ion selectivity filter and involves specific amino acid residues on each the extracellular domain of the α β γ ENaC subunits. Amiloride shares its binding site on ENaC with triamterene which blocks the channel with a lower affinity.

Since the distal nephron reabsorbs under physiological conditions less than 10% of the filtered load of

sodium, blockade of ENaC results only in a slight increase in urinary excretion of sodium. Consequently, amiloride is usually used in association with other diuretics. As suggested by genetic forms of hypertension associated with ENaC gain of function mutations, amiloride should be efficient in the treatment of low-renin, salt-sensitive hypertension but, unfortunately, its potency is markedly lowered by salt intake. The development of “noncompetitive” antagonists of ENaC (i.e., potent in the presence of high luminal sodium) would be a useful addition to the drugs available today.

The development of amiloride analogs targeted to block selectively ENaC in the lung could be useful in the treatment of ►cystic fibrosis (CF) patients or more generally of patients suffering from chronic bronchitis, a condition in which an increased mucociliary clearance is highly desirable. Channel activators are presently not available and will be useful for the treatment of RDS in newborn or HAPE in adult, or, possibly, lung edema in congestive heart failure.

Excitatory Postsynaptic Potential

Definition

A postsynaptic potential or PSP is the voltage response of a postsynaptic neuron to a neurotransmitter released by a nerve terminal. The response may be depolarizing, in which case the voltage shift is in a positive direction causing an excitatory effect or EPSP, or hyperpolarizing, in which case the voltage shift is in a negative direction causing an inhibitory effect or IPSP.

Ergot Alkaloids

Ergot alkaloids occur naturally in the fungus *Claviceps purpurea* which infects cereal crops. Contaminated grain has caused epidemics of ergot poisoning for centuries. The key symptom of ergot poisoning is irreversible, painful peripheral vasoconstriction leading to peripheral gangrene (St. Anthony's fire). Ergot alkaloids are a rather heterogeneous group acting on adrenoceptors, dopamine receptors and 5-HT (serotonin)-receptors. Examples are ergotamine, dihydroergotamine, bromocryptine and methysergide. They are used in the prophylaxis and treatment of migraine, the treatment of parkinsonism and in the prevention of postpartum haemorrhage.

Synonyms

Ethyl alcohol

Definition

C_2H_5OH , ►ethanol is formed by bacteria in the gastrointestinal tract in low amounts. Most of the ethanol of bacterial source is metabolized during the first liver passage yielding acetaldehyde and subsequently acetic acid.

Mechanism of Action

The main target structures in the brain that are affected by ethanol are ►GABA_A-receptors and glutamate-►NMDA-receptors. The action of the neurotransmitter γ -amino-butyric acid (►GABA) is facilitated, and the function of the NMDA-receptor is reduced by physiologically relevant concentrations of ethanol (10–50 mM). Therefore, this essay focuses on GABA and glutamate. Somewhat higher doses of ethanol affect other neuronal systems, among them endogenous opioids, dopamine and serotonin. Furthermore, second messenger and other intracellular mechanisms are altered after both acute and chronic exposure. Chronic ethanol abuse causes severe health problems. This essay does not deal with these aspects.

►GABA_A receptor: The inhibitory GABA_A and strychnine-sensitive glycine receptors are modulated positively by ethanol. Site-directed mutagenesis techniques have identified amino acid residues important for this action. Mutation of a single amino acid in specific transmembrane domains (TM2 (Ser270) and TM3) of the α_2 and β subunits of GABA_A and glycine (TM2) receptors abolish the action of ethanol. Initial studies of transgenic mice with a reduced sensitivity to ethanol as measured by loss of righting reflex revealed an ethanol-resistant α_1 -subunit of the glycine receptor [2]. The corresponding mutations introduced into the γ subunit of GABA_A-R had less effect. These findings indicate that in the GABA_A receptor, ethanol may bind in a cavity formed between TM2 and TM3, and that binding to the α or β subunit may be more critical than to the γ subunit.

In an attempt to visualize the site of action of ethanol, tryptophan mutation at position S270, TM2 and TM3 domains of the GABA_A α_2 subunit were modeled as antiparallel α -helices. The model showed that the region between S270 TM2 and TM3 contains a small cavity that may not be filled by side chains of adjoining helices. In contrast, the model of the S270W mutation demonstrated that the side chain of tryptophan completely occupied this cavity, which could eliminate occupation of the putative cavity by ethanol.

These findings were unexpected because previous studies had demonstrated that the γ_2 subunit is required for potentiation of GABA_A receptor function by low concentrations of ethanol [2]. The γ_2 subunit gene is located within a definitely mapped quantitative trait locus (QTL) for acute alcohol withdrawal on mouse chromosome 11 [1]. Allelic variation was genetically

correlated with acute alcohol withdrawal, ethanol-conditioned taste aversion, ethanol-induced motor incoordination and ethanol-induced hypothermia [1].

Furthermore, the γ_2 subunit of GABA_A-R is the most abundant subunit in the central nervous system (CNS) and is required for localization to synapses. The γ_2 subunit exists as two spliced variants, the long version (γ_{2L}) containing an additional eight amino acids in the large TM3/4 intracellular loop, relative to the short version (γ_{2S}). The extrapeptide sequence contains a consensus sequence for ►protein kinase C (PKC) phosphorylation. The γ_{2L} subunit was at one time claimed to be essential for ethanol modulation of GABA_A-R function, presumably related to the unique PKC substrate on this subunit. Differential functions for γ_{2L} and γ_{2S} might involve rapid regulation of GABA_A-R channels by PKC. Another possibility is regulation of GABA_A-R subcellular targeting, trafficking, or turnover, presumably involving interactions with other proteins. Chronic ethanol induced a drop in the γ_{2L}/γ_{2S} ratio, e.g., lower levels of the γ_{2L} splice variant. This might favor production of $\alpha_4\beta_2\gamma_{2S}$ receptor composition. This subtype differs markedly in various properties (compared to $\alpha_4\beta\gamma_{2L}$) including sensitivity to zinc inhibition, channel kinetics, and possibly sensitivity to positive modulation by neurosteroids. PKC involvement in ethanol pharmacology and interactions with GABA_A-R is also supported by changes in ethanol sensitivity of mice lacking PKC γ and other subtypes of PKC. PKC γ null mutant mice displayed reduced sensitivity to the effects of ethanol on loss of righting reflex and hypothermia, and abolished the ethanol-enhancement of GABA_A receptor agonist muscimol stimulated ³⁶Cl-uptake, demonstrating at least the link between behavioral actions of ethanol, PKC phosphorylation, and GABA receptor function [2].

PKC ϵ knockout mice are supersensitive to acute low-dose hyperlocomotor and high-dose sedative effects of ethanol and other drugs such as diazepam and pentobarbital, which allosterically activate GABA_A receptors. In addition, these mice voluntarily consume 75% less alcohol than wild-type mice when tested by using a two-bottle choice paradigm. They also showed about 50% less alcohol-reinforced operant responses than wild-type mice and reduced relapse drinking after a period of alcohol deprivation. These findings were not associated with metabolic changes of ethanol nor with receptor binding affinity or density in cerebral cortex, striatum or cerebellum. These findings suggest that PKC ϵ regulates sensitivity to ethanol intoxication and thereby influences alcohol consumption. GABA_A receptors from PKC ϵ -null mice were more sensitive to activation by muscimol (GABA agonist) plus ethanol or flunitrazepam. PKC ϵ might regulate sensitivity of GABA receptors to allosteric activators possibly by phosphorylating the polypeptide.

Furthermore, PKC ϵ is required for nerve growth factor-induced activation of mitogen-activated protein kinases and neurite outgrowth by ethanol. It is also required for ethanol-induced increases in N-type voltage-gated calcium channels in PC12 neural cells.

In several studies, chronic ethanol treatment has been associated with PKC upregulation. In PC12 cells, increased levels of PKC δ and ϵ were found (25–200 mM ethanol, 2–8 days of treatment) which was associated with increased PKC-mediated phosphorylation.

The possibility that acute ethanol directly activates PKC would seem to be ruled out by the lack of such effect occurring in various *in vitro* systems that have been studied. One possibility is the activation of a phosphatase, others are the modulation of the availability and type of activator. It is also possible that ethanol could modify the sensitivity of the ion channel to the effect of PKC phosphorylation or its proteolytic downregulation.

Overall, our understanding of the precise location and substrates for the different PKC isoforms and protein–protein interactions involving PKC is still in its infancy.

Subunit changes are other mechanisms that alter the physiology of GABA synapses and account for plastic changes seen following chronic ethanol treatment.

Dependent on the various treatment regimes (continuous administration, chronic intermittent administration with multiple ethanol withdrawal, CIE) chronic ethanol produced reduced GABA $_A$ -R mediated synaptic inhibition, hyperexcitability and seizure susceptibility. The α_6 subunit polypeptide was increased in cerebellum after both regimes, although there was no significant increase in α_6 mRNA in CIE in contrast to continuous ethanol paradigms and a decrease in α_1 subunit mRNA. A 20–30% increase in α_4 subunit mRNA was detected in hippocampal formation in CIE treatment paradigm. Thus, the cerebellar changes occur with chronic ethanol no matter which paradigm is used and are transient. They might contribute to short-term plasticity such as tolerance to motor impairment. Reduced function and altered pharmacological properties of GABA-R in the hippocampus of CIE rats were more persistent, lasting at least 2 days in some cases up to 40 days. Thus, the changes in this region such as increased α_4 and γ_{2S} subunits might be more important in the altered behavior of CIE rats. Continuous ethanol also produced an increase in diazepam-insensitive binding (involving α_4 and α_6 subunits) in the cortex (specifically α_4 because α_6 is not found in cortex).

NMDA-Glutamate Receptor

The other important molecular target of ethanol is the \blacktriangleright N-methyl-D-aspartate receptor (NMDA-R), which is acutely inhibited although the mechanism is not clear. It was speculated that at least in some brain region the coactivating glycine sites are involved and/or the coactivating polyamine sites. The receptors containing

the NMDA-R2B subunits are the most ethanol-sensitive [4]. The subunit has a fyn-kinase phosphorylation site that may rapidly render NMDA-R1 insensitive to ethanol during the development of acute tolerance.

NMDA-R play a major role in various aspects of chronic ethanol action, e.g., withdrawal and drug-dependent reorganization of neural circuitry [5]. Long-term potentiation (LTP) and long-term depression (LTD) are important candidate mechanisms for the drug-induced reorganization of neural circuitry that occurs during addiction. Both processes require activation of NMDA-R. One exception is the dorsal striatum in which the rise in Ca $^{2+}$ mediates the LTD by the activation of voltage dependent Ca $^{2+}$ channels. It is interesting to note that the numbers of both the NMDA-R and the voltage-dependent Ca $^{2+}$ channels (L-type, PKC δ -dependent, N-type, PKC ϵ -dependent) are increased after chronic ethanol [4]. This is paralleled by an increase in NMDA-R function as measured by an NMDA-induced increase in [21 Ca] influx. These events are present after 7 days of withdrawal and seem to be associated with lowered seizure threshold.

Distinct alterations in neural gene expression of NMDA-R1 splice variants and the NMDA-R2B subunit are observed after long-term ethanol ingestion. Increased mRNA levels of the NMDAR1–1 splice variant can be detected in all brain regions that expressed this isoform. On the other hand, the NMDA-R2B subunit decreases dramatically both at the mRNA and protein levels. However, 24 h after onset of withdrawal NMDA-R2B mRNA and hippocampal protein levels are elevated dramatically. Furthermore, NMDAR1–4 splice variant expression of mRNA and protein are elevated in the hippocampus 24 h after ethanol withdrawal. One may speculate that cells that express heterodimeric NMDA-R1/2B receptors are highly susceptible to ethanol. Another study found increases (–35%) in NR1, NR2A, and NR2B protein levels in homogenates from the cortex and hippocampus of rats exposed to intragastric infusions of ethanol for 6 days. There are consistent findings that during withdrawal, NMDA-Rs are over-activated pathologically by increased glutamate release and that this effect is accentuated by the interaction of polyamines acting via the 2B subunit.

AMPA receptor subunits GluR1, GluR2/3 and the kainate receptor subunits GluR5, GluR6 and KA2 are unaltered after 16 days of ethanol exposure. No adaptive changes of NMDA-R subunits are found in a recent study [6]. Therefore maladaptive changes in brain ionotropic glutamate receptor levels do not underlie, in all cases, the neurobiological consequences of chronic ethanol exposure.

Opioid Peptides

\blacktriangleright Opioid systems in the brain are important for the reinforcing effects of ethanol. Selective μ -opioid receptor antagonists reliably decrease ethanol drinking in rats.

Chronic free-choice ethanol consumption causes increased β -endorphin immunoreactivity in the hypothalamus and septum of alcohol-preferring mice (C57BL/6), and Met-enkephalin in the nucleus accumbens of ethanol-preferring AA rats. Continuous-access ethanol consumption caused a significant decrease in preproenkephalin mRNA expression in the nucleus accumbens and olfactory tubercle and a significant increase in mRNA in nuclei of the amygdala of fawn-hooded rats. Ethanol consumption had no significant effect on preprodynorphin mRNA. Thus, ethanol seems to negatively regulate enkephalin expression *in vivo*. The increase of preproenkephalin mRNA in the amygdala may be caused by the facilitating effect of ethanol on gabaergic neurons.

Cyclic AMP (►Cyclic Adenonine Monophosphate)

Acutely, ethanol has been shown to potentiate G_S -stimulated cAMP accumulation. Conversely, brain tissue and cell culture treated chronically with ethanol have decreased levels of adenylyl cyclase activity [5]. Tolerance to chronic ethanol is accompanied by a fall in the levels of $G_{\alpha S}$ -proteins and $G_{\alpha S}$ -mRNA in NG108-15 neuroblastomaxglioma cells and an increase in $G_{\alpha i2}$ -proteins, in blood platelets from alcoholics up to 6 months after ethanol withdrawal [3]. However, the contention that an increased level of $G_{\alpha i}$ and a reduced level of $G_{\alpha S12}$, respectively, are the cause of ethanol-induced tolerance was disputed in recent studies. Others have demonstrated a reduced catalytic activity of the ►adenylyl cyclase after 4 weeks ethanol in most but not all brain regions. The changes were not reflected by altered levels of the enzyme [3]. Among the nine isoforms of adenylyl cyclase, the type VII was activated by acute ethanol (50 mM) and prostaglandin E_1 (10 μ M) two- to threefold greater than that seen with the other tested adenylyl cyclases. PKC δ is involved in ethanol modulation of AC activity. Ethanol could promote a conformational change in AC that provides or enhances availability of a site(s) for PKC δ -mediated phosphorylation, or ethanol could promote the association of AC with PKC δ within a transducisome complex. In the presence of ethanol the more phosphorylated form of AC7 becomes more sensitive to activated $G_{\alpha s}$. The increased levels of cAMP during such a signaling process will produce a greater effect of PKA and a greater modification of downstream effectors dependent on cAMP signaling [5].

Clinical Use (Including Side Effects)

No clinical use, used in some medicinal drugs to solubilize active compounds.

Excitability

Excitability refers to the capacity of nerves and other tissues (e.g. cardiac), as well as individual cells, to generate and sometimes propagate action potentials, signals that serve to control intracellular processes, such as muscle contraction or hormone secretion, and to allow for long- and short-distance communication within the organism. Examples of excitable cells and tissues include neurons, muscle and endocrine tissues. Examples of nonexcitable cells and tissues include blood cells, most epithelial and connective tissues.

Excitation–contraction Coupling

Excitation–contraction coupling (EC coupling) is the mechanism underlying transformation of the electrical event (action potential) in the sarcolemma into the mechanical event (muscle contraction) which happens all over the muscle. In other words, it is the mechanism governing the way in which the action potential induces the increase in the cytoplasmic Ca²⁺ which enables the activation of myofibrils.

- ▶ Ryanodine Receptor

Excitatory Amino Acids

- ▶ Glutamate

Excitotoxicity

Excitotoxicity is the over-activity of the glutamatergic system responsible for the large number of dead neurons observed after ischemia (stroke) or epileptic seizures. This neuronal death is due to an over-excitation of the neurons and the massive Ca²⁺ entry

resulting from the depolarization. Because of their large Ca²⁺ permeability, the NMDA iGlu receptors play a major role in the excitotoxic effect of glutamate. Excitotoxicity also may have a part in the pathogenesis of neurodegenerative disorders such as Huntington's disease and amyotrophic lateral sclerosis (ALS).

Constitutive secretion; Regulated secretion; Neuronal secretion

Definition

Cellular secretion from macromolecules mediated by fusion of vesicles with the plasma membrane

Basic Mechanisms

Constitutive and Regulated Exocytosis

During exocytosis, intracellular vesicles fuse with the plasmalemma. As a consequence, the vesicle components are incorporated into the plasma membrane and the vesicle content is released into the extracellular space. We distinguish constitutive and regulated exocytosis.

Constitutive exocytosis/secretion takes place in all eukaryotic cells and is essential for cell viability and growth. Trafficking vesicles destined for constitutive exocytosis originate from the trans-Golgi-network and contain secretory macromolecules derived from the

biosynthetic pathway. They are transported along microtubules to the cell surface and fuse with the plasma membrane. Constitutive secretion leads to the continuous release of secretory products and to the incorporation of membrane constituents into the plasmalemma. Hence, constitutive cargo is not stored within the cell. Excess plasma membrane is retrieved by endocytosis. The balance between exocytosis and endocytosis ensures ordered cell growth during proliferation and maintains a constant surface area in nondividing cells. Proteins secreted by constitutive exocytosis include immunoglobulins, serum and milk proteins, and proteoglycans. In addition to vesicles derived from the biosynthetic route, recycling vesicles derived from endocytic precursor organelles (mostly endosomes) also fuse constitutively with the plasma membrane, thus returning endocytosed membrane constituents to the surface.

Regulated exocytosis differs from constitutive exocytosis, in that secretion-ready vesicles are stored in the cytoplasm, often in large numbers, and that they require a stimulus for fusion with the plasma membrane. Regulated secretory cells include, for instance, exocrine and endocrine cells, mast cells, platelets, large granular lymphocytes, neutrophils, and neurons. Depending on the cell type, exocytosis can be triggered by a variety of physiological stimuli that exert their action by means of receptor activation or electrical excitation. Release kinetics range from milliseconds in neurons to many minutes in exocrine and certain endocrine glands. All stimuli ultimately cause the transient rise of an intracellular second messenger, in most cases calcium. Calcium either directly activates exocytosis or it operates in conjunction with cAMP and protein kinases that potentiate the effect of calcium. In some systems, calcium ions are only permissive, and the triggering stimulus involves other second messengers and signaling cascades. In electrically excitable cells, the intracellular calcium concentration rises after depolarization by calcium entry through voltage-gated calcium channels. In cells lacking regulated calcium influx pathways, hormones, acting mostly through G-protein-coupled receptors, cause the release of calcium from intracellular stores. Regulated exocytosis also differs from constitutive exocytosis in that secretory products are often packaged at high concentrations within the secretory vesicles. Thus secretory cells are capable of rapidly discharging large amounts of secretory products in a short time without the need for concomitant product biosynthesis.

In addition to secretory cells, many non-secretory cells are capable of regulating exocytotic fusion of transport vesicles that are derived from endosomal precursors. For instance, vesicles enriched in plasma membrane transport proteins are incorporated in a regulated manner in order to alter metabolite fluxes. Examples include the glucose transporter GLUT-4 in muscle and fat tissues, a key element in the control of

serum glucose levels, and the vacuolar proton ATPase and aquaporins in the kidney that are essential for pH and water homeostasis. Last not least, regulated fusion of intracellular vesicles is used by many cells to repair tears in the plasma membrane.

Molecular Mechanisms of Exocytosis

Before exocytosis, the vesicle first moves from the cytoplasm to the plasmalemma. Second, the vesicle becomes attached to the plasma membrane, a process often referred to as docking. Third, activation involving metabolic energy, also referred to as priming, is required to achieve fusion competence. Finally, the vesicle and plasma membranes merge (Fig. 1). Each of these steps involves a multitude of proteins that operate by complex protein-protein and protein-phospholipid interaction networks. Although we are still far from a comprehensive molecular description, it is becoming clear that these steps are mediated by sets of common proteins that belong to evolutionary conserved protein families. While these proteins appear to operate in all intracellular fusion events (probably with the exception of mitochondria and peroxisomes), they are controlled by additional factors specific for a given fusion event or a given cell type.

Transport of vesicles occurs along microtubular tracks with the aid of kinesin motor proteins. In contrast, interactions with the actin-based microfilament network are thought to regulate the availability of vesicles for fusion, and they are also involved in certain types of vesicle movement. For instance, in neurons synaptic vesicles are thought to be attached to the actin cytoskeleton by crossbridges of synapsins that bind both to synaptic vesicles and to actin. Upon activation, synapsins are phosphorylated by calcium- and cAMP-dependent protein kinases, resulting in a weakening of binding affinities and the release of the vesicles from the cytoskeleton.

The initial contact between the vesicle and the plasma membrane is mediated by protein complexes that appear to be essential for ensuring that only appropriate membranes fuse. While more is known about the proteins involved in the “homotypic” docking of intracellular transport vesicles than in docking of vesicles to the plasma membrane, similar mechanisms may be involved. A key role has been assigned to Rab proteins, a family of Ras-related small GTPases. Apparently, each fusion step is controlled by a specific family member that resides on the vesicle membrane and appears to play a key role in recruiting docking proteins to the vesicle surface. Like ras, Rabs operate as molecular switches that are active in the GTP-form and inactive in the GDP-form. Active Rabs recruit a variety of structurally diverse effector proteins to the vesicle that may then bridge the membranes destined to fuse. Protein recruitment may also be assisted

Exocytosis. Figure 1 Model for protein-mediated membrane fusion in neuronal exocytosis. Syntaxin and SNAP-25 form a complex on the plasma membrane that interacts with synaptobrevin on the synaptic vesicle membrane. The assembly of the resulting ternary complex forces the opposing membranes into close apposition. Such complex assembly may be enough to induce constitutive exocytosis. For neuronal exocytosis, fusion requires calcium that enters the cell via voltage-gated calcium channels. Triggering of fusion involves probably Ca^{2+} -induced interactions implicating synaptotagmin. A network of cytoskeletal elements controls the availability of secretory vesicles at the plasma membrane, and targeting of synaptic vesicles to docking sites may be carried out by Rab-GTPases. Tetanus and Botulinum toxins block exocytosis by specifically cleaving the neuronal SNAREs.

by the phospholipid phosphatidylinositol bisphosphate (PIP₂). Several Rab effectors possess characteristic PIP₂-binding domains, and it is known that interference with the metabolism of PIP₂ inhibits exocytosis in some systems.

Membrane fusion itself is probably the best understood step in the sequence of events leading to exocytosis, although many questions remain. Essential for fusion are the **SNAREs**, a superfamily of small membrane proteins. Appropriate sets of three to four SNAREs spontaneously assemble from unstructured precursors into tight α -helical complexes that need metabolic energy for disassembly, and the assistance of the chaperone-like ATPase **NSF**, with additional cofactors for disassembly. Different sets of SNAREs are required for the various intracellular fusion steps. When appropriate SNAREs on the membranes destined to fuse contact each other, assembly is thought to pull the opposing membranes tightly together, a process that may suffice to initiate membrane fusion (Fig. 1). After fusion, the spent SNARE complexes are regenerated by ATP and NSF.

While the basic features of SNARE assembly and disassembly provide a convenient framework for explaining how membrane fusion works, both the regulation of SNAREs and the molecular details of fusion are not well understood. Most is known about the neuronal SNAREs that mediate regulated membrane fusion of synaptic vesicles and of secretory granules in neuroendocrine cells. They include synaptobrevin2, localized to the synaptic vesicle, and SNAP25 (**SNAPs**) and syntaxin1A, both of which are localized to the plasma

membrane. Several proteins are known that bind to these proteins and thus may regulate their activity. They include Munc-18, a syntaxin-binding protein, complexins that bind only to the fully assembled SNARE complex, and tomosyn which possesses a SNARE-like domain and competes with synaptobrevin. Genetic and physiological studies assign essential roles to these proteins in exocytosis, although their mechanism of action remains to be established.

While the steps described above are common to all exocytotic events, regulated secretion is distinguished by an additional layer of control proteins. Principally, each of the steps may be subject to regulation and thus controls the overall rate of exocytosis, and there appears to be a large variety of mechanisms that is reflected in a kinetic range covering several orders of magnitude. Even for the universal second messenger calcium there seems to be no universal mechanism of action. In chromaffin cells and possibly also in neurons, calcium controls the rate of several distinct and consecutive steps, the last being directly linked to membrane fusion. A prime candidate for the neuronal calcium receptor in the last step is **synaptotagmin**, a transmembrane protein of synaptic and secretory vesicles. Synaptotagmin possesses two calcium-binding modules (referred to as C2 domains) that interact in a calcium-dependent manner both with phospholipids and with SNAREs. Deletion of synaptotagmin largely abolishes calcium-dependent exocytosis, whereas exocytosis can still be elicited by calcium-independent pathways. In other cells, however, the control of the exocytotic rate appears

to occur at an earlier stage, e.g., by regulating vesicle availability through cytoskeletal interactions. Identifying and characterizing such control mechanisms remains one of the most urgent tasks for future research.

While recent attention has been largely on proteins, it should be borne in mind that membrane fusion ultimately involves the merger of phospholipid bilayers. However, little is known about the specific membrane lipid requirements. When membranes fuse, energetically unfavorable transition states are generated that may require specific lipids and lipid domains for stabilization. Although there is some evidence for a specific influence of lipids on exocytosis, it is still unclear whether specific lipid metabolites are needed or even generated at the site of membrane merger.

Pharmacological Intervention

Exocytosis represents the final step in a multistep pathway involving vesicle formation and storage, transport to the plasma membrane by microtubule dependent transport, possibly involving additional cytoskeletal elements (e.g., the actin-myosin system), vesicle attachment to the plasma membrane, vesicle activation ("priming"), and finally membrane fusion. Each of these steps is probably regulated, but the details of such regulation have only been worked out in a few cases. Exocytosis can be regulated by many membrane receptors, dependent on the cell type, via second messengers or by electrical activity. Accordingly, regulated exocytosis can be controlled by appropriate receptor agonists and antagonists, by drugs influencing second messenger levels (e.g., Ca-channel blockers) or by reagents interfering with the cytoskeleton. However, most of the second messenger targets in exocytosis remain to be identified, and it is conceivable that they may emerge as attractive drug targets. For instance, there is evidence that protein phosphorylation by protein kinases potentiates calcium-dependent exocytosis and in some cases suffices to induce exocytosis by itself, but it is not known which of the phosphorylated proteins are rate-limiting. Furthermore, the release of calcium from internal stores by second messengers may be an interesting point to control exocytosis by externally applied drugs. For example, hormones from pituitary gonadotropes are secreted in response to gonadotropin-releasing hormones. The gonadotropin-releasing hormone receptor couples to a G-protein, which activates the phospholipase C cascade with production of inositol trisphosphate and oscillatory release of calcium from intracellular stores. Hormone secretion may be controlled by interfering specifically with one of the steps in the cascade. Several biological toxins are known to directly affect exocytosis. Best characterized are the botulin and tetanus neurotoxins, proteinaceous AB-toxins with a heavy chain mediating cell entry and a light chain that carries the catalytic

activity. All light chains are proteases that cleave one of the three neuronal SNAREs and some of their close relatives. As a result, neuronal exocytosis is irreversibly inhibited. While extremely toxic upon systemic application, local application of botulinum neurotoxin A has become the treatment of choice for blepharospasm, hemifacial spasm, cervical dystonia, and laryngeal dystonia. The toxin also alleviates pain and may be used in therapeutic trials for prediction of the response to surgical elongation. New toxin serotypes are now being tested. There are also cosmetic uses of Botulinum neurotoxin A. Local injections are used to diminish the undesirably negative and expressive wrinkles of the face by producing a reversible weakness of the hyperfunctional mimetic muscles of facial expression. In addition, several animal toxins block neurotransmission but the mechanism is different. These toxins cause massive exocytosis until the synaptic vesicle pool is exhausted. Best studied among these toxins is α -latrotoxin, the active ingredient of black widow spider venom, and probably also some snake toxins (e.g., crotoxin, taipoxin). Their mechanism of action, however, is not understood.

Exogenous Pyrogens

Extraneous live microorganisms or their products or certain inanimate substances recognized as foreign and potentially deleterious by the afflicted host that promptly evoke fever. They do this, in most cases, by inducing endogenous pyrogens, obligatory inherent mediators of the febrile response. Endotoxic bacterial lipopolysaccharide is an exogenous, bacterial pyrogen.

Exon

A length of DNA in a gene that is transcribed into mRNA and translated into the final protein product.

► Intron

Exopeptidase

A peptidase that acts only at the amino- or carboxy-termini of proteins or peptides.

► Non-viral Peptidases

Exportins

Exportins are transport receptors at the nuclear pore complex needed for the selective export of proteins from the nucleus into the cytoplasm. They recognize nuclear export signal sequences of cargo proteins.

► Small GTPases

Extended Amygdala

The shell of the nucleus accumbens, the bed nucleus of the stria terminalis, and the central nucleus of the amygdala, together referred to as the extended amygdala, may play a role in drug addiction.

Extracellular Matrix (ECM)

In biology, extracellular matrix (ECM) is the extracellular part of animal tissue that usually provides structural support to the cells in addition to performing various other important functions. ECM is the defining feature of connective tissue in animals. ECM includes the interstitial matrix and the basement membrane.

► Matrix Metalloproteinases

Extrapyramidal Side Effects

Extrapyramidal side effects (EPS) are adverse effects of dopamine D₂-receptor antagonists (e.g. metoclopramide) acting on the nigrostriatal system. EPS include parkinsonism (stiffness, slow movements, stooped posture, and tremor of extremities), akathisia (an inner sense of restlessness or need to move), and dystonia (spasm of a muscle group, most commonly involving the neck, extraocular muscles, and the tongue). Dose adjustment is often sufficient in managing these side effects, though use of other medications such as beta blockers (e.g. propranolol for akathisia), anticholinergic medications (e.g. benztropine for dystonia and parkinsonism), and amantadine (for parkinsonism), may sometimes be necessary. The dopamine D₂-receptor antagonist domperidone does not readily penetrate the blood brain barrier. It is therefore less prone to produce EPS.

Extrasynaptic Receptors

Populations of receptors that are excluded from synaptic junctions. These may be distributed over neuronal cell bodies or located around but not directly beneath synapses (perisynaptic). Some receptors have become specialised to serve an extrasynaptic function producing a tonic level of activity in response to ambient levels of neurotransmitter. This tonic current can be used to maintain homeostatic control over neuronal excitation.

F-actin

F-actin (also called microfilament or actin filament) is a double-stranded, right-handed helix with 14 actin molecules per strand and turn. F-actin has a diameter of 8 nM and is polarized with a pointed (minus) and a barbed (plus) end.

Familial Alzheimer's Disease

This type of disease occurs in families and begins unusually at early age (i.e., onset below the age of 60). Approximately 10% of Alzheimer's disease are familial and are inherited in an autosomal dominant manner with high penetrance. Deterministic genes directly cause the disease. Mutations in three different genes encoding for the amyloid precursor protein (APP) and the presenilins 1 and 2 (PS1 and PS2) have been identified to be responsible for early-onset familial Alzheimer's disease.

In addition, other genes (risk genes) remain to be discovered. Risk genes, such as the apolipoprotein E-e4 (APOE-e4) gene, increase the likelihood of developing the disorder.

- ▶ Alzheimer's Disease

Familial Hypocalciuric Hypercalcemia (FHH)

A form of PTH-dependent hypercalcemia that results from the presence of one or two CaR alleles bearing inactivating mutations.

- ▶ Ca²⁺-Sensing Receptor (CaR)

Fanconi-Bickel Syndrome

Fanconi-Bickel syndrome (FBS) is a rare type of glycogen storage disease which is caused by homozygous or compound heterozygous mutations within the *SLC2A2* gene encoding GLUT2. More than 100

patients have been reported in the literature. Most patients have the typical combination of clinical symptoms: hepatomegaly secondary to glycogen accumulation, glucose and galactose intolerance, fasting hypoglycemia, a characteristic tubular nephropathy, and severely stunted growth. A total of 34 different *SLC2A2* mutations have been identified with none of them being particularly frequent. No specific therapy is available for FBS patients. Symptomatic treatment is directed towards a stabilization of glucose homeostasis and compensation for renal losses of various solutes.

Definition

Fatty acid transport proteins (FATPs) are an evolutionary conserved family of integral membrane proteins found at the plasma membrane and on internal membranes. FATPs facilitate the unidirectional uptake and/or intracellular activation of unesterified long-chain and very ► long-chain fatty acids (LCFAs) into a variety of lipid-metabolizing cells and tissues.

Basic Mechanisms

Introduction

LCFAs are vital components of our diet and contribute to cellular processes including metabolic energy generation and storage, plasma membrane synthesis, and protein anchoring. While in some tissues and cell types LCFAs can signal through membrane receptors, they typically have to first cross the plasma membrane to elicit cellular responses. In general, the uptake of fatty acids from the circulation into cells includes the sequence of (i) localized generation of free fatty acids through hydrolysis of triglycerides (TGs) from lipoproteins by lipases inside the endothelial lumen and rapid binding of fatty acids to albumin, (ii) fatty acid dissociation from albumin followed by passive or active transport across the plasma membrane, and (iii) their association with intracellular binding proteins and subsequent participation in metabolic and signaling processes (Fig. 1).

Uptake of LCFAs across the lipid-bilayer of most mammalian cells occurs through both a passive diffusion of LCFAs and a protein-mediated LCFA uptake mechanism. At physiological LCFA concentrations (7.5 nM) the protein-mediated, saturable, substrate-specific, and hormonally regulated mechanism of fatty acids accounts for the majority (>90%) of fatty acid uptake by tissues with high LCFA metabolism and storage such as skeletal muscle, adipose tissue, liver,

Fatty Acid Transporters. Figure 1 Free fatty acid uptake and action in mammalian cells. Serum free fatty acids (FFA) are generated from lipoproteins by the action of endothelial lipoprotein lipase (*LpL*). At physiological conditions, the majority of FFAs is bound to albumin while the concentration of unbound FFAs in this equilibrium is low. Plasma membrane traversing of FFAs into the cell under these conditions occurs mainly by a protein-mediated mechanism, either by interaction of the FFAs directly with FATP complexes or by a preceding binding to cell-surface proteins, such as CD36, which subsequently hands the FFAs on to the FATPs. On the cytosolic site, FFAs are quickly activated and coupled to coenzyme A (CoA) by the catalysis of long-chain fatty acyl-CoA synthetases (ACSLs) or the by FATPs itself. Fatty acid binding proteins (FABPs) or acyl-CoA binding proteins (ACBPs) facilitate an intracellular unloading of the transporters and the synthetases and can also function as an intracellular fatty acid buffer. In the cell, FFAs can act at different subcellular localizations and have functions in energy generation and storage, membrane synthesis, protein modification, and activation of nuclear transcription factors. In addition to acting intracellularly, unbound FFAs can also signal extracellularly in certain cell types (e.g., by stimulating the G-protein coupled receptor GPR40 in β -cells to induce insulin secretion, or by activating toll-like receptors – TLRs) to initiate the innate immune response).

and heart. The relative contribution of passive diffusion is thought to be higher in cell types that lack fatty acid transporters such as fibroblasts (see Fig. 2) and may be elevated as a result of super-physiological fatty acid concentrations. While several fatty acid handling proteins have been identified (see Fig. 1), recent *in vivo* studies have particularly highlighted the contribution of FATPs to LCFA uptake, lipid metabolism, and lipid-associated disorders [1].

The Family of FATPs

In humans and mice, the FATP family is comprised of six structurally related members (FATP1–6; 33–57.1%

identity in mice) that are found in all fatty acid-utilizing tissues of the body. While substrate preferences are comparable among the different FATPs paralogues, they differ widely in their tissue expression pattern [2]. FATP1 was the first FATP to be identified and is highly expressed in adipose tissue, skeletal muscle and, to a lesser extent, in heart. FATP2 is predominantly expressed in liver and kidney cortex. FATP3 shows a broader expression pattern with high mRNA and protein levels in lung. FATP4 is the only FATP expressed in small intestine and is localized to the apical brush border of the epithelial cells, where it is implicated in the absorption of dietary lipids. FATP4

Fatty Acid Transporters. Figure 2 Quencher-based real-time fatty acid uptake assay with a fluorescently labeled FFA analogue (C1-Bodipy-C12). Predominantly protein-mediated fatty acid uptake by 3T3-L1 adipocytes (diamonds) was compared with diffusion-driven uptake by fibroblasts (squares) using the QBT Fatty Acid Uptake reagent (Molecular Devices Corp., CA, USA), which contains C1-Bodipy-C12 as substrate in conjunction with a cell impermeable quencher. Uptake kinetics was recorded using a Gemini fluorescence plate reader. Error bars indicate the standard deviations from 12 independent wells. RFU: relative fluorescence units.

is also expressed to a lesser extent in other tissues including adipose tissue, liver, skin, and heart. Furthermore, FATP4 together with FATP1 are the predominant FATP paralogues in brain. FATP5 is expressed solely in liver. Confocal immunofluorescent microscopy with isolated primary hepatocytes demonstrated that FATP5 is localized to the plasma membrane of these cells, which was confirmed by immunoelectron microscopy of liver sections, showing a predominant localization of FATP5 protein to basal microvilli in the space of Disse. FATP6 is expressed specifically in heart where it is the predominant FATP paralogue. Immunofluorescence microscopy studies of FATP6 in primate and murine hearts have shown that the protein is exclusively located on the sarcolemma, where it is restricted to areas of the plasma membrane juxtaposed to small blood vessels [1]. In addition to vertebrates, FATP orthologs have been identified in invertebrate, fungi, and prokaryote genomes such as *Caenorhabditis elegans*, *Saccharomyces cerevisiae*, and *Mycobacterium tuberculosis*.

FATP Structure and Mechanism of Transport

Due to the high overall sequence similarity, the presumed secondary structure of all FATP members is assumed to be similar, with an extracellular N- and an intracellular
