A new hypothesis for purinergic **mechanosensory transduction** in visceral organs involved in the initiation of pain has been proposed. It is suggested that distension of tubes (such as the ureter, salivary duct and gut), and sacs (such as urinary and gall bladder), leads to the release of ATP from the lining epithelial cells that diffuses to subepithelial sensory nerves expressing P2X₃ and/or P2X_{2/3} nociceptive receptors, which mediate messages to pain centres in the central nervous system [5] (Fig. 4). Recording in P2X₃ knockout mice, has shown that the micturition reflex is impaired and that responses of sensory fibres to P2X₃ agonists are gone, suggesting that P2X₃ receptors on sensory nerves in the bladder have a physiological as well as a nociceptive role.

P1 (adenosine) receptors were explored as therapeutic targets before P2 receptors. Adenosine was identified early and is in current use to treat **supraventricular tachycardia**. A_{2A} receptor antagonists are being investigated for the treatment of **Parkinson's disease** and patents have been lodged for the application of P1 receptor subtype agonists and antagonists for myocardial ischaemia and reperfusion injury, cerebral ischaemia, stroke, intermittent claudication and renal insufficiency.

Purinergic receptors have a strong presence in bone cells. P2X and P2Y receptors are present on osteoclasts, with P2Y receptors only being present on osteoblasts. ATP, but not adenosine, stimulates the formation of osteoclasts and their resorptive actions in vitro and can inhibit osteoblast-dependent bone formation. A recent study has shown that very low (nM) concentrations of ADP acting through P2Y₁ receptors turn on osteoclast activity. Modulation of P2 receptor function may have potential in the treatment of osteoporosis. The anticancer activity of adenine nucleotides was first described in 1983 and since then, intraperitoneal injection of ATP into tumour-bearing mice has resulted in significant anticancer activity against several fast-growing aggressive carcinomas.

Purinergic signalling is important in the special senses. For example, P2Y₂ receptor activation increases salt, water and mucus secretion in the eye and thus represents a potential treatment for dry eye disease. P2 receptor agonists have greater efficacy in reducing intraocular pressure than cholinergic and adrenergic agents, raising possibilities for novel treatment of glaucoma. It has been

Purinergic System. Figure 4 Schematic representation of the hypothesis for purinergic mechanosensory transduction in tubes (e.g. ureter, vagina, salivary and bile duct and gut) and sacs (e.g. urinary and gall bladders, and lung). It is proposed that distension leads to release of ATP from the epithelium lining the tube or sac, which then acts on P2X_{2/3} receptors on subepithelial sensory nerves to convey sensory (nociceptive) information to the CNS. (From Burnstock G, Wood JN (1996) Purinergic receptors: their role in nociception and primary afferent neurotransmission. *Curr Opin Neurobiol* 6:526–532, with permission from Blackwell Publishing).

suggested that ATP may regulate fluid homeostasis, cochlear blood flow, hearing sensitivity and development, and thus may be useful in the treatment of Ménière's disease, tinnitus and sensorineural deafness.

There have been very promising recent developments concerning purinergic drugs aimed at treating ►thrombosis. Clopidogrel and ticlopidine are antagonists of the P2Y₁₂ receptor and appear to reduce the risks of recurrent strokes and heart attacks, especially when combined with aspirin. Further therapeutic targets include: chronic renal failure, congestive heart failure, hypertension, stroke, angina, asthma, chronic obstructive pulmonary disease, epilepsy, sleep apnea, diabetes, inflammation, erectile function and wound healing.

QA/QC Control Metrics

Quality Assurance/Quality Control parameter and metrics to ensure data reproducibility, e.g. the establishment of calibrated RNA samples and reference datasets to objectively assess the performance of different microarray platforms (see also MAQC project: ► <http://www.nature.com/nbt/focus/maqc/>).

► Gene Expression Analysis

QT Prolongation

The QT interval is measured in an electrocardiogram (ECG) between the onset of ventricular depolarisation (QRS) and the end of the repolarization process (T wave). The QT interval is rate-dependent and may be altered by numerous pathophysiologic and pharmacologic influences. The QT interval corrected for heart rate is termed QTc; its prolongation is known to be associated with various malignant tachyarrhythmias and specifically torsades de pointes. Drugs which prolong the cardiac action potential, lead to a prolongation of the QTc interval on the electrocardiogram. This may for instance be the case for drugs, which delay cardiac repolarisation (e.g. class III antiarrhythmic drugs). In addition antibacterial agents, such as macrolides and quinolones, as well as drugs from other classes, have the potential to prolong the QTc interval. A slight prolongation does not represent a risk per se, but when these drugs are combined with other agents known to prolong the QT interval in at-risk patients possible untoward effects might occur.

Definition

The term “quinolone antibacterials” describes a large group of drugs that are 4-quinolone derivatives with a

carboxylic acid moiety in position 3 of the basic ring structure or 1,8-naphthyridone (8-aza-quinolone) derivatives. They are active against a broad spectrum of gram-negative and gram-positive pathogens. They exhibit their antibacterial action by inhibiting topoisomerase II (so-called ►gyrase) and topoisomerase IV, which are enzymes that control structure and function of bacterial DNA. ►Topoisomerases in eukaryotic, mammalian cells are not inhibited by quinolone antibacterial agents. Among the quinolones in clinical use today, four groups can be distinguished: those which inhibit gram-negative bacteria, but are not sufficiently active against pneumococci (groups I and II, e.g. ciprofloxacin), those which exhibit increased activity against a broad spectrum of bacteria, including pneumococci (group III, e.g. levofloxacin) and those which act against a broad spectrum with high anti-pneumococcal activity and are also active against some anaerobic bacteria (group IV, e.g. moxifloxacin and gatifloxacin). All of these compounds are fluorinated in position 6 of their basic heterocyclic structure and therefore are also termed ►“fluoroquinolones”. However, quinolones without 6-fluorination are under development (e.g. garenoxacin, PGE9262932) and thus the term “quinolones” seems to be more appropriate for the whole group of antibacterials. According to their differences in antibacterial activity and also their pharmacokinetic properties the indications differ for their clinical use. When used therapeutically, also their potential toxicities and possible adverse reactions have to be taken into account [1].

Mechanism of Action

The ►chromosomes of *Escherichia coli* and other bacteria are single, double-stranded DNA molecules with a total length of more than 1,000 µm. Relaxed DNA exists as a helical molecule, with one full turn of the helix occurring approximately every 10.4 base pairs. This molecule must undergo several folding and compaction steps to fit into an *E. coli* cell which is only 1–3 µm long. Despite this enormous compaction, bacterial DNA must be accessible for the bacterial enzymes that catalyze DNA replication and transcription

into mRNA, the prerequisite for protein synthesis. These and other topological problems are solved by enzymes called DNA topoisomerases. DNA gyrase (topoisomerase II) was the first quinolone target identified on the basis of genetic studies with *E. coli* mutants that were resistant against nalidixic acid (i.e. the first quinolone antimicrobial which is no longer in clinical use). DNA gyrase has a tetrameric A₂B₂ structure (Table 1); the two subunits of gyrase are encoded by the *gyrA* and *gyrB* genes. The enzyme is responsible for introducing negative ►supercoils into DNA – negatively supercoiled DNA contains slightly less than one helical turn per 10.4 base pairs. This is an ATP-dependent reaction that requires both strands of the DNA be cut to permit passage of a segment of DNA through the break; the cleavage is then resealed. Topoisomerase IV is a homologue of gyrase, which is encoded by the *parC* and *parE* genes. This enzyme catalyzes the unlinking of replicated daughter chromosomes, a process that is called decatenation. Both enzymes cause double strand breakage of DNA strands and are called “type II topoisomerases” in contrast to “type I topoisomerases” that catalyze single-stranded DNA cleavage [2].

Quinolones inhibit bacterial DNA synthesis by their ability to bind to and to stabilize complexes of DNA and type II topoisomerases; there is strong evidence for a role of Mg²⁺ ions in this process. The enzymes break DNA and the quinolones prevent re-ligation of the broken DNA strands. Inhibition of DNA synthesis by interaction with gyrase occurs rapidly, but inhibition due to interaction with topoisomerase IV occurs with some delay. This is thought to relate to differences in the localization of DNA gyrase and topoisomerase IV on the bacterial chromosome; gyrase works ahead of replication forks and topoisomerase IV is located behind replication forks. Differences exist with respect to the primary targets of quinolones in different bacteria. For *E. coli*, DNA gyrase is more sensitive to many quinolones than topoisomerase IV, but for the gram-positive pathogen *Staphylococcus aureus* topoisomerase IV is the more sensitive of the two enzymes. The more sensitive enzyme usually represents the

Quinolones. Table 1 Quinolones – Classification of bacterial topoisomerases

Topoisomerase	Type	Structure	Gene	Predominant function in cell
I	I	1 subunit		Relaxes negatively supercoiled DNA
II (“gyrase”)	II	Tetramer (2 GyrA; 2 GyrB subunits)	<i>gyrA</i> / <i>gyrB</i>	Introduces negative supercoils into DNA
III	I	1 subunit		Decatenation of replication intermediate
IV	II	Tetramer (2 ParC; 2 ParE subunits)	<i>parC</i> / <i>parE</i>	Decatenation of linked daughter DNA molecules

primary quinolone target for a given organism. Events in addition to interaction of the quinolone with its target enzyme DNA complex are necessary for the rapid bactericidal action of quinolones, but these events are poorly understood. Probably at least two different lethal modes of action exist, one that requires protein synthesis and one that does not [3].

Most of our knowledge about the targets of quinolone action is the result of extensive studies performed to understand (and possibly overcome) the phenomenon of bacterial ►resistance against quinolones, which represents an increasing problem with the use of these and other antimicrobial agents. In *E. coli* and other gram-negative bacteria first step quinolone resistance mutations occur in *gyrA*, or less commonly, *gyrB*. In contrast, for many gram-positive bacteria, as for *S. aureus*, first-step mutations occur in *parC*, less commonly *parE*. To avoid the development of double mutants, the quinolone should be active enough to destroy pathogens with reduced susceptibility due to first step resistance. An optimal bactericidal effect requires the AUC/MIC ratio to be greater than 100, selection of resistant mutants is unlikely with a C_{max}/MIC ratio greater than 10.

Interestingly, rather slight modifications of the molecular structure of antibacterial quinolones can render them into substances that have the potential to inhibit mammalian topoisomerases. One of such compounds is CP-115,953 which is a more potent inhibitor for mammalian topoisomerases than etoposide, a drug that is used as a cytostatic agent in cancer patients. CP-115,953 and similar derivatives were not further developed for clinical use [4]. Because any inhibition of mammalian topoisomerases is unwanted with drugs used for the treatment of bacterial infections, quinolones are tested at very early stages during their preclinical development as to whether they exhibit such a potential. However, these antineoplastic quinolones represent a potentially important source of new anticancer agents.

Clinical Use

Besides the four most widely used fluoroquinolones (ciprofloxacin, levofloxacin, moxifloxacin, and gatifloxacin) several other derivatives of the same basic structure are available for clinical use. However, several shortcomings, such as relatively low antibacterial activity or poor pharmacokinetics, do not render them drugs of first choice. For example, enoxacin has a relatively low antibacterial activity and exhibits a pronounced potential for ►drug interactions by inhibition of CYP1A2 (theophylline metabolism). Another example is ofloxacin that represents a racemate consisting of equal parts of two substances (the R- and L-forms), but only one of these compounds – the L-form, also called levofloxacin – exhibits antibacterial activity. Thus, from a pharmacological point of view levofloxacin is the more rational choice than ofloxacin. The indications for the four most often used quinolones differ due to differences in their antimicrobial spectrum as well as their pharmacokinetics. Table 2 provides an overview of the indications of these drugs as licensed in Germany or other countries. They are available for oral as well as for intravenous application (gatifloxacin is available in the USA, but not in Europe).

As with all drugs, the specific side effects of the quinolones must be considered when they are chosen for treatment of bacterial infections [5]. Reactions of the gastrointestinal tract and the central nervous system are the most often observed adverse effects during therapy with quinolones. It should be underlined, however, that compared with many other antimicrobials, diarrhea is less frequently observed during quinolone treatment. Antibiotic-associated colitis has been observed rarely during quinolone therapy. Similarly, hypersensitivity reactions, as observed during therapy with penicillins and other β -lactams, is less frequently caused by quinolones. Some other risks of quinolone therapy have been defined and must be considered if a drug from this class is chosen for treatment of bacterial infections.

Quinolones. Table 2 Quinolones

Indication	Ciprofloxacin	Levofloxacin	Moxifloxacin	Gatifloxacin
Uncomplicated UTI*	X	X		X
Complicated UTI	X	X		X
Community-acquired pneumonia		X	X	X
Acute exacerbation of chronic bronchitis		X	X	X
Sinusitis		X	X	X
Uncomplicated skin and skin structure infections	X	X	X	X
Pseudomonas infections	X			
Sepsis	X			

*UTI = Urinary tract infection ("uncomplicated" = no obstruction).

Because quinolones can cause prolongation of the QTc-interval, they should not be used (i) in patients with inborn ►QT prolongation, (ii) in patients treated with other drugs that cause QT prolongation (e.g. antiarrhythmics), (iii) in patients with electrolyte disturbances, such as hypokaliemia or hypomagnesemia or (iv) in patients with severe heart disease. Alterations of glucose homeostasis have been observed with quinolone use and strict glucose controls of diabetic patients are recommended, especially if they are treated with sulphonylurea agents; such effects occur more frequently with gatifloxacin than with other quinolones. Damage of articular joint cartilage as well as the epiphyseal growth plate can be induced by quinolones in immature animals and these chondrotoxic effects have led to a restricted use of quinolones in pediatrics. Another manifestation of the connective tissue toxicity of quinolones is tendopathies. ►Tendinitis and tendon ruptures have occurred in rare cases as late as several months after treatment with quinolones.

A number of quinolones had to be taken off the market due to toxic effects on the liver, heart, or other organs, that became recognized only after marketing (e.g. temafloxacin, trovafloxacin, grepafloxacin). A risk for severe cardiotoxicity, hepatotoxicity, or phototoxicity is

not associated with the clinical use of those four quinolones (ciprofloxacin, levofloxacin, moxifloxacin, gatifloxacin) described as preferential quinolones in this chapter.

RAAS

- ▶ Renin–Angiotensin–Aldosterone System

Rab-GTPases

Rab proteins are a family of small GTPases related to ras. Rab proteins possess GTP-binding motifs, an effector loop that changes conformation concomitant with the GTP-GDP cycle and a C-terminal CXC or CC box that serves as attachment for the hydrophobic geranylgeranyl membrane anchors. Each intracellular membrane carries a specific set of Rab proteins. The GTP-GDP cycle of rab proteins is regulated by a complex network of protein-protein interactions. The GDP form of rabs is recognized by a soluble protein termed GDI (for GDP dissociation inhibitor). GDI dissociates GDP-rabs from the membrane and allows for re-binding, thus ensuring that rabs are not carried along the secretory pathway, which would result in a loss of membrane specificity.

Membrane-bound GTP rabs recruit effectors to the membrane. In neurons and neuroendocrine cells, the vesicle-associated Rab3 binds to rabphilin and to RIM. RIM is a component of the presynaptic cytomatrix and may thus serve as a docking receptor for synaptic vesicles at the active zone.

Radioiodine

The ^{131}I isotope of iodine is used for treatment of thyroid disorders. ^{131}I -iodine is administered orally as a single dose. It is rapidly and completely absorbed and is accumulated in the thyroid gland via an active transport mechanism. Thereafter it is oxidized and organified by thyroid follicular cells. Its physiologic half-life is 8 days. ^{131}I emits both beta and gamma radiation. The toxic effect on thyroid tissue is caused by the released beta particles, which have a path length of 1–2 mm. They destroy thyroid follicular cells. The additional fraction of gamma radiation is utilized for detection. When used for treatment of benign thyroid disorders (e.g. Graves' disease or thyroid autonomy), exposure of other organs is small. Infrequent side effects of radioiodine therapy are nausea, vomiting and anorexia. Although there is no established teratogenic risk, the use of radioiodine is contraindicated in pregnancy and breast-feeding women. It should be administered within 10 days of the onset of a menstrual period or after a negative pregnancy test and pregnancy should be avoided for 4 months after radioiodine treatment.

- ▶ Antithyroid Drugs

Radiomimetics

Radiomimetics are a class of agents that cause DNA damage of a similar quality to that resulting from exposure to ionizing radiation.

- ▶ Cancer (Molecular Mechanisms of Therapy)

Raf

Raf kinases such as Raf1 are serine/threonine-specific protein kinases which function in signal transduction

pathways between the cell surface and the nucleus. It is a downstream target of the monomeric GTPase Ras.

► Phospholipid Kinases

RAGE

► Receptor for Advanced Glycation End Products

Rapamycin Analogs

Rapalogs have been designed to be used in several different applications. Rapalogs used clinically have been designed to have superior pharmacokinetic properties. Other rapalogs have been designed to be used as experimental reagents. For example, some rapalogs induce heterodimerization of FRB- and FKBP-domain-containing protein construct but have lost the ability to inhibit TOR/mTOR activity.

► TOR Signalling

Raphe Nuclei

The raphe nuclei are a cluster of nuclei found in the brainstem, where they are located in the medial portion of the formatio reticularis, the raphe. (The raphe is the junction of the left and right brainstem hemisphere, hence the name raphe=seam). Serotonergic nerve cells in the CNS originate from the raphe nuclei, i.e., their rostral portion, and because of their wide-ranging projections appear to supply serotonin (5HT) to the rest of the brain.

► Neurotransmitter Transporters
► Serotonergic System

Rapid Eye Movement Sleep

Synonyms

REM Sleep

Definition

REM sleep is a paradoxical *sleep stage*, in that the brain activity as measured by the EEG resembles that of wake. Specifically, the EEG signal consists of high frequency, low amplitude activity, with a prevalent “theta” (4–8 Hz) component. In contrast to wake, however, during REM sleep, muscle atonia occurs, thereby inhibiting movement. REM sleep is so named because specific patterns of brain activity intrinsic to this sleep stage result in rapid movements of the eyeballs, as detected by *electro-oculogram* electrodes. It is thought that dreaming occurs primarily during REM sleep, based on reports of subjects waking at various points during the sleep–wake cycle, although some dreaming activity was found to occur during non-REM sleep. Loss of the so-called “REM atonia” can result in the sufferer effectively “acting out their dreams”, as observed in the clinical condition *REM behaviour disorder*.

► Sleep

Ras Protein

Ras is a G protein that cycle between two conformations, an activated Ras-GTP or inactivated form Ras-GDP. Ras, attached to the cell membrane by lipidation, is a key component in many signalling cascades, which couple growth factor receptors to downstream effectors that control such processes as cytoskeletal integrity, proliferation, cell adhesion, apoptosis and cell migration. Mutations and dysregulations of the Ras protein leading to increased invasion and metastasis, and decreased apoptosis are very common in cancers.

Ras activates a number of pathways among them is the mitogen-activated protein (MAP) kinases, which transmit signals downstream to other protein kinases and gene regulatory proteins

► Small GTPases

Raynaud's Phenomenon

Raynaud's phenomenon is an exaggerated vascular response to cold temperature or emotional stress. Clinical symptoms are sharply demarcated color changes in the skin of the digits. The underlying disorder consists of abnormal vasoconstriction of digital arteries and cutaneous arterioles due to a local defect in normal vascular responses.

► Ca^{2+} Channel Blockers

Rb Gene

► Retinoblastoma (Rb) Gene

Reactive Oxygen Species

Synonyms

► ROS

Definition

Reactive oxygen species like superoxide, hydrogen peroxide (H_2O_2) or hydroxyl radicals (OH) are formed in the course of a variety of enzymatic processes in cells. Although potentially very toxic, their concentrations are kept low due to the activity of various antioxidants. However, under pathological conditions reactive oxygen species can accumulate resulting in oxidative stress which may lead to cellular damage due to the oxidation of NA, proteins, or lipids.

► Antioxidants

Rebound Insomnia

A condition following treatment of *insomnia*, when on cessation of medication, the insomnia reoccurs and is

often more severe than before the treatment commenced. This often occurs following treatment with short half-life benzodiazepines, particularly if the drug is not gradually reduced but suddenly withdrawn.

► Sleep

Receptor for Advanced Glycation End Products

Receptor for advanced glycation end products (RAGE) is a member of the immunoglobulin-like cell surface receptor superfamily inter-acting with several S100 proteins.

► S100 Proteins

Receptor Occupancy

Receptor occupancy refers to the ratio of receptors occupied by a ligand at equilibrium and the total number of receptors available, usually expressed as a percentage of the total number of receptors. Since it is often not possible to quantify the total number of receptors or the number of receptors occupied by a ligand, another parameter called binding potential is often used to measure receptor occupancy. Binding potential (BP) refers to the ratio of the maximum number of receptors and the equilibrium dissociation constant of the drug, so that % receptor occupancy equals to

$$100 \times \text{BP}_{\text{baseline}} - \text{BP}_{\text{post-treatment}} / \text{BP}_{\text{baseline}}$$

► Drug–Receptor Interaction

Receptor Protein

► Table appendix: Receptor Proteins

Receptor Reserve

In terms of the relationship between receptor occupancy by an agonist and tissue response, if the maximal response to the agonist can be obtained with concentrations of agonist that do not occupy all of the receptors, then the system is said to have a receptor reserve. For example, if only 10% of the receptors need be occupied by a certain agonist to produce the system maximal response, then there is a 90% receptor reserve. Under these circumstances, 90% of the receptors could be irreversibly removed (i.e., by an irreversible antagonist) and the agonist would still produce the maximal response. However, the dose-response curve to the agonist would be shifted to the right by the presence of the irreversible antagonist. It should be noted that receptor reserve is not a property of the system but rather that it varies with different agonist efficacies in different systems.

► Drug–Receptor Interaction

Receptor Serine/Threonine Kinases

Receptor serine/threonine kinases function as hetero-oligomeric complexes, consisting of type I and type II serine/threonine kinase receptors. Ligand binding induces the oligomerization. Type II-receptors primarily bind the ligand and phosphorylate type I-receptors, which then specifically phosphorylate in turn receptor-regulated Smad-proteins (R-Smads). These then dimerize with Co-Smads in the cytosol. The R-Smad/Co-Smad complex then translocates to the nucleus where it binds to regulatory sequences in combination with specific transcription factors.

- Neurotrophic Factors
- SMADs
- Table appendix: Receptor Proteins

Receptor Subtype

Most hormones and neurotransmitters can interact with more than one receptor subtype. The different receptor isoforms may differ in their ligand-binding properties,

tissue distribution and signal transduction patterns. Subtype-specific ligands (agonists or antagonists) allow cell type- or tissue-specific targeting of receptor subtypes and thereby increase the specificity of cellular responses.

► Transmembrane Signaling

Receptor Tyrosine Kinases

A subclass of tyrosine kinases functioning as receptors for a variety of regulatory molecules, including growth factors and hormones. Ligand binding usually results in receptor dimerization and tyrosine autophosphorylation, which in turn initiates a signal transduction cascade. Mutations in receptor tyrosine kinases have been implicated in various malignancies.

- Vascular Endothelial Growth Factor
- Insulin Receptor
- Table Appendix: Receptor Proteins
- Growth Factors

Receptors

Scientists in the nineteenth century realized that some chemicals produced effects at extremely low concentrations and that these effects could be modified by equally low concentrations of other chemicals with a strict adherence to chemical structural guidelines. Thus, they proposed that “receptors” with strict recognition properties for these chemicals existed in biological systems. While receptors technically can be any biological entity such as enzymes, reuptake recognition sites, and genetic material such as DNA, the term is usually associated with proteins on the cell surface that transmit information from chemicals to cells. The most therapeutically relevant receptor class is G-Protein-Coupled Receptors (GPCR’s) presently comprising 45% of existing therapies.

- Transmembrane Signaling

Recombinant Protein

Recombinant protein is a protein produced by a genetically modified cell or an organism, which expresses a DNA that was subjected to recombination and inserted into its genome.

Rectification

In many channels the relation between current and membrane potential is nonlinear. These channels show rectification, i.e., the property of the channel to conduct ions more readily in one direction than in the other. Depending on the preferential current flow through channels, these are described as outward or inward rectifying.

- ▶ Inward Rectifying K⁺ Channels
- ▶ Ionotropic Glutamate Receptors

5 α -Reductase

5 α -Reductase is an enzyme, which converts testosterone to dihydrotestosterone, which has a greater affinity for androgen receptors. 5 α -Reductase is expressed in various peripheral organs. Inhibitors of 5 α -reductase (e.g., finasteride) are used to treat benign prostatic hyperplasia.

- ▶ Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor

Reelin

Reelin is an extracellular matrix protein, which is secreted by neuronal cells and binds to two lipoprotein receptors (VLDLR and ApoER2) that relay the Reelin signal inside target neurons by docking the tyrosine kinase adapter disabled-1 (Dab1). This allows neurons to complete migration and adopt their ultimate positions in laminar structures in the central nervous system. In

addition, the integrins α -3/ β -1 and protocadherins of the CNR family may also modulate the Reelin signal.

- ▶ Cadherins/Catenins
- ▶ Low Density Lipoprotein Receptor Gene Family

Reentrant Arrhythmia

Reentrant arrhythmia occurs when due to inhomogeneous repolarization or unidirectional block, heart tissue which is no longer refractory is close beside tissue which is still activated. This may result in a circuit propagation of activation serving as a reverberator.

Regulators of G-protein Signalling

Regulators of G-protein signalling (RGS) are a group of G-proteins which are able to act as GTP-activating proteins (GAPs) for heterotrimeric G-proteins. They are thus able to limit the signal generated by G-protein coupled receptors (GPCRs). RGS-proteins are a large family of structurally diverse proteins, which in addition to an RGS-domain carry variable sequence motifs, which are responsible for additional specific interactions.

Regulatory Myosin Light Chain II

Synonyms

rMLC

Definition

Smooth muscle myosin contains two myosin light chains. Phosphorylation of the regulatory light chain by myosin light chain kinase is a mandatory step to induce contraction.

- ▶ Smooth Muscle Tone Regulation

Regulatory Regions

Regulatory regions are transcriptional control sequences, which consist of promoters, response elements, enhancers and possibly silencers, located upstream of the start site of transcription. The overall effect on gene transcription is a sum of the contributions of these elements and the activities of proteins recruited to these sites. Promoters are located immediately upstream of the start site and initiate transcription. They often contain tissue- or cell-specific elements if the gene is not ubiquitously expressed. Enhancers are positive regulatory elements which function independently of orientation and distance from the genes they regulate.

Regulatory T-cells

Regulatory T cells are a subpopulation of T cells that are morphologically defined by expression of the surface markers CD4 and CD25 and the transcription factor FoxP3. There is growing evidence that regulatory T cells are substantially involved in mediating immunotolerance. This effect could be achieved by direct cell contact with other immune cells and by liberation of certain messenger molecules (cytokines like interleukin-10 or transforming growth factor β).

- ▶ T Cell Receptors

Reinstatement

The reinstatement model is the first choice for the measurement of craving and relapse behavior. In this paradigm, animals are trained to self-administer a drug and are then subjected to extinction – that is, they are tested under conditions of nonreinforcement until operant responding appears to be extinguished. When the animals reach some criterion of unresponsiveness, various stimuli are presented. A stimulus is said to reinstate drug-seeking behavior if it causes renewed responding, i.e., lever pressing, without any further response-contingent drug reward. At least three conditions can reinstate responding: drug priming – that is the injection of a small dose of the drug, stress, and conditioned stimuli.

- ▶ Drug Addiction/Dependence

Rel Homology Domain

The Rel homology domain (RHD) is an evolutionarily conserved domain found in some eukaryotic transcription factors, including NF- κ B, the nuclear factors of activated T-cells (NFATs) and the drosophila proteins Dif and Relish. Some of these transcription factors form

multiprotein DNA-bound complexes. Phosphorylation of the RHD appears to play a role in the regulation of the activity of some of these transcription factors and modulation of expression of their target genes. Structurally, the RHD is composed of two immunoglobulin-like RHD contains the site for interaction with the IκBs.

► Nuclear Factor Kappa B

Rel/NF-κB

Family of transcription factors that modulate the expression of genes which control immune, inflammatory, and acute-phase responses, as well as cell growth, responses to stress, apoptosis, and oncogenesis. All members of this family have a Rel-homology domain that contains sequences responsible for dimerization and DNA binding. In vertebrates, this family includes NF-κB1 (also known as p50), NF-κB2 (also known as p52), Rel (also known as cRel), Rel-A (also known as p65), and Rel-B.

► NFAT Family of Transcription Factors

Rel Proteins

► Nuclear Factor Kappa B

Relative Potency

The affinity of a drug is the ability of that drug to bind to the receptor. The efficacy of an agonist is its ability to activate (or inactivate in the case of an ► [inverse agonist](#)) the receptor. The relative potency of an agonist (with respect to another agonist at the same receptor) is therefore determined by both its affinity and efficacy and only gives an indication of the relative concentrations at which they produce a particular response.

Relaxin

Relaxin and its relative relaxin-like factor (RLF/INSL3) belong structurally to a group of peptide hormones, that includes insulin and insulin-like growth factor 1 (IGF1). Relaxin regulates the growth and remodeling of reproductive tissues during late pregnancy. It promotes expansion of the birth canal during parturition. In humans, the peak in circulating relaxin occurs during the first trimester. Relaxin is secreted by the ovary during pregnancy as well as by many other tissues. It may act as a vasoactive hormone, which has dilatory effects on blood vessels. The closely related relaxin-like factor is synthesized by Leydig cells in the fetal testis and appears to be responsible for the second phase of testicular descent by influencing the growth and differentiation of the cords, which connect the testes with the lower abdomen. The effects of relaxin and relaxin-like factors are mediated at least in part by G-protein coupled receptors (LGR7 and LGR8, which are coupled to G_s).

REM Sleep

Rapid eye movement sleep. Sleep stage characterized by rapid movements of the eyes and asynchronous EEG activity in the theta-frequency (5–10Hz) range. Counterpart is slow wave sleep, characterized by other electrophysiological (synchronized low frequency 1–2Hz, large amplitude EEG and neuronal sharp wave-ripple oscillations) and endocrine (growth hormone surge) activities.

R

Renal Glucosuria

Renal glucosuria is caused by a low renal threshold for glucose. The clinical picture is the daily loss of 50–60 g of glucose in the urine despite a normal glucose tolerance test. Autosomal dominant and autosomal recessive inheritance has been described. It has been suggested that the disease is caused by mutations in the SGLT2 (sodium-dependent glucose cotransporter 2) gene.

Renin–Angiotensin–Aldosterone System

MICHAEL BADER

Max Delbrück Center for Molecular Medicine (MDC),
Berlin-Buch, Germany

Synonyms

RAAS; Renin–angiotensin system (RAS)

Definition

The renin–angiotensin–aldosterone system (RAAS) generates the peptide hormone angiotensin II and subsequently the mineralocorticoid aldosterone, which both exert considerable impact on blood pressure (►blood pressure control) and fluid homeostasis, and

have prime etiologic and therapeutic significance for cardiovascular diseases.

Basic Characteristics

General

Renin is a circulating enzyme formed in specialized smooth muscle cells in the kidney that cleaves its only, liver-born substrate, angiotensinogen, in the plasma to form the inactive decapeptide angiotensin I. Angiotensin I is then metabolized further into the octapeptide angiotensin II via the endothelium-bound angiotensin converting enzyme (ACE). Angiotensin II elicits an increase in blood volume and blood pressure by stimulating vasoconstriction, sodium retention, thirst, the sympathetic nervous system, and aldosterone secretion from the adrenal gland (Fig. 1). Aldosterone is a steroid hormone that binds to the mineralocorticoid receptor and amplifies the sodium-retaining effect. Physiologically this makes sense, since the RAAS is activated under conditions of acute volume loss by the

Renin–Angiotensin–Aldosterone System. Figure 1 The renin-angiotensin-aldosterone system. Angiotensin II is generated in a two-step enzymatic process from the liver-born protein angiotensinogen by the kidney-derived enzyme renin and the endothelium-bound angiotensin converting enzyme (ACE). The octapeptide interacts with two receptors, AT1 and AT2. The AT1 receptor confers most of the known actions of angiotensin II such as the liberation of aldosterone from the adrenal gland. Aldosterone via the mineralocorticoid receptor (MR) and angiotensin II together induce sodium retention in the kidney and fibrotic processes in kidney and heart. Moreover, angiotensin II elicits constriction of vessels, has positive inotropic and chronotropic actions on the heart, promotes growth in vessels and heart, and induces thirst, salt appetite, vasopressin release, and the activation of the sympathetic nervous system in the brain. Some of these effects are also mediated by locally produced angiotensin II in the respective tissues.

induction of the rate-limiting enzyme renin. Major renin-inducing stimuli include a fall in renal perfusion pressure, a decrease in salt content in the distal tubule sensed and transmitted via the ►**macula densa**, an increase in the renal sympathetic tone, and a reduction in angiotensin II concentration employing a negative feedback mechanism. In addition to their hemodynamic actions, angiotensin II and aldosterone also induce growth- and fibrosis-related processes in several organs, such as vessels, heart, and kidney. Recently, a receptor for renin has been discovered, which activates the enzyme and exerts angiotensin-II dependent and independent signaling effects, which are deleterious for the heart and the kidney [1].

To elicit these effects, angiotensin II binds to two main receptors, AT1 and AT2, which both belong to the ►**G-protein-coupled receptor** family. Most of the abovementioned effects of angiotensin II are, however, mediated by the AT1 receptor, while the physiological function of the AT2 receptor is enigmatic. In most studied cases, the AT2 receptor counteracts the AT1 effects by exerting growth-inhibiting and vasodilating actions partly by the stimulation of kinin generation.

Angiotensin II binding to the AT1 receptor stimulates via the G-protein, G_q , the activity of phospholipase C to generate the second messengers inositol phosphate (IP3) and diacylglycerol, and inhibits via G_i the activity of adenylyl cyclase to reduce the synthesis of cyclic AMP. Diacylglycerol activates protein kinase C and can be converted to arachidonic acid and ►**eicosanoids**. Furthermore, angiotensin II induces the generation of ►**reactive oxygen species** by the stimulation of membrane-bound NAD(P)H oxidase. One of the immediate consequences of these early signals is activation of tyrosine kinases that include PYK2, c-Src, JAK2, platelet-derived growth factor (PDGF) receptor and the epidermal growth factor (EGF) receptor, as well as of the serine/threonine kinases, ERK, Akt/protein kinase B and S6 kinase, and subsequent induction of ►**immediate early genes** and protein synthesis.

Besides the plasma renin–angiotensin system (RAS), intrinsic tissue RAS exist [2]. Angiotensin II is generated not only in the circulation but also locally in organs from precursors and enzymes either locally synthesized or imported from the plasma. These systems are autonomously regulated and have physiological functions inside the respective organs. Local RAS have been described for organs involved in cardiovascular control such as kidney, vessels, heart, adrenal gland, and brain.

Adrenal Gland

In the ►**zona glomerulosa** of the adrenal gland, renin is locally synthesized, and together with angiotensinogen and ACE generates angiotensin II, which acts as

paracrine or intracrine hormone on adrenocortical cells. Circulating as well as this locally produced angiotensin II stimulates aldosterone release by increasing the expression of aldosterone synthase, the rate-limiting enzyme of aldosterone synthesis.

Kidney

The kidney contains the major site of renin synthesis, the juxtaglomerular cells in the wall of the afferent arteriole. From these cells, renin is secreted not only into the circulation but also into the renal interstitium. Moreover, the enzyme is produced albeit in low amounts by proximal tubular cells. These cells also synthesize angiotensinogen and ACE. The RAS proteins interact in the renal interstitium and in the proximal tubular lumen to synthesize angiotensin II. In the proximal tubule, angiotensin II activates the sodium/hydrogen exchanger (NHE) that increases sodium reabsorption. Aldosterone elicits the same effect in the distal tubule by activating epithelial sodium channels (ENaC) and the sodium–potassium-ATPase. Thereby, it also induces water reabsorption and potassium secretion.

In the interstitium, angiotensin II induces proliferation of mesangial cells and fibroblasts and the synthesis of collagen and other matrix molecules by these cells via the AT1 receptor. Moreover, by the concomitant stimulation of chemoattractant ►**cytokines**, inflammation is induced. These processes are mediated by endothelin, ►**transforming growth factor** β , and reactive oxygen species, and finally lead to interstitial fibrosis and glomerulosclerosis observed in hypertension and diabetes.

Heart and Vessels

In heart and vessels, angiotensin II is generated mostly by renin and angiotensinogen imported from the plasma and locally synthesized ACE. Additionally in the human heart, mast cells contain the enzyme chymase that also metabolizes angiotensin I to angiotensin II. The physiological relevance of this enzyme is controversial. Circulating as well as locally generated angiotensin II induces vasoconstriction and exerts direct inotropic and chronotropic actions on the heart. These effects are enhanced by a facilitation of noradrenaline release from sympathetic nerve endings.

Alike in the kidney, angiotensin II also in the heart induces inflammation and fibrosis by increasing endothelin, transforming growth factor β , reactive oxygen species, and proinflammatory cytokines. Furthermore, angiotensin II induces hypertrophy of cardiomyocytes and smooth muscle cells in the heart and vessels, respectively, partially employing the same mediators. This is aggravated by increased circulating aldosterone levels that also elicit fibrotic processes in the heart by a yet unresolved mechanism.

Brain

Circulating angiotensin II can only reach the ► **circum-ventricular organs** of the brain, which express AT1 receptors and lack a blood–brain barrier normally limiting the access of peptides to brain receptor sites. However, areas beyond the blood–brain barrier have been shown to be responsive to angiotensin II and to express AT1 receptors. These sites are affected by locally synthesized peptide from renin, angiotensinogen, and ACE present in the central nervous system. Possibly, also other enzymes may be involved in angiotensin II generation in the brain, e.g., cathepsins. Circulating and locally synthesized angiotensin II induces thirst, salt appetite, and ► **vasopressin** release, stimulates the sympathetic nervous system and moderates the ► **baroreceptor reflex**, and thereby increases blood volume and blood pressure.

Drugs

ACE Inhibitors

Pharmacological intervention in RAS began in the late 1960s with the discovery that the venom of the Brazilian snake *Bothrops jararaca* contains a substance that inhibits ACE. In first clinical trials this substance proved to be a potent antihypertensive agent but it had the disadvantage that it could only be taken by injection. By modeling the active site of ACE and designing drugs potentially binding to this site, the first orally available ACE inhibitor, captopril, was discovered. In the meantime, at least a dozen pills have been developed and marketed: captopril, enalapril, lisinopril, perindopril, cilazapril, benazepril, quinapril, fosinopril, ramipril, moexipril, and trandolapril. ACE inhibitors are first choice antihypertensive drugs. Furthermore, a multitude of large-scale clinical studies have proven a strong beneficial effect of these drugs on morbidity and mortality in congestive heart failure, e.g., after myocardial infarction, and chronic renal diseases, e.g., caused by diabetes or hypertension. In the heart, ACE inhibitors exert their beneficial actions by reducing preload and afterload and inhibiting myocardial fibrosis and remodeling processes. In the kidney, a reduction in glomerular pressure as well as antifibrotic and antiinflammatory actions contribute to the efficiency of the drugs.

ACE not only activates angiotensin but is also involved in the metabolism of other peptides, e.g., it is a major kinin-degrading enzyme. Therefore, ACE inhibitors also increase kinin concentrations. Furthermore, it has recently been shown that these drugs potentiate kinin effects by modulating a direct interaction between the ACE protein and the kinin B2 receptor, which is independent from the enzymatic activity of ACE. Kinin potentiation may be involved in the beneficial action of ACE inhibition since ► **kinins** are known to exert cardio- and renoprotective actions.

However, it is also the major reason for the adverse side effects of ACE inhibitors, namely cough and angioedema. Another observed side effect, first-dose orthostatic hypotension, is probably due to both angiotensin inhibition and kinin potentiation.

Since angiotensin II is important for kidney development in mammals, ACE inhibitors and other drugs interfering with RAS should not be given during pregnancy.

AT1 Antagonists

A second group of drugs interfering with RAS are specific antagonists for the AT1 receptor. The first example of this class was losartan which was followed by at least six other sartans (telmisartan, candesartan, valsartan, eprosartan, irbesartan, olmesartan). These drugs exert a more complete angiotensin blockade, since alternative pathways of angiotensin generation not affected by ACE inhibitors and employing cathepsins or chymase become ineffective by AT1 antagonism. They are also more specific for the RAS than ACE inhibitors, since other peptide systems should not be affected. However, the compensatory increase in renin concentration after AT1 blockade leads to an accumulation of angiotensin II, which activates the AT2 receptor. It is yet unknown whether this AT2 stimulation often followed by kinin generation is involved in the action of AT1 antagonists.

In clinical trials, AT1 antagonists have proven to be as effective as ACE inhibitors in hypertension, congestive heart failure, and renal failure [3]. The favorable side effect profile of AT1 antagonists argues for a greater use of these drugs. At present, due to still higher costs, they are indicated in patients who do not tolerate ACE inhibitor treatment.

Renin Inhibitors

The most logical point to interfere pharmacologically with the RAS is the rate-limiting enzyme renin. Intervention at this step is more specific than ACE inhibition and AT1 antagonism, since hardly any angiotensin peptide can be generated and no other peptide system is directly affected. Therefore, fewer compensatory and unwanted effects are expected, and thus renin inhibitors should be safe drugs. However, the development of such drugs faced several problems: First, since the human renin protein is different from the rodent enzymes and only interacts with primate or human angiotensinogen, the testing of such drugs can not be performed in classical animal models. Second, the first renin inhibitors were difficult to synthesize and exhibited a low bioavailability. However, with the availability of a transgenic rat model expressing the human renin and angiotensinogen genes as test system novel substances could be developed. Now,

a first renin inhibitor, aliskiren, has been approved for clinical use after first clinical trials which have proven its safety and efficacy [4]. Future large trials will be necessary to compare renin inhibitors with ACE inhibitors and AT1 antagonists, and to evaluate whether these substances also interfere with the renin/renin receptor interaction and thereby elicit additional beneficial effects.

Vasopeptidase Inhibitors

(► **Vasopeptidase inhibitors**) A new class of drugs has been developed that inhibits ACE and neutral endopeptidase 24.11 (NEP). NEP degrades vasodilatory peptides such as kinins, ► **natriuretic peptides**, and adrenomedullin, and, therefore, its inhibition should complement the vasodilatory action of ACE inhibition. Since ACE and NEP are very similar in structure it was possible to develop inhibitors with dual specificity for both enzymes such as omapatrilat, sampatrilat, and gemopatrilat. In first clinical trials, the patrilats have proven to be even more effective than ACE inhibitors in blood pressure reduction and in improving congestive heart failure, but more side effects have been observed, probably due to the fact that NEP metabolizes a multitude of peptide substrates. Thus, the usefulness of this class of drugs has been questioned.

Aldosterone Antagonists

ACE inhibitors do not completely block aldosterone synthesis. Since this steroid hormone is a potent inducer of fibrosis in the heart, specific antagonists, such as spironolactone and eplerenone, have recently been very successfully used in clinical trials in addition to ACE inhibitors to treat congestive heart failure [5]. Formerly, these drugs have only been applied as potassium-saving diuretics in oedematous diseases, hypertension, and hypokalemia as well as in primary hyperaldosteronism. Possible side effects of aldosterone antagonists include hyperkalemia and, in case of spironolactone, which is less specific for the mineralocorticoid receptor than eplerenone, also antiandrogenic and progestational actions.

Repolarization

Repolarization is a return of membrane potential to its resting value. It refers mostly to repolarization of an action potential, although a more general meaning of returning a membrane potential back to a more negative value after (forced) depolarization is also common.

- Antiarrhythmic Drugs

Resiniferatoxin

Resiniferatoxin (RTX) is the toxin isolated from the spurge *Euphorbia resinifera* which is responsible for the powerful burning sensation and skin irritation induced by the milky sap of these plants. Like capsaicin, resiniferatoxin activates TRPV1 currents, but not the currents through other members of the TRPV subfamily.

- TRP Channels
- Vanilloid Receptor

Resistance Plasmid

Extrachromosomal autonomously replicating circular closed DNA molecules encoding non-essential supplementary genetic information, like antibiotic resistance or metabolic capacities.

- Bacterial Resistance to Antibiotics

Respiratory Burst

The respiratory burst is the ability of phagocytes to destroy pathogens by the release of a variety of toxic products including, hydrogen peroxide, superoxide anion and nitric oxide. Production of these toxic metabolites is induced by the binding of aggregated antibodies to the Fc gamma receptors.

Restenosis

Restenosis is the phenomenon of vascular reocclusion postangioplasty or stent.

Resting Potential

Resting potential is a stable membrane potential in nonexcitable cells, or the most stable membrane potential between Action Potentials in excitable cells. In some excitable tissues it is impossible to define a resting potential because of continuous change in membrane potential.

► Inwardly Rectifying K^+ Channels

Resting Tremor

Resting tremor is a tremor present at rest, which usually abates during voluntary movements. Its frequency in Parkinsonism is 4–8 Hz and it occurs most often in the distal extremities.

► Parkinson's Disease
► Anti-Parkinson Drugs

Restless Leg Syndrome

Restless legs syndrome, also known as Ekbom's syndrome, causes unpleasant sensations in the legs such as tingling, discomfort and sometimes pain. Symptoms are usually worse at night and disturb sleep. Resting usually makes symptoms worse and activity relieves the condition. The cause of the condition is currently unknown but it is common and usually occurs in middle age. There are currently few treatments in place.

► Sleep

Retinal

Vitamin A.

► Retinoids

Retinitis Pigmentosa

Retinitis pigmentosa (RP) is a common inherited retinopathy associated with progressive retinal atrophy, and deposition of pigment. The final stage of RP are severe visual impairment or blindness. The genetic and clinical heterogeneity of RP is remarkably high. In the majority of the cases, however, mutations are found in the gene for the light receptor rhodopsin.

► Protein Trafficking and Quality Control

Retinoblastoma (Rb) Gene

The retinoblastoma protein was identified originally through studies of an inherited form of eye cancer in children, known as retinoblastoma. The loss of both copies of the Rb gene leads to excessive cell proliferation in the mature retina. This suggested that

Rb is the product of a tumour suppressor gene. Later it was shown that the retinoblastoma protein is a key regulator of a gene regulatory protein called E2F which plays a key role in the regulation of the cell cycle. E2F function is controlled primarily by the Rb protein. Rb binds to E2F and blocks the transcription of S-phase genes. When cells are stimulated to divide by extracellular signals, active G₁-Cdk accumulates and phosphorylates Rb, reducing its affinity for E2F. The Rb protein then dissociates, allowing E2F to activate S-phase gene expression.

► Cell Cycle Control

Retinoic Acid

Retinoic acid (RA) describes a group of vitamin A acid (synonym Vitamin A1 acid) derivatives such as all-*trans*-retinoic acid (tretinoin), 9-*cis*-retinoic acid and 13-*cis* retinoic acid (isotretinoin). Retinoic acids act through binding to retinoic acid and retinoid X response elements.

► Retinoic Acid Receptors

► Retinoids

Retinoic Acid Receptors

Retinoic Acid receptors (RARs) are nuclear receptors. Nuclear receptors are a large family of structurally related ligand-inducible transcription factors, including steroid receptors (SRs), thyroid/retinoids receptors (TR, RARs and RXRs), vitamin D receptors (VDR), LXR, peroxisome proliferator activated receptors (PPARs), estrogen receptors (ERa and ERb), and orphan receptors for which no ligand has been yet identified. While having in common a modular structure, they are activated by distinct lipophilic small molecules such as glucocorticoids, progesterone, estrogens, retinoids, and fatty acid derivatives.

All nuclear receptors have a hydrophobic pocket into which its specific ligand binds, with helix 12 (H12) being the key response element of NR's. When an agonist is bound to a NR, H12 is oriented antiparallel to H11, capping the ligand binding pocket. This leaves a hydrophobic groove exposed for the binding of coregulator proteins. When an antagonist is bound, H12 is displaced via an extended side chain. H12 moves outward, rotates, and packs into the hydrophobic

groove between helices 3, 4, and 5. As a result, coactivators needed for transcription cannot bind.

Several loci encoding RAR isoforms have been identified in mammals, RAR- α , - β and - γ . They respond to at-RA, 9-*cis*-RA and 13-*cis*-RA. The RARs show spatially restricted distribution patterns during embryogenesis, which have led to speculation on a variety of roles for RA in developmental processes. As with other enhancer-binding proteins, nuclear receptors act as transcription factors by binding to specific DNA recognition sequences generally located upstream of responsive genes. Although RARs can activate gene expression through binding to thyroid hormone response elements, much more specific and potent RA response elements (RAREs) have been identified within the promoter of the RAR gene. These RAREs are essential for RA induction of the RAR-gene and, when linked to heterologous promoters, can confer transcriptional activation via all three RARs.

► Retinoids

Retinoid-resistance

The major limitation to the application of retinoids is the retinoid resistance observed in cancer cells. This means that such cells do not respond either to physiological or therapeutic concentrations of retinoids. Silencing of RAR β has been suggested to contribute to the tumorigenicity and retinoid resistance of lung and breast cancer cells. RAR β silencing is caused by epigenetic changes, namely DNA methylation and repressive chromatin remodeling of the RAR β P2 promoter. Epigenetic changes can be reversed. Pili et al. developed a strategy to overcome the silencing at RAR β by specifically targeting the epigenetic defect at RAR β P2, using combinations of histone deacetylase inhibitors (HDACIs), a class of chromatin remodeling drugs and RAR β agonists.

► Retinoids

Retinoid X Receptor

The retinoid X receptor (RXR) is a nuclear receptor that binds and is activated by certain endogenous retinoids, such as 9-*cis*-retinoic acid. RXR is the obligatory heterodimerization partner for a large number of nonclassic steroid nuclear receptors, such as thyroid hormone receptor, vitamin D3 receptor, peroxisome proliferator-activated receptor and pregnane X receptor.

Retinoids

THOMAS C. ROOS

Reha Klinik Neuhaulingersiel, Interdisciplinary Center for Dermatology, Pneumology and Allergology, Neuhaulingersiel, Germany

Synonyms

Retinoids; Vitamin A; Carotinoids; Retinylesters; Retinol; Retinal; Retinoic acid; Vitamin A acid

Definition

Vitamin A (retinol) and its naturally occurring and synthetic derivatives, collectively referred to as retinoids (chemical structure), exert a wide variety of profound effects in apoptosis, embryogenesis, reproduction, vision, and regulation of inflammation, growth, and differentiation of normal and neoplastic cells in vertebrates.

Retinoids are alcohols and accordingly soluble in ethanol, isopropanol, and polyethylenglycol. Major sources of natural retinoids are animal fats, fish liver oil (retinylesters) and yellow and green vegetables (carotenoids). Ingested retinylesters (RE) are hydrolyzed to retinol by enteral hydrolases in the intestine. ROL and carotenoids are absorbed by intestinal mucosa cells.

Mechanism of Action

Retinoids mediate their biological effects through binding to nuclear receptors known as ▶retinoic acid receptors (RARs) and ▶retinoid X receptors (RXRs), which belong to the superfamily of ligand-inducible transcriptional regulators that include steroid hormone receptors, thyroid hormone receptors, and vitamin D₃ receptors [reviewed in [1]. RARs and RXRs act via polymorphic *cis*-acting responsive elements, the retinoic acid responsive elements (RAREs) and retinoid X responsive elements (RXREs), present in the promoters of retinoid-responsive genes (Fig. 1).

The known beneficial effects of retinoids on malignancies are assumed to relate to retinoid receptor-mediated antipromoting and anti-initiating effects. The latter appears to be influenced by interference of several xenobiotics with different steps of the retinoid metabolism in the target cell. Of the carotenoids, β-carotene is the most potent retinol precursor, yet being

six-fold less effective than preformed retinol, resulting from incomplete resorption and conversion (one retinol equivalent is equal to 1 μg of retinol, 6 μg of β-carotene, or 12 μg of mixed carotenoids) For retinoid metabolism review see [2].

Although all-*trans*- and 9-*cis*-RA are only minor metabolites of ROL and β-carotene, they display 100–1000-fold higher biological activity. Whereas all-*trans*-RA binds only to RARs, 9-*cis*-RA binds both RARs and RXRs. The stereoisomer of all-*trans*-RA, 13-*cis*-RA, exhibits a much lower affinity for RARs and RXRs and exerts its molecular effects mostly through its isomerization into all-*trans*-RA.

Clinical Use

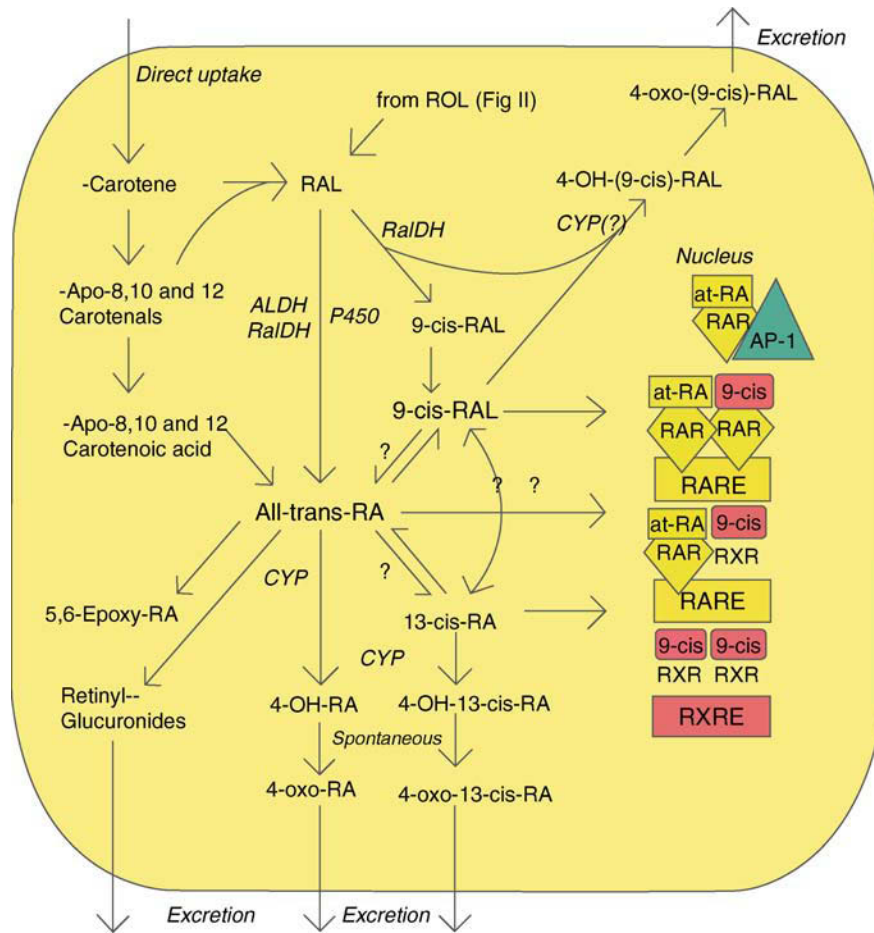

Up to now, far more than 5000 retinoic acid analogs have been synthesized, out of which the following three generations have been established for therapy of various disorders: First, the nonaromatic retinoids β-carotene (provitamin A), all-*trans*-retinoic acid (RA) (tretinoin) and 13-*cis*-RA (isotretinoin), second, the monoaromatic retinoid derivatives trimethyl-methoxyphenyl analog of RA (etretinate) and 9-(4-methoxy-2,3,6-trimethylphenyl)-3-2,4,6,8-nonatetraenoic acid (acitretin), and third, the polyaromatic retinoid derivatives tazarotenic acid and 6-[3-(1-adamantyl)-4-methoxy-phenyl]-2-naphthoic acid (adapalene) (see Table 1).

Synthetic Retinoid Receptor Selective Agonists/Antagonists

The concept of drug development is based on the findings that retinoid receptors (RARs and RXRs) offer a new approach by targeting different genes depending on the activated retinoid receptor complexes. The multiplicity of these retinoid signaling pathways affords potential for therapeutic opportunity as well as retinoid therapy associated undesired side effects. It is possible that the indiscriminate activation of all pathways by nonspecific retinoid ligands could lead to unacceptable side effects so that any enhanced efficacy would be obtained at the cost of enhanced toxicity.

The development of ligands selective for individual receptor subtypes relevant to a targeted disease could decrease these toxic effects thereby improving the therapeutic index. Two new retinoids are already available for topical use in skin diseases. These are tazarotenic acid (tazarotene) and 6-[3-(1-adamantyl)-4-methoxyphenyl]-2-naphthoic acid (adapalene) (Table 1), and other synthetic retinoid derivatives are in the pipeline. Also fenretinide, a synthetic amide of retinoic acid is available for systemic therapy in oncology.

Tazarotene (Table 1) is an acetylenic third generation retinoid derivative. It is a poorly absorbed, nonisomerisable retinoid, which is rapidly metabolized to its free carboxylic acid, tazarotenic acid, binding with high affinity to RARs, with the rank order of affinity being

Retinoids. Figure 1 Intracellular pathways and molecular action of retinoids.

$RAR\beta > RAR\gamma \gg RAR\alpha$. It does not bind to any of the RXRs. This retinoid derivative is said to have lower cytotoxic effects than other retinoids while achieving sustained therapeutic efficacy in the treatment of plaque psoriasis.

Adapalene (Table 1), a new highly stable naphthoic acid arotinoid with lipophilic properties, does not bind to CRABP, although it enhances its synthesis, and its rank-order of retinoid receptor affinity appears to be $RAR\beta > RAR\gamma \gg RAR\alpha$.

These arotinoids, which were first introduced for the treatment of skin diseases, may also have potential as anticancer drugs. For example, the synthetic retinoid 6-[3-(1-adamantyl)-4-hydroxyphenyl]-2-naphthalene carboxylic acid (CD437) has been shown to induce apoptosis in a variety of cancer cells including lung cancer cells *in vitro*, and studies concerning the use of this agent *in vivo* would be desirable.

Future generations of such receptor subtype-selective retinoids or also retinobenzoic acids [3] may provide clinicians with more specific and less toxic drugs for dermatologic therapy.

Retinoids in Dermatology

Hyperkeratotic Disorders

The topical and oral use of retinoids for treatment of hyperkeratotic disorders such as psoriasis and Darier's disease has long been established. Systemic retinoid therapy is often combined with topical drugs such as corticosteroids, dithranol, tar, and also UVA/UVB phototherapies where synergistic effects have been reported.

Acne

Among retinoids, 13-*cis*-retinoic acid is known to have not only anti-inflammatory but also sebostatic effects. Therefore it is one of the most potent topical and also systemic agents for therapy of acne.

Photoaging and Wound Healing

Drug treatment of photoaged skin can be categorized as antioxidants, α -hydroxy acids and topical retinoids. Of these three approaches only topical retinoids, particularly retinaldehyde and all-*trans*-retinoic acid, have a well documented ability to restore the repair

function of photoaged skin at the clinical, histological and molecular level [4]. According to these observations, retinoids were also shown to accelerate wound healing [4] and reduction of early striae distensae.

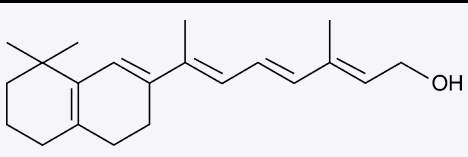

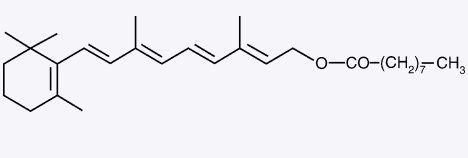

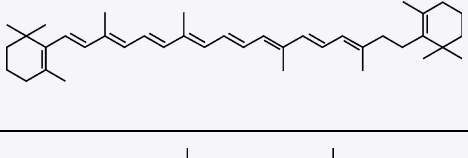

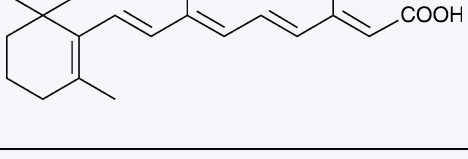

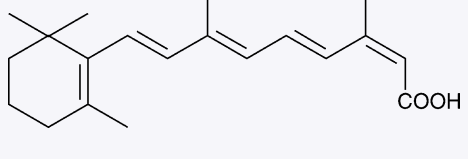

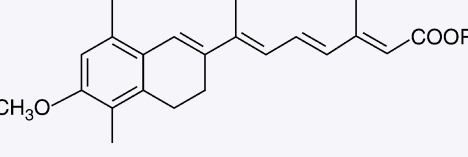

Skin and Oral Malignancies

Actinic keratoses were the first skin lesions to be treated topically with all-*trans*-retinoic acid. In various clinical trials, retinoids have been shown to be active in chemoprevention and treatment or prevention skin malignancies [2].

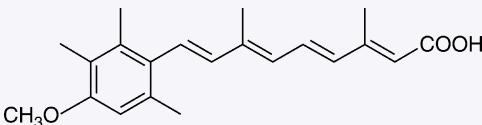

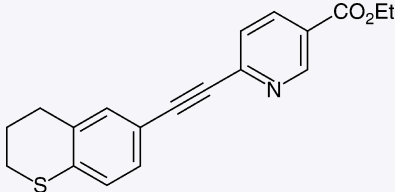

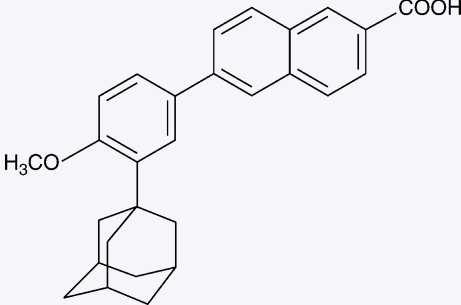

Currently, 13-*cis*-retinoic acid is the most studied chemopreventive agent that decreases the incidence of second primary tumors in patients with head-and-neck cancer, reverses premalignant lesions, and reduces appearance of nonmelanoma skin cancer in patients with xeroderma pigmentosum. Unfortunately, this vitamin A derivative has a significant clinical toxicity, which limits its utility in a practice setting.

Molecular epidemiological studies to assess the risk associated with metabolic polymorphisms for cancers of head-and-neck and the lung have shown that the overall

Retinoids. Table 1 Indications and mode of administration of commercially available retinoids in dermatological therapy

β -Carotene (provitamin A)		Topical	Hypopigmentations, hyperpigmentations, radical protection	Nutrient color
Tretinoin		Topical 0.025– 0.1% Gels or creams	Acne vulgaris, parakeratosis, hyperkeratosis	Photoaging, actinic keratosis
Isotretinoin		Topical 0.05% cream Oral 0.251.0 mg/kg/ d	Cystic acne, recalci- trant nodular acne	Rosacea gram-negative folliculitis pyoderma faciale hidradenitis suppurativa cancer prevention
Etretinate		Oral 0.25–1.0 mg/kg/d	Generalized pustular psoriasis, exfoliative psoriasis, plaque psoriasis	

Retinoids. Table 1 Indications and mode of administration of commercially available retinoids in dermatological therapy (Continued)

Generic name	Chemical structure	Mode of administration	Principal indication	Other indications
Acitretine		Oral 0.25–1.0 mg/kg/d	Psoriasis (erythrodermic, pustular, and severe recalcitrant)	Palmoplantar keratoderma, pustulosis palmoplantaris, ichthyosis, Darier's disease, pityriasis rubra pilaris, lichen ruber planus
Tazarotene		Topical 0.05–0.1% gels	Psoriasis vulgaris	
Adapalene		Topical 0.1% gel	Acne vulgaris	

effect of common polymorphisms is moderate in terms of penetrance and relative risk. However, some gene combinations, such as mutated CYP1A1/GSTM1-null genotype, seem to predispose the lung and oral cavity of smokers to an even higher risk for cancer or DNA damage. These results require confirmation in larger studies that take into account the existence of ethnic variations even within the commonly defined groups.

Retinoids, isothiocyanates and tea polyphenols have been identified as possible chemopreventive agents for cancers of the lung and oral cavity. While a number of trials have been conducted with retinoids or β -carotene, the results were ambiguous and the causes are still being debated.

Newly acquired knowledge in the field of tumor biology and of the genetic changes underlying carcinogenesis through the use of new molecular technology represents the basis on which chemoprevention efforts should be based.

Retinoids in Oncology

Since retinoids play an important role in the molecular regulation of growth, differentiation and apoptosis of normal, premalignant and malignant cells, especially epithelial cells, numerous studies have focussed on the effect of retinoids on a variety of malignancies. In animals, vitamin A deficiency has been shown to be associated with an increased incidence of cancer and an increased susceptibility of chemical carcinogens. On the molecular level, aberrant expression and function of nuclear retinoid receptors have been found in various types of premalignant lesions and cancers. Thus, aberrations in retinoid signalling appear to be early events in carcinogenesis, and retinoids at pharmacological doses have been shown to exhibit a variety of beneficial effects associated with cancer prevention and cancer therapy e.g., by suppression of transformation, inhibition of carcinogenesis in various organs in animal models.

Lung Cancer

Epidemiological and animal studies have demonstrated that retinoids are effective agents in preventing the development of tobacco-associated cancers. Unfortunately, clinical trials of retinoids on cigarette smokers have shown lack of efficacy in preventing lung cancer. A study investigated the effect of nicotine on the anticancer activity of all *trans*-retinoic acid (trans-RA) in human lung cancer cells and demonstrated that nicotine could abrogate the growth inhibitory effect of trans-RA by suppressing its ability to induce the expression of RA receptor β (RAR β), a tumor suppressor. The inhibitory effect of nicotine was accompanied with induction of orphan receptor TR3. Inhibition of TR3 expression by overexpression of TR3 antisense RNA in H460 lung cancer cells strongly prevented the suppressive effect of nicotine on *trans*-RA activity. These results suggest that nicotine suppresses the growth inhibitory effects of all-*trans*-RA by inhibiting RAR β expression through its induction of TR3 expression. Accordingly, RXR-selective retinoids may be more effective than classical retinoids for preventing and treating tobacco-associated cancers. Another study indicates the epidermal growth factor to be a target for the lung cancer preventive effect of retinoic acid.

Encouraging findings concerning effective therapy strategies derive from combination studies in which retinoids, especially all-*trans*-retinoic acid, are added to either α -interferon or chemotherapy and radiotherapy. Here, more retinoid receptor-selective molecules may have a greater activity against lung cancer, with a more favorable toxicity profile, as recently suggested by preliminary data on Ro 41-5253 [5].

Breast Cancer

Studies with fenretinide in woman with stage I breast cancer did not show an overall effect of decreasing the risk of contralateral breast cancer. A protective effect could only be observed in premenopausal women, probably due to the modulation of the insulin-like growth factor 1 (IGF-1) by fenretinide in this population.

Liver Cancer

Hepatocellular carcinoma (HCC) develops in patients with chronic liver diseases associated with hepatitis B and hepatitis C virus infections with high incidences. Here, an acyclic retinoid has been shown to suppress the posttherapeutic recurrence after interferon- γ or glycyrrhizin treatment in cirrhotic patients who underwent curative treatment of preceding tumors. The retinoid induced the disappearance of serum lectin-reactive α -fetoprotein (AFP-L3), a tumor marker indicating the presence of unrecognizable tumors in the remnant liver, suggesting a deletion of such minute (pre)malignant clones (clonal deletion). As a molecular mechanism of the clonal deletion, a novel mechanism of

apoptosis induction by the retinoid via tissue transglutaminase has been implicated [6]. In future, a combination of immunopreventive and chemopreventive therapies may give a clue to the further advances of cancer prevention, and thereby to the improvement of the prognosis of cirrhotic patients.

Leukaemia

Acute promyelocytic leukaemia (APL) is known as the most curable subtype of acute myeloid leukaemia in adults. Here, all-*trans*-retinoic acid induces differentiation of the leukemic cells into mature granulocytes. On the basis of clinical and *in vitro* studies, the following mechanisms have been proposed to explain the frequently occurring ATRA resistance: (i) induction of accelerated metabolism of ATRA, (ii) increased expression of cellular retinoic acid-binding proteins (CRABPs), (iii) constitutive degradation of PML-RAR α , (iv) point mutations in the ligand-binding domain of RAR α of PML-RAR α , (v) P-glycoprotein expression, (vi) transcriptional repression by histone deacetylase activity, (vii) isoforms of PML-RAR α , (viii) persistent telomerase activity, and (ix) expression of type II transglutaminase. It is yet unclear which of these factors is mainly responsible for retinoid resistancies. Patients, who relapse after retinoic acid therapy, should be transferred to arsenic trioxide or stem cell transplantation therapy.

Neuroblastoma

Most recently, a phase-I-study defined a dose of 13-*cis*-retinoic acid that was tolerable in patients after myeloablative therapy, and a phase-III-trial showed that postconsolidation therapy with 13-*cis*-retinoic acid improved EFS for patients with high-risk neuroblastoma [7]. Preclinical studies in neuroblastoma indicate that ATRA or 13-*cis*-RA can antagonize cytotoxic chemotherapy and radiation, such that use of 13-*cis*-RA in neuroblastoma is limited to maintenance after completion of cytotoxic chemotherapy and radiation. It is likely that recurrent disease seen during or after 13-*cis*-RA therapy in neuroblastoma is due to tumor cell resistance to retinoid-mediated differentiation induction. Studies in neuroblastoma cell lines resistant to 13-*cis*-RA and ATRA have shown that they can be sensitive, and in some cases collaterally hypersensitive, to the cytotoxic retinoid fenretinide. Here, fenretinide induces tumor cell cytotoxicity rather than differentiation, acts independently from RA receptors, and in initial phase-I-trials has been well tolerated. Clinical trials of fenretinide, alone and in combination with ceramide modulators, are in development.

Side Effects of Retinoids

Hypervitaminosis A is characterized by hepatomegaly, cerebral edema and bone structure alterations. β -Carotene

causes yellow-orange coloring of the skin by binding to keratins. Topically applied retinoic acids can lead to irritation, rash and Xerosis. Also worsening of atopic dermatitis and increased light sensitivity has been reported.

Systemic treatment of 13-*cis* retinoic acid frequently leads to cheilitis and eye irritations (e.g., unspecific cornea inflammation). Also other symptoms such as headache, pruritus, alopecia, pains of joints and bone, and exostosis formation have been reported. Notably, an increase of very low density lipoproteins and triglycerides accompanied by a decrease of the high density lipoproteins has been reported in 10–20% of treated patients. Transiently, liver function markers can increase during oral retinoid therapy. Etretinate causes the side effects of 13-*cis* retinoid acid at lower doses. In addition to this, generalized edema and centrilobular toxic liver cell necrosis have been observed.

The most important clinical side effects of systemically applied retinoic acid therapy are teratogenicity and embryotoxicity. Topical administration of retinoic acid does not appear to cause such effects. This is supported by the observation that nutritional retinoid administration can lead to higher plasma levels than topical treatment with retinoic acid. However in several countries, the topical administration during pregnancy is prohibited. In the USA, contraception during topical use of retinoic acid is recommended. This narrow therapeutic frame requires a pregnancy testing, measuring of liver enzymes, triglycerides, cholesterol and glucose before and frequent follow up examinations during retinoid therapy (every third or fourth week).

Increased risk factors for suffering retinoid side effects are adipositas, alcohol abuse, diabetes, nicotine abuse, familiar lipid metabolism alterations and other concomittant therapies (see below).

Interactions with Other Agents

Dexamethasone, the macrolide antibiotic triacetyloleandomycin, and phenobarbital are all well established inducers of the CYP3A subfamily, and can increase microsomal 4-hydroxylation of RA in rat liver. To what extent this is also the case for humans is not completely clear.

Glucocorticoids (clobetasol) also induce the expression of CYP1A1 in human skin. This is mediated through glucocorticoid receptor responsive elements (GRE) that have been identified in the first intron of the rat and human *CYP1A1* genes. These findings suggest the possibility that skin changes caused by long-term treatment with topical or systemic glucocorticoids could be mediated by a steroid-induced depletion of active retinoids. Therefore, we hypothesize that tandem treatment of patients with both glucocorticoids and low-dose RA may prevent some steroid side effects. In a mouse model this idea has already been confirmed.

Interestingly, there retinoids showed a steroid-sparing effect.

Skin procarcinogens, such as 3-MC and the polycyclic aromatic hydrocarbon (PAH) benzo[a]pyrene, can increase RA catabolism in human skin and induce local tissue depletion of retinoids, respectively. This can be antagonized by high dietary intake of β -carotene or retinoid acid. This acceleration of retinoid cleavage is primarily due to the xenobiotic-mediated induction of CYP1A1, which is also involved in the inactivation of RA to 4-OH-RA. Accordingly, retinoid-induced inhibition of basal as well as coal tar- and glucocorticoid-induced CYP1A1-expression in human skin as reported in [2] seems to reflect a competitive feedback inhibition of CYP1A1 activity by RA. Interestingly, CYP1A1 is one major enzyme that converts the procarcinogens mentioned above into active carcinogenic metabolites in skin. The induction of this enzyme, leading to an acceleration of the turnover of RA to inactive metabolites and a local RA deficiency, might further explain the profound effect of these carcinogenic CYP1A1-inducers on cell proliferation and tumor formation. In support of this notion, 7,8-benzoflavone, an inhibitor of CYP1A1 activity, increases local vitamin A concentrations, and reduces tumor formation in mouse skin [review see [2]].

Imidazole antimycotics, ketoconazole, clotrimazole, and miconazole are potent inhibitors of various cytochrome P450-isoenzymes that also affect the metabolism of retinoids. They were first shown to inhibit the metabolism of RA in F9 embryonal carcinoma cells. When tested *in vitro* liarazole, a potent CYP-inhibitor, suppressed neoplastic transformation and upregulated gap junctional communication in murine and human fibroblasts, which appeared to be due to the presence of retinoids in the serum component of the cell culture medium. Furthermore, liarazole magnified the cancer chemopreventive activity of RA and β -carotene in these experiments by inhibiting RA-catabolism as demonstrated by absence of a decrease in RA-levels in the culture medium in the presence of liarazole over 48 h, whereas without liarazole 99% of RA was catabolized. *In vivo*, treatment with liarazole and ketoconazole reduced the accelerated catabolism of retinoids and increased the mean plasma all-*trans*-RA-concentration in patients with acute promyelocytic leukemia and other cancers.

Vitamin D3 (VD3) and retinoids synergistically inhibit the growth and progression of squamous cell carcinomas and actinic keratoses in chronically sun exposed skin. One reason for this synergism may be the direct influence of VD3 on the isomerization and the metabolism of RA. Here, VD3 inhibits the isomerization of 13-*cis*-RA to the more receptor active all-*trans* and 9-*cis*-isomers. Moreover, the VD3 derivative secocholestra-trien-1,3,24-triol (tacalcitol), used for the treatment of severe keratinizing disorders inhibits 4-hydroxylation of all-*trans*-RA.

Ethanol also inhibits ADH-catalyzed retinol oxidation *in vitro*, and ethanol treatment of mouse embryos has been demonstrated to reduce endogenous RA levels. The inhibition of cytosolic RoldH activity and stimulation of microsomal RoldH activity could explain ethanol-mediated vitamin A depletion, separate from ADH isoenzymes. Although the exact mechanism of inhibition of retinoid metabolism by ethanol is unclear, these observations are consistent with the finding that patients with alcoholic liver disease have depleted hepatic vitamin A reserves [review see [2].

Different combinatory therapy regimens are known which additively or synergistically act in a variety of diseases:

Combinations of drugs displaying distinct effects on cell proliferation/ differentiation and immunomodulation (e.g., retinoids and chemotherapy in advanced cutaneous T cell lymphoma).

Combinations of retinoids with ultraviolet A or B radiation (and other drugs). For example, RePUVA-therapy (retinoids and psoralen and UVA combination) is currently one of the most effective regimens for recalcitrant severe psoriasis.

Drugs with metabolic interactions that can enhance the half-life of active compounds. An example of this regimen is the interaction between azole- and vitamin D-derivatives that inhibit the metabolism of retinoids in skin cells leading to increased intracellular amounts of active RA-isomers. Further study and the identification of novel interactions of this type of drug interaction is of great clinical interest since they may decrease the dose of retinoids required for efficacy thereby also reducing the risk of side effects of the retinoids.

Retinoid-Resistance

(►Retinoid-resistance) Two possible explanations for accelerated clearance of retinoids in patients during long-term treatment with retinoids have been suggested: First, RA-mediated induction of CRABP-expression, which is known to lower the plasma and intracellular levels of active RA by binding RA, and second, the RA-mediated induction and/or constitutive overexpression of P-glycoprotein, which is encoded by the multidrug resistance gene-1, leading to decreased intracellular levels of RA by enhancing active transport of intracellular retinoids out of the target cells [review see [2].

The knowledge concerning the molecular action of retinoids is steadily increasing but still the many steps of retinoid metabolism especially retinoid inactivation are not fully understood. The interaction of retinoids as the central agent with other drugs represents a new dimension of disease therapy providing us with more specific and less toxic therapy approaches to influence cell proliferation and differentiation. Perhaps in no other area of pharmacology is the concept of using drug–drug interactions as a rationale for therapy more

advanced than with retinoids in dermatology. It is likely that this strategy will prove useful in other areas as well.

Retrograde Messenger

A neuromodulator that is released from the post-synaptic neuron and acts at the pre-synaptic neuron that makes a

synapse with the post-synaptic neuron. Retrograde messengers are involved in synaptic plasticity.

- ▶ Endocannabinoids

Retroviruses

- ▶ Gene Therapy Vectors
- ▶ Antiviral Drugs

Reuptake Transporter

Reuptake transporters are structures within the cell membranes of the presynaptic nerve terminal that serve to transport biogenic amines released from vesicles back into the nerve cell. These structures are targets for antidepressants, which block the transporter, thus increasing the bioavailability of neurotransmitters at postsynaptic receptors.

- ▶ Antidepressant Drugs
- ▶ Neurotransmitter Transporters

Reverse Complementary Oligonucleotides

- ▶ Antisense Oligonucleotides (ASON)

Reverse Mode

Mode of operation of the sodium calcium exchanger extruding sodium and intruding calcium ions.

- ▶ $\text{Na}^+/\text{Ca}^{2+}$ Exchangers

Reverse Pharmacology

A scientific procedure that turns the classical pharmacology approach “upside down.” Instead of finding the elusive receptor for a known hormone or transmitter what classical pharmacology aims at, reverse pharmacology is initiated through the discovery of the receptor gene and aspires to the identification of the receptors unknown ligand.

- ▶ Orphan Receptors

Reverse Transcription

Reverse transcription is the copying of an RNA molecule back into its DNA complement. The enzymes that perform this function are called reverse transcriptases. Reverse transcription is used naturally by retroviruses to insert themselves into an organism’s genome. Artificially induced reverse transcription is a useful technique for translating unstable messenger RNA (mRNA) molecules into stable cDNA.

Rheumatoid Arthritis

PETER C. TAYLOR

The Kennedy Institute of Rheumatology Division,
Faculty of Medicine, Imperial College London,
London, UK

Definition

Rheumatoid arthritis (RA) is a chronic inflammatory disease of unknown aetiology with some autoimmune features. Current thinking favours the hypothesis that interplay between genetic factors, sex hormones, and possibly an infectious agent or another immune activating agent initiates an autoimmune pathogenic mechanism that culminates in a disease with inflammatory and destructive features.

To date there is no diagnostic test specific for rheumatoid arthritis. Revised classification criteria for the diagnosis of RA were formulated by the American College of Rheumatology [1] based on a hospital

population of patients with established, active disease. These criteria combine a constellation of clinical, serological and radiological features and have become widely accepted for epidemiological and clinical studies. By emphasising key features of the disease, the criteria help to differentiate RA from other forms of inflammatory arthritis with a diagnostic sensitivity and specificity of about 90% for active disease. However, these requirements have a much poorer sensitivity for a diagnosis of RA in the early stages of presentation at which time there may be an insufficient number of features required to satisfy the classification criteria.

Basic Mechanisms Characteristics

Once established, RA is characterised by deforming symmetrical polyarthritis associated with synovitis of joint and tendon sheaths, articular cartilage loss and erosion of juxta-articular bone of varying extent and severity [2]. IgM ► [rheumatoid factor](#) is detectable in the blood in a majority of patients. It is an autoantibody whose autoantigen is the Fc portion of IgG. The prevalence of rheumatoid factor increases with duration of disease in rheumatoid arthritis: at 3 months the prevalence is 33%, while at 1 year it is 75%. Up to 20% of RA patients remain negative for rheumatoid factor (also known as “seronegative rheumatoid arthritis”) throughout the course of their disease. ► [Antibodies to cyclic-citrullinated peptides](#) (anti-CCP) have a similar sensitivity to rheumatoid factor, but higher specificity [3]. As in the case of high-titre rheumatoid factor, anti-CCP antibodies are associated with persistence and destructiveness of rheumatoid arthritis and may precede the onset of clinical disease.

In a proportion of patients systemic and extra-articular features may be observed during the course of the disease (and rarely prior to joint disease). These include anaemia, weight loss, vasculitis, serositis, nodules in subcutaneous, pulmonary and sclera tissues, mono-neuritis multiplex, and interstitial inflammation in lungs as well as in exocrine salivary and lacrimal tissue. However, these systemic manifestations occur relatively late in the disease progression.

The clinical presentation of RA is heterogeneous with a wide spectrum of age of onset, degree of joint involvement and severity. Similarly, the disease course of RA is variable. This ranges from a brief, mild, self-limiting oligoarticular illness with minimal joint damage to a sustained polyarticular, synovial inflammation resulting in relentlessly progressive cartilage destruction, erosion of bone and ultimately changes in joint integrity with corresponding functional impairment. Up to 90% of patients with marked synovitis have radiographic evidence of bone erosion within 2 years of diagnosis, despite treatment with traditional disease modifying agents (such as methotrexate,

sulphasalazine and gold). The majority of patients with a more aggressive disease evolution become clinically disabled within 20 years (Fig. 1). For those with severe disease or extra-articular features the mortality is equivalent to that of patients with three vessel coronary artery disease or stage IV Hodgkin's lymphoma.

Cellular Pathology

RA is characterised by chronic inflammation of synovial joints with synovial proliferation and infiltration by blood derived cells, in particular, memory T cells, macrophages and plasma cells, all of which show signs of activation. Prominent vasculature is a feature of RA synovitis that is observed as a fine network of vessels over the rheumatoid synovium at arthroscopic inspection of RA joints. Angiogenesis is evident on microscopic examination of synovial biopsies from the earliest stages of disease development. Formation of new blood vessels permits a supply of nutrients and oxygen to the augmented inflammatory cell mass and so contributes to the perpetuation of synovitis. In the chronic phase of disease, capillaries and post-capillary venules are particularly evident in the synovial sublining region. In histological sections mononuclear and polymorphonuclear leukocytes can sometimes be found in close apposition to vascular endothelium, probably in the process of margination and adhesion prior to migration into the inflamed tissue. The synovial tissue becomes markedly hyperplastic and locally invasive at the interface of cartilage and bone with progressive destruction of these tissues in the majority of cases. This invasive tissue is referred to as 'pannus', comprising mainly lining cells with the appearance

of proliferating mesenchymal cells with very little sublining lymphocytic infiltration. The accompanying destruction of bone and cartilage is thought to be mediated by cytokine-induced degradative enzymes, notably the matrix metalloproteinases. Although RA has its principal manifestation in joints there is also evidence of systemic involvement, for example the upregulation of acute phase proteins, and a wide variety of extra-articular features may develop. These occur predominantly in patients who are rheumatoid factor positive and carry the HLA-DR4 gene.

Genetic Factors

Genetic factors were originally implicated in the aetiopathogenesis of RA following the discovery that in population studies there is a slight increase in the frequency of RA in first-degree relatives of patients with this disease, especially if seropositive for rheumatoid factor. In hospital-based population studies of identical twins, concordance rates of disease are around 30%, compared with 5% in non-identical twins. The figures are lower in community-based studies and although still supportive of the concept of a genetic contribution, argue against the proposition that RA is the result of a dominant single-gene disorder. These and other epidemiological studies have led to the conclusion that RA is a polygenic disease, and that non-inherited factors are also of great importance [3].

Genes encoding particular class II ▶**Human Leucocyte Antigens** (HLA) are among candidates for involvement in predisposition to RA. This discovery came about with the observation that 60–70% of Caucasian patients with RA are HLA-DR4 positive by

Rheumatoid Arthritis. Figure 1 The development of disability over time in a group of RA patients studied prior to the early 1990s. FDI = functional disease index where 1 = moderate disability, 2 = more marked disability, 3 = severe disability and 4 = very severe disability (from Wolfe, Cathey (1991) *J Rheumatol* 18:1298).

cellular or serological techniques compared with 20–25% of control populations. Furthermore, patients with more severe RA, especially those with extra-articular complications such as vasculitis and Felty's syndrome, are even more likely to be HLA-DR4 positive than patients with less severe disease confined to joints.

Class II HLA molecules are expressed on the surface of antigen-presenting cells. They play a key role in presentation of processed linear peptide antigens of at least nine amino acids to T cells. Antigen is bound to the HLA antigen binding cleft formed by the α and β chains of the HLA class II molecule. This tri-molecular HLA–antigen complex binds in turn to the variable portion of the T-cell receptor.

Nucleotide sequencing of HLA-DR β_1 exons coding amino acid residues 70–74 has revealed that HLA-DR4 subtypes Dw4, Dw14, and Dw15 share similarities with each other (with a conservative substitution of glutamine with lysine at position 71 in Dw4) and with HLA-DR1. The sequence predicts susceptibility to RA and is associated with RA in 83% of Caucasian patients in the United Kingdom. In contrast, negative associations are observed in individuals who are DR4w10, in whom the charged basic amino acids glutamine and arginine in positions 70 and 71 are replaced by the acidic amino acids aspartic and glutamic acid. In Dw13 individuals, in whom a negative association is also observed, arginine is substituted for glutamic acid in position 74. Molecular modelling studies suggest that amino acid residues 70–74 are located in the α -helix forming the wall of the peptide-binding groove, and thus likely to be involved in antigen binding and subsequent interaction with T-cell receptors. Acidic substitutions could profoundly alter protein structures and thereby alter affinity for peptide antigens. However, molecular mechanisms accounting for susceptibility to RA remain to be elucidated. Possibilities include permissive binding of specific peptides such as those on autoantigens or on environmental antigens, initiation of disease by specific binding of superantigens to HLA molecules, or modulation of the T-cell repertoire by selection or tolerance. It has been hypothesized that the severity of disease and extra-articular complications are related to homozygosity and the density of disease-associated MHC molecules that critically influence the selection of the T-cell repertoire and tolerance to antigens.

Cytokines

Cytokines are small, short-lived proteins and important mediators of local intercellular communication. They play a key role in integrating responses to a variety of stimuli in immune and inflammatory processes. By binding their cognate receptors on target cells in their immediate vicinity, these molecules participate in many important biological activities including cell proliferation, activation, death and differentiation. In

experimental systems, some cytokines are proinflammatory, such as interleukin-1 (IL-1) and TNF α ; others, such as interleukin-10 (IL-10) and transforming growth factor β (TGF β) exert predominantly anti-inflammatory effects. However, it is now known that many cytokines, for example, interferon γ (IFN- γ), with chiefly proinflammatory activity can also in some instances have anti-inflammatory properties. Similarly, IL-10 and TGF β may also exhibit proinflammatory properties under certain experimental conditions. Interleukin-6 (IL-6) does not have a classical proinflammatory action but has been implicated in the process of erosion of bone in inflammatory arthritis. ▶Paracrine or ▶autocrine pathways involving cytokines with either pro- or anti-inflammatory activity form complex networks determining whether chronic inflammation results.

Role of Cytokines in the Pathogenesis of RA

Cytokines derived from macrophages and fibroblasts are abundant in the rheumatoid synovium. These include IL-1, TNF α , granulocyte macrophage colony stimulating factor (GM-CSF), IL-6, and numerous chemo-attractant cytokines known as chemokines [4]. Many of these factors are of importance in regulating inflammatory cell migration and activation. By contrast, given the extent of synovial inflammation and lymphocytic infiltration, factors produced by T cells, for example, IFN γ , interleukin-2 (IL-2) and interleukin-4 (IL-4) are surprisingly sparsely expressed. However, there are a number of cytokines that cause ▶co-stimulation of T helper cells including interleukin (IL)-7, IL-12, IL-15 and IL-18. There is a predominance of Th1 cell activity, as defined by IFN γ production, and low Th2 cell activity as defined by IL-4 production.

An extensive range of proinflammatory cytokines can be detected in RA synovial samples, regardless of differences in donor disease duration, severity or even conventional (non-biologic) drug therapy. Proinflammatory cytokines are spontaneously produced over several days in dissociated RA synovial membrane cell cultures comprising a heterogeneous population of cells. This occurs in the absence of extrinsic stimulation, suggesting that the cultures produce one or more soluble factors regulating prolonged cytokine synthesis. Addition of anti-TNF antibodies to these cell cultures was observed to strikingly reduce the production of other proinflammatory cytokines, including IL-1, GM-CSF, IL-6 and IL-8. In contrast, blockade of IL-1 by means of the IL-1 receptor antagonist results in reduced production of IL-6 and IL-8 but not that of TNF α . These observations led to the concept that TNF α occupies a dominant position at the apex of a proinflammatory cytokine network.

In support of the concept of a cytokine dysequilibrium within the chronic inflammatory situation in rheumatoid synovium is the observation that multiple

anti-inflammatory mediators are also upregulated, but at a level insufficient to suppress synovitis. Examples include the abundant expression of IL-10, IL-13 and TGF β both in latent and active form. Naturally occurring cytokine inhibitors, such as interleukin-1 receptor antagonists (IL-1ra) and soluble TNF receptors, the specific inhibitors of IL-1 and TNF respectively, are also upregulated in the rheumatoid joint (Fig. 2).

TNF α is a pleiotropic cytokine with biological properties that include enhanced synovial proliferation, production of prostaglandins and metalloproteinases as well as regulation of other proinflammatory cytokines. The predicted clinical success of anti-TNF therapy in RA was based on the demonstration of RA synovial tissue expression of TNF α and its receptors, in vitro experiments employing dissociated synovial cell cultures and pre-clinical in vivo studies [4]. A number of independent in vivo studies demonstrated that antibody therapies blocking bioactivity of TNF α , administered either during the induction phase of murine collagen-induced arthritis or, more importantly, after the onset of disease, were able to ameliorate clinical symptoms and prevent joint destruction. Furthermore, in a murine model, the over-expression of a human TNF α transgene modified at its 3' end to prevent degradation of its mRNA was associated with the development of a destructive form of polyarthritis 4–6 weeks after birth. This could be prevented by administration of a human TNF-specific mAb.

Pharmacological Intervention

The treatment approach to RA has undergone a major evolutionary change in recent years with a move away from predominantly symptomatic treatment approaches towards much earlier intervention with ►disease-modifying anti-rheumatic drug (DMARD) therapy and

the use of treatment regimes designed to optimally suppress synovitis at any given stage of disease [2]. This is a consequence of a growing appreciation of the severity of this condition, better understanding of the most effective use of conventional DMARDs and advances in development of biologic treatments. Conventional DMARDs include low dose once weekly methotrexate, sulphasalazine, hydroxychloroquine and leflunomide. Corticosteroids are often used as a “bridging” therapy when a more slowly acting oral DMARD is initiated so that rapid suppression of synovitis can be achieved before the slower benefits of the DMARD are expressed. ►Biologics are protein-based drugs derived from living organisms that are designed to either inhibit or augment specific component of the immune system. The major impetus for development of biologic therapies has come from advances in molecular technology that have facilitated identification of cell subsets and cytokines contributing to the inflammatory and destructive components of the disease, prompting development of specific targeted therapies directed at relevant disease molecules [5].

Very considerable progress in understanding the important role of cytokines in the immunopathogenesis of RA has led to two potential approaches to cytokine modulation of rheumatoid synovitis: inhibition of dominant proinflammatory cytokines such as TNF α , IL-1, IL-6 or IL-15, or augmenting the inadequate anti-inflammatory activity of certain cytokines or naturally occurring cytokine inhibitors as, for example, by administration of soluble TNF receptors or IL-1ra. It is now established that the long-term use of biological agents targeting TNF α gives rise to sustained improvements in symptoms and signs of rheumatoid disease.

Anti-TNF therapy, particularly when used in combination with methotrexate, gives rise to substantial

Rheumatoid Arthritis. Figure 2 The concept of a cytokine dysequilibrium. Many cytokines are detectable in rheumatoid synovial tissues, including those with predominantly anti-inflammatory properties. But the net effect is a dominance of proinflammatory activity.

improvements in symptoms and signs of disease in about two-thirds of RA patients. Furthermore, this treatment combination protects joints from structural damage in a majority of patients. Furthermore, this can occur irrespective of whether a clinical response is achieved or not [2].

Although anti-TNF α agents are well tolerated and have a good overall safety profile, pitfalls to the use of these drugs apparent with increasing clinical experience include infective complications and, in particular, reactivation of tuberculosis. To date, no statistically significant increased rate of tumour occurrence over that expected has been noted although cases of lymphoma have rarely been reported in patients treated with TNF α blockade.

Clinical trials of IL-1 receptor antagonist show relatively modest anti-inflammatory efficacy but radiographic evidence indicative of retardation of joint damage. Several other proinflammatory cytokines represent potential therapeutic targets including IFN- β , IFN- γ , IL-6, IL-15, IL-17 and IL-18 and biological interventions targeting these molecules are in clinical trials. For example, data for blockade of the biological effect of IL-6 by means of intravenously administered antibodies to the IL-6 receptor added to background methotrexate therapy demonstrate efficacy for reduction in symptoms and signs with acceptable safety.

In contrast to the dramatic success of TNF blockade as a new approach to RA therapy, early randomised, placebo-controlled clinical studies exploring the potential of biological therapies targeting T cells in the treatment of RA have had generally disappointing results. Some anti-T cell agents were non-efficacious whereas other preliminary trials demonstrating some clinical efficacy were terminated due to adverse events, particularly prolonged and profound T cell depletion. However, the primatized monoclonal anti-CD4 antibody keliximab results in dose-dependent clinical responses when administered once weekly over 4 consecutive weeks and the clinical response correlates with CD4⁺ T cell coating with keliximab rather than T cell depletion.

An alternative approach seeks not to deplete or inactivate T cells, but to modulate their function in such a way as to reduce their pathogenicity. For example, the co-stimulation blocker abatacept (CTLA4-Ig), which blocks the interaction between the B7 receptor on antigen presenting cells and CD28 on T cells, has efficacy in RA patients with an inadequate response to methotrexate although in general, it takes longer for the maximum benefit to be achieved as compared with anti-TNF agents.

The potential of B lymphocyte depletion as an approach to therapy has been confirmed in RA patients seropositive for rheumatoid factor and/or anti-CCP antibodies using the anti-CD20 mAb, rituximab.

In summary, recent years have seen the emergence of encouraging data for antibodies in clinical development that are directed against proinflammatory cytokines, inflammatory cells or co-stimulatory molecules. In particular, anti-TNF α therapies have set a new standard for symptom control and prevention of joint destruction in RA.

Rheumatoid Factor

It is an autoantibody whose autoantigen is the Fc portion of IgG. Rheumatoid factors may be of any immunoglobulin isotype but it is IgM rheumatoid factor that is commonly measured in rheumatoid arthritis. Classification criteria for rheumatoid arthritis include only one serological test, namely rheumatoid factor. However, it is not diagnostic test; rather it may be confirmatory when a number of other clinical features are present.

Ribosomal Protein Synthesis Inhibitors

KATHERINE S. LONG

Department of Molecular Biology, University of Copenhagen, Copenhagen, Denmark

Synonyms

Translation inhibitors; Ribosome-targeting antibiotics

Definition

The ribosome is the cellular target of a large and chemically diverse group of antibiotics. The antibiotic binding sites are clustered at functional centers of the ribosome and the majority are composed exclusively of RNA. The drugs interfere with the positioning and movement of substrates, products and ribosomal components that are essential for protein synthesis.

Basic Characteristics

Ribosomes and Protein Synthesis

Ribosomes are ancient ribonucleoprotein complexes that are the sites of protein synthesis in living cells. Their core structures and fundamental functional mechanisms have been conserved throughout the three domains of life: bacteria, archaea and eukaryotes. All ribosomes are organized into two subunits that are defined by their apparent sedimentation coefficient, measured in Svedberg units (S). There is a general

increase in ribosome size with organism complexity from bacteria to archaea to eukaryotes. The smaller bacterial ribosome has a molecular mass of approximately 2.5 MD and is composed of a 30S small subunit, with 16S ribosomal RNA (rRNA; 1,540 nucleotides) and 21 proteins, and a 50S large subunit, with 23S rRNA (2,900 nucleotides), 5S rRNA (120 nucleotides) and over 30 proteins. Progress in the structural elucidation of the ribosome through X-ray crystallography has resulted in atomic resolution structures of ribosomal subunits and their complexes in association with antibiotics. These structures reveal molecular details into the structural basis for antibiotic inhibition and resistance [1].

Protein synthesis is a complex multi-step process that can be divided into initiation, elongation and termination stages. In the initiation phase, the 30S subunit binds to messenger RNA (mRNA), along which triplet base codons specify the individual amino acids in a protein sequence that will be added via cognate transfer RNAs (tRNAs). tRNAs span the interface between the subunits, with the tRNA anticodon and aminoacylated ends interacting with the 30S and 50S subunits, respectively. The tRNA carrying the first amino acid (methionine) binds the mRNA on the 30S subunit through codon-anticodon base pairing, followed by positioning of the 3'-end in the peptidyl-donor site in a cavity on the 50S subunit. The second tRNA binds at the aminoacyl-acceptor site with its 3'-end positioned next to that in the donor site. Peptide bond formation occurs, catalyzed by the 50S subunit and resulting in transfer of the nascent peptide to the aminoacylated tRNA. The precise positioning of the 3'-ends of aminoacyl- and peptidyl-tRNA substrates is achieved in part through base pairing interactions with the A-loop and P-loop of 23S rRNA, respectively. Although the mechanism of peptidyl transferase remains unclear, the atomic resolution structure of the archaeon *Haloarcula marismortui* 50S subunit complexed with a transition state analog reveals that there are no ribosomal proteins within 18 Å of the nascent peptide bond [2]. Peptide bond formation is followed by translocation of the mRNA-tRNA complex, leaving a vacant A-site for the tRNA carrying the next encoded amino acid. Incoming tRNAs move through successive sites on the ribosome in a unidirectional manner, including aminoacyl-acceptor (A), peptidyl-donor (P) and exit (E) sites. This elongation cycle is repeated for each encoded amino acid. Termination occurs upon recognition of a termination codon, which triggers release of the nascent polypeptide along an exit channel through the 50S subunit, followed by subunit dissociation. The entire process is aided by protein factors at every stage, including aminoacyl-tRNA selection and translocation of the mRNA-tRNA complex.

The Ribosome as a Target for Antibiotics

The ribosome is an important target for a wide variety of antibiotics. Antibiotics inhibit protein synthesis at different functional steps and have served as valuable tools in determining the mechanisms of translation. Although a few universal antibiotics inhibit protein synthesis in most, if not all, living organisms, the majority of antibiotics exhibit selectivity for ribosomes from one or two domains of life. Consequently, many of the drugs have important medical applications in the treatment of serious bacterial infections. The wide clinical use of some antibiotics, however, has been curtailed in recent years due to problems of toxicity and antibiotic resistance. A detailed understanding of antibiotic inhibitory mechanisms has remained elusive despite the fact that many of the drugs have been known for decades. An important step forward has come with the breakthroughs in ribosome crystallography and the structural elucidation of ribosomal subunit-antibiotic complexes, obtained from crystals of ribosomal subunits through either soaking or co-crystallization with antibiotics. These complexes localize antibiotic binding sites and yield molecular insights into the structural basis of antibiotic inhibition and resistance.

A number of general points can be made on antibiotic targeting of the ribosome: First, antibiotics bind to specific sites on the ribosome, with the majority targeting ribosomal RNA and not ribosomal proteins. This is consistent with crystallographic data showing that many functional centers on the ribosome are composed largely of rRNA. In addition, many antibiotics bind to regions of rRNA that are near mRNA template or tRNA substrate binding sites. Finally, antibiotics bind to regions of the ribosome that undergo conformational changes or rearrangements during translation. Most antibiotics that target the ribosome act at or near one of the following functional centers (Fig. 1). These are (i) the decoding center on 16S rRNA, (ii) the GTPase-associated region, (iii) the ribotoxin site and (iv) the ▶peptidyl transferase center, where the latter three involve 23S rRNA. This review will focus on antibiotics that target functional centers (i) and (iv), on which there is high-resolution structural information available from ribosomal subunit-antibiotic complexes.

Drugs

Antibiotics and the 30S Subunit

The two primary functions of the 30S subunit in protein synthesis are (i) decoding, the discrimination between cognate and non-cognate tRNAs by monitoring codon-anticodon base pairing in the ribosomal A site, and (ii) translocation, where, together with the 50S subunit, tRNAs and the associated mRNA are moved by precisely one codon. The high degree of translational

Ribosomal Protein Synthesis Inhibitors.

Figure 1 Schematic drawing of the morphology of the ribosome. The ribosomal subunits are labeled, as are the approximate locations of their respective functional centers. The drawing is a transparent view from the solvent side of the small subunit. Transfer RNAs are shown in different binding states with the arrow indicating their direction of movement through the ribosome. The tRNA anticodon ends are oriented towards the viewer, whereas the 3'-ends of the tRNAs are oriented towards the peptidyl transferase region on the large subunit. The letters "h" and "b" denote the head and body regions on the 30S subunit, respectively.

accuracy achieved by the ribosome is thought to involve both initial selection (via codon-anticodon base pairing) and proofreading steps, with the latter important for discrimination between cognate and near-cognate tRNAs. The structures of bacterial 30S-antibiotic complexes yield insights into how the following drugs interfere with 30S function: spectinomycin, streptomycin, paromomycin, tetracycline and pactamycin [3, 4].

Spectinomycin inhibits translocation of peptidyl-tRNA from the A- to the P-site. The antibiotic has a rigid structure composed of three fused rings that binds at one end of helix 34 in the minor groove, interacting mostly with nucleotides G1064 and C1192. Translocation requires movement of elements of the head of the 30S subunit, including helix 34. Through binding near a pivot point of the head, spectinomycin can interfere with movements of the head through steric hindrance and thereby block translocation.

Streptomycin is thought to make ribosomes error-prone by affecting proofreading and initial selection steps. The antibiotic interacts with four points of the phosphate backbone of 16S rRNA (at nucleotides 13, 526, 915 and 1,490) through salt bridges and hydrogen bonds. It also contacts lysine 45 of protein S12. The binding site suggests that streptomycin affects the helix 27 accuracy switch by stabilizing the *ram* state of the ribosome. In the *ram* state there is a higher affinity for tRNA in the A-site, which increases binding of non-cognate tRNAs. Stabilization of the *ram* state would make switching to the restrictive state more difficult and

thereby affect proofreading. A number of streptomycin-resistance mutations in 16S rRNA and protein S12 result in a hyperaccurate phenotype. In general, these mutations disrupt interactions that contribute to stabilization of the *ram* state.

Paromomycin belongs to a subclass of aminoglycoside antibiotics that target an asymmetric internal loop element in helix 44 of 16S rRNA, where they decrease the fidelity of translation. These antibiotics contain a 2-deoxystreptamine ring and an aminoglycoside ring that is either 4,5-disubstituted (neomycin and paromomycin) or 4,6-disubstituted (gentamycin and kanamycin). Paromomycin binds in the major groove of helix 44, where rings i and ii direct the specific interaction with 16S rRNA (Fig. 2). Ring i stacks against G1491 and hydrogen bonds to A1408 and the backbone of A1493, to flip A1492 and A1493 out of the helix. The unstacked bases point into the A-site and are positioned to interact in the major groove of the codon-anticodon helix. The bases hydrogen bond to 2'-hydroxyl groups on both sides of the codon-anticodon helix and are thereby able to monitor the shape and width of the minor groove of three consecutive base pairs, allowing for discrimination between correct base pairing and mismatches. Structural data suggests that unstacking of A1492 and A1493 occurs during normal translation if favorable interactions can be made across the minor groove with both mRNA and

Ribosomal Protein Synthesis Inhibitors.

Figure 2 The bound structures of paromomycin and hygromycin B in helix 44 of the 30S subunit. Two nucleotides in helix 44, A1492 and A1493, are labeled, as are rings i–iv of paromomycin and rings I–IV of hygromycin B (from Brodersen et al. [4] with copyright permission).

cognate tRNA in the codon-anticodon helix. When paromomycin is bound, the bases are flipped out of the helix causing an increase in the affinity of cognate and near-cognate tRNAs, and also the error rate. NMR studies show that paromomycin and gentamycin interact with 16S rRNA in the same manner, indicating that other aminoglycosides induce errors in translation via the same mechanism.

Hygromycin B is an aminoglycoside composed of four rings (I–IV) that inhibits translocation by sequestering tRNA in the A-site. It binds above paromomycin in the major groove near the top of helix 44 (Fig. 2), contacting rRNA from both strands (nucleotides 1,400–1,410 and 1,490–1,500). Hygromycin B binds exclusively to RNA bases in a sequence-specific manner. The drug adopts an extended structure and makes base-specific hydrogen bonds spanning more than three bases along one strand of helix 44. Hygromycin B prevents movement from the A- to the P-site by interacting with regions of helix 44 that are known to be involved in translocation. Binding of the drug could also disrupt the switch between *ram* and restrictive states since this transition affects bases in the hygromycin B binding site.

► **Tetracycline** is known to block binding of aminoacyl-tRNA to the A-site, but not initial binding of the EF-Tu:aminoacyl-tRNA:GTP ternary complex. The primary binding site is located just above the binding site for aminoacyl tRNA, between the head and the body of the 30S subunit. The drug interacts with the sugar phosphate backbone of residues in helices 31 and 34 through hydrogen bonds with oxygen atoms and hydroxyl groups on the hydrophilic side of the drug (Fig. 3). A magnesium ion is found in the binding site that mediates salt bridge interactions between the drug and the backbone of 16S rRNA. The binding site is not well conserved between bacteria and eukaryotes, providing a rationale for the specificity of the drug for bacteria. Tetracycline prevents binding of tRNA in the A-site through steric hindrance. The initial binding of tRNA in the ternary complex is not affected since its angle of approach is different from free tRNA in the A-site, avoiding a steric clash with the antibiotic.

Tetracycline has a secondary binding site in the H27 switch region that may also be functionally significant. The drug binds at the interface of the three domains of 16S rRNA, close to helix 44 and between helices 11 and 27. As with the primary binding site, contacts are made from the hydrophilic face of the drug to the backbone of 16S rRNA. In this binding site, tetracycline may function to stabilize the *ram* state.

The universal antibiotic pactamycin targets a highly conserved region of 16S rRNA, contacting the tips of helices 23b and 24a in the central domain. Pactamycin folds up to mimic a RNA dinucleotide in that its

Ribosomal Protein Synthesis Inhibitors. Figure 3 The chemical structure of tetracycline and possible interactions with 16S rRNA in the primary binding site. Arrows with numbers indicate distances (in Å) between functional groups. There are no interactions observed between the upper portion of the molecule and 16S rRNA, consistent with data that these positions can be modified without affecting inhibitory action (from Brodersen et al. [4] with copyright permission).

two distal aromatic rings stack on each other and G693 (Fig. 4). The central ring of the drug interacts with nucleotides in helices 23b and 24a. The stacked aromatic rings lie in the position occupied by the last two bases of the E-site codon, displacing mRNA from its normal position and disrupting interactions with the E-site tRNA (Fig. 4). The position of the bound drug also suggests that it would disrupt the ►Shine-Dalgarno interaction, which is important for initiation in bacteria.

Antibiotics and the Peptidyl Transferase Center

The peptidyl transferase center is the site where peptide substrates, bond formation occurs, and is located in a cavity on the interface side of the 50S subunit that leads into the peptide exit channel. It is the binding site for the 3'-termini of both donor and acceptor tRNA substrates, and is targeted by a group of structurally diverse antibiotics that either inhibit peptide bond formation directly (including ampicillin, chloramphenicol, puromycin and sparsomycin) or indirectly by interfering with movement of the nascent peptide (including erythromycin and the streptogramin B drugs). The structures of bacterial 50S-antibiotic complexes have localized binding sites of chloramphenicol, erythromycin and clindamycin that are consistent with biochemical and genetic data (Fig. 5) and represent progress towards understanding their inhibitory mechanisms [5].

Chloramphenicol is a competitor of puromycin and thereby considered to be an inhibitor of the A-site. Several functional groups on the drug are within hydrogen-bonding distance of nucleotides in the peptidyl transferase cavity including G2061, C2452, U2504, G2505 and U2506 (Fig. 5). Two divalent magnesium ions are involved in chloramphenicol binding and mediate some interactions between the drug and the peptidyl transferase cavity. Chloramphenicol binds in the A-site and may interfere with the positioning of the aminoacyl moiety and formation of the transition state.

Erythromycin is a macrolide antibiotic composed of a 14-membered lactone ring, substituted with desosamine and cladinose sugars, which does not block peptide bond formation directly. The ►macrolides are believed to function primarily by blocking the nascent peptide from the exit tunnel. Reactive groups of the desosamine sugar and the lactone ring mediate all hydrogen bond interactions with the peptidyl transferase cavity. The second generation derivatives, clarithromycin and roxithromycin, bind to the ribosome in the same fashion as erythromycin. The 2'-hydroxyl group of the desosamine sugar interacts with the N6 and N1 atoms of A2058, providing an explanation for why A2058 is essential for macrolide binding. Two common macrolide resistance mechanisms include (i) dimethylation of N6 of A2058, and (ii) rRNA mutations at

Ribosomal Protein Synthesis Inhibitors. Figure 4 The binding site of pactamycin on the 30S subunit. The positions of mRNA, the RNA elements H28, H23b, H24a, and the C-terminus of protein S7 are depicted in the E-site of the native 30S structure (*left*) and in the 30S-pactamycin complex (*right*). In the complex with pactamycin, the position of mRNA is altered (from Brodersen et al. [4] with copyright permission).

Ribosomal Protein Synthesis Inhibitors. Figure 5 Nucleotides at the binding sites of chloramphenicol, erythromycin and clindamycin at the peptidyl transferase center. The nucleotides that are within 4.4 Å of the antibiotics chloramphenicol, erythromycin and clindamycin in 50S-antibiotic complexes are indicated with the letters C, E, and L, respectively, on the secondary structure of the peptidyl transferase loop region of 23S rRNA (the sequence shown is that of *E. coli*). The sites of drug resistance in one or more peptidyl transferase antibiotics due to base changes (*solid circles*) and lack of modification (*solid square*) are indicated. Nucleotides that display altered chemical reactivity in the presence of one or more peptidyl transferase antibiotics are *boxed*.

A2058. Dimethylation causes steric hindrance and prevents hydrogen bonds to the desosamine sugar. The importance of A2058 for macrolide binding explains the selectivity of macrolides for bacterial ribosomes. Position 2058 is one of a few nucleotides in the peptidyl transferase loop that is not conserved in all phylogenetic domains, with the mitochondrial and cytoplasmic 23S rRNAs of larger eukaryotes having a G at this position. Binding of erythromycin and an adjacent magnesium ion reduces the diameter of the peptide tunnel entrance by over 50%, suggesting that macrolides can sterically block progression of the nascent peptide into the tunnel.

Clindamycin, a lincosamide antibiotic, binds to the peptidyl transferase center so as to contact both A- and P-sites. The three hydroxyl groups and carbonyl group on the drug are positioned to interact with nucleotides A2058, A2059, A2503 and G2505 (Fig. 5). Two hydroxyl groups interact with the N6 group of A2058, explaining its importance in lincosamide binding and why modifications or mutations at this position lead to drug resistance. The binding site of clindamycin suggests that it can interfere with the positioning of the 3'-ends of tRNA in the A- and P-sites, while also blocking access to the peptide tunnel.

RNA Interference (RNAi) – siRNA

ARNDT BORKHARDT, ASTRID NOVOSEL
Universität Düsseldorf, Children's University Hospital,
Department of Paediatric Haematology & Oncology &
Clinical Immunology, Düsseldorf, Germany

Synonyms

RNA interference

Definition

RNA interference (RNAi) is triggered by double-stranded RNA (dsRNA) and causes sequence-specific mRNA degradation of single-stranded target RNAs. The mediators of mRNA degradation are small interfering RNA duplexes (▶siRNAs), which are produced from long dsRNA by enzymatic cleavage in the cell, being incorporated into a protein complex, dissociated, and used as a guiding sequence to recognize homologous mRNA that is subsequently cleaved. siRNAs are approximately 21-nucleotide length and have a base-paired structure with 2-nucleotide 3'-overhangs. Due to the catalytic nature of RNAi one siRNA can be used over and over to guide the cleavage of many mRNA molecules. Beyond their value for target validation, antisense molecules and siRNAs also hold great potential for all kinds of modulating gene expression, and furthermore as gene-specific therapeutic tools. Therefore synthetic oligonucleotides have entered clinical trials for treatment of viral diseases, cancer, and inflammatory diseases.

Description

Introduction of double-stranded RNA (dsRNA) into cells leads to the sequence-specific destruction of endogenous RNA that matches the dsRNA. The remarkable potency of the RNAi reaction enables a complete "knock-down" of a specific protein. The key enzyme required for processing of long dsRNAs to siRNA duplexes is the RNase III enzyme ▶dicer. The silencing effect is long-lasting, typically several days, and extraordinarily specific, because one nucleotide mismatch between target and the central region of the siRNA is frequently sufficient to prevent silencing. A schematic illustration of the mechanism of RNAi is shown in Fig. 1.

siRNAs can be rapidly chemically synthesized and are now broadly available. More recently, it has also become possible to express siRNAs from short inverted repeat genes in order to silence genes expressed in somatic cells. The RNAs were expressed under the control of a compact ▶RNA polymerase III promoter, which normally drives the expression of human H1 RNA, the RNA subunit of RNase P enzyme. The short hairpin loop constructs gave

rise to siRNAs presumably because ▶dicer RNase III recognizes these hairpin RNAs and excises siRNAs. Transfection of plasmids encoding siRNAs therefore represents an alternative to direct siRNA transfection and may facilitate certain applications of gene targeting. A prerequisite for the application of siRNAs for validation and therapeutic applications is the need for functional RNAi machinery within the targeted cells or tissue to bind to siRNAs and mediate mRNA degradation.

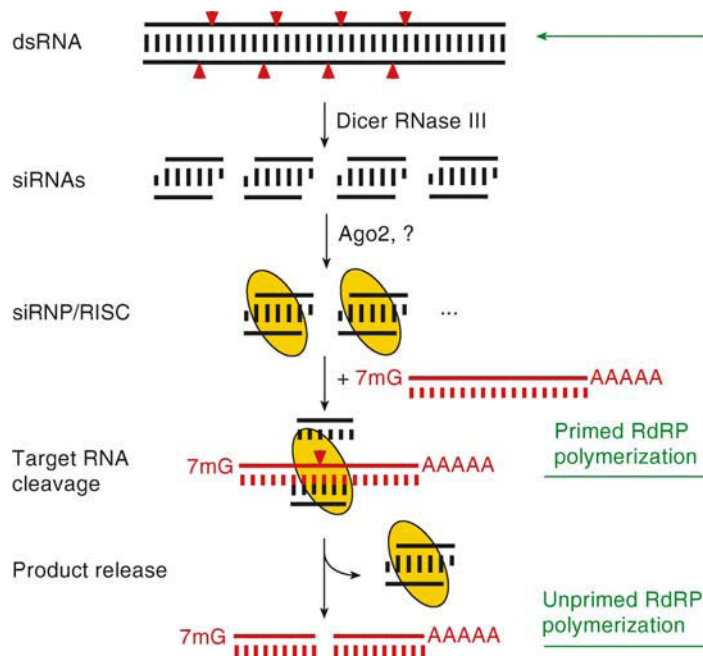

siRNAs are highly sequence-specific reagents and discriminate between single mismatched target RNA sequences and open new avenues for gene therapy. mRNAs coding for mutated proteins, which give rise to dominant genetic disorders and neoplastic growth, may be down-regulated by specific siRNAs.

Although RNAi generally works in a highly specific manner, recent studies revealed unforeseen off-target gene regulation by siRNAs. So far the small molecules have been considered to circumvent the interferon response of cells triggered by double-stranded RNA, but Sledz and co-workers demonstrated a PKR-mediated activation of the Jak-Stat pathway and a global up-regulation of interferon-stimulated genes after transfection of siRNAs. Jackson et al. used gene expression profiling to characterize the specificity of gene silencing by RNAi but found siRNA-specific rather than target-specific signatures. The signatures showed temporally distinct groups of which the fastest responders shared sequence similarities with the target site. Apart from that off-target gene silencing was caused by the sense as well as the antisense siRNA strand. Also a siRNA targeting luciferase, regulated the expression of several genes and even by decreasing the siRNA concentrations enormously the authors were unable to avoid off-target effects completely.

In sum the concept of an ideal siRNA identification attempt can be summarized as follows: (i) screen of an siRNA library, (ii) validation of the siRNA-effect by additional siRNAs targeting the same gene product, (iii) identification of the physiological role of the gene product identified, (iv) recapitulation of the in vitro findings in vivo, (v) optimization of the delivery rate to the target cells, e.g., by RNA-modifications like cholesterol-conjugation, and (vi) avoiding of unspecific and undesired siRNA effects in vivo.

Pharmacological Relevance

Especially in leukemias and lymphomas the oncogene activation frequently occurs through reciprocal ▶chromosomal translocations. These translocations split genes on both partner chromosomes leading to juxtaposition of part of each gene in the joint segments and the creation of a composite gene. Silencing of these tumor-specific chimerical mRNAs by siRNAs or ASON may become fusion gene-specific tumor therapy (Fig. 2). The extraordinary sequence specificity of the RNAi

RNA Interference (RNAi) – siRNA. Figure 1 A model for RNA interference. dsRNA is processed to 21–23-nt siRNA duplexes by Dicer RNase III and possible other dsRNA-binding factors. The siRNA duplexes are incorporated into the RISC endonuclease (RNAi inducing silencing complex), which targets homologous mRNAs for degradation. Ago2 and yet to be characterized proteins are believed to be required for RISC formation. The RISC complex mediates sequence-specific target RNA degradation. In plants and nematodes, it is thought that targeted RNAs may also function as templates for double-strand RNA synthesis giving rise to transitive RNAi. Two possibilities have been suggested, siRNA-primed dsRNA synthesis or unprimed synthesis from aberrant RNA, which could represent the cleaved target RNA. In mammals or in fruit fly, however, RdRP (RNA dependent RNA polymerase) genes have yet not been identified and the major mechanism of siRNA action is believed to be endonucleolytic target RNA cleavage guided by siRNA-protein complexes (RISC).

mechanism may also allow the targeting of individual polymorphic alleles expressed in loss-of-heterozygosity tumor cells as well as point-mutated transcripts of transforming ►**oncogenes** such as RAS. The great potential of RNAi-mediated tumor therapy was first demonstrated by Brummelkamp et al. who used a retroviral version of their plasmid vector system “pSUPER” (suppression of endogenous RNA) for targeting the mutated RAS oncogene. They strongly inhibited the expression of mutated K-ras^{V12} while leaving other RAS isoforms unaffected. This extraordinary sequence specificity of RNAi, which clearly exceeds that of DNA antisense approaches, makes it a very attractive tool for cancer therapy. Brummelkamp et al demonstrated the power of RNAi-mediated gene therapy not only in cell culture but, encouragingly, in an animal model as well.

For patients with leukemia, the transfer of siRNA-based strategies into clinical applicability will certainly be both frustrating and time-consuming and many hurdles still have to be overcome in order to realize the therapeutic potential of siRNAs. Efficient delivery of siRNA into the leukemic stem cell and their unknown influence of the patient’s immune system are the most challenging issues that need to be addressed.

With respect to future medical applications, ►**siRNA** were recently directed against a pathological transcript associated with the spinal and bulbar muscular atrophy (SBMA) in tissue culture. SBMA belongs, together with the Huntington’s disease (HD), to a growing group of neurodegenerative disorders caused by expansion of trinucleotide repeats. Caplen et al. successfully targeted pathologic RNA of the androgen receptor in human kidney 293T cells that was introduced by transfection of a plasmid encoding the expanded CAG construct. Therapeutically most important, the authors achieved a rescue of the polyglutamine-induced cytotoxicity in cells treated with dsRNA molecules. Even if this study did not knockdown an endogenous disease-related transcript, the approach underlines the remarkable broad potency and sequence-specificity of RNAi mediated gene therapy. Whether the RNAi pathway is functionally active in various neuronal cells irrespective of their state of differentiation remains to be shown.

In Huntington’s disease the polyglutamine repeat expansion in exon 1 of HD leads to a toxic gain of the protein huntingtin (htt). Harper et al. could show that siRNA directed against mutant human htt reduced htt mRNA and protein expression in cell culture and in HD

RNA Interference (RNAi) – siRNA. Figure 2 A model for RNA interference. dsRNA is processed to 21–23-nt siRNA duplexes by Dicer RNase III and possible other dsRNA-binding factors. The siRNA duplexes are incorporated into the RISC endonuclease (RNAi inducing silencing complex), which targets homologous mRNAs for degradation. Ago2 and yet to be characterized proteins are believed to be required for RISC formation. The RISC complex mediates sequence-specific target RNA degradation. In plants and nematodes, it is thought that targeted RNAs may also function as templates for double-strand RNA synthesis giving rise to transitive RNAi. Two possibilities have been suggested, siRNA-primed dsRNA synthesis or unprimed synthesis from aberrant RNA, which could represent the cleaved target RNA. In mammals or in fruit fly, however, RdRP (RNA dependent RNA polymerase) genes have yet not been identified and the major mechanism of siRNA action is believed to be endonucleolytic target RNA cleavage guided by siRNA-protein complexes (RISC).

mouse brain. htt silencing improved behavioral and neuropathological abnormalities associated with HD [1]. Targeting the CAG expanded mRNA transcript by dsRNA is becoming an attractive alternative to commonly used therapeutic strategies that, beyond symptomatic treatment, mainly focus on the inhibition of the toxic effects of the polyglutaminated protein.

With respect to targeting viral gene products expressed in virus-infected cells, it should be considered that infectious mammalian viruses may express inhibitors of RNAi similar to plant viruses.

HSV2 (herpes simplex virus 2), which causes significant morbidity and is an important cofactor for the transmission of HIV infection was recently targeted in a mouse model by local application of siRNA mixed with lipids. The results suggested that siRNA could work as active components of microbicides to prevent viral infection or transmission [2].

As the repertoire of potential HIV targets is expanding, multitargeting RNAi approaches advance to inhibit HIV replication. Herein included are methods

to avoid toxicities associated with saturation of RNAi pathways or the immune stimulatory pathways by RNAi therapeutics.

A triple combination is about to enter human clinical trials for AIDS/lymphoma patients using autologous hematopoietic progenitor cells as target for vector insertion. This triple combination was introduced by Scherer et al. and consists of a lentiviral construct with three different expression cassettes (combining a U6-driven TAR RNA decoy appemdem upon a U16 snoRNA, a U6 promoted shRNA targeted to tet and rev open reading frames, and an anit-CCR5 trans-cleaving hammerhead ribozyme) [3].

siRNAs also offered protection against respiratory syncytial virus, parainfluenza and influenza. siRNA against RSV (respiratory syncytial virus, a negative strand RNA virus causing childhood respiratory diseases) has entered Phase I clinical trials in humans, and preliminary reports are promising. If appropriately formulated for improved specificity, delivery, and pharmacokinetics, siRNAs may indeed become effective antivirals in the clinics of the future.

Another field where RNAi became beneficial is the relatively isolated tissue compartment of the eye. Here RNAi has been used to identify genes that promote apoptosis or oxidative damage in retinal cells in vitro and in vivo and could therefore lead to new treatments for several ocular diseases. The feasibility of using siRNA for treatment of choroidal neovascularization using siRNA against VEGF receptor 1 or against vascular endothelial growth factor (VEGF) is being tested in clinical trials [4].

In sum, RNAi clearly has the potential to change the nucleic-based therapies for cancer, infectious diseases, and many other diseases. However, the universality of this approach, the types of genes that can be silenced using these strategies in human cells, remain unknown to date.

Outlook

MicroRNAs (miRNAs) are small (22–25 nucleotides in length) abundant class of noncoding RNAs that are believed to be important in many biological processes through regulation of gene expression by effectively reducing the translation of mRNAs binding to their 3' untranslated region (UTR). This occurs through the assembly of an RNA-induced silencing complex composed of a variety of proteins including Argonaute. If the homology between the miRNA and the target 3'-UTR is incomplete, this complex reduces expression by blocking translation. If the homology is complete, then degradation of the target mRNA can result. The precise function of miRNAs in mammals is largely unknown, but Tuschel et al. already developed a pharmacological approach for silencing miRNAs in vivo – chemically modified, cholesterol-conjugated

single-stranded RNA analogues complementary to miRNA, termed “antagomirs.” These are efficient and specific silencers of endogenous miRNAs in mice [5]. The mechanisms by which miRNA can activate or decrease gene expression is currently unknown, but may be the result of a direct (chromatin remodeling) or an indirect (suppression of transcriptional repressor) effect. Because it has been shown that miRNAs are involved in viral infection, cell growth and differentiation, insulin secretion and cancer, silencing of miRNAs with antagomirs could become a strategy for diseases.

RNA Polymerase

Definition

The multiprotein unit that synthesizes RNA by copying the sequence information from the leading strand of the DNA. Its activity is tightly controlled by phosphorylation of the C-terminal domain (CTD), access to DNA and interaction by general and sequence specific transcription factors and coactivators and corepressors.

- ▶ Transcriptional Regulation
- ▶ Glucocorticoids

RNA Polymerase III Promoter

Promoters expressing transfer RNAs (tRNAs), U6 small nuclear (sn) RNAs, and adenovirus (Ad) virus associated (VA) RNAs are transcribed by RNA

polymerase III. They produce small, compact RNA that possess stability in the intracellular environment.

- ▶ Chromosomal Translocations
- ▶ RNA Interference (RNAi) – siRNA

RNA Polymerase Inhibitors

The inhibitors of RNA polymerase, which generates RNA from DNA, inhibit a crucial step in gene expression. Inhibition of the eukaryotic form of RNA polymerase is used in cancer chemotherapy and is also an important experimental tool. For example, actinomycin D binds to the guanine residues in DNA and blocks the movement of the eukaryotic RNA polymerase. Specific inhibitors of bacterial RNA polymerase can be used as antibacterial agents. Most of these inhibitors like rifamycin bind to the prokaryotic enzyme.

RNAi

- ▶ RNA Interference

RNAases

RNAse is an enzyme that catalyzes the breakdown of RNA molecules into their component nucleotides. RNAases are extremely common in the modern world, resulting in very short life spans for any RNA that is not in a protected environment.

- ▶ Antisense Oligonucleotides

RTK

- ▶ Receptor Tyrosine Kinase

RT-PCR

This acronym stands for Reverse Transcriptase Polymerase Chain Reaction, a method used to first copy a strand of RNA into cDNA, then amplify it through standard PCR methods.

Ca²⁺-induced Ca²⁺ release (CICR) channel, Foot

Definition

Ryanodine receptor (RyR) is an intracellular Ca²⁺ release channel in the ► [sarcoplasmic reticulum](#) (SR) or the endoplasmic reticulum (ER). RyR binds ryanodine (a plant alkaloid, see [Drugs](#)) with a high affinity, after which it is named.

Basic Characteristics

Occurrence and Role

There are three genetically distinct isoforms of RyR in mammals: RyR1, RyR2 and RyR3 ([Table 1](#)). RyR1 is predominantly expressed in the skeletal muscles, and RyR2 is the major isoform in the heart and, albeit in a lesser amount, the brain. RyR3 is ubiquitously expressed in a minute amount over various tissues. RyR1 and RyR2 play a pivotal role in ► [excitation–contraction coupling](#) (E–C coupling) of skeletal and cardiac muscles, respectively [[1–3](#)].

Structure

RyR forms a large homotetrameric channel composed of four identical monomers of ~5,000 amino acid

residues. Three-dimensional architectures obtained by cryo-electron microscopy demonstrates a large, fourfold symmetric cytoplasmic assembly and a small transmembrane assembly forming an ion channel ([Fig. 1](#)). The cytoplasmic assembly, which is identified as “foot” in the electron microscopic observation of the skeletal muscle triads ([Fig. 3](#)), consists of a series of interconnected tubular structures, forming such complex structure with several cavities. All the three isoforms show very similar structures. RyR forms multi-protein complex with several associated proteins, such as calmodulin (CaM) and 12 kDa FK506-binding protein ► ([FKBP12](#)) ([Fig. 1c](#)).

Mapping of functional domains in the RyR monomer is shown in [Fig. 2](#). Although 65% amino acid residues are identical between any two of the RyR isoforms, there are three major regions of diversity, designated DR1, DR2 and DR3. DR2 is characteristically missing in RyR3. These divergent regions likely account for functional differences between these isoforms. A C-terminal ~1/10 of the sequence is hydrophobic and has 4–8 transmembrane segments that constitute the ion channel. Like many other ion channels, the two C-terminal transmembrane segments constitute part of the ion-conducting pore, and a loop between them forms a “P-loop” containing a short pore helix and the selective filter. RyR constitutes a cation channel characteristic of a large conductance (~700 pS with Na⁺ or K⁺ and ~100 pS with Ca²⁺). The RyR channel is selective for Ca²⁺ over monovalent cations (pCa/pNa = 6–7). The selectivity, however, is less than that of the voltage-dependent Ca²⁺ channel (VDCC) showing pCa/pNa > 1,000.

A large hydrophilic N-terminal region (~4,500 residues) forms the cytoplasmic assembly and serve as the regulatory domain for a large number of endogenous ligands, drugs and associated proteins (see below). The putative binding sites for FKBP12 and CaM are mapped near the middle and end of the cytoplasmic assembly, respectively.

Ca²⁺ Release Mechanisms

All the RyR channels are gated by cytoplasmic Ca²⁺, known as Ca²⁺-induced Ca²⁺ release (CICR). CICR functions as an amplifier of small Ca²⁺ signals in various excitable and non-excitable tissues and well documented in E–C coupling in the heart. In addition, RyR1 can also mediate “depolarization-induced Ca²⁺ release (DICR)”, which is controlled by some protein–protein interactions. “DICR” is the principal Ca²⁺ release mode in E–C coupling in the skeletal muscle.

Ca²⁺-Induced Ca²⁺ Release and its Modulators

In CICR, the RyR channel is activated by μM Ca²⁺ and inhibited by mM Ca²⁺. This biphasic Ca²⁺ dependence can be explained by two distinct Ca²⁺ binding sites: high-affinity (K_D ~μM) Ca²⁺ site for activation (A-site)

Ryanodine Receptor. Table 1 Three Mammalian RyR isoforms

	RyR1	RyR2	RyR3
Gene locus (human)	19q13.1	1q42.1–43	15q14–15
Amino acid residues	5,037	4,976	4,872
<i>Occurrence</i>			
Peripheral	Skeletal muscle	Heart	Ubiquitous (minuscule) Skeletal muscle ^a
CNS	Purkinje cells	Ubiquitous	Hippocampus Corpus striatum
<i>Trigger for Ca²⁺ release</i>

Ca _v 1.1 (DICR)	Yes	No	No
Knockout mice	Perinatally lethal	Embryonic lethal	No gross abnormalities ^b
Related diseases	MH/CCD/MmD	CPVT/ARVD	Unknown

^aRyR3 is temporarily expressed in mammalian skeletal muscle during development and down-regulated to a negligible amount in adult except for diaphragm and soleus muscles. In some nonmammalian vertebrates (e.g. fish, frogs and birds), nearly equivalent amounts of RyR1 and RyR3 are expressed in adult skeletal muscles.

^bSome alterations in CNS function (e.g. enhanced locomotor activity or alterations in synaptic plasticity) are reported.

Ryanodine Receptor. Figure 1 Three-dimensional architecture of the RyR1 by cryo-electron microscopy. (a), top view (from the T-tubule); (b), bottom view (from the SR lumen); (c), side view (parallel to the SR membrane). The binding sites of FKBP12, apo-CaM and Ca²⁺-CaM are indicated in the side view. Courtesy of Dr. M. Samsó (modified from Samsó et al. (2005) *Nat Struct Mol Biol* 12: 539–544).

and low-affinity ($K_D \sim$ sub-mM (RyR1) to \sim mM (RyR2)) Ca²⁺ site for inactivation (I-site). In addition to the occupation with Ca²⁺ of the A- and I-sites, the CICR activity of RyR is also determined by a third

parameter independent of Ca²⁺ which sets the maximal attainable level.

CICR is modulated by several endogenous ligands. Mg²⁺ inhibits CICR by acting as a competitive

Ryanodine Receptor. Figure 2 Schematic illustration of characteristic structure in the linear sequence of the RyR monomer. Structural features of the RyR monomer are depicted with RyR1 as the representative of the three isoforms. A C-terminal ~500 residues (pink) form hydrophobic transmembrane assembly that constitute the ion channel. Pore-forming segment (P-loop) is marked in green. DR1, DR2 and DR3 represent divergent regions between the isoforms. DR2 is characteristically missing in RyR3. The putative binding sites for FKBP12 and CaM are indicated in purple and light blue, respectively. The putative Ca^{2+} sensor is in orange. Mutated sites linked to malignant hyperthermia (MH) and central core disease (CCD) cluster in the three regions (regions 1–3) of the *RyR1* gene (red bars). Mutation sites in RyR2 associated with CPVT and ARVD also cluster in similar regions (blue bars).

antagonist to Ca^{2+} in the A-site and as an agonist of Ca^{2+} in the I-site. In addition to these effects, a cytoplasmic concentration (0.3–1 mM) of Mg^{2+} is necessary for RyR2 to function properly. Adenine nucleotides such as ATP greatly stimulate CICR without changing Ca^{2+} sensitivity. Oxidation or *N*-nitrosylation of some hyperreactive sulfhydryl residues stimulates CICR activity. Cytoplasmic pH affects CICR: acidification decreases the activity and alkalization increases it. The effect of phosphorylation on RyR is controversial. The CICR activity may be modulated by a large number of associated proteins. Among them, CaM and FKBP12 are well investigated. CaM binds RyR on the cytoplasmic side (Figs. 1 and 2). The action of CaM is isoform-dependent: it activates RyR1 and RyR3 at a low (submicromolar) Ca^{2+} and inhibits at a higher Ca^{2+} , whereas it inhibits RyR2 irrespective of Ca^{2+} concentrations. FKBP12 similarly interacts with RyR1 to stabilize the channel activity (Figs. 1 and 2).

The RyR channels seem to be regulated by luminal Ca^{2+} . Luminal Ca^{2+} may activate the RyR2 channels in the heart. The association of **calsequestrin** with RyR2 via triadin or junctin is proposed as a possible regulatory mechanism. Such activation by luminal Ca^{2+} remains controversial in the skeletal muscle.

E-C Coupling in Heart

In E-C coupling in the heart, the RyR2 channel releases Ca^{2+} from the SR on depolarization of the plasma membrane or T-tubules by CICR mechanisms. The

cardiac junctional SR form dyad structure (similar to triad structure in the skeletal muscle, see below) with the plasma membrane or T-tubule, where L-type VDCC (cardiac **dihydropyridine receptor** (DHPR) containing $\text{Ca}_v1.2$ as the pore-forming subunit) is closely apposed to RyR2 in the SR. RyR2 is activated by Ca^{2+} , which enters via the DHPR on depolarization. Thus, cardiac muscle contraction requires extracellular Ca^{2+} . “ **Ca^{2+} sparks**” are thought to be an elementary event of the Ca^{2+} release in which multiple RyR2 channels in a cluster open synchronously. In the Ca^{2+} overloaded muscles, Ca^{2+} release via RyR2 may occur spontaneously without Ca^{2+} influx, and propagate in the cell as **Ca^{2+} waves**.

Similar Ca^{2+} release mechanism operates also in smooth muscles, neurons and some peripheral tissues.

E-C Coupling in Skeletal Muscle

In E-C coupling in vertebrate skeletal muscle, the RyR1 channel releases Ca^{2+} from the SR on depolarization of the T-tubules. This process seems similar to that in the heart, but skeletal muscle contraction does *not* require Ca^{2+} influx that triggers CICR. The mechanism is known as “depolarization-induced Ca^{2+} release (DICR)”. DICR requires regular and specific configuration of molecules involved. In skeletal muscle, T-tubule invaginates at the specific sites to form “triad” structure with the terminal cisternae (TC) of the SR on both sides (Fig. 3a). At the triad, four skeletal muscle-type DHPRs (containing $\text{Ca}_v1.1$) assemble into “tetrad” and are closely apposed (coupled) in precise register to

Ryanodine Receptor. Figure 3 Schematic drawings of mammalian skeletal muscle (a) and characteristic configuration of the components essential for E–C coupling in the triad (b). (a), the T-tubule invaginates at the A–I junction to form triad structure with terminal cisternae (TC) of the SR. LT, longitudinal tubule of the SR. Modified from Fawcett (1994) Bloom and Fawcett a Textbook of Histology (12th ed., Chapman & Hall, New York and London), p278. (b), at the triad, two rows of feet (RyR1 tetramers) are aligned in the junctional face of the TC, and tetrads (four DHPRs) in T-tubules are located in precise register with opposite alternate feet. Modified from Block et al (1988) J Cell Biol 107: 2587–2600.

the alternate RyR1 homotetramers (feet), which are aligned in two rows on each junctional face of the TC (Fig. 3b). The current view of DICR is that depolarization of T-tubule induces the conformation change in the $Ca_v1.1$, which in turn, activates the coupled RyR1 channels directly or indirectly (via other proteins such as the $\beta 1$ subunit of DHPR). In this view, DHPR serves as the voltage sensor rather than the Ca^{2+} channel. Thus, DICR is thought to occur on the basis of the $Ca_v1.1$ -RyR1 interaction. The RyR1- $Ca_v1.1$ interaction is specific and cannot be replaced by any other isoforms of RyR or DHPR. Studies with chimeric RyRs have proposed that multiple regions within the cytoplasmic assembly may be involved in this interaction.

In the skeletal muscle, RyR1 can also mediate CICR. Therefore, it may reasonably be hypothesized that Ca^{2+} released from the RyR coupled with DHPR might

induce CICR via the uncoupled RyR in physiological **twitch** or **tetanus**. The rate of CICR estimated under physiological condition, however, is much slower than the rate of DICR, suggesting only minor contribution of CICR to the physiological muscle **contraction**. The slow CICR rate is primarily due to a low maximal attainable level of the CICR activity of RyR1. Enhanced CICR is implicated in the pathogenesis of some muscle diseases (see Disease).

Diseases

Several human diseases are associated with mutations in RyR1 or RyR2, whereas RyR3-linked diseases are unknown so far. Mutations in RyR1 are linked to some cases of **malignant hyperthermia (MH)**, **central core disease (CCD)** and multi-minicore disease (MmD) [4]. Mutations in RyR2 are associated with **catecholaminergic polymorphic ventricular tachycardia (CPVT)** and a form of **arrhythmogenic right ventricular dysplasia (ARVD)** [5]. These mutated sites cluster in three regions: the N-terminal region (region 1), the central region (region 2), and the C-terminal region (region 3) that includes the transmembrane region (Fig. 2).

These mutations may alter the Ca^{2+} release channel functions. MH mutations in RyR1 largely cluster in the cytoplasmic regions 1 and 2 and tend to make the channel easier to open (enhanced CICR activity), whereas most CCD mutations are in the pore-forming region 3 and seem to form the “leaky channel” at resting cytoplasmic Ca^{2+} . Some CCD mutations lead to a severe inhibition of pore opening. Alterations of Ca^{2+} handling are reported in the RyR2 channels carrying CPVT and ARVD mutations.

Drugs Ryanodine

Ryanodine is a neutral plant alkaloid from *Ryania speciosa* and was used as an insecticide. It also has been well known by the characteristic action on mammalian skeletal muscle of slowly developing, and intensive and irreversible **contracture**. Ryanodine binds specifically to the “open” RyR channel at the stoichiometry of 1 mol/mol homotetramer with a high affinity ($K_D \sim nM$) and leads the channel to “ryanodine modified” state characteristic of long-lasting subconductance ($\sim 50\%$ of normal) opening. At higher concentration, it blocks the channel.

Ryanodine leads to contracture of mammalian skeletal muscle, whereas it causes negative inotropism in cardiac muscle. This apparent opposite effects are due to difference in the Ca^{2+} extruding activity: the released Ca^{2+} remains within cytoplasm in skeletal muscle because of low Ca^{2+} extruding activity, whereas the increased cytoplasmic Ca^{2+} is rapidly excluded out of the cytoplasm in cardiac muscle via $Na^+ - Ca^{2+}$ -exchange.

Caffeine

Caffeine is a strong activator of CICR: it sensitizes RyR to activating Ca^{2+} and increases the maximum attainable level. Because high concentrations (>mM) of caffeine effectively discharge Ca^{2+} from the Ca^{2+} store, it is frequently used for experimental evaluation of functional occurrence of RyRs. Caffeine is used for diagnosis of MH: muscles biopsied from MH patients contract by a lower dose of caffeine than normal human, due to an enhanced CICR activity (see Disease)./Para>

4-Chloro-m-cresol (4-CmC)

4-CmC, a preservative in commercial preparations of some intravenous drugs, activates CICR in a way similar to that of caffeine. 4-CmC is more potent than caffeine and shows isoform-dependent activation profiles: it is much less effective in RyR3 than RyR1 or RyR2.

Inhalation General Anaesthetics (halothane)

Inhalation general anaesthetics, such as halothane, stimulate CICR in a way similar to that of caffeine. Administration of these agents to patients with MH mutations in *RyR1* gene will cause the MH episodes.

FK506 and Rapamycin

These immunosuppressants increase the activity of RyR1 by deprivation of FKBP12. Their effect on RyR2, which binds FKBP12/12.6, is controversial. RyR3 could bind FKBP12 with unchanged activity.

Dantrolene

Dantrolene is an antidote for MH, which inhibits the CICR activity. Action of dantrolene may be isoform specific (less effective on RyR2), Ca^{2+} -dependent (more effective at a lower Ca^{2+} concentration), and temperature-dependent (more effective at 37°C than at 25°C).

Procaine and Tetracaine (Local Anaesthetics)

They decrease the CICR activity without changing the Ca^{2+} sensitivity. Tetracaine is more potent than procaine. It should be noted that some local anaesthetics, e.g. dibucaine may stimulate CICR.

Ruthenium Red

Ruthenium red inhibits the CICR activity at μM range. The site of ruthenium red action seems to be near or within ion channels. It also inhibits mitochondrial function.

Ryk/Derailed

Ryk and its *Drosophila* homolog, derailed, are receptor tyrosine kinases which have been shown to act as co-receptors with the Fz proteins for Wnt signaling. The first evidence for an interaction with Wnts came from genetic studies in *Drosophila* which showed axon-guidance defects due to misexpression of *derailed* that was rescued by deletion of the *wnt5* gene. Later work in mice confirmed the role of Ryk in axon guidance and in Wnt signal transduction by linking similar axon defects to the presence or absence of Ryk and Wnt3 in affected neurons. In mammalian cell culture Ryk can interact with both Fz and Dvl. Wnt signaling mechanisms downstream of Ryk are not well defined, but probably do *not* rely on Ryk kinase activity, as the kinase domain has been shown to be without normal activity.

► Wnt Signaling

S6K1

S6K1 (also known as p70S6 kinase) is a serine/threonine protein kinase which is involved in the regulation of translation by phosphorylating the 40S ribosomal protein S6. Insulin and several growth factors activate the kinase by phosphorylation in a PI 3-kinase dependent and rapamycin-sensitive manner. Phosphorylation of S6 protein leads to the translation of mRNA with a characteristic 5' polypyrimidine sequence motif.

S100 Proteins

CLAUS W. HEIZMANN

Department of Pediatrics, Division of Clinical Chemistry and Biochemistry, University of Zurich, Zurich, Switzerland

Synonyms

Ca²⁺ regulation; S100 proteins; EF-hand; RAGE

Definition

► S100 proteins (named because of their solubility in a 100% ammonium sulfate solution) constitute the largest family within the EF-hand Ca²⁺-binding proteins superfamily [1]. S100 proteins are small, acidic proteins containing two distinct Ca²⁺-binding ► EF-hand structural motifs [2]. The C-terminal EF-hand contains the

classical Ca²⁺-binding motif, common to all EF-hand proteins. This Ca²⁺-binding motif has a typical sequence signature of 12 amino acids and is flanked by two helices. The N-terminal EF-hand, different from the classical EF-hand motif, contains a 14 amino acid consensus sequence motif, named the 'S100-specific' or 'pseudo' EF-hand.

Among the different human S100 genes, most are clustered on human chromosome 1q21, a region frequently involved in chromosomal rearrangements in cancer. Based on these findings, an official nomenclature for S100 proteins was introduced (Table 1).

► <http://www.gene.ucl.ac.uk/nomenclature/index.html>

S100 proteins have multiple biological functions in cells; some are secreted from cells and activate receptor for advanced glycation end products (RAGE)-dependent cellular pathways.

Basic Characteristics

Intracellular Ca²⁺-levels are controlled by release into, and removal from, the cytoplasm (Fig. 1). Ca²⁺-pumps in the plasma membrane and endoplasmic reticulum (ER; the Ca²⁺-store in a cell) keep cytoplasmic Ca²⁺-levels low (about 0.1 μmol/L in resting cells) and generate a 10,000-fold concentration gradient across membranes (because extracellular Ca²⁺ is in the millimolar range). Upon stimulation, Ca²⁺ enters the cytosol of the cell via Ca²⁺-channels (plasma membrane) or via Ca²⁺-channels in the ER, leading to the activation of a great variety of Ca²⁺-dependent processes in the cell.

Ca²⁺-channels mediate Ca²⁺-entry into cells and Ca²⁺-pumps of the plasma membrane and of the endoplasmic reticulum remove the ion from the cytoplasm. The Ca²⁺-signal is mediated by the EF-hand Ca²⁺-binding proteins (including the S100 protein family) which have INTRA- and EXTRACELLULAR cytokine-like functions. Ligands including S100 proteins activate RAGE of neighbouring cells leading to physiological or pathological responses. RAGE ligands: S100 proteins; AGEs: Advanced Glycation End Products amphoterin/high mobility group 1 proteins (HMG-1); LPS, (lipopolysaccharide/endotoxins) β-amyloid.

RAGE, (domains V, C1, and C2) belongs to the immunoglobulin family of proteins.

A large group of diseases is associated with mutations in Ca²⁺-channels (channelopathies) and

**S100 Proteins. Figure 1** Pathways of Ca²⁺-release and uptake.

Ca²⁺-pumps. After entering the cell, Ca²⁺ is reversibly complexed to specific Ca²⁺-binding proteins that fulfil multiple functions, including Ca²⁺-buffering and transport, activation of enzymes, regulation of contraction,

secretion, and proliferation. This large family of Ca²⁺-binding proteins is characterized by a common structural element, the EF-hand [2, 3]. These proteins decipher the information carried by Ca²⁺ and pass it on

to various targets regulating biological functions. The largest group within the EF-hand Ca^{2+} -binding proteins are the S100 proteins. S100 proteins are cell- and tissue-specific expressed and regulate many intra- and extracellular processes by interacting with specific target proteins.

In general the affinities of S100 proteins for Ca^{2+} are low with a binding affinity of 100–500 μM . Binding of Ca^{2+} to S100 proteins induces helix rearrangement within each subunit of the dimer, resulting in the exposure of two hydrophobic surfaces (one in each monomer), which are involved in target protein recognition. Beside Ca^{2+} , a number of S100 proteins can also bind Zn^{2+} or Cu^{2+} that can influence the affinity of Ca^{2+} -binding. Thus, S100 proteins display variable transition metal-binding properties in agreement with their highly diversified and specialized functions, such as cell proliferation, migration differentiation, as well as in cognition.

Recent advances in the elucidation of the biological functions of a selection of S100 proteins are summarized below.

In response to a rise up calcium, S100 proteins interact with distinct target proteins and some members relocate to different cellular compartments and are implicated in multiple intracellular and extracellular activities.

The brain-specific S100B regulates enzyme activity by rendering certain phosphorylation sites inaccessible to their interaction partners, as was reported for neurogranin, tau protein, glial fibrillary acid proteins (GFAP), and the p53 transcription factor. In addition, several S100 proteins have been shown to be secreted via different mechanisms, including the classic endoplasmic reticulum-Golgi pathway, or alternative pathways involving cytoskeletal components, such as actin and tubulin. S100B secretion from astroglial cells is induced by serotonin 1a receptor agonist binding. Moreover, the release of S100 protein from apoptotic cells following brain injury may be sufficient to induce cellular responses. In vitro, extracellular S100B and S100A4 promote neurite outgrowth and neuronal survival by acting through \blacktriangleright RAGE and heparan sulfate proteoglycans, respectively, both located at the cell surface. Moreover, extracellular S100B has been shown to modulate long-term neuronal synaptic plasticity, glutamate uptake of hippocampal astrocytes, and inflammation.

S100A1 is the most abundant in the myocardium but is also expressed in brain and other tissues. S100A1 was found to stimulate Ca^{2+} -induced Ca^{2+} -release (CICR) in skeletal muscle terminal cisternae. In the presence of nanomolar Ca^{2+} -concentrations, S100A1 binds to the ryanodine receptor increasing its channel open probability, and was shown to enhance SR Ca^{2+} -release and contractile performance. Several animal models (over expressing S100A1 or S100A1-deficient mice) have

emphasized the importance of S100A1 in calcium-cycling of the heart and its association with heart failure.

Furthermore, we also found behaviour differences in our mouse models of S100A1 deficiency. The male S100A1 knockout mice showed reduced anxiety-like responses and enhanced explorative activities and we concluded that S100A1 plays a role in modulating innate fear and exploration of novel stimuli.

S100A2 encoding cDNA was first identified as a novel tumour suppressor gene. S100A2 interacts in a Ca^{2+} -dependent manner with the tumour suppressor p53 and activates its transcriptional activity. S100A2 was shown to interact with the same p53 binding site as S100B.

A recent DNA microarray-based search for proliferation control genes showed that 28 genes are cooperatively activated by IFN- α and TGF- β . Among these are the insulin-like growth factor-binding protein 3 (IGFBP3) and S100A2. IGFBP3 protein was found to be a potent growth inhibitor requiring TGF- β activity. The antiproliferative activity of S100A2 is significantly enhanced by IFN- α in stably transfected human melanoma cell lines. IFN- α was found to be a potent inducer of intracellular Ca^{2+} -release required for activation of S100A2. This study provides a functional link between IFN- α and TGF- β signalling and extends the functions of IFN signalling to calcium-sensitive processes.

S100A4 is implicated in tumour progression and metastasis and high S100A4 expression levels have been correlated with reduced patient survival and poor prognosis. The relevance of S100A4 to clinical parameters was investigated in several archival colon cancer specimens, without metastasis at the time of surgery [4]. Remarkably, S100A4 mRNA levels were found to be higher in the primary tumours, which later developed distant metastases. Patients whose tumours were heterozygous for activating β -catenin mutation were identified, and the tumours showed both nuclear β -catenin staining and high S100A4 expression. All these patients developed metastases in the liver. This was the first demonstration that mRNA expression of S100A4, determined in primary tumours in a quantitative manner, is of value for the prediction of metastasis cancer.

The results also showed an interconnection of two previously unconnected molecular pathways which play important roles in tumour progression and metastasis, the β -catenin/TCF signalling pathway and S100A4, that controls motility and invasiveness. The finding demonstrated that β -catenin/TCF directly regulates the expression of the S100A4, and that β -catenin-induced effects on cell migration and invasion are mediated by S100A4 in colon cancer cells. New therapeutic strategies aimed at disrupting this regulation

and the function of S100A4 protein may be of particular value for prevention of colon cancer metastasis.

S100A10 was found to interact with the serotonin 1B receptor increasing its presence at the cell membrane. S100A10 was found to be closely associated with the pathophysiology of depression.

S100A16 is the latest example. This protein was found to accumulate within nucleoli of glioblastoma cells and translocate to the cytoplasm in response to Ca^{2+} -stimulation. This suggested a possible role of S100A16 in ribonucleoprotein complex processing, gene silencing, or cell cycle progression. Like other members of the family, S100A16 lacks the canonical nuclear localization signal. Nuclear import may require interaction with transporter proteins or phosphorylation, as it was described for S100A11, or may occur via facilitated diffusion pathways, as observed for calmodulin.

S100 Proteins and RAGE Signalling

Some S100 proteins are secreted from cells and exert their extracellular functions through their interaction with the [▶receptor for advanced glycation end products \(RAGE\)](#) [5]. RAGE is a member of the immunoglobulin-like cell surface receptor superfamily with multiple functions. RAGE is composed of three extracellular immunoglobulin domains, (a ‘V’ domain followed by two ‘C’ type domains), a single spanning transmembrane region, and a short cytosolic domain (Fig. 1). Recently, RAGE isoforms lacking the transmembrane and cytosolic regions (endogenous

secreted RAGE or esRAGE) or the ‘V’ immunoglobulin domain (N-truncated RAGE or NtRAGE) were identified in the human brain. RAGE can be activated by S100 proteins, amyloid- β ($A\beta$), amphoterin, LPS, or advanced glycation end products (AGEs). The RAGE ligands activate different signalling pathways, p21^{ras} and mitogen-activated protein kinases (MAPK). Depending on the pathways activated the RAGE ligand signal leads to the activation of transcription factors like NF- κ B or Sp1 and to cellular responses. Activation of RAGE enhances the expression of the receptor itself and initiates a positive feedback loop, resulting in sustained RAGE up-regulation, which has been suggested to be the starting point of chronic cellular activation and tissue damage. Several studies have succeeded to block the RAGE/ligand interactions, resulting in a suppression of atherosclerosis and improved wound healing in diabetic animal models.

Drugs

Disease Association and Molecular Drug Targets

Proteins of this family are closely associated with a number of human diseases such as cardiomyopathy, inflammation, cancer, Alzheimer’s disease, and depression (Table 2). They have also been proven to be valuable in the diagnosis of these diseases (Table 3) in order to improve clinical management, outcome and survival of patients. They are considered as having a potential as drug targets to improve therapies. Moreover, S100A1 gene therapy is suggested as a novel

treatment to improve existing contractile performance, e.g. after myocardial infarction.

Outlook

Many vital physiological functions and metabolic processes are regulated by Ca^{2+} and a large number of human diseases are linked to an altered Ca^{2+} -homeostasis. The Ca^{2+} -signal within cells is transmitted by many Ca^{2+} -binding proteins, including the S100 proteins family. S100 proteins have received increased attention recently because of their close association with human diseases and their use in diagnosis. S100 proteins are also considered (together with their extracellular receptor RAGE) to have a potential as drug targets to improve therapies in the future.

Germany

Synonyms

Lead discovery by NMR; NMR-screening

Definition

NMR can be used as a method for monitoring protein-ligand interactions, either by detecting protein signals or the signals of the ligand. The detection of protein signals requires isotope labeling, usually with ¹⁵N, whereby ligand observed techniques maybe applied without any labeling. Ligand observed techniques are commonly used for screening purposes with the ability to detect binding in the micro- and millimolar range. NMR techniques applied for this purpose are the so called “waterLOGSY” experiment [1], saturation transfer difference spectroscopy [2], and the T1 ρ experiments [2]. The saturation transfer difference technique is often used to determine pharmacophores of the binding ligand. For design purposes, protein observed techniques are preferred since they allow the application of the so called SAR-by-NMR methodology.

SAR-by-NMR is a method for generating systematically lead compounds in the early stages of a drug finding process. NMR is used as a method for detecting protein ligand interactions site-specifically through the application of correlation spectroscopy [3]. The inherent parameter of NMR signals, the chemical shift, is dependent on the chemical environment of the respective nucleus that gives rise to the signal. Binding of a ligand close to this nucleus changes the chemical environment and therefore also the chemical shifts. The monitoring of chemical shift changes through correlation spectroscopy indicates thus the binding site. This information can be used to either i) search for two compounds that bind close to each other in the active center of a protein, and that can be linked chemically to one compound that supposedly binds tighter [3], or ii) to detect the binding of so-called molecular frameworks (small organic compounds) as a basis for the design of focused compound libraries and improvement of the binding affinity of these frameworks by addition of further substitutions to them through a library approach [4]. This procedure is often called “fragment based ligand design.”

Both approaches outlined deliver information that is best used in cycles of medicinal chemistry/computer aided drug design in order to refine the compounds.

In its original form (version i), SAR-by-NMR involved the following steps:

Screening of a compound library to detect compounds that bind to the active site of the protein by correlation spectroscopy.

Screening of derivatives of these compounds, optional a synthesis of a focused library yielding such derivatives to obtain compounds with improved affinity.

Screening for a second compound that binds in the vicinity of the first one using the same procedure.

Determination of a three-dimensional structure of the protein with both ligands.

Design of a linker for both ligands and synthesis of this compound.

Detection of the affinity of the new compound and further improvement by synthesis of focused library on the basis of the design.

Typically, between 1,000 and 10,000 substances are screened to find weakly binding ligands.

The linking of two weaker binding compounds may lead to strong binding one, primarily due to the saving of one entropical factor if both original compounds are chemically connected:

$$\Delta G_{AB} = \Delta G_A + \Delta G_B + \Delta G_{\text{link}}$$

The binding constant increases then:

$$K_d(AB) = K_d(A) * K_d(B) * L,$$

where L is the linking coefficient derived from ΔG link.

In its modified form ii, the first three steps of the original procedure as outlined above are applied to obtain a good starting point for the chemists to synthesize new compounds in a more focused manner.

Description

The NMR screening technology in general is a tool to detect interactions between ligands and proteins in the milli- to picomolar range, using a direct binding assay that detects binding in a site specific manner.

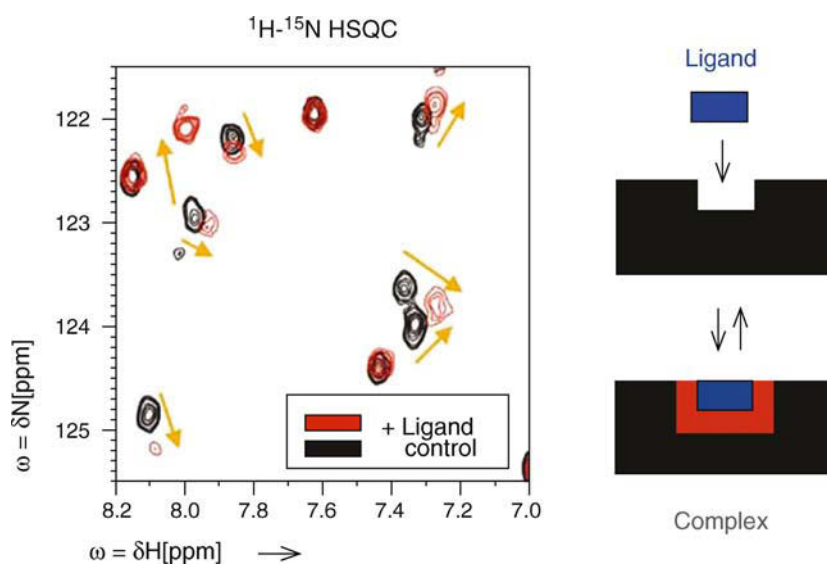

In both variants of the approach, i) and ii), the ligands detected in a NMR screen would be subjected to further modifications, and become larger during the design process. The properties of the compound library need to fulfill therefore a number of NMR-specific requirements. The compounds need to be soluble in water, their molecular properties should not exceed half the number that is defined in the Lipinski rules for molecular

weight, hydrogen bond donors and acceptors. This allows to generate still pharmacologically relevant molecules that satisfy the Lipinski rules at the end of the design process.

Most commonly, protein ligand interactions are monitored by ^1H - ^{15}N correlation spectroscopy (Fig. 1), requiring ^{15}N -labeled protein and approximately 10 min of measurement time for each spectrum. These correlation spectra are particularly well suited for the detection of the binding site, as each amino acid in the protein leads to exactly one cross peak caused by its backbone amid moiety in a usually well-resolved spectrum. Only few amino acids, like arginine, asparagine, glutamine and lysine show additional NH correlation peaks due to the presence of such moieties in the side chain. The correlation signals in ^1H - ^{15}N correlation spectra are the so-called finger print of a protein, since the ^1H and ^{15}N chemical shifts depend on the protein sequence and structure, and occur therefore on individual positions, whereby the secondary structure has a systematical influence on peak position. Due to the occurrence of only a few signals, such spectra are usually also well resolved. Upon binding of a ligand (Fig. 1, right) only those signals in the spectrum of the undistorted protein (black) show chemical shift changes, which are in the direct neighborhood of the ligand in the complex (red). Chemical shift changes are usually quantified as a linear combination of $\delta^1\text{H}$ and $\delta^{15}\text{N}$, e.g.

$$\Delta\delta(^1\text{H}, ^{15}\text{N}) = \Delta\delta(^1\text{H}) + \Delta\delta(^{15}\text{N})/5$$

In principle, any type of NMR spectroscopy may be used to detect the chemical shift changes upon ligand binding. For very small proteins, 1D-NMR might even

SAR-by-NMR. Figure 1 Overlay of regions from ^1H - ^{15}N correlation spectra of a protein without (*black*) and with (*red*) bound ligand (*left*). In case of ligand binding, only signals in the vicinity of the binding sites show chemical shift changes (*red, right*).

be sufficient. Other two-dimensional techniques, such as ^1H - ^{13}C correlation spectroscopy or 2D-TOCSY might be useful in individual cases.

Screening of compound libraries with medium throughput is only possible if the spectra can be recorded in a short period of time, and if one measurement gives simultaneously a number of answers. In practice, several ligands are usually measured in one protein sample, depending on the problem [5]. Mostly 10–20 ligands are combined to multiplexes, which need to be deconvoluted if a positive answer, as shown in Fig. 1 is obtained. The hits obtained maybe analyzed automatically or by hand through manual inspection of the spectra.

Several ligands are often found to interact with the protein, but showing different binding modes. An analysis concerning the binding modes of groups of ligands is possible through a principle component analysis that is used to cluster the results according to concerted chemical shift changes in the respective correlation spectra [6].

The chemical shift changes observed in correlation spectra may be used for measuring binding constants. The position of the protein signal in the absence of a ligand is the concentration of the free protein, whereas an excess of ligand shifts the signal to the position of the one in the complex. A binding curve is the result that maybe evaluated by applying standard methods. The data are conveniently fitted with the following equation:

$$K_D = \frac{([P]_0 - x)([L]_0 - x)}{x}$$

$[P]_0$ is the total molar concentration of the protein and $[L]_0$ is the total molar concentration of ligand. X is the molar concentration of the bound species determined according to the chemical shift change:

$$x = \frac{\delta_{\text{obs}} - \delta_{\text{free}}}{\Delta}$$

δ_{obs} and δ_{free} are the chemical shift values for the target molecule determined at each concentration of ligand and for the protein in the absence of ligand, respectively. Δ is the difference between the chemical shift at saturating amounts of ligand and δ_{free} .

In the case of tighter binding (nanomolar range), the signal of the free protein would not start to change its position upon addition of a ligand, but rather decrease in intensity, and at the position of the chemical shift of the respective resonance in the complex, a signal would appear and its intensity rise with increasing ligand concentration. This may also be plotted as a binding curve.

Examples of the application of SAR-by-NMR include the design of stromelysin and human papillomavirus E2 protein inhibitors [7, 8].

A detailed analysis of designed inhibitors for stromeolysin by thermodynamical methods [7] showed

that the combination of two ligands, a biphenyl derivative and acetohydroxamic acid, yield an increase in the enthalpic contributions to the binding energy, whereas the entropic factor remained constant. In the application of the method to the design of the virus E2 protein the potential of NMR to detect low affinity binding was exploited by starting a ligand refinement from compounds that bound in the millimolar range, and combining features of two compounds to one which finally showed an IC 50 of 10 μM in the applied test.

Sarcolemma

The sarcolemma is the plasma membrane of muscle cells.

- Cardiac Glycosides
- Antiarrhythmic Drugs

Sarcoplasmic Reticulum

Synonyms

SR

Definition

Sarcoplasmic reticulum (SR) is a form of the smooth-faced endoplasmic reticulum (ER) in muscles. It functions as an intracellular Ca^{2+} store for muscle contraction. Ca^{2+} is energetically sequestered into the SR by Ca^{2+} -pump/sarcoplasmic endoplasmic reticulum Ca^{2+} -ATPase (SERCA) and released via Ca^{2+} release channels on stimuli (ryanodine receptor in striated muscles and inositol 1,4,5-trisphosphate receptor in most smooth muscles). Endoplasmic reticulum in non-muscle tissues also functions as an intracellular Ca^{2+} store.

In striated muscles, SR is well developed to surround the myofibrils and is divided into two parts, the terminal cisternae (TC) and longitudinal tubules (LT). TC forms triad (skeletal muscle) or dyad (heart) structure with transverse tubules. The ryanodine receptor is located only in the TC, whereas the Ca^{2+} pump/SERCA is densely packed in both TC and LT.

Saxitoxin

Saxitoxin (STX) is a toxin which is found in marine microorganisms. It is most likely synthesized by bacteria which live in symbiosis with dinoflagellates, a component of phytoplankton. Through the marine food chain, it can lead to poisoning of humans. The mechanism of toxicity of saxitoxin is very similar to that of tetrodotoxin. Saxitoxin binds from the outside of the membrane to various forms of voltage-sensitive Na^+ channels and blocks the channel in an activation state-independent manner.

- ▶ Voltage-dependent Na^+ Channels

Scaffold

- ▶ Adaptor Proteins

Scaffolding Proteins

Scaffolding proteins are proteins, which are able to bind several other proteins in order to organize these interacting proteins into functional complexes. Scaffold proteins often guide the interactions between components in such complexes. This allows, for instance in signaling cascades, a precise relay of the signal with high speed and efficiency. Scaffolding proteins also avoid unwanted cross talk between different functional protein complexes.

In *Drosophila* eyes, the light-activated TRP channel is organized into a supramolecular complex, the “transducisome”, along with other transduction proteins, such as phospholipase C (PLC) and protein kinase C, through association with the scaffolding protein INAD, a multi PDZ domain-containing protein. The mammalian TRPC4 is associated with calmodulin, the inositol 1,4,5-trisphosphate (IP_3)-receptor and, via the scaffolding protein ezrin-binding phosphoprotein 50 or NHERF, with PLC and the actin cytoskeleton.

Scatchard Plot

A Scatchard plot is a plot of B/x against B (where B is the amount of bound ligand and x is the ligand concentration), which is used to estimate the maximal binding, B_{max} as well as the binding affinity (K).

Scavenger Receptors

Cell-membrane proteins that endocytose oxidatively or otherwise modified low-density lipoproteins.

- ▶ Atherosclerosis
- ▶ Lipoprotein Metabolism

Schild Analysis

Schild analysis is a very powerful method to quantify the potency of a competitive antagonist and to test whether the blockade of response by a molecule is consistent with simple competitive antagonism. Devised by Arunlakshana and Schild (1959), it is based on the principle that the antagonist-induced dextral displacement of a dose-response curve is due to its potency (K_{eq} value, affinity) and its concentration in the receptor compartment. Since the antagonism can be observed and the concentration of antagonist is known, the K_{eq} (denoted K_B for antagonist) can be calculated. The relationship between antagonism and concentration must be log-linear with a unit slope to adhere to true competitive kinetics.

- ▶ Drug–Receptor Interaction

Schizophrenia

Schizophrenia is a psychiatric disorder characterized by a number of psychotic manifestations including delusions, hallucinations, disorganized thinking and behavior, amotivation, paucity of thought and speech, flat affect and anhedonia. The aetiology of schizophrenia is thought to involve a combination of genetic and environmental factors. While florid symptoms most commonly present in adolescence or early adulthood, they are usually preceded by premorbid changes in personality and social functioning. Diagnosis is made after exclusion of other causes of psychotic symptoms (e.g., head injury, cerebrovascular accident, substance intoxication) and based on the presence of at least two clinical manifestations present for at least 6 months in the presence of social dysfunction (DSM-IV criteria). Classical antipsychotic drugs (dopamine D2-like receptor blockers) are effective in reducing the positive symptoms of schizophrenia (delusions, hallucinations) but are less useful in treating the negative symptoms of the disorder (loss of affect, withdrawal).

- ▶ Dopamine System

Second Messenger

A second messenger is an intracellular metabolite or ion whose concentration is altered when a receptor is activated by an agonist, considered to be the “first messenger.”

Secretase

The enzymes that are involved in the processing of APP into amyloid peptides are known as secretases. Beta-secretase is an enzyme that catalyzes the initial proteolytic event leading to the production of Abeta amyloid peptides. If APP is cleaved by beta-secretase it can then be further cleaved by gamma-secretase. Abeta peptides are either secreted or intracellularly released. They have varying lengths and represent intermediate degradation products of its precursor (i.e., β -secretase cleaved APP). Especially the 42 amino acid peptide ($A\beta_{42}$) aggregates to form “insoluble” amyloid plaques.

- ▶ Alzheimer’s Disease

Secretory Pathway

Transport of proteins and lipids occurs between the organelles of the secretory pathway, i.e. endoplasmic reticulum (ER), Golgi, endosomes, lysosomes and the plasma membrane.

- ▶ Intracellular Transport

Sedatives

Sedatives decrease activity, moderate excitement and calm the recipient. In contrast to hypnotic drugs, they do not produce drowsiness and do not facilitate the onset

and maintenance of sleep. The most important group of sedatives are the benzodiazepines given at low or moderate doses.

- ▶ Benzodiazepines

Seizure

A seizure is an abnormal behavioral (often motoric) activity caused by abnormal electrical activity of the brain. Seizures can be the symptom of a chronic neurological malfunction, i.e. epilepsy, or can appear as single events, e.g. during fever in infants.

- ▶ Antiepileptic Drugs

Selectins

The three selectins are related both structurally and functionally. They are transmembrane proteins, with an N-terminal C-type actin domain, followed by an EGF repeat and a variable number of complement control protein (CCP) domains. Selectins bind carbohydrates, which are present in various glycoproteins.

Selective Noradrenaline Reuptake Inhibitors

Selective noradrenaline reuptake inhibitors (SNRIs) are a group of drugs, which act as antidepressants by the selective inhibition of the reuptake of noradrenaline from the synaptic cleft via the selective blockade of the noradrenaline-specific neurotransmitter transporter (e.g. reboxetine).

- ▶ Antidepressants
- ▶ Neurotransmitter Transporters

Selective Progesterone Receptors Modulators

Selective progesterone receptor modulators (SPRMs, mesoproggestins) are progesterone receptor (PR) ligands

that exhibit agonistic and antagonistic activities. Examples are J876 and J1042.

► Selective Sex Steroid Receptor Modulators

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitor (SSRI) is an abbreviation for the class of antidepressants known as the Selective Serotonin Reuptake Inhibitors. Examples of SSRIs include fluoxetine, paroxetine, citalopram, and sertraline. These drugs selectively inhibit the serotonin transporter thus prolonging the synaptic lifespan of the neurotransmitter serotonin.

Definition

Compounds that mimic the effects of sex steroids in some tissues, while at the same time can oppose endogenous hormone action in other tissues.

Background

The sex steroids comprise a class of hormones, including ►estrogens, ►progestins, and ►androgens, which play important roles in the development and maintenance of

the male and female reproductive systems. In addition, sex steroids have functions in tissues other than those related to reproduction. For example, estrogen is involved in the development and maintenance of skeletal integrity and is an important regulator of triglyceride and cholesterol homeostasis. Not all of the biological functions of the sex steroids are beneficial, however, as chronic stimulation by estrogens, progestins, and androgens has been implicated in the genesis and progression of cancers in a number of tissues. The necessity for compounds that retain the beneficial effects of sex steroids in some tissues but oppose the action of endogenous hormones in others has resulted in the generation of a novel class of pharmaceuticals termed ►selective steroid receptor modulators (SSRMs). This chapter will focus primarily on known ►selective estrogen receptor modulators (SERMs), which represent a class of pharmaceuticals used clinically for cancer and osteoporosis, and for sustaining beneficial effects of estrogen in postmenopausal women [1]. The general mechanisms of SERMs are similar to that of ►selective progesterone receptor modulators (SPRMs) and ►selective androgen receptor modulators (SARMs), which are currently in development for the treatment of progesterone- and androgen-associated pathologies, respectively.

Mechanism of Action

Targeting Estrogen Action in a Tissue-Specific Manner: The SERM Concept

The ovarian hormone estrogen is a key regulator of the processes involved in the growth, differentiation and function of a wide variety of tissues of diverse functions. The importance of estrogen in sustaining overall health is evidenced by the adverse effects of hormone deficiency in postmenopausal women who experience increased hot flashes, depression, cardiovascular disease, and losses in bone mineral density that often lead to osteoporosis. These observations have led to the development of ►estrogen replacement therapies (ERT), where premenopausal estrogen levels are restored, and the symptoms of menopause are alleviated. The most well studied responses are in bone, where ERT can decrease the incidence of hip fractures by 50%, and in the central nervous system, where up to 90% inhibition of hot flashes is observed. ERT has also been shown to be associated with improvement in cognitive function in postmenopausal women and may delay the onset of Alzheimer's disease [1].

Although the positive effects of ERT have been well established, it has been shown that the cell proliferative actions of estrogen can increase the incidence of breast cancer in some patients. In addition, duration of exposure to physiological levels of unopposed estrogens is an established risk factor for breast, uterine, and ovarian cancer. In an effort to attain pharmaceutical agents that oppose the carcinogenic

actions of estrogens, ►**antiestrogens** have been developed, and are being used clinically for the treatment of ►**estrogen receptor (ER)**-positive breast cancers. The necessity for compounds that retain the beneficial effects of estrogen in some tissues has resulted in the generation of a novel class of antiestrogens, (SERMs), which display tissue-specific ►**agonist** and ►**antagonist** activities [1].

Molecular Mechanisms of SERM Action as a Means of Understanding their Tissue-Selective Activities

The molecular pharmacology of estrogens and antiestrogens is complex. It is clear, however, that all of these compounds mediate their biological activities through two intracellular receptors, the ERs (ER α and ER β) which function as ligand-inducible transcription factors in target cell nuclei [1]. Hormone binding to the receptors transduces the endocrine signal into genomic responses, resulting in the upregulation or downregulation of specific genes at the messenger RNA (mRNA) level. The mRNAs are then translated into proteins that function within the cells of hormone-responsive tissues to regulate proliferation, differentiation, and homeostasis (Fig. 1).

In addition to the well-established genomic signaling pathway through ER α and ER β , estrogens have recently been shown to display rapid responses that do not require gene transcription. This 'nongenomic' signaling is associated with estrogen activation of other receptor classes such as membrane associated receptor tyrosine kinases and G protein coupled receptors (GPCR), such as the recently described ►**GPCR**, ►**GPR30** [2]. Specific biological functions of this receptor have yet to be defined, however, the ability of GPR30 to bind both classical ER agonists and antagonists suggests that GPR30 may play a role in antiestrogen pharmacology [2].

Ligand binding is an event that initiates ER signaling. According to classical receptor theory, agonists (such as endogenous estrogens) act as molecular switches, converting ER from an inactive to an active form. Antiestrogens, synthetic compounds developed to oppose the action of natural hormone, were thought to competitively inhibit agonist binding and in doing so were able to lock the receptor in a latent state. Thus, it was considered that when corrected for affinity all agonists were functionally indistinguishable, and likewise, antagonists were all the same. However, the existence of SERMs indicated that this model is oversimplified, as it does not account for the biology of known antiestrogens. Some of the first evidence that antiestrogens do more than freeze ER in a latent state and thus play a more active role in ER action came from clinical studies of patients that were administered ►**tamoxifen** as adjuvant therapy for estrogen-dependent breast tumors. Strikingly, while tamoxifen blocked the

Selective Sex Steroid Receptor Modulators.

Figure 1 The biological effects of estrogens are mediated through estrogen receptors (ERs). Hormone diffuses into target cells where it binds to nuclear ERs. This event induces a conformational change in ER that enables the receptor to bind to the regulatory region of estrogen-responsive genes. The DNA-bound ER interacts with components of the general transcriptional apparatus (GTA) to induce gene transcription. The resultant mRNAs are transported into the cell cytoplasm where they are translated into proteins. These proteins function with the cell to mediate biological responses. In addition to classical nuclear ER-mediated pathways, nongenomic, rapid actions of estrogens have recently been identified. Estrogen binds cell surface receptors such as membrane-associated ERs or GPR30, a G-protein activated receptor. Hormone binding to either membrane ERs or GPR30 can activate downstream kinase signaling pathways. The biological consequences of nongenomic estrogen signaling are currently under investigation.

actions of estrogen in breast cancer cells, it was shown to function as an agonist in bone and the uterus, mimicking the actions of estrogen. The observation that tamoxifen displays tissue-specific agonist/antagonist activities was inconsistent with the classical definition of antagonist action, and furthermore, suggested that this compound may alter ER in such a way that the liganded receptor would be recognized differently in distinct cell types [1].

The concept that different ligands play an active role in ER function is apparent at the biochemical level. In addition to competitive inhibition of estrogen binding, antiestrogens induce unique conformations/structures of both ER α and ER β . This provides a structural basis for the unique biological activities displayed by the different compounds [1].

The understanding of diversity in ligand-mediated ER activity was advanced by the discovery of transcriptional cofactors. These proteins, termed ►**coactivators** and ►**corepressors**, bind the liganded ER and enhance

or decrease ER-mediated transcription of target genes, respectively. The ability of different ER agonists and antagonists to induce different conformations of the receptors influences the binding of coactivators and corepressors to the receptors (Fig. 2). Different ligands induce unique structural changes in ER that result in differential recruitment of coactivators and corepressors, leading to diversity in biological response. This provides a mechanism by which different ligands acting through the same receptor can mediate unique biological effects [1]. For example, estrogen induces coactivator recruitment to ER, whereas when bound to the pure antiestrogen ICI 182,780, (A pure ER antagonist that opposes estrogen action in all tissue contexts.) the conformation of ER is compatible with corepressor (but not coactivator) binding. Correspondingly, estrogen is a full agonist of ER, while ICI functions as a pure antagonist on the receptor. In contrast, when bound to the SERM tamoxifen, which displays both agonist and antagonist activities, ER is capable of interacting with either coactivators or corepressors. It is likely that diversity in the availability of coactivators or corepressors in different target cells may be the mechanism underlying the tissue-specific agonist/antagonist activities of tamoxifen and other SERMs. Thus, it will be important to identify the cofactor proteins present in different ER target cells in order to allow mechanistic screening for new tissue-targeted SERMs.

Interestingly, the antagonist activity of ICI and other antiestrogens has also been recently attributed to the ability of these compounds to induce degradation of the ER protein in estrogen target tissues. It is thought that

Selective Sex Steroid Receptor Modulators.

Figure 2 Cofactor binding is regulated by the structure of the ligand–ER complex. Different ligands induce distinct conformations of ER, leading to differential cofactor recruitment. Pure agonists like estrogen, drive the receptor into a structure compatible with coactivator binding, whereas pure antagonists (ICI182,780) induce a conformation recognized by corepressors. SERMs like tamoxifen, which display both agonist and antagonist activities on ER, permit the receptor to interact with either coactivators or corepressors.

coactivator and corepressor recruitment to the ER is involved and may facilitate receptor degradation, however, further investigation is needed to define the specific cofactor complexes involved [3].

Clinical Use

Mechanistic Classes of Antiestrogens and SERMs

ER antagonists comprise two broad categories: pure antiestrogens and SERMs. A summary of the different biological functions associated with some of the known antiestrogens is displayed in Table 1.

Pure Antiestrogens: Pure antiestrogens, represented by ICI 182,780, oppose estrogen and ER activity in all tissues [1]. In theory, these properties make Type I antiestrogens useful in cancer therapy, since they block the carcinogenic effects of estrogen in the breast and reproductive system. However, since ICI 182,780 lacks the beneficial agonist effects of estrogen in bone, the cardiovascular, and the central nervous systems, the clinical use of this compound is limited to patients with advanced breast cancer who have become resistant to tamoxifen (see below).

SERMs:

1. First Generation: The triphenylethylene tamoxifen (Nolvadex) is the most well-characterized SERM, used clinically since 1971. The notable antagonist effects of tamoxifen in the breast make it a first line therapy for the treatment of pre- and postmenopausal women with estrogen-responsive advanced (Stage IV) breast cancer. In addition to the use in the prevention and treatment of cancer, tamoxifen has very beneficial effects in the maintenance of bone mineral density and decreases serum triglyceride (LDL) levels in postmenopausal women. Unfortunately, the estrogenic activity of tamoxifen provides for undesirable uterotrophic effects, leading to an increased risk for endometrial cancer in women undergoing prolonged tamoxifen therapy. Similar to that seen in women on ERT, tamoxifen also induces ovarian cysts due to its agonist activity in the ovary.

Selective Sex Steroid Receptor Modulators.

Table 1 Biological activities of ER ligands in selected target tissues

	Bone	Breast	Cardiovascu- lature	Uterus
Estrogen	+++	+++	+++	+++
IC1182,780	-	-	-	-
Tamoxifen	+	-	+	+
Raloxifene	+	-	+	-
Lasofexifene	++	-	++	-

+ denotes agonist activity; - denotes antagonist activity

An additional concern has been the observed development of “tamoxifen resistance” in a significant proportion of women after 5 years of antiestrogen therapy. This term refers to the phenomenon by which certain breast cancers alter their biology and recognize the compound as an agonist for growth. Other tamoxifen-derived compounds such as toremifene, droloxifene and idoxifene are currently being evaluated in clinical studies for their potential long-term beneficial effects in antagonizing ER-positive breast tumor growth [1].

2. **Second Generation:** Second generation SERMs were developed with the objective of obtaining ER-targeted pharmaceuticals that lacked the uterotrophic and carcinogenic effects of tamoxifen. The most well characterized second generation SERM is ►**raloxifene** (EVISTA). This compound functions as an estrogen in bone and the cardiovascular system, but acts as a pure antagonist in the breast and uterus. Type II antiestrogens are currently in clinical use; raloxifene was shown to prevent bone loss in preclinical trials of postmenopausal osteoporosis. Consequently, raloxifene received FDA approval for the prevention and treatment of osteoporosis in 1999 and is now widely used in the clinic [1, 3]. The ►**STAR trial** (Study of tamoxifen and raloxifene), which was completed in 2006, demonstrated additional utility of raloxifene in the prevention and treatment of breast cancer. In fact, the absence of associated uterotrophic effects with raloxifene suggests that it may be a safer agent than tamoxifen for use as a chemopreventative in high-risk postmenopausal women [3]; therefore, raloxifene has very recently become a new option for breast cancer prevention now available for physicians and their patients.
3. **Third Generation:** Third generation SERMs are ER-targeted pharmaceuticals that possess the favorable qualities of raloxifene, but are more effective in their estrogenic effects of enhancing bone mineral density and in decreasing serum LDL and cholesterol levels. Many of these compounds, such as ►**bazedoxifene** and ►**lasofoxifene** are presently being evaluated in clinical trials for their efficacy in the prevention of osteoporosis [3].

Quest for the “Perfect” SERM

Recently, leaders in the pharmaceutical industry have developed a list of desired properties for a fourth generation of SERMs (Table 2). In general, future SERMs must oppose endogenous hormone action in the breast and reproductive system while displaying full estrogenic effects in the cardiovascular, bone and central nervous systems. Additional criteria are that fourth generation compounds possess superior bioavailability compared with existing SERMs and have

Selective Sex Steroid Receptor Modulators.

Table 2 Criteria for fourth generation SERMs

1	Antagonize estrogen action in the breast and ovary
2	Display no uterotrophic activity
3	Bone protective to the full extent of estrogen
4	Possess better cardiovascular and central nervous system profiles than current SERMs
5	Possess superior bioavailability than current SERMs
6	Contain potential benefits for men in protection against age-related bone loss and increases in cholesterol levels, without displaying estrogenic proliferative effects in the prostate

additional indications in men for bone protection and cardioprotection.

In addition to those described above, some of the newest compounds emerging in SERM development are ER β -selective ligands and pathway-selective modulators that target the interaction of the ERs with the transcription factor NF κ B. While such compounds are in the early stages of clinical evaluation, thus far they demonstrate great potential for use in the treatment of inflammatory disorders such as arthritis, inflammatory bowel disease, and like other SERMs, cancer [4].

Selective Progesterone Receptor Modulators (SPRMs)

Progestins (progesterone and related compounds) are ovarian hormones that mediate their biological effects through an intracellular ►**progesterone receptor** (PR), a hormone-inducible transcription factor. Progesterone is involved in the development of the female reproductive system, pregnancy and fertility, and in regulation of gonadotropin hormone secretion. Progestins are used clinically in oral contraceptives, to induce abortion and missed menses, and in treatment of endometriosis and fibroids [1]. Since progestins function as antiestrogens in the uterus, yet display proliferative effects in the breast, pharmaceutical companies are currently engaged in efforts to develop compounds that display tissue-targeted progestin/antiprogestin activities. This should provide for an additional class of anticancer agents that retain the beneficial effects of progesterone in selected tissues.

The first SPRM to reach the advanced stage of clinical development for treatment of ►**endometriosis** and uterine fibroids, ►**asoprisnil**, is expected to receive FDA approval this year. The therapeutic effect of asoprisnil stems from its PR antagonist/antiproliferative activity in the endometrium and breast. Unlike classical PR antagonists however, this compound does not induce labor in animal models of pregnancy and parturition. Recent structural studies

demonstrated that asoprisnil-bound PR resides in a different conformation than PR complexed with progesterone. These structural differences might explain the agonist/antagonist behavior of this compound, as in contrast to progesterone or PR antagonists, asoprisnil facilitates recruitment of both coactivators and corepressors to PR [5].

Selective Androgen Receptor Modulators (SARMs)

Androgens (testosterone and related compounds) comprise a class of male steroid hormones secreted by the testes. Androgens are essential for spermatogenesis, formation of reproductive organs and development of secondary sexual characteristics. In addition, androgens are involved in bone and muscle growth, regulation of hypothalamic–pituitary hormone secretion, reproductive behavior, and neural regeneration [1]. Unfortunately, prolonged exposure to unopposed androgens is an established risk factor for prostate cancer, a serious health concern among middle-aged and elderly men. The proliferative effects of androgens in the prostate are mediated through the ► **androgen receptor (AR)**, which like ER and PR, functions as a hormone-inducible transcription factor in target cells. AR antagonists (antiandrogens) are currently in development and clinical use for prostate cancer, as they oppose the proliferative actions of androgens in the prostate [1].

Tissue-targeted antiandrogens termed SARMs are currently in the early stages of development, and preclinical data is very promising. The high anabolic activity in selective tissues such as muscle and bone indicates that SARMs could be used in the treatment or prevention of many diseases such as muscle wasting, osteoporosis, frailty, or other conditions that are a consequence of aging or androgen deficiency. Two other indications for SARMs are currently under investigation: (i) partial anti-androgenic activity of some compounds in the prostate suggests their utility in benign prostate hyperplasia and (ii) the identification of agents that selectively inhibit spermatogenesis may provide a novel hormonal means of male contraception.

Summary

The sex steroids comprise a family of hormones, which share a similar mode of action through binding nuclear receptors and regulating the expression of genes involved in cell proliferation, differentiation and function. Sex steroids have a wide range of biological roles in reproduction and in other organ systems. While many hormone functions are critical for homeostasis, chronic stimulation of sex steroid-mediated pathways has also been implicated in cancer and other pathologies. The necessity for compounds that retain the beneficial effects of sex steroids in some tissues

but oppose the action of endogenous hormones in others has resulted in the generation of SSRMs, which display tissue-specific agonist and antagonist activities. Further investigation into the mechanisms by which different cells recognize liganded–receptor complexes in a unique manner will provide for mechanistic screening for new pharmaceuticals that display more specific and effective tissue-targeted activities.

Self Tolerance

During differentiation of T- or B-lymphocytes[®] antigen receptors are generated which react to selfor[®] autoantigens. These are generally eliminated by the mechanisms of central tolerance or kept silent by the mechanisms of peripheral tolerance ([®] autoimmune disease).

► Autoimmune Disease

Sema Domain

The Sema domain consisting of about 500 amino acids is characterized by highly conserved cysteine residues that form intramolecular disulfide bonds. Crystal structures have revealed that the Sema domain folds in the manner of the β propeller topology which is also found in integrins or the low-density lipoprotein (LDL) receptors. Sema domains are found in semaphorins, plexins and in the receptor tyrosine kinases Met and Ron.

► Plexins

Semaphorins

Semaphorins are secreted, membrane-associated or transmembrane proteins defined by the presence of a semaphorin protein domain (Sema domain). In the mammalian system, more than 20 semaphorins have been identified which play important roles in a variety of tissues. The best characterized receptors for mediating semaphorin effects are members of the neuropilin and plexin families of transmembrane proteins. Semaphorin functions are best described in the regulation of neural development, angiogenesis, immunoregulation and cancer.

- ▶ Plexins

Senescence

Senescence is defined as cellular ageing resulting in an irreversible cell cycle arrest. Primary cells divide about 50 times and then are arrested due to senescence. Senescence is associated with shortening of telomeres.

- ▶ Cell Cycle Control
- ▶ Telomerase

Sensitization

Sensitization has been implicated in the development of compulsive drug use and involves a dramatic augmentation of behavioral and neurochemical responses associated predominantly with mesolimbic dopamine transmission that often develops with intermittent exposure to drugs of abuse. Whether sensitization of mesolimbic dopamine neurons is linked to enhanced rewarding efficacy remains unclear. Indeed, current conceptualizations of the significance of sensitization in compulsive drug-seeking behavior hold that, rather than enhancing “reward,” repeated drug use leads to a progressive and persistent hypersensitivity of neural systems that mediate “incentive salience” resulting in excessive craving.

- ▶ Drug Addiction/Dependence

Sensory Nerves

Sensory nerves are peripheral nerves involved in the detection of exogenous and endogenous stimuli for transmission into the CNS. They can be subdivided into RARs and C-fibres according to their channel characteristics.

SERCA

Sarcoplasmic calcium ATPase; this enzyme utilizes the energy gained from hydrolysis of ATP to pump calcium from the cytosol into the stores of the sarcoplasmic reticulum. Its activity is negatively regulated by the closely associated protein phospholamban, and this inhibition is relieved upon phosphorylation of phospholamban by protein kinase A (PKA).

Serine-hydroxymethyltransferase

The amino acid glycine, a neurotransmitter at inhibitory synapses throughout the central nervous system (CNS),

is preferentially synthesized by the tetrahydrofolate and pyridoxal phosphate-dependent enzyme serine-hydroxymethyltransferase. In the CNS, glycine synthesis involves the mitochondrial isozyme. While serine-hydroxymethyltransferase may also contribute to glycine catabolism, the preferred degradation is via the glycine cleavage system, resulting in the formation of CO₂ and ammonia.

Serotonin

Serotonin or 5-hydroxytryptamine is an important biogenic amine, which is synthesized via 5-hydroxytryptophan from the amino acid tryptophan. The highest concentration of serotonin occurs in the wall of the intestine. About 90% of the total amount is present in enterochromaffin cells, which are derived from the neural crest, similarly to those of the adrenal medulla.

Enterochromaffin cells are interspersed with mucosal cells mainly in the stomach and small intestine. In the blood, serotonin is present at high concentrations in platelets, which take up serotonin from the plasma by an active transport process. Serotonin is released on platelet activation. In the central nervous system, serotonin serves as a transmitter. The main serotonin-containing neurons are those clustered in form of the Raphe nuclei. Serotonin exerts its biological effects through the activation of specific receptors. Most of them are G-protein coupled receptors (GPCRs) and belong to the 5-HT₁-, 5-HT₂-, 5-HT₄-, 5-HT₅-, 5-HT₆-, 5-HT₇-receptor subfamilies. The 5-HT₃-receptor is a ligand-operated ion channel.

- ▶ Serotonergic System
- ▶ Psychotomimetic Drugs

Serotonergic System

DANIEL HOYER

Psychiatry/Neuroscience Research, Novartis Institutes for Biomedical Research Basel, Basel, Switzerland

Synonyms

Serotonin = 5-Hydroxytryptamine = 5-HT (= enteramine)

Definition

The serotonergic system is one of the oldest neurotransmitter/hormone systems in evolution, which may explain why ▶5-HT interacts with such a diversity of receptors of the G protein-coupled family and the ligand-gated family, similarly to acetylcholine, GABA or glutamate. 5-HT was discovered in the gut in the 1930s and called enteramine, then rediscovered in the 1940s in the blood and called serotonin, since it constricted smooth muscle in vessels and gut. 5-HT is synthesized from L-tryptophan, there are two tryptophan hydroxylases forming 5-hydroxytryptophan (5-HTP), which by the L-amino acid decarboxylase leads to 5-HT; serotonin can be conjugated with glucuronide or sulfate or in the nervous system, metabolized via monoamine oxydase to 5-hydroxyindolacetaldehyde and finally to 5-hydroxyindolacetic acid (via aldehydedehydrogenase). It can also lead to 5-hydroxytryptophol by an aldehydereductase in some peripheral nerves. Thus, 5-HT acts both as a neurotransmitter with all the features, such as intracellular storage, activity-dependent release, the existence of both pre- and post-synaptic receptors, an active uptake

system, via the serotonin transporter and metabolizing/inactivating enzymes and a hormone, released into the blood or gut to work more distantly.

Basic Characteristics Physiology

The main source of 5-HT (95%) is in the enterochromaffin cells of the gut, where it is synthesized from tryptophan. It can be released into the gut lumen, e.g. as a reaction to pressure and act on receptors located on the smooth muscle, or into the portal blood circulation, by a variety of nervous or alimentary stimuli. 5-HT is also found in enteric neurons. In the blood, the vast majority of 5-HT is found in storage granules in the platelets, which are endowed with a very active uptake system (they probably do not synthesize 5-HT). Large amounts of 5-HT are released during platelet aggregation, and it can act locally on endothelial cells and vascular smooth muscles. 5-HT is also found in mast cells. In the central and peripheral nervous system, 5-HT acts as a neurotransmitter on a large variety of receptors, which may be located pre- or post-synaptically. 5-HT is also found in the pineal gland, where it is believed to serve essentially as a precursor for the synthesis of melatonin by 5-HT-N-acetyltransferase and hydroxyindole-O-methyltransferase, under the control of the clock genes in the suprachiasmatic nucleus, which during the circadian rhythm modulates enzyme activity levels up to 50 fold.

Multiple 5-HT Receptor Subtypes

There are at least 15 different 5-HT receptors, and the system is probably more complex (see Tables 1–3 and Fig. 1). With the exception of 5-HT₃ receptors, (ligand-gated ion channels), 5-HT receptors belong to the ▶G protein-coupled receptor (GPCR) superfamily and represents one of the most complex families of neurotransmitter receptors. Multiple splice variants (5-HT_{2C}, 5-HT₄, 5-HT₇) or RNA edited isoforms (5-HT_{2C}) have been described; there is also evidence that homo- and hetero-dimerization (5-HT_{1B/1D}) can occur. Furthermore, peptide or lipid modulators of 5-HT receptors have been described such as 5-HT moduline (Leu-Ser-Ala-Leu (LSAL), a putative product of a chromogranin), which has selectivity for the 5-HT_{1B} and 5-HT_{1D} receptors, or oleamide, which acts on several receptors (e.g. 5-HT_{2A/2C} and 5-HT₇). As molecular biology started to play a prominent role in the discovery of additional receptors, the Serotonin Club Receptor Nomenclature Committee proposed a classification system based on operational, structural, and transductional information [1]. The current classification [4] was progressively adapted to incorporate new information, obtained from both recombinant and native receptors, and favors an alignment of nomenclature with the human genome to avoid species differences.

Serotonergic System. Table 1 5-HT₁ receptors

Currently, seven families of 5-HT receptors have been recognized, 5-HT₁ to 5-HT₇.

The 5-HT₁ receptor class comprises five receptors (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}) which, in humans, share 40–63% overall sequence identity and couple somewhat preferentially to G_{i/o} to inhibit cAMP formation (see [Tables 1–3](#)). The 5-HT_{1E} receptors are given a lower case appellation to denote that

endogenous receptors with a physiological role have not yet been found, and may not even exist in rodents (rat, mouse). In contrast, 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, and 5-HT_{1F} receptors have been demonstrated functionally in a variety of tissues. The 5-HT_{1C} designation is vacant, as the receptor was renamed 5-HT_{2C}, due to structural, operational, and transductional similarities with the 5-HT₂ receptor family.

Serotonergic System. Figure 1 Graphical representation of the current classification of 5-hydroxytryptamine (5-HT) receptors. Receptor subtypes represented by shaded boxes and lower case designate receptors that have not been demonstrated to definitively function in native systems. Abbreviations: 3'-5' cyclic adenosine monophosphate (cAMP); phospholipase C (PLC); negative (-ve); positive (+ve)

5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} receptors exhibit 46–50% overall sequence identity and couple preferentially to G_{q/11} to increase inositol phosphates and cytosolic [Ca²⁺] (see Tables 1–3).

5-HT₃ receptors belong to the ligand-gated ion channel receptor superfamily, similar to the nicotinic acetylcholine or GABA_A receptors and share electrophysiological and structural patterns. The receptors

are found on central and peripheral neurons where they trigger rapid depolarization due to the opening of nonselective cation channels (Na^+ , Ca^{2+} influx, K^+ efflux). The response desensitizes and resensitises rapidly. The native 5-HT₃ receptor, as revealed by electron microscopy in neuroblastoma-glioma cells, is a pentamer, and there may exist three different subunits, 5-HT_{3A}, 5-HT_{3B}, and 5-HT_{3C}. Currently, the consensus is that native receptors are best reproduced by the heteromeric combination of 5-HT_{3A} and 5-HT_{3B} subunits. 5-HT_{3B} homomers lack functions (as is the case for 5-HT_{3C}), and it appears that 5-HT_{3A} receptors need to form heteromers to become functional (with, e.g. 5-HT_{3B}). It has been suggested that 5-HT₃ receptors can heterodimerize with other members of the superfamily (e.g. nicotinic $\alpha 7$), but this has not been demonstrated *in situ*.

5-HT₄, 5-HT₆, and 5-HT₇ receptors all couple preferentially to G_s and promote cAMP formation, yet they are regarded as distinct receptor classes because of their limited (<35%) overall sequence identities. This subdivision is arbitrary and may be subject to future modification.

Two subtypes of the 5-HT₅ receptor (5-HT_{5A} and 5-HT_{5B}), sharing 70% overall sequence identity, have been found in rodents. The human 5-HT_{5B} receptor gene does not encode a functional protein due to the presence of stop codons in its coding sequence. Human recombinant 5-HT_{5A} receptors inhibit forskolin-stimulated cAMP production, although the receptor may also couple positively to cAMP. Currently, a physiological readout for this receptor is still missing, although A-843277, a selective 5-HT_{5A} antagonist has antidepressant/antipsychotic properties in rodent models.

Additional endogenous 5-HT receptors have been defined pharmacologically, although a corresponding gene product encoding the receptor has not yet been identified. As long as their structure is unknown, these receptors are regarded as orphans in the current nomenclature. One of these however, the so-called "5-HT₁-like" receptor mediating direct vasorelaxation corresponds to the 5-HT₇ receptor. On the other hand, the situation with the remaining ►orphan receptors (see 3) has not evolved further and thus the status quo ante remains. In particular, no progress has been made with the so-called 5-HT_{1P} receptor, which is present in the gut and whose pharmacology is reminiscent of the 5-HT₄ receptors, with the restriction that some of the ligands described, like the 5-HT dipeptides do not affect 5-HT₄ receptors. The 5-HT_{1P} could be a heterodimer, but the putative partners remain to be identified.

Pathophysiology/Clinical Applications

5-HT has been implicated in the etiology of numerous disease states, including depression, anxiety, social phobia, schizophrenia, obsessive compulsive disorders,

panic and sleep disorders, migraine, vascular and pulmonary hypertension, eating disorders, nausea/vomiting, ►irritable bowel syndrome (IBS) and other functional GI disorders, by interacting at different receptors or transporters (see 2, 3, 5, 6).

Indeed, 5-HT is also a substrate for the 5-HT transporter, itself an important player in the treatment of depression, and more recently for the whole range of anxiety disorders spectrum (GAD, OCD, social and other phobias, panic and post-traumatic stress disorders). It is the target for ►SSRIs (selective serotonin reuptake inhibitors) such as fluoxetine, paroxetine, fluvoxamine, and citalopram or the more recent dual reuptake inhibitors (for 5-HT and noradrenaline, also known as SNRIs) such as venlafaxine. Currently, there are efforts to develop triple uptake inhibitors (5-HT, NE, and DA). Further combinations are possible, e.g. SB-649915, a combined 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D} inhibitor/selective serotonin reuptake inhibitor (SSRI), is investigated for the treatment of major depressive disorder.

5-HT_{1A} receptor agonists, such as buspirone or gepirone, are being used/developed for the treatment of anxiety and depression. Furthermore, the 5-HT_{1A} receptor and β -adrenoceptor antagonist, pindolol, was reported to enhance the therapeutic efficacy and shorten the onset of action of SSRIs upon co-administration in severely depressed patients. Both positive and negative findings have been reported, as is common in depression trials; it is suggested that the combination therapy functions provided that sufficient 5-HT_{1A} receptor occupancy is reached. Flesinoxan, a 5-HT_{1A} receptor agonist, was initially developed as an anti-hypertensive agent, however its effects in patients were disappointing and this approach has now been abandoned. S-37245 is a 5-HT_{1A} antagonist which is under investigation for the potential treatment of anxiety and depression.

Interest in 5-HT_{1B} receptor agonists has been triggered by the anti-migraine properties of sumatriptan, a non-selective 5-HT_{1D/1B} receptor agonist and many others (dihydroergotamine (DHE), zolmitriptan, naratriptan, rizatriptan, eliotriptan, almotriptan, donitriptan, etc). The development of 5-HT_{1B} agonist "serenics" such as eltoprazine was not successful; the expected anti-aggressive effects were not observed in patients. AZD-8129 a 5-HT_{1B} was recently discontinued in anxiety/depression.

Sumatriptan and Naratriptan also bind to 5-HT_{1F} receptor. It has been hypothesized that they might be a target for antimigraine drugs. 5-HT_{1F} receptor mRNA has been detected in the trigeminal ganglia, stimulation of which leads to plasma extravasation in the dura, a component of neurogenic inflammation thought to be a possible cause of migraine. LY 334370, a selective 5-HT_{1F} receptor agonist, inhibits trigeminal stimulation-induced early activated gene expression in nociceptive

neurons in the rat brainstem. LY-349950 was in clinical development for migraine, but was discontinued.

Ketanserin a selective 5-HT_{2A} antagonist was developed for the treatment of hypertension, but 5-HT_{2A} receptor antagonism as an antihypertensive principle has been abandoned, since ketanserin is a potent α_1 adrenoceptor antagonist. LSD and other hallucinogens most probably produce hallucinations by activating 5-HT_{2A} receptors. Although their selectivity vis-a-vis 5-HT_{2B} and 5-HT_{2C} receptors is rather limited, this represents currently the best possible explanation. 5-HT_{2A} receptor antagonists such as risperidone, ritanserin, seroquel, olanzapine, or MDL 100907 have been indicated/developed for the treatment of schizophrenia. However, development of MDL 100907 for acute schizophrenia was stopped. The combination of dopamine D₂ and 5-HT_{2A} receptor antagonism may still explain the beneficial antipsychotic activity of drugs such as clozapine, olanzapine, seroquel, and others.

BW 723C86 has agonist selectivity at the rat 5-HT_{2B} receptor, although less marked at human receptors, but activation of the 5-HT_{2B} receptor is most probably responsible for the valvulopathies reported for appetite suppressant preparations containing dex-fenfluramine, and 5-HT_{2B} agonism is therefore not being pursued anymore. 5-HT_{2B} receptor antagonists such as SB 200646 may be indicated for the treatment of migraine prophylaxis, given the vasodilatory role of this receptor and that a number of "older" antimigraine drugs share 5-HT_{2B} receptor antagonism. 5HT_{2B} antagonism may be a viable principle in pulmonary hypertension. On the other hand, PGN-1164 a 5-HT_{2B} receptor antagonist was in clinical trials for IBS, but stopped for PK reasons.

The anxiogenic component of mCPP may be mediated by 5-HT_{2C} receptor activation, and selective 5-HT_{2C} receptor antagonists such as SB 242084 or agomelatine display anxiolytic/antidepressant properties in animal models. Central 5-HT_{2C} receptor activation produces a tonic, inhibitory influence upon frontocortical dopaminergic and adrenergic, but not serotonergic transmission. 5-HT_{2C} receptor knockout mice have spontaneous convulsions, cognitive impairment, increased food intake, and obesity, but similar effects are not reproduced by selective antagonists, suggesting that these changes may result in part from neuroadaptation. Agomelatine a 5-HT_{2C} antagonist, combined with melatonin 1/2 receptor agonist, is effective in several animal models of depression and anxiety; it increases prefrontal dopamine and noradrenaline release. Several large, double bind placebo-controlled studies of Agomelatine have demonstrated that it is a clinically effective and well-tolerated antidepressant with a very low incidence of side effects. 5-HT_{2C} agonists (e.g. Org 37684, Ro 60-0175, YM348, or WAY-163909) produce positive effects in rodent models of depression, panic, and compulsive disorders.

On the other hand, 5-HT_{2C} agonists are being investigated in obesity, depression, and schizophrenia, and SCA-136, has entered phase II trials in schizophrenia.

The 5-HT₃ receptor antagonists ondansetron, granisetron, and tropisetron are used clinically in chemotherapy- and radiotherapy-induced nausea and vomiting. Since 5-HT₃ receptor activation in the brain leads to dopamine release, and 5-HT₃ receptor antagonists produce central effects compared to those of antipsychotics and anxiolytics, schizophrenia and anxiety were considered as potential indications. 5-HT₃ receptor antagonists have been reported to induce cognition enhancing effects. However, there are not enough clinical data to substantiate such activities. Similarly, that 5-HT₃ antagonists should prove useful in the treatment of migraine did not materialize in clinical studies. E-3620, a dual 5-HT₃ antagonist and 5-HT₄ agonist activity, was under development for IBS, chemotherapy-induced emesis, gastro-esophageal reflux but has been stopped. On the other hand, Alosetron (Lotronex[®]) is now indicated for women suffering from IBS with diarrhea (IBS-D).

Selective 5-HT₄ receptor ligands may have therapeutic utility in a number of disorders, including cardiac arrhythmia, neuro-degenerative diseases, depression, urinary incontinence, and GI motility disorders. Cisapride, a gastroprokinetic agent, acts as an agonist at the 5-HT₄ receptor, but was withdrawn due to side effects (QT prolongation). Metoclopramide is a 5-HT₄ agonist, but carries dopaminergic side effects. Other 5-HT₄ agonists in development are mosapride and prucalopride: the latter has been shown to increase bowel movement in volunteers, whereas mosapride had positive effects in functional dyspepsia. Piboserod (SB 207266), a potent and selective 5-HT₄ antagonist was investigated in IBS-D and increases oro-caecal transit time. Tegaserod (Zelmac/Zelnorm[®]), a new generation 5-HT₄ receptor partial agonist, was recently introduced in various markets to treat constipation predominant IBS (IBS-C) and constipation. Tegaserod's therapeutic activity in functional motility disorders of the upper G.I. tract is under clinical investigation.

Antipsychotics (clozapine, olanzapine, fluperlapine, and seroquel) and antidepressants (clomipramine, amitriptyline, doxepin, and nortriptyline) act as 5-HT₆ receptor antagonists. This attribute tempted speculations of an involvement of the 5-HT₆ receptor in psychiatric disorders, although these drugs are by no means selective. Selective 5-HT₆ receptor antagonists (e.g. Ro 04-6790, SB-399885, and BGC20-760) have positive effects in preclinical models of memory impairment and cognition, presumably by modulating Ach release. Clinical developments in 5-HT₆ antagonist field therefore concentrates on Alzheimer's disease. On the other hand, 5-HT₆ receptor agonists (e.g. WAY466 or LY586713) presumably by modulating GABA and BDNF have been shown to produce positive effects in preclinical

models for anxiety and depression. WAY-181187, a 5-HT₆ agonist, is being developed for generalized and acute anxiety disorders.

Atypical antipsychotics, e.g., clozapine, risperidone and antidepressants also have high affinity for the 5-HT₇ receptor. 5-HT₇ receptor downregulation occurs after chronic antidepressant treatment, and acute, but not chronic, stress regulates 5-HT₇ receptor mRNA expression. The presence of 5-HT₇ sites in the limbic system and thalamocortical regions, suggests a role in affective disorders, and the expression in the supra chiasmatic nucleus suggests a role in circadian rhythms. Various 5-HT₇ antagonists (e.g. SB-258741) were/are investigated in psychosis, schizophrenia, and circadian disorders.

Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor

JUDITH M. MÜLLER, ROLAND SCHÜLE
Universitäts-Frauenklinik und Zentrum für Klinische
Forschung, Klinikum der Universität Freiburg,
Freiburg, Germany

Definition

Sex steroid receptors are members of the steroid hormone receptor (SHR) family that ligand-dependently regulate functions of the sexual organs. Sex steroid receptors are the androgen receptor [1] (AR), the estrogen receptor α [2] and β [3] (ER α , ER β), and the progesterone receptor [4] (PR).

Basic Characteristics

The subgroup of SHRs belongs to the superfamily of ▶ nuclear receptors (NRs), which transactivate target genes ligand-dependently. Unliganded SHRs are associated with large multiprotein complexes of ▶ chaperones in the cytoplasm, in contrast to other NRs. SHRs comprise the glucocorticoid receptor and the mineralocorticoid receptor and the sex ▶ steroid receptors.

SHRs are built in a modular structure with similar structure elements. They contain a DNA-binding domain (DBD), a hinge region with a nuclear location signal (NLS), a ligand-binding domain (LBD) and several transcriptional activation functions (Fig. 1).

Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor.
Figure 1 Schematic structures of AR, ER α , ER β , and PR.

Their ligands are fat-soluble steroid hormones derived from cholesterol that bind to the LBD of their specific intracellular SHR after diffusing into the cell. After binding of the steroid hormone (K_d between 0.1 and 4 nM) the conformation of the SHR changes, exposing the NLS and the complex of steroid hormone and SHR gains access to the nucleus (Fig. 2). Utilizing the two zinc fingers of their DBD, SHRs bind as homodimers to unique DNA sequences called hormone response elements (HREs). The HRE is comprised of two half-sites organized as palindrome with a three nucleotide spacer. SHRs regulate the expression of target genes after association with large multisubunit complexes that contain transcriptional co-activators such as histone acetylases and several other proteins that facilitate transcription. Several signalling pathways furthermore influence the activity of SHRs, by modifying either SHRs directly or partner proteins. SHRs can also act without binding to DNA via interaction with other transcription factors, thereby altering their own or their partner's properties.

The physiological and pathophysiological roles of the sex steroid receptors are diverse and will be summarized separately for AR, ER α , ER β s, and PR in the following paragraphs. Estrogen related receptors (ERRs) share structural and functional similarities with ERs. They are orphan receptors indicating that there is no known natural ligand and are therefore not grouped as SHR.

Androgen Receptor

Androgens act via the AR and play an important role in the development and differentiation of the male sexual organ. Furthermore, they are involved in several diseases, the most important being partial and complete androgen insensitivity syndrome (AIS; formerly known as the testicular feminization syndrome), spinal and bulbar muscle atrophy (SBMA; Kennedy's disease), and the neoplastic transformation of the prostate. The two natural occurring androgens are testosterone (T) and the

Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor.

Figure 2 The classical activation pathway of SHR. SHRs (gray circle) are associated with chaperones (rectangles). After binding of steroid hormones (black circle) SHRs activate target genes in the nucleus. Additional regulation mechanisms, e.g., phosphorylation are described in the text.

more potent 5 α -dihydrotestosterone (DHT). T is mainly produced by the Leydig cells of the testis and can also be produced in most peripheral tissues from the adrenal-produced inactive steroid precursors dehydroepiandrosterone, its sulfate, and androstenedione. T is converted into DHT by the 5 α -reductase enzyme expressed in the urogenital tract. Besides positive regulation of target genes by the androgen-loaded AR, there is growing evidence of additional regulation pathways and indirect regulation mechanism of the AR. The expression of specific transcriptional coactivators of the AR in different tissues can fine-tune the transcriptional AR-activity. Ligand-independent activation of the AR by protein kinase pathways can circumvent the need for androgens. In addition, protein–protein interactions of the AR with

other transcription factors regulate the transcriptional activity of these partner proteins.

Eight exons of the AR gene encode a protein of around 917 aa depending on two polymorphic regions of polyglutamines (CAG) and polyglycines (GGN) in the N-terminal activation domain. Two isoforms are detected in tissues: the predominant (80%) 110 kD (B isoform) and 87 kD (A isoform). It is not clear whether the two isoforms also serve different functions.

The structure of the AR comprises an N-terminal transactivation domain of around 500 aa, a DBD of 66–68 aa, and a LBD of 250 aa. The hinge region contains the lysine-rich NLS. The AR possesses two activation functions (AFs): AF-1 in the N-terminal region and the AF-2 core domain in the LBD.

The AF-1 contains two polymorphic regions of CAG and GGN repeats. Normally the number of the 5' CAG repeats is 11–31 (average 21) whereas up to 50 repeats are found in individuals affected with SBMA. Since the number of glutamines inversely correlates with the transcriptional activity of the AR these amplified repeats lead to a reduced activity of the AR. The increased size of a polymorphic tandem CAG repeat is associated with the X-linked spinal and bulbar muscular atrophy and may also be associated with oligospermic infertility in men and with low serum androgens in a subset of anovulatory female patients. On the other hand, a shorter CAG length correlates with a higher risk; more severe and earlier onset of prostate cancer probably resulting from a higher activity of the AR. Experimental evidence also correlates increased or prolonged induction of AR activation with a higher incidence or acceleration of prostate cancer.

In the beginning, prostate cancer cells are largely dependent on androgens for growth and survival. Observations, that castration is beneficial in prostate cancer made androgen ablation and antiandrogen therapy a standard treatment for patients with metastatic prostate cancer following surgery of the tumor tissue. Antiandrogen therapy includes inhibition of androgen synthesis by aminoglutethimide or ketoconazole, inhibition of **▶5 α -reductase** by finasteride in combination with AR **▶antagonists** such as flutamide, or cyproterone acetate.

Unfortunately, remaining prostate cancer cells eventually adapt to grow in the low-androgen environment, rendering the tumor growth independent of androgens. Androgen-independent prostate cancer may result from one or more of the following mechanism: increased gene copy number, altered interaction of the AR with coregulatory proteins, e.g., resulting from AR mutations, bypassing of the AR pathway, or ligand-independent activation of AR, e.g., by protein kinase pathways.

Estrogen Receptor

Estrogens mainly affect the growth and maturation of the female reproductive system and the maintenance

of its reproductive capacity [5]. In addition, estrogens act on several other tissues, e.g., on lipid and bone metabolism. Uterus, placenta, and testis are the principal sites of 17 β -estradiol (E2) production. **▶Agonists** of ERs are used for treatment of menopausal symptoms **▶hormone replacement therapy (HRT)**, osteoporosis and cardiovascular diseases. **▶Antagonists** of ERs such as tamoxifen are used for treatment of breast cancer. Pure antagonist of ER that are as effective as tamoxifen without having tamoxifen's partial agonistic effects on ERs are in different phases of testing. The pure antagonist fulvestrant (ICI 183,780) is licensed as treatment for advanced breast cancer.

The main isoforms of the human ERs are ER α and ER β , which display distinct expression patterns. Additional ER isoforms, generated by alternative mRNA splicing, have been identified in several tissues. A cell-specific localization for each of the ER subtypes is found in the majority of the reproductive organs studied. The role of the different ER isoforms in modulating the estrogen response or in tumorigenesis is not completely understood. In addition, ERRs where coexpressed with ERs can influence the expression level of ER target genes either directly or by interaction with ERs. ERs bind most ligands with similar affinities and display equal transcriptional activation. However, in some assays ER isoforms respond differently to ligands. The naturally occurring phytoestrogen genistein or antiestrogens, such as tamoxifen or raloxifen are examples of these selective ERs modulators (**▶SERMs**). The characterization of SERMs that specifically regulate defined functions promises to increase efficacy and reduce side effects in estrogen-regulated processes (Table 1).

ER α

ER α (also called ESR1 and ESRA) is involved in the differentiation and maintenance of reproductive, neural, skeletal, and cardiovascular tissues. Two separate AFs mediate transcriptional activation, the ligand-dependent AF-2 in the LBD, and the ligand-independent AF-1 in the N-terminus. After binding of estrogen to the LBD, ER α activates target genes such as the progesterone receptor gene by binding to the estrogen response elements (EREs). Besides this classical activation, nonestrogen-dependent activation of ER α has been described. Signaling pathways and extracellular signals such as EGF, IGF-I, or insulin, stimulate phosphorylation of the receptor. Phosphorylation of ER α affects all steps of transcriptional activation, such as ligand binding, dimerization, DNA binding and interaction with cofactors. Heregulin is an example of an extracellular signal modulating ER activity. After binding to its receptor HER-2 ER is rapidly phosphorylated on tyrosine residues, followed by transcription of the *PR* gene. Since heregulin promotes hormone-independent

Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor. Table 1 Basic characteristics of sex steroid receptors

SHR	Gene map locus	cDNA size	Natural agonist	Binding half-site	Main expression
AR	Xq11–q12	ca. 919 aa (see text)	5 α -Dihydrotestosterone (DHT), testosterone (T)	AGAACA	Prostate, male urogenital system, muscle
ER α	6q25.1	595 aa	17 β -Estradiol (E2)	AGGTCA	Ovary, uterus, mammary gland, vagina, testis (Leydig cells), bone
ER β	14q22–q24	530 aa, 583 aa, further isoforms	17 β -Estradiol (E2)	AGGTCA	Ovary, testis (Sertoli and Leydig cells, efferent ducts), prostate, bone, thymus, spleen, brain
PR	11q22	Two isoforms: PRA 769 aa, PRB 933 aa	Progesterone	AGAACA	Uterus, ovary, central nervous system

growth of breast cancer cells, activation of ER by heregulin or HER-2 may be involved in the development of E2-independent cancer cells growth.

ER α can also regulate gene expression by interacting with different transcription factors. For example, interaction of ER α with the c-Rel subunit of NF- κ B prevents binding to NF- κ B response element resulting in reduced interleukin-6 transcription. Here, ER α acts E2-dependently but without directly binding to DNA. However, the complex formation of ER with the transcription factor Sp1 is hormone-independent and enhances Sp1 binding to DNA. ER α as well as ER β thereby enhance transcription of the retinoic acid receptor *al* gene. Other partner proteins are fos/jun family members, which regulate gene expression via AP-1 sites. In this situation E2 can either act as agonist in the presence of ER α or as antagonist in the presence of ER β . Another possibility to modulate ER signaling is the aryl hydrocarbon receptor (AhR). Ligands for AhR mediate antiestrogenic effects by several pathways.

The measurement of ER has become a standard assay in the clinical management of breast cancer. The presence of ER α identifies those breast cancer patients with a lower risk of relapse and better clinical outcome. Receptor status also provides a guideline for those tumors that may be responsive to hormonal intervention. But only about half of ER-positive patients respond to hormonal therapies. Of those who respond initially, most will eventually develop an estrogen unresponsive disease following a period of treatment even though ER α is often still present. Mutant receptors and constitutively active receptors as well as hormone-independent activation of the ER α are discussed. The involvement of ER β isoforms is under investigation.

Analysis of ER α -deficient mice showed that both sexes are infertile and display a variety of phenotypic changes associated with the gonads, mammary glands, reproductive tracts, and skeletal tissues. In addition,

both hyperplasia and hypertrophy of adipocytes were found in these mice.

In females, ovariectomy or menopause leads to rapid loss of trabecula bone and the osteoporosis indicating that E2 maintains bone mass. E2 enhances bone formation by osteoblasts and suppresses bone resorption by osteoclasts by regulating several important growth factors. In mice, ER α seems to induce growth but not maintenance of trabecular bone whereas ER β terminates growth during late puberty. However, while in humans the role of ER α and ER β in bone is not completely clear, ESRA polymorphism is related to bone density and height during late puberty and at attainment of peak bone density in young men.

ER β

In 1995 the discovery of ER β (also called ESR2 and ESRB) explained many actions of estrogens in tissues where no ER α was found. ER β shows high homology to ER α in the DBD and LBD, but encodes a distinct transcriptional AF-1 domain. At least five isoforms, designated ER β -1 through ER β -5, are described that differ in their C-terminal sequences and tissue expression patterns, or have extended N-termini. This new complexity of isoforms is further enhanced by the fact that ER β isoforms cannot only heterodimerize with each other but also with ER α . The functional consequences for the action of estrogens depending on the expression pattern are only beginning to be evaluated.

ER β is highly expressed in ovary, male organs, and parts of the central nervous system (CNS), but also in other organs such as spleen and thymus. The phytoestrogen genistein binds better to ER β than to ER α , whereas the partial ER α agonists tamoxifen, raloxifen and ICI-164 384 are antagonists for ER β . It has been postulated that co-factor recruitment is different for the ERs, however knowledge about this interesting field of selective ER regulation is only beginning to accumulate. Since only ER β is expressed widely in the male

urogenital tract of several animals it is now under evaluation whether the pronounced effects of E2 in men are caused by direct action of E2 on ER β in these reproductive organs. The view that E2 acts only indirectly by reducing androgen levels via the CNS clearly has to be corrected.

Analysis of ESRB^{-/-} mice showed fewer and smaller litters than wild type mice as well as abnormal vascular function and hypertension. The reduction in fertility was attributed to reduced ovarian efficiency. Mutant females had normal breast development and lactated normally. Older mutant males displayed signs of prostate and bladder hyperplasia. *Esr2*-deficient mice furthermore display diverse regulatory defects in the function of brain, lung, and white blood cells. The results indicated that ESRB is essential for normal ovulation efficiency but is not essential for lactation, female or male sexual differentiation, or fertility.

Progesterone Receptor

The PR is involved in diverse functions in female reproduction, such as implantation of the embryo, and in the maintenance of pregnancy. Progesterone is mainly produced in the corpus luteum in the second half of the menstrual cycle and in early pregnancy, later in the placenta. The PR is expressed in the uterus, ovary, and the CNS. In men there is no known function. Estrogens induce expression of the *PR* gene. PR agonists such as medroxyprogesterone or the synthetic R5020 are called progestins or gestagens.

The human PR exists as two functionally distinct isoforms PRA and PRB transcribed from two promoters from a single gene. PRA lacks the N-terminal 164 aa and is a 769 aa protein. PRB functions as a transcriptional activator in most cell and promoter contexts. In contrast, PRA is transcriptionally inactive and functions as a strong ligand-dependent transdominant repressor of SHR transcriptional activity. Different cofactor interactions were demonstrated for PRA and PRB, probably due to an inhibitory domain within the first 140 aa of PRA, which is masked in PRB. Both PR isoforms however, repress estradiol-induced ER activity when liganded. Several other mRNA isoforms are present in PR-positive tissues such as breast cancer with unknown clinical significance.

PRs also interact with other signaling pathways, which can, e.g., be regulated by phosphorylation. Independent of transcriptional activation of PR, progestins can activate cytoplasmic signaling molecules including SRC and downstream MAP kinase in mammalian cells via interaction by a specific polyproline motif in the N-terminal domain of PR.

Mice models reveal that both PR forms are physiologically important. Mice lacking the *PR* gene fail to ovulate, are infertile, and have impaired thymic function. Selective PRA-deficient female mice are infertile due to reduced oocyte and uterine deficiency

in implantation. However, these mice had normal mammary epithelium proliferation and differentiation and showed normal thymic involution. In mice, PR regulates expression of proteases that degrade the follicular wall thereby facilitating ovulation.

In breast cancer patients, total PR status is measured for hormonal treatment. The presence of PR is associated with increased survival rates and hormonal responsiveness of mammary tumors. PR agonists are widely used in contraception, HRT, breast cancer, and endometrial hyperplasia. ▶ **Antiprogestins** such as RU486 are used for blocking ovulation and preventing implantation, and in addition they are in clinical testing for the induction of labor and to control various neoplastic transformations.

▶ **Selective progesterone receptor modulators (SPRM)** (mesoproggestins) are PR ligands with agonistic and antagonistic activities. Some SPRM show weak antigluco-corticoid or mixed androgenic/antiandrogenic activities. SPRM are currently tested and may be useful, e.g., for the treatment of endometriosis.

Drugs

In clinical use are pure and partial agonists and antagonists (see individual SHR) as contraceptives, treatment for hormonal ablation in breast and prostate cancer, and HRT in osteoporosis.

SH2, Domains

The Src homology 2 domain (or SH2-domain) is a protein domain of about 100 amino acid residues first identified in the tyrosine kinase Src. SH2-domain

mediates protein–protein interaction with a phosphorylated tyrosine residue in interacting proteins. This binding triggers a change in sub-cellular localization or enzyme activity crucial in signalling pathway.

- ▶ Phospholipids Glossary
- ▶ Adaptor Proteins
- ▶ Tyrosine Kinases

SH3 Domain

Synonyms

src homology 3

Definition

Protein-protein interaction domain that binds to poly-proline motifs with the sequence PXXP. Particularly important in assembling protein complexes at activated receptors which contain intrinsic tyrosine kinases.

- ▶ Adaptor Proteins

Shaker-Channels

Shaker-channels, eag (ether-á-go-go)-channels, slo (slow-poke)-channels were cloned from behavioral *Drosophila melanogaster* mutants. The channels were named according to the *Drosophila* mutant phenotype, Shaker, ether-go-go, slow-poke. Subsequently, eag-cDNA was used to clone related voltage-gated potassium channel subunits erg (eag-related) and elk (eag-like). The human erg ortholog (HERG) mediates cardiac IKS.

- ▶ Voltage-gated K⁺ Channels

Shine-Dalgarno Interaction

The Shine-Salgano interaction is a base pairing interaction that occurs during translation initiation in prokaryotes between the Shine-Dalgarno sequence on messenger RNA (mRNA) and the anti-Shine-Dalgarno

sequence on 16S ribosomal RNA (rRNA). The Shine-Dalgarno sequence is a purine-rich sequence located four to seven bases upstream of the initiation codon in prokaryotic mRNAs. It has variable length and complementarity to the anti-Shine-Dalgarno sequence found in the 3'-end region of all bacterial 16S rRNAs (and in archaeal and chloroplast 16S rRNAs).

SIADH

Syndrome of inappropriate antidiuretic hormone is defined by water retention, dilutional hyponatraemia and decreased volume of highly concentrated urine. There are several causes which can result in SIADH, neoplasms ectopic secreting AVP, ectopic release of AVP by various diseases or drugs, exogenous administration of AVP, desmopressin, lysipressin or large doses of OT (iatrogenic SIADH).

- ▶ Vasopressin/Oxytocin

Sialic Acid

Sialic acid is a carbohydrate that can be attached to certain molecules, e.g., epoetin alfa.

- ▶ Hematopoietic Growth Factors

Sialin

Sialin was first identified as the product of the gene defective in sialidosis, a lysosomal storage disorder. The transporter mediates the movement of sialic acid out of lysosomes by coupling to the proton electrochemical gradient across the lysosomal membrane. Unlike the vesicular neurotransmitter transporters which are antiporters, sialin is a symporter with sialic acid and protons both moving out of the lysosome.

Signal Peptidases

Specific proteases located on the luminal side of the endoplasmic reticulum. They cleave the amino-terminal peptides from the precursor forms of membrane and secretory proteins.

► Protein Trafficking and Quality Control

Signal Recognition Particle

The signal recognition particle (SRP) is a cytosolic ribonucleoprotein complex which binds to signal sequences of nascent membrane and secretory proteins emerging from ribosomes. The SRP consists of a 7S RNA and at least six polypeptide subunits (relative molecular masses 9, 14, 19, 54, 68, and 72 kD). It induces an elongation arrest until the nascent chain/ribosome/SRP complex reaches the translocon at the endoplasmic reticulum (ER) membrane.

Simulated Annealing

Simulated annealing is a type of molecular dynamics experiment in which the temperature of the system is cycled over time with the goal of widely sampling conformational space. There are two basic ideas. The first is to create a computational analog of experimental annealing techniques and the second is to use controlled mechanisms for obtaining different initial structures by using temperature to surmount torsional barriers. Heating to a higher temperature (e.g., 1,000K) allows the system to rearrange from the present state, cooling to a lower temperature brings the system into a stable state. The cycle is repeated several times (e.g., 100), so that multiple conformations may be obtained. Favorable and stable geometries occur in clusters of similar conformations. During the cooling phases it is possible to introduce constraints between atoms coming from experiments. This procedure is applied to calculate structures based on atom distances like nuclear Overhauser effect (NOE) distances and other geometrical data produced by nuclear magnetic resonance (NMR) spectroscopy.

► Molecular Modeling
► NMR-based Ligand Screening

Single Nucleotide Polymorphism

Single Nucleotide Polymorphisms (SNPs) are single base pair positions in genomic DNA at which normal individuals in a given population show different sequence alternatives (alleles) with the least frequent allele having an abundance of 1% or greater. SNPs occur once every 100–300 bases and are hence the most common genetic variations.

► Bioinformatics
► Pharmacogenomics

Sinus Rhythm

The sinus rhythm is the heart rhythm in which the sinus node generates an electrical impulse that travels through specialized cells (that form a conduction system) and leads to a ventricular contraction.

- ▶ Cardiac Glycosides
- ▶ Antiarrhythmic Drugs

siRNAs

Small interfering RNAs (siRNA) are the mediators of gene-specific silencing by RNA interference. SiRNA stands for small interfering RNA duplexes. They are typically 21-23 bp in length. SiRNA were either chemically synthesised for experimental purposes or produced by Dicer-mediated cleavage of long double-stranded RNA.

Sleep

BJARKE EBERT¹, KEITH WAFFORD²,
NEIL ANDERSON³

¹Department of Electrophysiology, Copenhagen, Denmark

²Lilly and Co. Eri Wood Manor, Windlesham, Surrey, UK

³Department of Neuropharmacology, Copenhagen, Denmark

Definition

Sleep is a state common to most mammals, birds, fishes and invertebrates. It describes a state in which brain activity changes from that of the waking brain, resulting in outward signs such as immobility and a decreased responsiveness to external stimuli. The function of sleep is not yet fully understood, although its importance is undeniable, in that an organism chronically deprived of sleep will eventually die. Sleep itself is not homogenous, and can be divided into various states representing different patterns of electrical activity. The underlying biology and complex interaction of various neurotransmitter systems in initiating, maintaining and shaping sleep are now beginning to be better understood, paving the way for more precise and effective pharmacological treatment of sleep disorders.

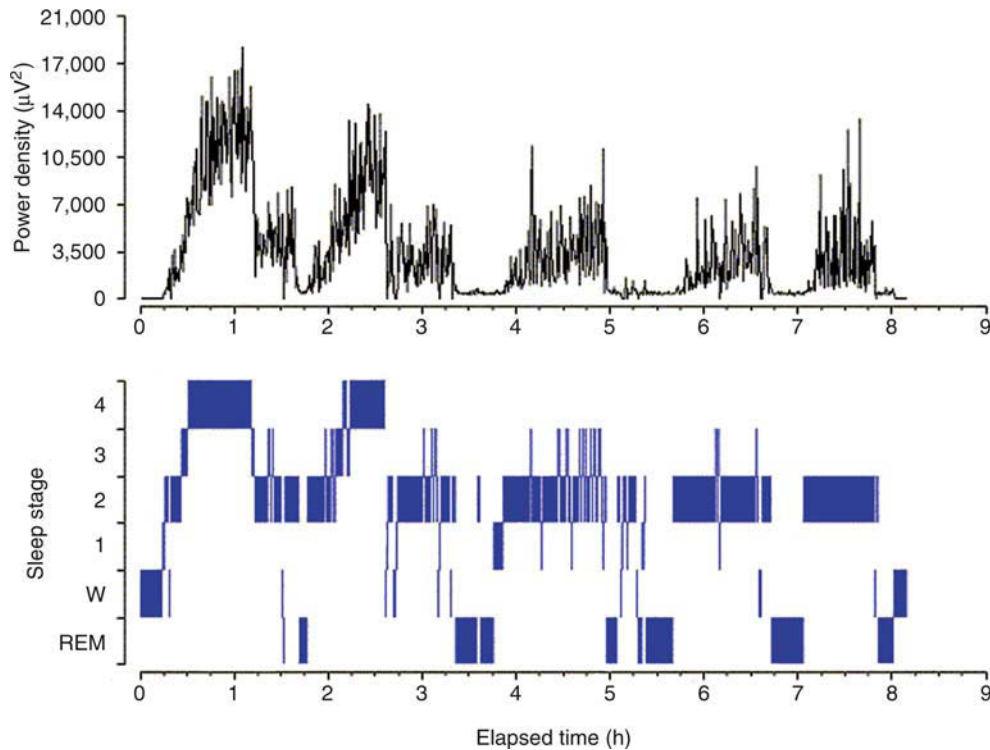

Basic Mechanisms

Molecular Mechanisms Underlying Sleep: Focus on GABA

Like waking, sleep is an active state of the brain. During this heterogeneous and rapidly changing state several restorative functions take place, although the neural substrates of somatic and cognitive restoration remain elusive. A detailed description of the components of sleep, as well as the underlying neurochemistry and circuitry is now slowly emerging.

Division of Sleep States

Sleep is generally considered to consist of two substates, ▶ Rapid Eye Movement (REM) and ▶ non-Rapid Eye Movement (NREM) sleep, which alternate to form a cycle lasting ~90 min in man (Fig. 1). ▶ REM and

Sleep. Figure 1 Slow wave sleep (SWS) and slow wave activity (SWA). The bottom panel illustrates a *hypnogram* showing the amount of time spent in the different sleep stages over the course of the night, using traditional visual scoring criteria. Each progression through the 5 stages (Stages 1–4 and REM) constitutes a sleep cycle. The top panel represents a fast Fourier transform of EEG data. The frequency band selected for power analysis was 0.75–4.5 Hz. This representation illustrates that SWA is present throughout the night, even when the sleeper does not reach stage 3 or 4 according to traditional visual scoring criteria (Dijk, unpublished data).

► **NREM** sleep can clearly be differentiated on the basis of a number of physiological variables including muscle tone, ► **electroencephalographic** (EEG) and electromyographic (EMG) features, and the presence or absence of rapid eye movements [1]. Distinct physiological roles for REM and NREM stages have been proposed, but compelling empirical data are scarce.

Real sleep in a living brain is a continuous state without clear transitions. Therefore, a temporal description of the waves and alterations in the amount of both frequencies and amplitudes should most likely be based on an analysis of these waveforms. However, for historical reasons, ► **sleep stages** are described as either REM or NREM stages 1–4 using visual scoring criteria based, in part, on the quantity and gross type of EEG waveforms per unit time. These are combined together graphically into a hypnogram (A graph detailing time along the *x* axis and *sleep stage* on the *y* axis. These are commonly used to depict the progression and relative proportion of the various *sleep stages* through a night's sleep) as shown in Fig. 1. NREM stages 1 and 2 have been described as light sleep, while stages 3 and 4 are often described as deep or ► **slow wave sleep (SWS)**. The hallmark waveform of SWS consists of rhythmic,

low-frequency waves (~ 0.5 – 4.5 Hz). These electrical patterns also occur outside of stages 3 and 4, but to a much smaller extent, and are referred to as ► **slow wave activity (SWA)**. The amount of SWA in the ► **EEG** can be quantified by application of the Fourier transform to the complex signal, providing another objective means of evaluating the sleep process (Fig. 1).

SWS/SWA, in particular, may play an important role in somatic and cognitive restoration, including the consolidation of certain forms of procedural and declarative memory. A substantial diminution in the amount of SWS/SWA occurs across the human lifespan. This decline is beginning already in adolescence and middle-aged adults have only 25% of the SWS observed in young adults, whereas the elderly have almost none. While the clinical importance of these phenomena is unknown, it is reasonable to speculate that they may be related to the increase of sleep complaints associated with aging.

Regulation of Sleep

Sleep is thought to be under the control of two independent processes: one homeostatic (process S) and the other circadian (process C), which together

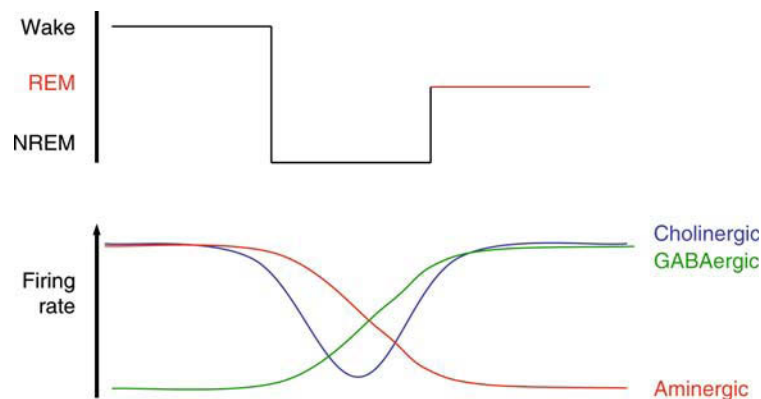

determine sleep propensity [2]. Process S represents a drive for sleep that increases progressively with wakefulness, and is most clearly seen under conditions of sleep deprivation, when “sleep debt” accumulates [2]. Failure to liquidate the debt through sleep results in profound neurobehavioral and cognitive deficits, as demonstrated during sleep restriction studies. Dissipation of the homeostatic drive for sleep is hypothesised to depend on time spent in NREM sleep. The amount of SWS/SWA in particular is thought to be an important marker of process S, since this parameter correlates strongly with sleep need.

Several gaps remain in our understanding of the neurobiological basis of the homeostatic process S. However, the data support a critical role for the ventrolateral preoptic area (VLPO), a dense cluster of neurones that inhibit ascending brainstem ►arousal pathways [3]. Specifically, the VLPO contains inhibitory (GABAergic and galanergic) efferent projections to arousal centres in the posterior hypothalamus and brain stem – including the tuberomammillary nucleus (TMN; histaminergic), locus coeruleus (noradrenergic) and the dorsal raphé (serotonergic). These ►arousal systems promote wakefulness via signals to thalamocortical and cortical pathways, with neuronal firing highest during wakefulness, declining through NREM sleep to quiescence during REM sleep (Fig. 2). In contrast, cholinergic activity is linked directly to the degree of cortical activation (observed in the EEG signal as high frequency, low amplitude activity), with the highest firing rates during waking and REM sleep [4]. While the mechanistic details are still under investigation, lesion studies have shown that VLPO neuronal activity (as indicated by expression of the

immediate-early gene *c-fos* and discharge rates) correlates closely with the onset, maintenance, and depth of NREM sleep. Conversely, during wake, VLPO activity is opposed by that of the major arousal systems. According to the model proposed by Saper et al., these reciprocal inhibitory projections produce a bistable system that resists change [3]. When pressure to change increases – during extended wakefulness, for example – the system flips from one state to another. The opposing, mutually inhibitory, actions of the ascending arousal and descending VLPO systems are stabilised by the orexin (hypocretin) system. During wakefulness, orexinergic activity is high, reinforcing the ascending arousal drive. In contrast, during sleep, this reinforcement is removed via VLPO inhibition of the orexinergic neurones [3].

Pathological conditions in which the VLPO system is weakened (i.e. less drive for sleep) could, therefore, result in more frequent changes between wakefulness and sleep, as has been demonstrated in animal models. Interestingly, elderly individuals have significantly reduced numbers – often by as much as 50% – of sleep-promoting VLPO neurones, an age-related loss of VLPO cells that may explain, at least partially, this population’s characteristic difficulty in falling and staying asleep.

Subserving process C is an endogenous ►circadian “clock” in the suprachiasmatic nucleus (SCN) of the anterior hypothalamus that regulates the timing of daily transitions through sleep and wake. Incoming light from the retinal hypothalamic tract triggers the SCN to increase arousal levels. The arousal pathway is tightly regulated, as SCN innervation of the pineal gland also triggers the secretion of ►melatonin, which

Sleep. Figure 2 Relative activity of the aminergic (red), cholinergic (blue) and GABAergic systems (green) systems in relation to the arousal states. Cholinergic activity is directly correlated with cortical activation, as seen in the high frequency EEG activity recorded during the wake and REM states. The aminergic (NA, 5-HT, histamine) system is considered to be an arousal system, and accordingly activity is highest during wake and lowest during REM sleep. Aminergic activity is regulated by negative feedback from the GABAergic system emanating from the diffuse ventrolateral preoptic (VLPO) region. Figure constructed from information in the reviews by Jones [4] and Saper et al. [3].

substantially reduces this wake-promoting output. Melatonin is an important phase marker and regulator of the circadian clock, with secretion normally synchronised with nocturnal sleep and daytime wakefulness. However, melatonin is more correctly regarded as a “darkness hormone” rather than a sleep-inducing hormone, since it is secreted at night in nocturnal species as well as those active during daylight. The chronobiotic rather than hypnotic role of melatonin is further highlighted, however, by the fact that following ►phase shifts and in certain pathological conditions, melatonin secretion becomes uncoupled from sleep.

These insights into the structure of sleep and the neurobiological processes underlying it have yielded several targets for therapeutic intervention and provided novel methods by which to assess the differential effects of hypnotics on sleep-relevant neural circuits.

Sleep Disorders

Sleep disorders can be broadly divided into two categories: *dysomnias and parasomnias* (Table 1). *Dysomnias* are conditions of either too much sleep (hypersomnolence), or too little sleep (insomnia). ►Insomnias defined as difficulty in initiating or maintaining sleep, or poorer overall sleep quality. This is the most prevalent of sleep disorders, with as many as one in four reporting having experienced symptoms, and at least 10% of the population that consider this a chronic problem. ►Insomnia can be caused either by internal influences (e.g. dysfunction in the sleep–wake control mechanisms), external influences (e.g. changes in sleeping environment, light cycle, stimulant drugs) or as a secondary symptom of a comorbid disease (e.g. depression, anxiety, schizophrenia, Parkinson’s disease). ►Narcolepsy – a disease characterised by sudden, unpredictable transitions from wake to sleep and vice versa – is one of the few disorders for which a direct molecular basis has been established. Patients suffering from narcolepsy have been found to have under active orexin systems, usually as a result of cell loss, thereby removing the stabilising “finger on the switch” influence

of the system on arousal [3]. In contrast to the dysomnias, which are related to disruption of the sleep/wake control mechanisms, parasomnias are characterised by the presence of abnormal events during sleep. One intriguing parasomnia is that of REM sleep behaviour disorder, where patients experience an increased amount of REM sleep during which the normal inhibition of motor activity is absent. This manifests itself as sudden and violent outbursts during sleep (both vocal and physical) that can be immensely distressing for both the patient and those sleeping in the same environment. REM sleep behaviour disorder is often comorbid with Parkinson’s disease, and is currently thought to potentially represent an early indication of disease progression.

Pharmacological Intervention

Currently, the majority of all approved drugs for treating insomnia interact with the ►GABA_A receptor system. The major focus of the rest of this overview will therefore be on these types of drugs and the introduction of two novel approaches, either recently approved or in late stage development.

The most widely prescribed group of hypnotics all belong to the ►benzodiazepine receptor agonists (BzRAs). Biochemical and animal model studies have contributed greatly to our understanding of the receptor interactions by which the BzRAs achieve their sedative–►hypnotic effects. However, a clear understanding of exactly how these mechanisms contribute to the transition between different brain states is still rudimentary. At the receptor level, BzRAs allosterically enhance the ability of GABA to increase inhibitory chloride currents through the ion channel intrinsic to GABA_A receptors [5]. Diazepam, temazepam and other classical benzodiazepines bind at the interface between γ_2 and α subunits, within the same binding pocket as zolpidem and other non-benzodiazepine hypnotics, so called because of their chemically distinct structure. Classical benzodiazepines demonstrate roughly equivalent binding affinities for all γ_2 -containing GABA_A receptor subtypes, while the non-benzodiazepines zolpidem and zaleplon demonstrate about tenfold binding selectivity for the $\alpha_1\beta\gamma$ subtype. The extent to which this ►binding selectivity translates into ►functional selectivity in vivo is a matter of intense interest. Indeed, using a variety of expression systems, investigators have measured the enhancement of GABA-evoked chloride conductance to characterise the potency and efficacy of these types of compound. Results suggest that in the context of physiological concentrations, the majority of BzRAs demonstrate little in the way of subtype selectivity.

BzRAs significantly reduce ►sleep latency and the number and duration of awakenings, resulting in increased total sleep and improved sleep continuity.

Sleep. Table 1 Examples of various dysomnias and parasomnias

Dysomnias	Parasomnias
►Insomnia	Sleep walking
►Narcolepsy	Bedwetting
►Restless legs syndrome	Sleep talking
►Sleep apnea	►REM (sleep) behaviour disorder
►Periodic limb movements	
Circadian sleep disorders	

Their clinical profile, however, is marked by residual daytime sleepiness, ►anterograde amnesia, and, importantly, withdrawal symptoms on discontinuation of therapy, reflecting their significant potential for physical dependence and abuse. Studies in baboons also demonstrate reinforcing properties underlying their abuse liability. The relatively non-selective binding and long half-lives of the benzodiazepines – ranging from 47–100 h for flurazepam to 2–5 h for triazolam and 8–20 h for temazepam, the two short-acting benzodiazepines currently indicated for insomnia – are believed to account for their significant residual effects.

The non-benzodiazepine BzRA hypnotics have pharmacological profiles distinct from those of the classical benzodiazepines, and are regarded as an important advance in the treatment of insomnia. Firm generalisations about clinically important differences between these and classical benzodiazepines cannot be made, however, given the paucity of head-to-head clinical comparisons at equipotent doses. Pharmacokinetic properties such as bioavailability, plasma half-life, elimination rate, and blood–brain barrier penetration more transparently influence the onset and duration of hypnotic effects and, to some extent, next-day neuro-behavioral and cognitive consequences. Compounds in this class include zolpidem, zopiclone, eszopiclone, indiplon and zaleplon. The receptor subtype selectivity and improved pharmacokinetic profile of the non-benzodiazepines compared with the benzodiazepines have yielded some clinically important benefits. Nonetheless, the abuse liability of these compounds, particularly that of zaleplon, zopiclone and eszopiclone, has been suggested to be similar to that of benzodiazepines like temazepam and triazolam. In addition, at least at higher doses, tolerability concerns exist even with the newer medications, particularly with respect to residual and amnesic effects. There is thus interest in developing compounds that target different receptors, having more specific effects on the regulation of sleep without these side effects.

Several novel approaches to the treatment of insomnia have attracted much attention among researchers.

Gaboxadol is a Selective ►Extrasynaptic GABA_A receptor Agonist (SEGA), a new class of GABAergic drug that activates receptors located primarily at regions outside of the synapse. In functional assays, gaboxadol selectively elicits chloride conductance through δ -subunit containing ►GABA_A receptor subtypes. The biophysical basis of this functional selectivity remains an active area of research. Notably, the BzRAs are unable to bind δ -containing GABA_A receptor subtypes, suggesting a completely different target to that of BzRAs. These ►extrasynaptic receptors show a limited CNS distribution and are particularly enriched in the cerebral cortex, limbic system and thalamus. Recent studies have demonstrated that gaboxadol enhances a

bicuculline-sensitive but zolpidem- and midazolam-insensitive tonic current in thalamic relay neurones in mice. Whether this extrasynaptic conductance is linked to the ►thalamocortical synchronisation that drives SWS and SWA is a question of particular interest, since gaboxadol significantly increases SWS and SWA in animals and humans. In drug discrimination studies, rats and primates trained to recognise BzRAs did not respond when administered gaboxadol, demonstrating a qualitative difference in the effects of gaboxadol compared with the BzRAs, and highlighting the novelty of this compound with respect to the older medications.

Ramelteon, a selective melatonin receptor agonist with high affinity for MT₁ and MT₂ receptors located in the SCN, has recently received FDA approval for patients with difficulty falling asleep. Studies in animals indicate that ramelteon significantly decreases wakefulness and increases SWS and ►REM compared with placebo. Beneficial effects of ramelteon on sleep have been confirmed in clinical studies. However, in contrast to findings in animals, clinical studies have not indicated an increase in SWS with ramelteon. Neither ►rebound insomnia nor withdrawal effects have been observed following chronic administration. Ramelteon thus lacks abuse potential, a direct consequence of its distinct mode of action, and is therefore not a scheduled drug.

Serotonin_{2A} receptors have also been the focus of sleep enhancing agents on the basis that they promote SWS in both animal models as well as clinical trials, without the side effects associated with BzRAs. The precise interactions of these compounds within the sleep control pathway remain to be elucidated.

In addition to insomnia, narcolepsy is also relatively well treated by the range of medications available today. Daytime sleep intrusions are generally combated using stimulants such as amphetamine or modafinil, and cataplexy (sudden loss of muscle tone during the sleep episode) using some of the older antidepressant compounds. A more novel approach is offered by the hypnotic sodium oxybate, which is reported to alleviate symptoms of narcolepsy by improving the continuity of the night time sleep. The wake promoting medication modafinil is of particular note, in that it appears to be able to elicit periods of extended wakefulness, without causing rebound hypersomnolence.

Much has been discovered recently regarding the molecular mechanisms and pathways involved in sleep and its associated disorders. It is hoped that this knowledge will lead to improved therapeutics lacking the side effects of currently available drugs.

Sleep Apnea

A condition which is characterised by pauses in breathing during sleep. Each pause lasts long enough to miss several breaths and is normally repeated throughout the night. Can be caused centrally by a disruption in respiratory control or obstruction of airways during sleep through lack of muscular tone or some other obstruction. Sleep apnea can cause deprivation of deep sleep and daytime sleepiness.

► Sleep

Sleep Continuity

A measure used to assess sleep quality, usually determined by means of *polysomnography*. A parameter such as “wake after sleep onset” (WASO) is often used to describe sleep continuity.

► Sleep

Sleep (Onset) Latency

Time taken to fall asleep from full wakefulness. Used clinically as a measure of insomnia, and to determine the effectiveness of *hypnotic* medications.

► Sleep

Sleep Quality

Determinations of the quality of sleep can either be made based on patient report (i.e. perceived sleep quality), using standardised questionnaires, or by more

objective measurements (e.g. *sleep latency*, *sleep continuity*) obtained via *polysomnographic* recording of the sleep period.

► Sleep

Sleep Stages

Since the publication of the *Standardised Sleep Manual* by Rechtschaffen and Kales (Eds) in 1968, human sleep has been described using a classification system based on a combination of EEG, EMG and EOG features. The acquisition and use of such data is known as *polysomnography*. Note, that when including the state of WAKE in the classification, these are most accurately described as *arousal states* in place of sleep stages.

Electroencephalographic (EEG), electro-oculographic (EOG) and electromyographic (EMG) feature characteristic of the stages of sleep (NREM stages 1–4 and REM) and wake. The distinctions between REM and NREM sleep are dramatic and qualitative, including differences in EEG and EOG patterns, changes in heart

Stage	EEG characteristics	EOG	EMG muscle activity
W	Predominant alpha activity (more than 50% of the epoch) mixed with EEG beta	Slow and rapid	High
1	Alpha activity is replaced by predominant low-voltage, mixed-frequency background activity sometimes with vertex sharp waves	Slow	Decreased from wake
2	Sleep spindles and K complexes in a background EEG that has less than 20% delta activity	None	Decreased from wake
3	Slow waves (EEG delta activity) comprise 20%–50% of the epoch; sleep spindles usually are present	None	Decreased from wake
4	More than 50% of the epoch has EEG delta activity	None	Decreased from wake

rate and respiration, and the presence or absence of muscle tone. Distinctions between NREM stages are more arbitrary and are centred on a progressive increase in amplitude and slowing of the EEG with successive stages. “Depth” of sleep, as indexed by an increase in the arousal threshold, increases with progression through NREM stages.

Slow Wave Activity

Synonyms

SWA

Definition

Oscillations in the EEG of between 0.5 and 4 Hz, sometimes also called delta activity. SWA is a hallmark of the sleeping brain, and is most prevalent in the deepest *sleep stages* (stages 3–4). The slow oscillations arise from widespread synchrony of neuronal firing, particularly in the thalamocortical circuits.

► Sleep

Slow Wave Sleep

Generic term usually applied to the deeper *stages* of NREM sleep (stages 3 and 4), so called because of the high proportion of slow wave activity (SWA).

► Sleep

Smad

(Mothers against decapentaplegic homolog) A group of related intracellular proteins with a key role in the transforming growth factor- β signaling cascade composed of three domains: an N-terminal Mad homology 1 (MH1) domain, a nonconserved linker region, as well as a C-terminal MH2 domain. There are at least eight different Smad proteins in vertebrates responsible for transmitting TGF- β signals from the cell surface to the nucleus and are grouped into three classes: (i) Receptor-activated Smads (R-Smads) – Smad1, Smad2, Smad3, Smad5 and Smad8; (ii) Comediator Smad – Smad4; and (iii) Inhibitory Smads (I-Smads) – Smad6 and Smad7.

Low molecular mass GTPases; Small G proteins

Definition

Small GTPases are monomeric 20 to 40 kD GTP-binding proteins that interconvert between an active (GTP-bound) and an inactive (GDP-bound) state. As molecular switches they are involved in the regulation of complex cellular processes.

Basic Characteristics

Regulation

Activation of small GTPases occurs by GDP/GTP exchange catalyzed by ► [guanine nucleotide exchange factors \(GEFs\)](#) (Fig. 1). They stimulate the dissociation of GDP in response to an upstream signal and results in the binding of GTP. In the GTP-bound form the GTPases are active, and bind to and activate a number of effector molecules. The small G proteins are able to

Small GTPases. Figure 1 The GTPase cycle: GTPases are inactive in the GDP-bound form. In a complex with guanine nucleotide dissociation inhibitors (GDIs) the inactive form is stabilized (note, not all small GTPases are regulated by GDIs, e.g. not Ras, Ran and Arf subfamily proteins). Guanine nucleotide exchange factors (GEFs) cause the release of GDP and binding of GTP, and thereby the activation of the proteins. The active state of the GTPases is turned off by GTP hydrolysis catalyzed by GTPase activating proteins (GAPs).

hydrolyse the bound nucleotide to GDP. This inactivation step is accelerated by **GTPase activating proteins (GAPs)**. In the GDP-bound form the GTPases are inactive and some bind then to **guanine nucleotide dissociation inhibitors (GDIs)** that stabilize the inactive form and cover the lipid modification of the GTPase as a cytosolic complex. Novel roles of GDI in GTPase regulation like the delivery of GTPases to specific sites within the cell are discussed. Moreover, local synthesis and degradation of GTPases seem to play additional roles in the spatial regulation of small GTPases. In mammalian cells, each family of GTPase regulating proteins comprise numerous members which are more or less specific for individual GTPases, cell types, GTPase functions and signal pathways.

General Structural Properties

All small GTPases are folded in a similar way. They possess four consensus amino acid sequences in common, which are involved in nucleotide binding and hydrolysis: GXXXXGK, DXXG, NKXD and EXSAX. Two highly flexible regions (Switch I and Switch II regions) determine the nucleotide-dependent activity state of the GTPases and the protein–protein interactions with effectors and regulatory proteins.

Post-Translational Modification

All small GTPases (except Ran) are post-translationally modified. Most important is the isoprenylation of the C-terminus. The type of modification is determined by

the COOH-terminal amino acid sequence. GTPases with a C-terminal CAAX-box (A = aliphatic amino acid, X = any amino acid) are farnesylated at the cysteine residue followed by the proteolytic degradation of the last three amino acids and subsequent methylation of the carboxy-terminus. In the case of a CAAL or CAC, the cysteines are modified by geranylgeranylation. In some cases an additional cysteine is palmitoylated or N-terminal myristoylation occurs. All these post-translational modifications allow the interaction of GTPases with the phospholipid bilayer. Lipid modification of the GTPases is required for their membrane localization and GDI binding.

Families

The superfamily of small GTPases consists of more than 100 members from yeast to human with more than 80 members expressed in mammalian cells. Based on structural and functional similarities the GTPases are subdivided into five major classes.

Ras GTPases

The mammalian family of Ras GTPases consists of more than 15 members which share high homology to each other and include Ha-Ras, Ki-Ras, N-Ras, R-Ras, Rap, Ral, Rheb, Rin and Rit proteins (1). Ras proteins have achieved attention with the discovery that they contain point mutations in 15% of all human tumours (more than 90% in pancreatic tumours), leading to the exchange of conserved amino acids, e.g. at positions 12 and 61. Amino acid exchanges at these positions block the GTP hydrolase activity of the GTPases, resulting in constitutive activation. Ras GTPases are involved in signal transduction of proliferation and/or differentiation. They couple receptor tyrosine kinases with a protein kinase cascade termed Raf/ERK kinase pathway (also known as MAP kinase cascade). Activation of this pathway leads to phosphorylation and activation of transcription factors like Elk-1, and stimulate gene expression. Activated Ras has been shown to transform culture cells and to produce tumours in nude mice. Besides the Raf kinase, the RalGDS, which is an activator of the Ral subfamily proteins, and the PI3 kinase, which is involved in inositol signalling, are important effectors of Ras. Ral GTPases (<50% identical with Ras) control cell proliferation, Ras-mediated cell transformation, vesicle traffic, phospholipase D and cytoskeleton organization. Rap GTPases have been identified in a screen for cDNAs that are able to revert the transforming phenotype of Ki-Ras (Kirsten Ras) and, therefore, were also termed K-rev proteins.

Rho GTPases

Members (>20) of the Rho family of GTPases, including RhoA, B and C, Cdc42 and Rac1, 2, 3,

share more than 50% sequence identity. The GTPases are important regulators of the actin cytoskeleton (2). RhoA regulates the formation of actin stress fibres, whereas Cdc42 is known to induce filopodia. Rac is involved in the formation of lamellipodia and membrane ruffles. Rho GTPases are involved in migration, phagocytosis, endo- and exocytosis, cell–cell and cell–matrix contact. Rac regulates NADPH oxidase. Furthermore, Rho GTPases are involved in transcriptional activation, cell transformation and apoptosis. Rho GTPases are regulated by a large number of GEFs and GAPs (>60 members of each family have been identified), suggesting function-specific regulation of the activity state.

A subfamily of Rho proteins, the Rnd family of small GTPases, are always GTP-bound and seem to be regulated by expression and localization rather than by nucleotide exchange and hydrolysis. Many Rho GTPase effectors have been identified, including protein and lipid kinases, phospholipase D and numerous adaptor proteins. One of the best characterized effector of RhoA is Rho kinase, which phosphorylates and inactivates myosin phosphatase; thereby RhoA causes activation of actomyosin complexes. Rho proteins are preferred targets of bacterial protein toxins (►bacterial toxins).

Rab GTPases

The largest family of small GTPases with more than 40 members identified are the Rab GTPases (3). Rab proteins are important regulators of specific steps of vesicle trafficking, including budding, targeting, docking and fusion with acceptor membranes. Each Rab protein has an organelle-specific subcellular localization and seems to be functionally specialized. Rab1A and Rab1B are two of the most extensively studied members of the Rab family. Both proteins are found in membranes of the ER, Golgi apparatus and intermediate vesicles between these compartments. They appear to function in the anterograde trafficking of proteins from the ER to the Golgi compartment. Rab4 and Rab5 are present on early endosomes and are involved in the endocytic process, whereas Rab6 is localized at the Golgi apparatus regulating processes of the secretory pathway. One of the best studied members of the Rab protein family is Rab3a. This GTPase is a key regulator of Ca²⁺-induced exocytosis, particularly in nerve terminals. Several effectors of Rab proteins like Rabphilin, Rabaptin and Rim have been identified and characterized as essential for vesicle trafficking. Recently, the Rab effector Rabkinesin6 has been identified that links Rab proteins to the microtubule cytoskeleton. Rabkinesin6 may be the motor driving vesicles along microtubules from the Golgi apparatus to the periphery.

Arf/Sar1 GTPases

The name Arf (ADP-ribosylation factor) stems from its discovery as a cytosolic factor with the ability to enhance the ADP-ribosylation of the α -subunit of the G protein G_s by ►cholera toxin. Arf is known to regulate phospholipid metabolism. Studies with dominant active or dominant negative mutants of Arf proteins in mammalian cells suggest the involvement of these GTPases in the trafficking of coated vesicles, and it is now known that Arf1 regulates the formation of COPI-coated vesicles for retrograde transport between Golgi apparatus and endoplasmic reticulum (4). Sar1, which is 37% identical to Arf1, is needed for the assembly of COPII proteins for vesicle transport in the opposite direction. Taken together, Arf and Sar proteins play crucial roles in the recruitment of COP components to vesicles thereby regulating vesicle budding. In contrast to the other small GTPases, Arf/Sar1 proteins are not regulated by GDI proteins, whereas different GEF and GAP proteins have been identified. Myristoylation of Arf proteins at the N-terminus is required for its membrane localization.

Ran GTPases

In mammalian cells there is only one *Ran* gene, which was discovered as a Ras-like gene (Ran: Ras-related nuclear protein) (5). In contrast, in yeast more than one related *Ran* genes have been identified. The predominant nuclear localization of the GTPase was the first hint that Ran is involved in nucleocytoplasmic transport processes. Interestingly, the only Ran GEF present in mammalian cells, RCC1 (regulator of chromatin condensation), is localized exclusively in the nucleus, whereas the single Ran GAP (Ran GAP1) is in the cytoplasm. This specialized localization of the regulators is the prerequisite for the asymmetric distribution of the GDP- and GTP-bound form of Ran and for its role as a nucleocytoplasmic transporter. In contrast to other GTPases, the activity of Ran is dependent on the gradient of the GTP-bound GTPase from cytoplasm to nucleoplasm that allows the transport of cargo proteins. Ran is involved in nuclear import as well as in export of proteins through the ►nuclear pore complex. Both processes require the formation of protein complexes, including Ran, the cargo protein and Ran-binding proteins like ►importins or ►exportins. In addition to its transporter function, Ran has been shown to participate in microtubule organization during the M phase of the cell cycle.

Cascades and Cross-Talk

Small GTPases are not isolated molecular switches regulating cellular processes. Signalling cascades within one subfamily as well as cross-talk between

members of different subfamilies are known. For example, Cdc42/Rac/Rho are sequentially activated after extracellular stimuli in quiescent Swiss 3T3 cells. Moreover, reciprocal modulation between Rho GTPases has been described. Ras and Rho proteins act in a cooperative manner in Ras-induced transforming. A further example of cross-talk between GTPase families is the cooperative function of Rho and Rab proteins during cell migration, with Rho proteins controlling the actin cytoskeleton, and Rab proteins regulating vesicular traffic for the recruitment of membrane material, and the recycling of proteins like integrins. Arfaptn connects signalling via Arf and Rac in regulating fundamental processes like endocytosis and secretion.

Drugs

Small GTPases, among other activities, regulate cell growth, neurite outgrowth and signalling of immune cells involved in inflammation. Pharmacological modulation of the activity of small GTPases is thus a useful aim in cancer and anti-inflammatory therapies. Farnesyltransferase inhibitors can be used to block the post-translational modification of the GTPases, which for example is essential for the transforming activity of Ras or Rho GTPases. Moreover, inhibitors of GTPase effectors like Rho kinase inhibitors have been generated. Such agents are at present in clinical trials.

Regulation of smooth muscle contractility

Definition

Following organs contain as major functional part smooth muscles layers: Arterial and venous vessels; lung and bronchia; oesophagus, stomach, small and large intestine; urinary tract and bladder; uterus. Hormones, locally released transmitters and shear stress or pressure regulate the tonus of these organs. Each organ has a slightly different regulation of its contractility, but the basis for this regulation, i.e. the intracellular signalling pathways, are very similar or identical. This article will focus on major findings that may be identical in all smooth muscles.

Basic Mechanisms

Key mechanism of smooth muscle tone regulation is the phosphorylation of Ser-19 of the ▶regulatory myosin light chain II (rMLC) [1]. Phosphorylation and dephosphorylation is catalysed by ▶myosin light chain kinase (MLCK) and the type 1 ▶myosin phosphatase (MLCP), respectively. Calcium-dependent and calcium-independent signal pathways regulate the activity of both enzymes and thereby the phosphorylation status of rMLC. An increase in the cytosolic calcium concentration leads to phosphorylation of the rMLC and contraction within 4 s. The correlation between percent phosphorylated rMLC and developed force is quite variable. Maximal force can be attained at 0.2–0.3 mol phosphate per mol rMLC. Phosphorylation can decline during maintenance of tension suggesting that even dephosphorylated cross-bridges can contribute to force maintenance.

Calcium-dependent regulation involves the calcium-calmodulin complex that activates smooth muscle MLCK, a monomer of approximately 135 kDa. Dephosphorylation is initiated by MLCP. MLCP is a complex of three proteins: a 110–130 kDa myosin phosphatase targeting and regulatory subunit (MYPT1), a 37 kDa catalytic subunit (PP-1C) and a 20 kDa subunit of unknown function. In most cases, calcium-independent regulation of smooth muscle tone is achieved by inhibition of MLCP activity at constant calcium level inducing an increase in phospho-rMLC and contraction (Fig. 1).

Calcium-Dependent Contraction

Different agonists such as norepinephrine, acetylcholine or angiotensin II activate smooth muscle contraction by binding to a heptahelical receptor, i.e. α -adrenergic, muscarinic or AT-1 receptors, followed by an increase in cytosolic calcium (Fig. 1 and 2). The activation of the trimeric G Proteins G_q or G_{11} increases the activity of phospholipase C β (PLC) generating inositol trisphosphate (IP $_3$) and diacylglycerol (DAG) and other fatty acid derived compounds. Classical findings suggested that IP $_3$ stimulates calcium release from intracellular stores that binds to calmodulin and activates MLCK. This simple scheme is not in line with the fact that a block of the ▶L-type Ca $^{2+}$ channel inhibits

Smooth Muscle Tone Regulation. Figure 1 Mechanisms leading to agonist stimulated calcium-dependent and calcium-independent contraction of smooth muscle. NE, norepinephrine. See text for the other abbreviations.

Smooth Muscle Tone Regulation. Figure 2 Membrane mechanisms leading to an increase in cytosolic calcium concentration. depolar, depolarisation of the membrane; see text for abbreviations.

contraction. The importance of the L-type calcium channel is further supported by genetic deletion of the corresponding $Ca_v1.2$ gene. Mice lacking the smooth muscle $Ca_v1.2$ channel have severe difficulties to contract intestinal and other smooth muscle. It is therefore likely that activation of a heptahelical receptor leads to depolarisation of the membrane and activation of the L-type calcium channels (Fig. 2). Possible candidates are ►TRP channels (most likely TRPC6) activated either by DAG or by interaction with empty IP_3 -stores. The inflowing cations may depolarise the membrane to potentials that activate T- and thereafter L-type calcium channels or directly L-type channels. A second channel depolarising the membrane is the calcium-activated chloride channel present in many smooth muscle cells. Calcium released from IP_3 -stores or flowing in through TRP channels could activate this chloride channel and depolarise thereby the membrane. The L-type calcium channel provides calcium to trigger calcium release from ryanodine receptor controlled

calcium stores and for refilling various intracellular calcium stores ([2]). The mechanism behind pressure or shear stress induced contraction is unsolved, but may again involve TRP channels.

Calcium-Independent Contraction

Agonist-activated receptors can induce contraction at a constant intracellular calcium concentration [3], if the receptor activates the G proteins G_{12} or G_{13} (Fig. 1). Activation of these G proteins recruits the monomeric GTPase ►Rho to the membrane, where Rho exchanges GDP against GTP and activates ►Rho-kinase. By a still unsolved cascade eventually involving ZIP kinase, the MYPT1 subunit of MLCP is phosphorylated at Thr-697 and Thr-854 (rat MYPT1) which reaction inhibits MLCP activity. Since the activity of MLCK is not affected by this cascade, rMLC is phosphorylated to a higher level. Phosphorylation and inhibition of MLCP activity is only observed, if a central exon of MYPT1 is present. These results could explain the old finding that certain agonists

induce calcium sensitization of the contractile machinery in most but not all smooth muscles. MLCP activity is also affected by a smooth muscle specific inhibitor protein of PP-1C, named \blacktriangleright CPI-17. Protein kinase C (PKC) phosphorylates CPI-17, which becomes then a high affinity inhibitor of the catalytic subunit of MLCP. The nature of the PKC subtype is not clear. It is possible that it is one of the atypical PKC enzymes that is activated directly (?) by arachidonic acid (AA). Rho-kinase which phosphorylates CPI-17 in vitro apparently may affect directly in vivo the phosphorylation status of CPI-17 [4]. Arachidonic acid inhibits dephosphorylation of MLCs, i. e. by a second mechanism by dissociating the MLCP holoenzyme.

Relaxation of Smooth Muscle

The major relaxing transmitters are those that elevate the cAMP or cGMP concentration (Fig. 3). Adenosine stimulates the activity of cAMP kinase. The next step is not clear, but evidence has been accumulated that cAMP kinase decreases the calcium sensitivity of the contractile machinery. In vitro, cAMP kinase phosphorylated MLCK and decreased thereby the affinity of MLCK for calcium-calmodulin. However, this regulation does not occur in intact smooth muscle. Possible other substrate candidates for cAMP kinase are the heat stable protein HSP 20, (A heat stable protein of 20 kDa that is phosphorylated by cGMP kinase. It has been postulated that phospho-HSP 20 interferes with the interaction between actin and myosin allowing thereby smooth muscle relaxation without dephosphorylation of the rMLC.) Rho A and MLCP that are phosphorylated also by \blacktriangleright cGMP kinase I (Fig. 3).

A major relaxing factor is NO, a signal molecule synthesized by three different \blacktriangleright NO synthases (NOS). NO synthesized in the endothelial layer of the vessels diffuses into the smooth muscle layer, where NO activates soluble guanylate cyclase (GC) and generates high concentrations of cGMP. In non-vascular systems such as the intestinal smooth muscle, NO is released from non-adrenergic, noncholinergic neurons. An alternative pathway for the production of cGMP, is the stimulation of particulate GC by the \blacktriangleright natriuretic peptides ANF and BNF. ANF and BNF are released from cardiac atrial and ventricular muscle, respectively, and lower blood pressure. The effects of the natriuretic peptides are mediated through cGMP and cGMP kinase I, whereas NO has effects which are not mediated by cGMP kinase I.

Smooth muscle contains the two cGMP kinase isozymes Ia and Ib and a number of identified substrates [5]. The NO/cGMP/cGMP kinase pathway interferes with the calcium-dependent and the calcium-independent contraction. A number of researchers have shown that cGMP-dependent phosphorylation of the \blacktriangleright BK_{Ca} channel increases its open probability resulting in hyperpolarization of the membrane potential and closure of voltage-dependent calcium channels. The activity of the BK_{Ca} channel is upregulated by the intracellular calcium concentration establishing a negative feedback loop. It is well established that cGMP kinase decreases the release of calcium from intracellular stores. Recently, it was found that cGMP kinase Ib is associated with the IP₃ receptor type 1 and the 130 kDa protein \blacktriangleright IRAG. Phosphorylation of IRAG inhibited the release of calcium from IP₃-sensitive stores in COS cells. However, isozyme-specific reconstitution of cGMP kinase I

Smooth Muscle Tone Regulation. Figure 3 Major mechanisms leading to relaxation of smooth muscle. See text for the abbreviations.

deficient mice suggested that, in murine aortic smooth muscle cells, cGMP kinase I α and I β lowered norepinephrine-stimulated increases in the cytosolic calcium concentrations. This result is in line with the recent notion, which calcium-dependent contraction of smooth muscle requires membrane depolarisation and calcium influx through membrane localized ion channels (see above). It is possible that the IP₃-sensitive calcium pool associated with IRAG and cGKI β controls other smooth muscle functions such as phenotype changes and smooth muscle growth.

Recently it was demonstrated that cGMP kinase I inhibits also smooth muscle contraction due to the calcium-insensitive pathway. A possible mechanism could be phosphorylation of Rho by cGMP kinase I. The phosphorylation site is identical with a cAMP kinase site identified in Rho from non-smooth muscle cells. It was reported that phosphorylation of Rho by cGMP kinase I prevents membrane association of Rho, that is required to stimulate the GDP/GTP exchange. Alternatively, phosphorylation of telokin may interfere with the calcium sensitisation of contraction. cGMP kinase I α interacts specifically with a leucine zipper present at the C-terminus of MYPT1. Depending on the tissue, this leucine zipper is present or not. MLCP activity increased when MYPT1 is phosphorylated by cGMP kinase I α at Ser-696.

Pharmacological Intervention

A large number of drugs interfere with the smooth muscle contraction. These compounds lower blood pressure and are referred to as antihypertensive. In this section, only those compounds will be mentioned that have a direct effect on smooth muscle tone. Phenylephrine is an agonist on most smooth muscles and activates α_1 adrenoceptors. Carbachol is an agonist on some smooth muscles and activates contraction through muscarinic receptors. Blockers of the α_1 -adrenoceptors such as prazosin and urapidil are competitive inhibitors of the α_1 -receptor in vascular and bladder smooth muscle. Phenoxybenzamine is an irreversible blocker of α_1 receptors and phentolamine blocks α_1 and α_2 receptors. **▶Ca²⁺ channel blockers** such as the dihydropyridines, phenylalkylamines and benzothiazepines lower smooth muscle tone by blocking the L-type calcium channel.

▶Nitrates (glycerol trinitrate, isosorbit dinitrate, pentaerythritol tetranitrate, molsidomine, sodium nitropruside), that generate NO, increase cGMP concentrations and lower smooth muscle tone by activation of cGMP kinase I. Nitrates relax in vivo mainly the capacitative part of the circulation system, i.e. the venous part. **▶Sildenafil**, a specific inhibitor of phosphodiesterase V, a cGMP hydrolysing enzyme, increases cGMP in the corpus cavernosum and lowers together with nitrates the blood pressure by the combined effect on cGMP level. An additional potentially important drug family are

compounds that stimulate the soluble guanylyl cyclase independent of NO [6] and lower elevated blood pressure. The inhibitor of Rho-kinase, **▶Y-27632**, lowers elevated blood pressure in hypertensive animals, without affecting significantly the blood pressure of non-hypertensive animals ([7]).

SMURF

Synonyms

Smad ubiquitin regulatory factor

Definition

Smad specific E3 ubiquitin ligases that associate with and lead to the degradation of the cytoplasmic receptor activated R-Smads. This regulatory protein serves to keep the available R-Smad pools low. Smurfs have been shown to regulate PRAJA ubiquitination of ELF which can be displaced from the TGF- β signaling pathway. Additionally, Smurfs can ubiquitinate phosphorylated nuclear R-Smads leading to their degradation. Through the nuclear R-Smad/Smurf complex ubiquitination of transcriptional repressors, the repressors can be down-regulated allowing the removal of inhibitory activities from target genes that require transcriptional induction by Smad complexes.

▶Transforming Growth Factor-Beta

SNAPs

SNAPs is an acronym for soluble NSF attachment proteins. They were originally discovered as cofactors for NSF that mediate the membrane binding of NSF in *in vitro* transport assays. Several isoforms of SNAPs exist in mammalian cells. SNAPs are also highly conserved proteins. Crystallographic studies indicated that the proteins form a very stiff and twisted sheet that is formed by a series of antiparallel and tightly packed helices connected by short loops.

- ▶ Exocytosis

SNARE Proteins

SNAREs is an acronym for soluble NSF acceptor protein receptors. They are a superfamily of small and mostly membrane-bound proteins that are distinguished by the presence of a conserved stretch of 60 amino acids referred to as a SNARE motif. With few exceptions, a single transmembrane domain is located adjacent to the SNARE motif at the C-terminal end. Many SNAREs possess in addition an independently folded N-terminal domain whose structures are more diverse.

SNARE motifs spontaneously assemble into SNARE complexes. These consist of a bundle of four intertwined α -helices that are connected by a total of 16 layers of mostly hydrophobic amino acid side chains. In the middle of the bundle, there is a highly conserved and polar “0-layer” consisting of three glutamine and one arginine residue. These residues are among the most conserved in the SNARE superfamily and led to a classification of SNAREs into Q- and R-SNAREs, respectively. Different fusion steps require different sets of SNAREs but some SNAREs can participate in different complexes, and some fusion steps involve several SNARE complexes that appear to operate in parallel and independently.

In vitro, SNARE-complex formation is irreversible. Disassembly requires the concerted action of the chaperone-like ATPase NSF and SNAPs.

Somatomedins

Somatomedins are polypeptide mediators produced in response to growth hormone in the liver, e.g. insulin-like growth factors (IGFs). In particular, IGF-1 is the main mediator of growth hormone action.

Somatostatin

GISELA OLIAS, WOLFGANG MEYERHOF
Department of Molecular Genetics, German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, Germany

Synonyms

Somatostatin; SOM; SST14; SST28; Somatotropin release inhibitory factor (SRIF); Growth hormone release-inhibiting factor

Definition

Somatostatin is a regulatory cyclic peptide, which has originally been described as a hypothalamic growth hormone release-inhibiting factor. It is produced throughout the central nervous system (CNS) as well as in secretory cells of the periphery and mediates its regulatory functions on cellular processes such as neurotransmission, smooth muscle contraction, secretion and cell proliferation via a family of seven transmembrane domain G-protein-coupled receptors termed *sst*₁₋₅.

Basic Characteristics

Biosynthesis

The human somatostatin gene is located on chromosome 3q28 and contains a single intron of 876 bp in its coding sequence. Its 5' upstream region includes several

regulatory domains such as a cAMP ► response element (CRE). The intracellular mediator cAMP is one of the activators of somatostatin gene transcription, but also many other factors such as Ca²⁺, glucocorticoids and growth hormone are able to influence somatostatin gene expression [1].

As other neuropeptides, somatostatin is synthesised as a preprohormone on ribosomes of the rough ► endoplasmic reticulum (RER). Translation product of the 351 bp long mRNA coding sequence is preprosomatostatin, a peptide of 116 amino acids. After translocation of the precursor molecule into the ER lumen and cleavage of the signal peptide the prohormone is further transported by transfer vesicles through the Golgi stacks into the *trans* compartment of the ► golgi apparatus. Differential posttranslational processing of prosomatostatin on the way from the ER to the *trans* Golgi network results in two biologically active isoforms, the tetradecapeptide somatostatin-14 and the aminotermally extended octacosapeptide somatostatin-28, respectively. Cleavage of the C-terminal region of prosomatostatin at a dibasic Arg-Lys site produces somatostatin-14 and cleavage at a monobasic Gln-Arg site results in somatostatin-28. Candidates for somatostatin-14 converting enzymes are prohormone convertases PC1 and PC2 whereas ► furin is a candidate somatostatin-28 convertase. The amounts of produced isoforms are tissue specific. Whereas the hypothalamus synthesises both, somatostatin-14 and somatostatin-28 in a ratio of 4:1, the intestinal mucosal cells produce mainly somatostatin-28.

In the *trans* Golgi compartment the peptide is sorted via secretory vesicles into a regulated pathway. In contrast to vesicles of the constitutive pathway, vesicles of the regulated pathway are stored in the cytoplasm until their stimulated release. Membrane depolarisation as well as a wide range of substances such as intracellular mediators, neuropeptides, neurotransmitters, classical hormones, cytokines, growth factors, ions and nutrients induce somatostatin secretion. General inhibitors of somatostatin release are opiates, GABA, leptin and TGF-β.

Tissue Distribution

High amounts of somatostatin are found in the CNS, the peripheral nervous system, the gut and the endocrine pancreas whereas the kidneys, adrenals, thyroid, submandibular glands, prostate and placenta produce rather low amounts. In particular, the hypothalamus, all limbic structures, the deeper layers of the cerebral cortex, the striatum, the periaqueductal central grey and all levels of the major sensory pathway are brain areas that are especially rich in somatostatin. Eighty percent of the somatostatin immunoreactivity in the hypothalamus is found in cells of the anterior periventricular nucleus (Fig. 1, [1]). The gut δ cells of the mucosa and neurons, which are intrinsic to the submucous and

Somatostatin. Figure 1 Somatostatin-like immunoreactivity in neurons of the periventricular hypothalamic nucleus of the rat. Coronal brain cryostat sections have been processed for immunohistochemistry and sequentially incubated with a primary monoclonal mouse antihuman somatostatin antibody and secondary antimouse antibody conjugated with the fluorescence-dye Cy-3. Images have been taken with a Zeiss Axioplan fluorescence microscope. Scale bar, 100 μ m.

myenteric plexuses, produce somatostatin. Furthermore, somatostatin has been found in δ cells of the pancreas and within the thyroid where somatostatin has been detected in a subpopulation of C cells that additionally contain calcitonin. Somatostatin has also been localised in the inner part of the retina and in cells and organs of the immune system, for example within macrophages, lymphocytes and the thymus.

Somatostatin Receptors

Somatostatin acts on various organs, tissues and cells as neurotransmitter, paracrine/autocrine and endocrine regulator on cell secretion, smooth muscle contractility, nutrient absorption, cell growth and neurotransmission [1]. Some of its mainly inhibitory effects are listed in Table 1. Somatostatin mediates its function via a family of heptahelical G-protein-coupled receptors termed

*sst*₁, *sst*₂, *sst*₃, *sst*₄ and *sst*₅, which were cloned about 15 years ago. Despite a high degree of sequence homology the receptors derive from separate genes localised on different chromosomes (Table 2). The genes of *sst*₁, *sst*₃, *sst*₄ and *sst*₅ do not contain any introns in their protein coding regions. In contrast to this, the *sst*₂ gene contains a cryptic splice site at the 3' end of its coding region giving rise to two splice variants, *sst*_{2A} and *sst*_{2B}.

Studies investigating the distribution of *sst* mRNAs have shown that *sst* gene expression varies during ontogeny. Moreover, all five genes are tissue specifically expressed. However, expression pattern overlap and different mRNA levels have been demonstrated in brain, pituitary, pancreas, adrenals, kidneys, liver, lung, placenta, stomach, gut, thyroid and immune cells. In addition to the *sst* gene expression in organs, many tumour cell lines, such as AtT20 and GH3 pituitary cells, and numerous human tumours, benign or malignant, have been shown to be a rich source of *sst* subtypes. *sst*₂ mRNA is highly expressed in many tumours, while *sst*₅ mRNA is abundant in breast tumours and *sst*₁ appears to be preferentially expressed in primary prostate cancers [1, 3]. Laboratories investigating neuroendocrine tumours, such as gastrinomas and insulinomas, reported not only a general expression of *sst*₁, *sst*₂, but also varying levels of *sst*₃, *sst*₄ and *sst*₅ mRNAs have been observed. Interestingly, in gastrinomas and carcinoids only low amounts of *sst*₃ mRNA have been detected so far. However, it should be noted that these results may not automatically mirror functional receptor levels, since to date nearly all investigations of *sst* subtypes in tumours are based on mRNA studies.

Besides developmental and tissue-specific regulation of *sst* gene expression, regulation by extracellular signals, such as estrogen and thyroid hormone, has been observed. The underlying mechanisms still remain to be elucidated, although promoter studies of various laboratories have begun to work out the molecular basis for a better understanding. All *sst* subtype promoters investigated to date contain consensus sequences for several common transcription factors. For example, the *sst*₂ gene contains estrogen response elements whereas progesterone/glucocorticoid and thyroid response elements were found in the *sst*₁, and *sst*₅ genes [1].

The human *sst* receptor protein isoforms range in size from 364 amino acids to 418 amino acids (Table 2). The *sst* subtypes show highest sequence identity in their putative transmembrane domains and can be divided, on the basis of amino acid homologies and by their ability to bind somatostatin analogues (Table 3), into two subclasses, termed SRIF₁ and SRIF₂. The SRIF₁ group comprises *sst*₂, *sst*₃ and *sst*₅ (SRIF_{1A}, SRIF_{1B} and *srif*_{1C}) and the SRIF₂ group includes *sst*₁ and *sst*₄ (SRIF_{2A} and *srif*_{2B}). Receptors of the SRIF₁ group bind

Somatostatin. Table 1 Somatostatin effects in different tissues (Data adapted from [1, 2])

Site	Effects
Hypothalamus	Inhibition of norepinephrine, GHRH, TRH and CRH release
	Inhibition of endogenous SST release
	Effects on leptin signalling
Other brain regions	Effects on cognitive, locomotor, sensory and autonomic functions, analgesic effects
	Inhibition of dopamine release from the midbrain
	Stimulation of dopamine release in basal ganglia
Pituitary	Inhibition of basal and stimulated release of GH
	Inhibition of TSH release
	No effects on LH, FSH release
	No effect on ACTH release in normal subjects, but suppresses elevated levels in Addison's disease and in ACTH producing tumours
	No effect on prolactin release in normal subjects, but diminishes increased prolactin levels in acromegaly
Gastrointestinal tract	Inhibition of most gut hormones, gastric acid, pepsin, bile and colonic fluid secretion
	Suppression of motor activity in general, inhibition of gallbladder contraction, gastric emptying
	Stimulation of migrating motor complex activity
Thyroid	inhibition of TSH-stimulated T4 and T3 release
	Inhibition of calcitonin secretion from thyroid parafollicular cells
Adrenal	Inhibition of angiotensin II stimulated aldosterone release
	Inhibition of acetylcholine stimulated medullary catecholamine release
Kidney	Inhibition of hypovolemia stimulated renin secretion
	Inhibition of ADH-mediated water absorption
Immune cells	Diminishing IFN- γ secretion from lymphocytes
Lymphocytes, inflammatory cells, intestinal mucosal cells, cartilage cells and bone precursor cells	Inhibition of proliferation
Other tissues/cells	Inhibition of growth factor (IGF1, EGF, PDGF) and cytokine (IL6, IFN- γ) secretion

seglitide and octreotide with high (sst₂ and sst₅) to moderate (sst₃) affinity while members of the SRIF₂ group are insensitive to these compounds.

All six receptors seem to couple to ►**pertussis toxin-sensitive ►G proteins** of the Gi/Go type [1]. Depending on the sst subtype, cell type, and species different G-proteins couple the individual receptor isoforms to various second-messenger systems which include ►**adenylyl cyclase**, K⁺ and Ca²⁺ channels, Na⁺/H⁺ exchanger, ►**phospholipase C**, phospholipase A2, mitogen activated protein kinase, serine–threonine phosphatase, and phosphotyrosine phosphatase (Table 2). The fact that sst subtypes share transduction mechanisms, bind their endogenous ligands with nanomolar affinities, and that more than one receptor isoform can be expressed in a single cell, might indicate a functional interaction between the different receptor isoforms. In this respect

it should be noted that heterodimerisation of sst subtypes has been reported.

Physiological functions for sst subtypes have not yet been unequivocally recognised. It appears, however, that sst₂ predominantly mediates inhibition of glucagon release from pancreatic alpha-cells whereas sst₁ and sst₅ seem to be important regulators of insulin secretion and glucose regulation. For example, sst₁ or sst₅ knockout mice develop diabetes, and double-gene ablation of both receptors results in a distinct phenotype with hyperinsulinemia, islet cell hyperplasia and improved glucose tolerance. Furthermore, it is thought that sst₂ contributes to the regulation of gastric acid release and that sst₁, sst₂ and sst₅ inhibit hormone-stimulated and/or basal level secretion of GH secretion from the pituitary [1, 2]. Knockout mice have also helped to elucidate a role for sst₁ and sst₂ receptors in retinal functions [5].

Somatostatin. Table 2 Properties of sst subtypes (Data are adapted from [1, 2])

Receptor type	sst ₁ /SRIF _{2A}	sst ₂ /SRIF _{1A}	sst ₃ /srif _{1C}	sst ₄ /srif _{2B}	sst ₅ /SRIF _{1B}

Transduction mechanism	Inhibition of adenylyl cyclase; stimulation of tyrosine phosphatase activity; stimulation of MAP kinase activity; activation of ERK; inhibition of Ca ²⁺ channel activation; stimulation of Na ⁺ /H ⁺ exchanger; stimulation of AMPA/kainate glutamate channels	Inhibition of forskolin-stimulated adenylyl cyclase; activation of phosphoinositide metabolism; stimulation of tyrosine phosphatase activity; inhibition of Ca ²⁺ channel activation; activation of K ⁺ channel; inhibition of AMPA/kainate glutamate channels; inhibition of MAP kinase activity; inhibition of ERK; stimulation of SHP-1 and SHP-2	Inhibition of adenylyl cyclase; stimulation of phosphoinositide metabolism; stimulation of tyrosine phosphatase; activation of K ⁺ channel; inhibition/stimulation of MAP kinase activity; induction of p53 and Bax	Inhibition of adenylyl cyclase; stimulation of MAP kinase; stimulation of p38; activation of tyrosine phosphatase; stimulation of K ⁺ channels and phospholipase A ₂	Inhibition of adenylyl cyclase; activation/inhibition of phosphoinositide metabolism; inhibition of Ca ²⁺ influx; activation of K ⁺ channels; inhibition of MAP kinase; stimulation of tyrosine phosphatase

Somatostatin Related Peptides

Natural binding partners of all sst subtypes cloned to date are somatostatin-14 and somatostatin-28, which are bound with nanomolar affinity. sst₁₋₄ bind somatostatin-14 with comparable affinities, while sst₅ may have a slight preference for somatostatin-28. Cortistatin, a recently discovered closely related peptide, also binds sst subtypes with high affinity *in vitro*. Initially it was thought that it is mainly restricted to the cerebral cortex and the hippocampus, but recent studies have shown that cortistatin mRNA can also be obtained from peripheral tissues and tumour cells. Cortistatin shows functional characteristics that have not been demonstrated for somatostatin, such as sleep modulating properties. So far a cognate cortistatin receptor has not been identified, although an orphan receptor called MrgX2 has been shown to bind cortistatin, but not somatostatin, with high affinity *in vitro*. However, the MrgX2 mRNA expression pattern is not entirely consistent with the pattern expected for a cortistatin receptor. In addition, cortistatin binds to the ghrelin receptor GHSR1a with similar affinity than ghrelin [1].

Drugs

The diverse effects of somatostatin, such as inhibition of cell proliferation and hormone release, led to the suggestion that it could be used for the treatment of various diseases. However, its short plasma half-life (less than 3 min) and its relative low receptor subtype

selectivity make it less useful for therapeutic purposes. Therefore, several synthetic analogues (Table 3) with a higher stability to enzymatic degradation and a higher selectivity for specific sst subtypes have been synthesised. The synthetic peptide analogues have a decisive amino acid motif in common, since pharmacological studies have shown, that the amino acid residues 7–10 (Phe⁷-Trp⁸-Lys⁹-Thr¹⁰) of somatostatin are the responsible segment for receptor binding. In particular Trp⁸ and Lys⁹ are essential, while the remaining two amino acids may be replaced. Phe⁷ can be exchanged with tyrosine and Thr¹⁰ can be substituted by serine or valine. To date, only a few potential antagonists, such as cyanamid 154806, sst₃-ODN-8 and BIM-23056 are available, which preferentially bind to human sst₂, sst₃ and sst₅, respectively [1, 2, 4].

Today three analogues, octreotide, lanreotide and vapreotide are clinically used. All three substances display high affinity for sst₂ and sst₅. Already in the 1980s octreotide was used in the therapy of acromegaly and other neuroendocrine tumours. Acromegaly is a chronic disease of growth hormone (GH) hypersecretion and in most cases is caused by a pituitary adenoma. Somatostatin analogues have been shown to improve the clinical symptoms of acromegaly, for example gigantism in children, disfigurements of the hands, feet and the face in adults, headache and perspiration. Moreover, tumour shrinkage has been observed in about 50% of the patients, even though the tumour size reduction is reversible. The

Somatostatin. Table 3 Selected somatostatin analogues

sst Subtype ligands and analogues	Binding properties
<i>Endogenous Ligands</i>	
Somatostatin-14	Binding to all sst subtypes with high affinity
Somatostatin-28	Binding to all sst subtypes with high affinity, but slightly higher preference for sst ₅
Human cortistatin-17	Binding to sst ₂₋₅ with high affinity, slightly lower preference for sst ₁
Rat cortistatin-29	Binding to sst ₃ with high affinity, slightly lower preference for sst ₁ , sst ₄ and sst ₂ , and lower preference for sst ₅ (i.e. ~100-fold lower than that of somatostatin-14)
<i>Synthetic peptide analogues</i>	
Octreotide (SMS201-995)	Binding to sst ₂ with high affinity, slightly lower affinity to sst ₅ and sst ₃
Vapreotide (RC-160)	Binding to sst ₅ and sst ₂ with high affinity, moderate affinity for sst ₃ and sst ₄
Lanreotide (BIM23014)	Binding to sst ₂ and sst ₅ with high affinity, moderate affinity for sst ₃ (and sst ₄).
Seglitide (MK678)	Binding to sst ₂ and sst ₅ with high affinity, moderate affinity for sst ₃
BIM23268	Binding to sst ₅ with high affinity, slightly lower preference for sst ₂ , sst ₄ and sst ₁ , moderate affinity for sst ₃
NC8-12	Binding to sst ₃ and sst ₂ with very high affinity
BIM23197	Binding to sst ₂ and sst ₅ with high affinity, moderate affinity for sst ₃
CH275	Binding to sst ₁ and sst ₄ with high affinity
SOM230	Binding to sst ₁ , sst ₂ , sst ₃ and sst ₅ with high affinity, lower affinity to sst ₄
<i>Nonpeptide agonists</i>	
L-797,591	Binding to sst ₁ and sst ₂ with high affinity
L-779,976	Binding to sst ₂ with very high affinity
L-796,778	Binding to sst ₃ with moderate affinity.
L-803,087	Binding to sst ₄ with high affinity
L-817,818	Binding to sst ₅ with high affinity, with slightly lower affinity to sst ₁ , moderate affinities for sst ₂ , sst ₃ and sst ₄
<i>Radioligands</i>	
¹²³ I-Tyr ³ -octreotide	Binding to sst ₂ and sst ₅ with high affinity, lower affinity to sst ₃
¹¹¹ In-DTPA- _D Phe ¹ -octreotide ^a	Binding to sst ₂ and sst ₅ with high affinity, lower affinity to sst ₃
¹¹¹ In/ ⁹⁰ Y-DOTA-lanreotide ^b	Binding to sst ₂ , sst ₃ , sst ₄ and sst ₅ with high affinity, lower affinity to sst ₁
¹¹¹ In-DOTA- _D Phe ¹ -Tyr ³ -octreotide	Binding to sst ₂ and sst ₅ with high affinity, lower affinity to sst ₃
^{99m} Tc-depreotide	Binding to sst ₂ , sst ₃ and sst ₅ with high affinity

decreased tumour volume is presumably caused by a shrinkage of individual tumour cells. Recently, sustained release formulations of octreotide and lanreotide have been developed. These new drugs are administered by intramuscular injections only every 7–28 days making life of patients easier, who need a long-term therapy. Furthermore, a novel sst analogue named SOM230 [4] that binds to sst_{1–3} and sst₅ with high affinity has been tested in a first trial in 12 acromegalic patients. The study showed that SOM230 was more effective in suppressing GH concentrations than octreotide. Thus, results of larger ongoing clinical trials testing this promising analogue are eagerly awaited.

Octreotide treatment achieves also good results in patients with insulinomas, gastrinomas, glucagonomas, ►VIPomas and metastatic carcinoids expressing sst₂ and sst₅. Symptoms such as peptic ulceration, diarrhoea, dehydration and necrolytic skin lesions rapidly improve giving the life of patients a higher quality. Despite the successful reduction of symptoms only in about 20% of the patients a tumour shrinkage was observed and, in contrast to acromegalic patients, most patients suffering from carcinoids became insensitive to octreotide therapy within weeks to months. The desensitisation might be explained by a *downregulation* of sst subtypes or more likely by an outgrowth of sst subtype-negative cell clones.

Other tumours, such as ACTH-secreting pituitary adenomas, prolactinomas, pancreatic and prostate cancer, which express no or other sst subtypes than sst₂ and sst₅ are rather unresponsive to octreotide therapy. Therefore, the development of new sst-subtype-selective analogues is required. Transfer of genes encoding sst₂ or sst₅ into such tumour types might also be a strategy, since clinically used somatostatin analogues exert the majority of their antineoplastic effects via these receptor subtypes. Furthermore, stable transfection of human pancreatic cancer cell lines with human sst₂ cDNA resulted in a significant reduction of tumour cell growth, indicating that the loss of sst₂ expression in pancreatic cancer could be responsible for the growth advantage of this kind of tumour [3, 4].

Somatostatin Receptor Scintigraphy and Receptor-Targeted Radiotherapy

Radiolabelled somatostatin analogues, such as ¹¹¹In-DTPA-D-Phe¹-octreotide or ¹¹¹In-DOTA-lanreotide are employed for somatostatin receptor scintigraphy (SRS), an imaging technique which nowadays is used in many hospitals to visualise sst subtype positive tumours in vivo. The high sensitivity of this method can be explained by an accumulation of radioligands within the tumours, which is presumably caused by the internalisation of the agonist-receptor complex [3]. Many human tumours seem to contain high mRNA levels for specific sst subtypes. For example, sst₂ is the

predominant isoform expressed by neuroendocrine tumours, whereas intestinal adenocarcinomas mostly contain sst₃ and sst₄. Therefore, in particular ¹¹¹In-DOTA-lanreotide is a very suitable tool for the detection of a wide range of tumours, since it binds not only sst₂ and sst₅ with high affinity but also sst₃ and sst₄ and to a lesser extent sst₁.

Furthermore, some of these radioligands have been used in first trials of receptor-targeted radiotherapy. Although ¹¹¹In is not the most favourable substance for radiotherapy, large amounts of ¹¹¹In-DTPA-D-Phe¹-octreotide were used for the treatment of patients suffering from neuroendocrine tumours. In a patient with an inoperable metastasised glucagonoma treatment with ¹¹¹In-DTPA-D-Phe¹-octreotide led to a small but significant reduction of tumour size and transiently lowered plasma glucagon levels [3]. Two further analogues, ⁹⁰Y-DOTA-lanreotide and ⁹⁰Y-DOTA-D-Phe¹-Tyr³-octreotide, have also been tested for tumour therapy. In a phase II study investigating more than 60 tumour patients treated with ⁹⁰Y-DOTA-lanreotide about 35% of the patients showed a stabilisation of tumour growth and in 15% of the cases a tumour regression was observed. However, clinical long-term trials are still needed to evaluate the therapeutic effectiveness of somatostatin analogues in cancer treatment.

Sphingosine Kinases

Sphingosine kinases (SphKs) catalyse the phosphorylation of sphingosine to sphingosine-1-phosphate (S1P).

Until now, two mammalian isoforms of SphK, SphK1 (43 kDa) and SphK2 (65 kDa) have been identified. Their catalytic domain is homologous to that of diacylglycerol kinases. SphK1 and SphK2 have distinct kinetic properties and are differentially expressed. SphK1 promotes cell growth and protects from apoptosis. It is upregulated in tumour cells and has features of an oncogene. SphK2, in contrast, mediates apoptosis. Deficiency of either SphK1 or SphK2 in mice does not cause obvious abnormalities, while double knockout mice die during embryogenesis. These data suggest that despite opposing functions the two sphingosine kinase isoenzymes can substitute for each other. SphK activity is regulated both transcriptionally and post-transcriptionally by GPCRs, receptor tyrosine kinases, cytokine and antigen receptors. However, SphK1 has a high basal activity and is probably mainly regulated by control of its subcellular localization. Several stimuli induce a rapid translocation of SphK1 from the cytosol to the plasma membrane. S1P that is formed in close vicinity to the membrane can then be extruded and act on S1P-GPCRs, a process named "inside-out signalling". Examples are NGF-induced neurite extension in dorsal root ganglion cells (via S1P₁ and S1P₅) and antigen-induced degranulation of mast cells (via S1P₂). Another model suggests receptor signalling platforms rather than autocrine activation of S1P-GPCR, for example in platelet-derived growth factor-induced migration. Other stimuli, such as phosphatidic acid, induce a translocation of SphK1 to intracellular sites, supporting the view that S1P can also act as an intracellular mediator. Both SphK1 and SphK2 furthermore occur in the nucleus.

► Lysophospholipids

Sphingosine-1-phosphate

Sphingosine-1-phosphate (S1P) is a versatile bioactive lipid which can act as first and second messenger. Extracellular S1P is a *lysophospholipid* mediator and activates specific G-protein-coupled receptors (see: *lysophospholipids*). On the other hand, stimulation of many cells with diverse agonists causes a rapid and transient increase in intracellular S1P formation, and inhibition of this S1P formation by *sphingosine kinase* inhibitors abrogates agonist-induced Ca^{2+} mobilization. Approaches such as microinjection of S1P, or photolysis of caged S1P, support the hypothesis that intracellular S1P mediates mobilization of Ca^{2+} from intracellular stores. The sphingosine kinase/S1P signal transduction pathway may thus be a Ca^{2+} mobilization pathway in

addition to the well-characterized phospholipase C/inositol-1,4,5-trisphosphate pathway, however, intracellular target sites of SIP have not been identified so far.

► Lysophospholipids

Sphingosylphosphorylcholine

Synonyms

SPC

Definition

Signaling phospholipid derived from sphingomyelin by phospholipase action. Activates SIP receptors.

► Proton-Sensing GPCRs

Spike-ins

Spike-ins are usually RNA transcripts used to calibrate measurements in a DNA microarray experiment. Each spike-in is designed to hybridize with a specific control probe on the target array. Manufacturers of commercially available microarrays typically offer companion RNA spike-ins ‘kits’. Known amounts of RNA spike-ins are mixed with the experiment sample during preparation. Subsequently the measured degree of hybridization between the spike-ins and the control probes is used to normalize the hybridization measurements of the sample RNA.

► Gene Expression Analysis and Microarray Technology

Spindle Assembly Checkpoint

A signal transduction pathway required for proper chromosome alignment during mitosis. The spindle assembly checkpoint is activated during mitosis in response to the presence of chromosomes that are not attached to spindle microtubules or that are not properly aligned at the metaphase plate. The spindle checkpoint

is turned off when all chromosomes are attached to microtubules and when a tension across kinetochores has been generated. The spindle checkpoint is essential for maintaining chromosomal stability.

► Cell Cycle Control

Splice Variant

A splice variant can arise when a gene contains at least two introns leading to the possibility that the DNA between them (an exon) may not be included in the final mRNA and protein product. Thus, the final protein product may exist in two forms: one containing the amino-acid sequence encoded by the exon that is located between the introns in the original DNA, and another form in which the amino-acid sequence encoded by that exon has been ‘spliced out’. These two products are referred to as splice variants.

Splicing

Splicing is a processing step of the pre-mRNA to become a mature transcript. This involves the excision of intervening noncoding sequences (introns) from coding sequences (exons) by a multiple protein complex, the spliceosome. After splicing the mRNA molecule is ready for translation, since it contains a continuous sequence that encode an entire protein.

► Transcriptional Regulation

Sporotrichosis

Sporotrichosis is the fungal disease caused by *Sporotrix schenckii* and involves the lymphatic and subcutaneous tissues. The lesions spread via the lymphatics from the original wound and form nodules or pustules that quickly ulcerate. Dissemination is rare.

Src Gene

The c-src gene encodes the non-receptor tyrosine kinase pp60^{c-src} that is involved in signal transduction. The pp60^{c-src} protein consists of a tyrosine kinase domain, a src homology 2 (SH2) domain that can bind to receptor tyrosine kinases, and a src homology 3 (SH3) domain that binds to proline rich sequences. The viral homolog of c-src, v-src, from the Rous sarcoma virus is a potent oncogene.

- ▶ Tyrosin Kinases

Src-homology 2 Domain

The Src-homology 2 (SH2) domain is a protein domain of roughly 100 amino acids found in many signaling molecules. It binds to phosphorylated tyrosines, in particular peptide sequences on activated receptor tyrosine kinases or docking proteins. By recognizing specific phosphorylated tyrosines, these small domains serve as modules that enable the proteins that contain them to bind to activated receptor tyrosine kinases or other intracellular signaling proteins that have been transiently phosphorylated on tyrosines.

Steroids

Steroids are a group of natural substances which share a common basic structure consisting of four condensed rings (sterane). Cholesterol is the precursor for the group of steroid hormones which are mainly formed in the adrenal medulla and in the gonads, including androgens, progesterone and estrogens as well as the mineralocorticoids. Steroid Hormones are lipophilic substances which bind to intracellular receptors. Other important steroids include the bile acids and the D-vitamins. Many related substances are found in plants, often present as glycosides. An important example of plant steroids are the cardiac glycosides.

Sterol Transporters

GERD SCHMITZ

Institute of Clinical Chemistry and Laboratory
Medicine, University of Regensburg, Regensburg
Germany

Definition

Transport of sterols, in particular reverse cholesterol transport, plays a central role in the pathogenesis of atherosclerosis. In addition to almost inefficient passive diffusion, sterol transport to various acceptors is mediated by membrane-bound energy-dependent transporters. The so far best characterized transporters belong to the family of ATP-binding cassette (ABC) transporters (▶ATP-binding cassette transporter superfamily) of which ABCA1, ABCG1, and ABCG5 and ABCG8 are well-known sterol transporters. Moreover, two further members of this family, ABCA7 and ABCB1 have been implicated to sterol transport.

Basic Characteristics

ABC-transporters are multispan membrane proteins that mediate the active uptake or efflux of specific substrates across various biological membrane systems. A functional ABC-transporter protein usually consists of two transmembrane domains and two ABCs. These cassettes consist of a Walker A and a Walker B motif, short conserved peptides, which are required for ATP binding. Between the two Walker motifs an additional element, the signature motif is localized, which is characteristic for each ABC subfamily. Genes of the ABC-transporter family either encode for full size transporter including already the two transmembrane domains and the two ABCs or, alternatively, encode for so called half-size transporters which have to assemble to homo- or heterodimers to constitute a fully functional transporter. The final localization of the full-size transporter is the plasma membrane, however, due to vesicular trafficking processes, they can also be found intracellularly. Depending on their mode of action ABC-transporters can be split into two different sections. The active transporters or pumps couple the hydrolysis of ATP and the resulting free energy to movement of molecules across membranes against a chemical concentration gradient. In contrast several other ABC proteins show nucleotide binding and a subsequent conformational change but very low ATP hydrolysis including ABCA1. To date, 48 human ABC-transporters, which are subdivided into seven subfamilies, have been identified and many of these proteins exert their biological activities in lipid metabolism and are themselves

regulated by lipids including phospholipids, sterols, and fatty acids.

ABCA1

ABCA1 is the founding member of the ABCA-family and is still under extensive investigation. The *ABCA1* gene encodes a full size transporter and consists of 50 exons located on chromosome 9q31. The predominant role of ABCA1 is the regulation of cellular ▶cholesterol and phospholipid efflux to cholesterol acceptors such as high-density lipoproteins (HDL) and lipid-poor apolipoproteins. This process may be indirect and ATP-dependent. ABCA1 expression is found in a variety of human organs such as placenta, liver, intestine (Fig 1), lung, and adrenal glands with very high expression levels in cholesterol loaded macrophages. The cholesterol induced transcription of ABCA1 is primarily mediated by the activation of the nuclear hormone receptor heterodimer liver X receptor (LXR) (▶nuclear receptors) with oxysterols as naturally occurring ligand and retinoid X receptor RXR. In addition, ABCA1 expression is induced indirectly via LXR induction by peroxisome proliferator activated receptor γ (▶PPAR γ) (PPARs). The ABCA1 promoter is further stimulated by the ubiquitous transcription factor Sp1 and the hypoxia-induced factor 1 (HIF1). Shutdown of ABCA1 expression in the absence of sterol or in certain tissues is mediated by corepressor complexes involving unliganded LXR, SREBP2, Sp3, and the SCAN-domain zinc finger transcription factor ZNF202, which also impacts nuclear signaling.

Mutations of the human ABCA1 gene are the direct cause of HDL-deficiency syndromes such as Tangier disease. In these patients the most striking feature is the almost complete absence of plasma HDL with low serum cholesterol levels and significantly reduced cellular efflux of cholesterol and phospholipids. The very low levels of plasma HDL observed in these patients are mainly caused by an enhanced catabolism of HDL precursors. The patients have high risk of premature atherosclerosis and coronary artery disease. Furthermore, these patients display accumulation of cholesteryl esters in the cells of the reticuloendothelial system resulting in splenomegaly and enlargement of lymph nodes and tonsils.

ABCA7

Based on experimental data the full-length transporter ABCA7 has been implicated in the cellular efflux of serine containing lipids such as phosphatidylserine and ceramide and maybe cholesterol. Novel data also demonstrate a role for ABCA7 in phagocytosis. Since ABCA7 knockout animals also display gender-dependent reduction in serum cholesterol levels as well as in visceral fat, strong evidence suggests a significant role for ABCA7 in sterol transport. The human *ABCA7* gene consists of 46 exons and, due to

Sterol Transporters. Figure 1 Proposed role of ABC proteins in intestinal sterol metabolism. ABCG 5, ABCG8 and ABCA1 are sterol-induced members of the ABC-transporter family. ABCG5 and ABCG8 mediate the export of plant sterols and cholesterol into the gut lumen. In contrast, ABCA1 expression and function are required for the uptake of sterols into intestinal epithelial cells. Implications for intracellular location and vesicular trafficking of these proteins are presented. Abbreviations not defined in the text: CE, cholesteryl ester; DAG, diacylglyceride; DGAT, acyl-CoA: diacylglycerol transferase, HSP70, heat shock protein 70; L, lysosome; MAG, monoacylglyceride; Mic, micelle; MTP, microsomal transfer protein; Sit, sitosterol (adapted from Schmitz and Langmann, 2003 [5]).

alternative splicing, two main ABCA7 isoforms, type I and type II, with distinct expression patterns do exist. While type I mRNA is higher expressed in brain and bone marrow, type II is predominantly found in spleen, thymus, lymph node, and trachea. The ABCA7 gene is located in close proximity to the gene for the minor histocompatibility antigen HA-1 on chromosome 19p13.3 in a head-to-tail array. Between both genes a functional and regulatory interlink might exist, which is especially interesting since ABCA7 has been shown to be regulated by sterols via SREBP2. In addition to its role in lipid metabolism ABCA7/HA-1 may be related to autoimmune disorders such as Sjögren's syndrome.

ABCB1

ABCB1 (also called MDR1) has initially been described by its ability to confer a multidrug resistance phenotype to cancer cells upon chemotherapy. This full-size

transporter is localized to the apical membrane of polarized cells (Fig 1) and the major sites of expression are found in liver, intestine, and the blood-brain barrier. One main physiological function of ABCB1 is the protection of cells by extruding lipophilic drugs. Indeed, ABCB1 is a highly promiscuous transporter of a variety of hydrophobic drugs including vinblastine, colchicines, VP16, and adriamycin. In addition, cholesterol and a number of different other lipids like phosphatidylcholine, phosphatidylethanolamine, sphingomyelin, and glucosylceramide are substrates for ABCB1-mediated transport. In addition to its role in drug and lipid transport, ABCB1 has also been related to inflammatory processes and immune response as well as to Alzheimer's disease, since it is able to translocate, e.g., bioactive lipids like platelet-activating factor and has been implicated in the in the efflux of brain β -amyloid protein.

ABCG1

The half-size transporter ABCG1 reveals a strikingly similar expression and regulation pattern to ABCA1. Like ABCA1, ABCG1 is upregulated during the differentiation process of monocytes to mature macrophages and is strongly induced by foam cell formation of these macrophages under sterol loading conditions, while cholesterol deloading of the cells with lipid acceptors such as ►HDL results in a downregulation of ABCG1 mRNA and protein expression. This regulation of ABCG1 exclusively occurs in human or murine monomyeloid cells, such as primary human macrophages, THP-1 cells, RAW246.7 cells, or foam cells from atherosclerotic lesions. This sterol-sensitive induction of ABCG1 is independent of proinflammatory stimuli and the oxidative state of the cell and is mediated by the LXR/RXR pathway. Similar to ABCA1, an additional inhibitory mechanism involving the transcription factor ZNF202 has been described. However, due to multiple alternative promoters transcriptional regulation of ABCG1 appears very complex and several different isoforms with obviously distinct tissue expression patterns do exist. Besides monomyeloid cells, ABCG1 is mainly expressed in spleen, thymus, lung, and brain.

The function of ABCG1 in lipid transport is not fully understood so far. In contrast to ABCA1, ABCG1 is not able to efflux lipids to lipid-poor lipoproteins, but requires more mature α -HDL subclasses as acceptor particles rather than pre- β -HDL or other lipid acceptors such as phosphatidylcholine vesicles. Since the activity of ABCA1 in lipidation of lipid-poor apolipoproteins is sufficient to generate an efficient acceptor for ABCG1-mediated cholesterol efflux, a two-step model for ABCA1- and ABCG1-mediated cellular lipid efflux is proposed: Initially, ABCA1 may promote cholesterol and phospholipid efflux to lipid-poor Apo AI and ABCG1 subsequently promotes the efflux of additional cellular cholesterol to perform lipid-protein complexes.

Although mutations of the human ABCG1 gene have not been described so far, data from ABCG1 knockout mice recently gave novel insights into ABCG1 function in vivo. Targeted disruption of the ABCG1 gene caused massive deposition of neutral lipids and phospholipids in liver, lungs, and tissue macrophages further supporting a critical role of ABCG1 in lipid transport.

ABCG5 and ABCG8

In addition to the described lipid pathways mainly operative in macrophages, two further ABC-transporters, ABCG5 and ABCG8 have been implicated in the efflux of dietary sterols from intestinal cells back into the gut lumen and from liver to the bile duct (Fig 1). Both ABC-transporters form a functional heterodimer with highest expression levels in liver and intestine and are regulated

by a common bidirectional promoter. Therefore, ABCG5 and ABCG8 share common regulatory elements, in particular, the LXR/RXR heterodimer that mediates cholesterol-induced expression of both genes. Mutations in ABCG5 or ABCG8 lead to β -Sitosterolemia, also called phytosterolemia or shellfishsterolemia, a rare autosomal recessive disorder. The disease is characterized by enhanced trapping of cholesterol and other sterols, including plant and shellfish sterols, within the intestinal cells and the inability to concentrate these sterols in the bile. As a consequence, affected individuals have strongly increased levels of plant sterols, e.g., β -sitosterol, campesterol, stigmasterol, avenosterol, and 5α -saturated stanols, whereas total sterol levels remain normal or just moderately elevated. Patients mainly suffer from tendon and tuberous xanthomas at early age and premature development of atherosclerosis and coronary heart disease.

In addition to the ABCG5/ABCG8 heterodimer, a specific transporter termed Niemann–Pick C1 like 1 (NPC1L1) as well as aminopeptidase N (CD13) were recently identified to play a critical role in intestinal absorption of cholesterol and plant sterols. Both genes are expressed predominantly in the gastrointestinal tract with peak expression levels in the small intestine. CD13 is localized in the brush border membrane and is the target of ezetimibe, a specific inhibitor of intestinal cholesterol absorption. Deep tubular invaginations connect CD13 to the NPC1L1 pathway that controls downstream cholesterol trafficking by directing exogenous sterols toward the late endosome. Thereby, CD13 and NPC1L1 act as gatekeepers for absorption of cholesterol and plant sterols from the lumen of the small intestine. Sterols that have entered the intestinal cell can then be directly transported back to the gut lumen by the ABCG5/ABCG8 complex by means of a sort of kick-back mechanism. Although, the function of CD13, NPC1L1 and ABCG5/ABCG8 is not fully understood, it is very likely that these proteins play a key role in the regulation of total cholesterol absorption.

Drugs

Although no drugs directly targeting the sterol transporters described above are available, the function of several lipid lowering drugs is associated with interaction with ABCA1.

Adenosin A_{2A} receptor antagonists are novel drugs for the prevention and treatment of vascular and tissue injuries. The antiatherogenic effects of ►adenosin are at least partially mediated by an induction of ABCA1 expression. The observed upregulation of ABCA1 following A_{2A} receptor ligation is mediated by cAMP/protein kinase A (PKA) potentially acting via phosphorylation of Sp1 and the ABCA1 promoter.

Niacin is a further very potent drug in increasing HDL-cholesterol levels and lowering plasma low-density

lipoprotein (LDL) cholesterol and triglycerides which has a significant effect on cholesterol transport in macrophages. ► **Niacin** is able to upregulate LXR-mediated transcription of ABCA1 via an activation of transcription and nuclear translocation of PPAR γ as well as to increase cellular cAMP levels. It is very likely that niacin mediates its effects by affecting several key genes of reverse cholesterol transport which underlie nuclear receptor and PKA signaling, including ABCA1 and ABCG1.

In addition to Niacin, **fibrates** are very effective in raising HDL-cholesterol and lowering triglycerides. In particular efficacy of gemfibrozil and bezafibrate in reducing cardiovascular morbidity, mortality and progression of atherosclerosis has been demonstrated. Fibrates are synthetic PPAR α ligands, which impact HDL and triglyceride metabolism by regulating the expression of important genes in reverse cholesterol transport and fatty acid metabolism including ABCA1 and ABCG1 as well as Apo AI, Apo AII, Apo CIII, and lipoprotein lipase.

► **Ca²⁺ channel blockers**, such as verapamil, are known to exert potent antihypertensive, antiarrhythmic, and antiatherosclerotic effects. In some reports an increase in HDL-cholesterol was attributed to verapamil treatment which may be mediated by a verapamil-induced increase in ABCA1 expression that is independent of oxysterols and LXR, but may be caused by direct interaction of verapamil with the ABCA1 promoter.

Ezetimibe is a novel selective cholesterol absorption inhibitor, which does not affect uptake of fatty acids, bile acids, fat soluble vitamins, or carotenoids. The molecular target for ezetimibe is in the intestinal brush border membrane of CD13. In clinical trials with hypercholesterolemic patients ezetimibe has been shown to be highly effective in inhibiting intestinal cholesterol absorption and reducing plasma LDL-cholesterol.

Sulfotransferase

Sulfotransferases are a group of cytosolic enzymes, which catalyze the transfer of the sulfonate group from 3'-phosphoadenosine-5'-phosphosulfate (PRPS) to an acceptor substrate to form either a sulfate or sulfonate conjugate. Sulfotransferases metabolize a variety of small lipophilic endobiotics (e.g. estrogen, corticoid, thyroxin) as well as a variety of xenobiotics. Genes of cytosolic sulfotransferases (SULT) have been identified and several genetic polymorphisms have been observed in human sulfotransferases, such as ST1A2, ST1A3 and ST2A3.

SUMO

Small ubiquitin-like modifier represents a family of evolutionary conserved proteins that are distantly related in amino-acid sequence to ubiquitin, but share the same structural folding with ubiquitin proteins. SUMO proteins are covalently conjugated to protein substrates by an isopeptide bond through their carboxyl termini. SUMO addition to lysine residues of target proteins, termed SUMOylation, mediates post-translational modification and requires a set of enzymes that are distinct from those that act on ubiquitin. SUMOylation regulates the activity of a variety of target proteins including transcription factors.

Definition

► **Small Ubiquitin-like modifier** (SUMO) is a conserved protein that is ubiquitously expressed in eukaryotes and is essential for viability. It serves as a reversible posttranslational modifier by forming an ► **isopeptide bond** with lysine residues in many target proteins, in a catalytic process termed SUMOylation. SUMOylation of proteins results in altered inter- or intramolecular interactions of the modified target (Fig. 1).

Basic Mechanisms

The SUMO Family

SUMO proteins belong to a family of posttranslational protein modifiers (Ubl for ubiquitin-like) of which ubiquitin is the founding member. Common to these proteins is the ubiquitin fold, an approximately 9 kDa globular core that consists of a $\beta\beta\alpha\beta\beta\alpha\beta$ fold, and a GlyGly motif at the C-terminus of the mature Ubl. Like all other Ubls, SUMO proteins are translated as precursors that are processed before they are conjugated to their targets (see below). A characteristic feature of the SUMO family is a flexible amino terminus of 15–25 amino acids. The number of SUMO paralogs expressed in eukaryotic organisms varies from one (yeast) to eight (plants).

The vertebrate genome encodes two subfamilies of SUMO proteins, the first consists of SUMO1, and the second includes SUMO2, SUMO3, and SUMO4. The mature forms of SUMO2 and SUMO3 are 96% identical, but share only 45% identity with SUMO1. SUMO4 shares 85% identity with SUMO2 and -3; however, it is currently unclear whether this homolog is processed to a mature form and conjugated to substrates. SUMO1, -2, and -3 are expressed in all tissues, but vary in their cellular localization, target specificity, and function. While SUMO1 is found mostly conjugated to substrates, SUMO2/3 are found predominantly in the unconjugated form under normal growth conditions. Most targets are modified by attachment of one or a few single SUMO entities. In some cases, however, chains of SUMO2/3 are formed

SUMOylation. Figure 1 SUMOylation is a reversible and regulated process. Target protein modification by SUMO can be initiated and terminated by different cues. Sumoylation leads to changes in the behavior of the modified protein, for example, different cellular localization, enhanced/reduced activity, or increased stability. These changes are due to alterations either in protein interactions or protein folding.

on the target. The function of these chains is largely unknown.

The Enzymatic Process

Proteins are conjugated to SUMO via an ► **isopeptide bond** formed between an exposed carboxy terminal glycine residue of SUMO and the ϵ -amino group of a lysine residue of the target protein. In most cases, the modified lysines in target proteins are found in a consensus SUMOylation site: ψ KxE/D, in which ψ is a large branched hydrophobic residue, and X is any amino acid. SUMOylation occurs if the motif is exposed and in an unstructured region. The reaction is carried out by at least two enzymes that act on all SUMO proteins: the E1 SUMO activating enzyme, a heterodimer consisting of Aos1 (SAE1) and Uba2 (SAE2), and the E2 enzyme also known as Ubc9 (Fig. 2).

In the first step, the E1 enzyme activates SUMO in an ATP-dependent manner. This reaction generates a high-energy thiol ester intermediate between the glycine residue at the C-terminus of SUMO and the active site cysteine of Uba2. Subsequently, SUMO is transferred from the E1 to a cysteine in the active site of Ubc9. In some cases, Aos1/Uba2 and Ubc9 are sufficient to modify a target. This is the case, for example, for RanGAP1, which interacts with Ubc9 by virtue of two binding interfaces, the SUMO consensus motif and an additional interface at its C-terminus. Most targets interact with Ubc9 only via their SUMOylation site and can be sumoylated efficiently only in the presence of additional factors, so called ► **E3 ligases**. SUMO E3 ligases function by stabilizing the Ubc9-target interaction and/or by accelerating transfer rates. Three types of E3 enzymes are known to act in SUMOylation.

SUMOylation. Figure 2 SUMO enzymatic machinery. SUMO is translated as a precursor with a short C-terminal prosequence. SUMO specific isopeptidases (SENPs) remove this sequence to reveal a double Glycine motif in SUMO that is essential for conjugation. The E1 heterodimer Uba2/Aos1 activates SUMO in an ATP-dependent reaction by forming a thioester bond between the C-terminal Glycine in SUMO and the active site Cysteine of the E1. SUMO is transferred from the E1 to the Cysteine of Ubc9. In most cases an E3 facilitates the transfer of SUMO from Ubc9 to the substrate (bold arrow). In rare cases Ubc9 can transfer SUMO directly to the substrate (broken arrow). As a result, a covalent bond is formed between the C-terminal Glycine of SUMO and a Lysine in the target protein. Finally, this modification can be reversed by SENPs.

The first family of SUMO E3 ligases is present in all eukaryotic organisms and is characterized by a **SP-RING finger domain** that mediates the interactions of the SUMO E2 enzyme Ubc9 with the substrate. The SP-RING is related to RING finger domains found in most ubiquitin E3 ligases. The group of vertebrate SP-RING finger E3 ligases includes PIAS proteins (PIAS1, PIAS3, PIAS α , PIAS β , PIAS γ and Mms21). Interestingly, PIAS proteins (*Protein inhibitor of activated STAT*) were initially identified as proteins that interact with and inhibit the STAT transcription factors (signal transducer and activator of transcription), or modulate transcriptional activity of the androgen receptor (shown for PIAS α also known as ARIP3). The second SUMO E3 ligase family is apparently vertebrate specific. It consists of the nuclear pore protein RanBP2/Nup358 that faces the cytosolic side of the nuclear envelope. The minimal E3 ligase activity of RanBP2 was mapped to an unfolded area of 120 amino acids in its C-terminus that does not resemble other known E3 ligases. Other domains of RanBP2 serve as binding sites for nuclear transport factors. Whether SUMOylation and nucleocytoplasmic transport are coupled events remains to be seen.

The third type of E3 ligases is represented by the polycomb protein 2 (Pc2), which was reported to enhance sumoylation of the substrate CtBP. N- and C-terminal domains in Pc2 that have been implicated in CtBP sumoylation do not resemble known E3 ligases. Like RanBP2, Pc2 expression is restricted to higher eukaryotes.

Modification by SUMO is a reversible and often highly dynamic process. Cleavage of the isopeptide bond between SUMO and its targets is accomplished by SUMO specific **cysteine proteases** of the Ulp/SENPs family (Fig. 2). Six members were identified in humans,

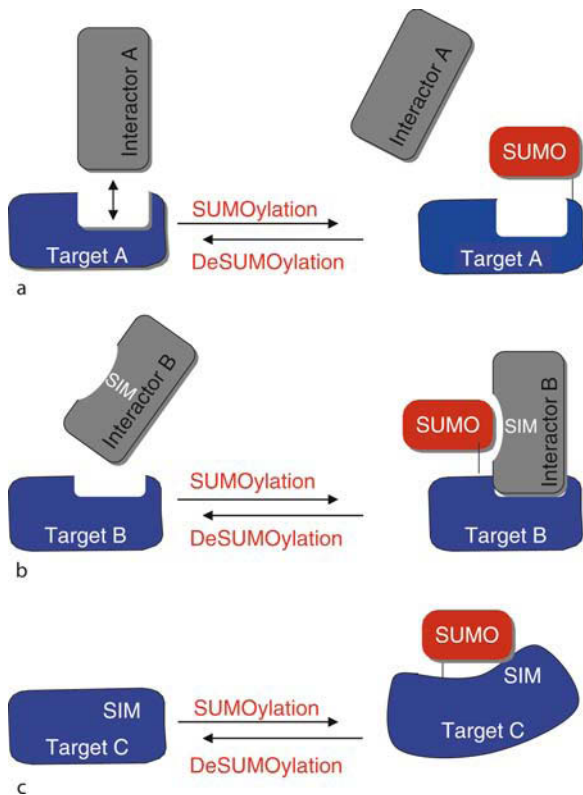

SENP1–3, and SENP5–7. They all share a 30 kDa catalytic domain at their C-terminus, but differ greatly in size and sequence. SENP3, -5, and -7 reside in the nucleus, SENP1 appears to shuttle between the cytoplasm and nucleus, SENP2 is at the nuclear pore complex, facing the nucleoplasm, and SENP6 is in the cytoplasm. SUMO isopeptidases also differ in their specificity against different SUMO-proteins (e.g., SENP3 and -5 preferentially deconjugate SUMO2/3) and may display selectivity toward modified targets. Due to these differences in activity and different localization, SENP proteases are believed to have distinct functions in vivo.

In addition SENPs are required for maturation of SUMO precursors. SUMO proteins are translated as inactive precursors with a short C-terminal prosequence of variable length. This sequence needs to be removed to expose a double glycine motif at the C-terminus of SUMO that is required for conjugation.

Molecular Consequences of SUMOylation

What does SUMOylation do? The answer to this question is almost as long as the number of substrates to which SUMO is conjugated. Protein modification by SUMO can lead for example to altered localization, activity, or stability of the target proteins. Although downstream consequences of sumoylation are target specific and highly diverse, the general feature underlying all effects is a change in inter- or intramolecular interactions (Fig. 3) SUMOylation leads to such changes by masking binding sites, formation of a new binding interface, or by inducing conformational changes in protein structure.

Masking of a site: Association between two proteins can be disrupted by SUMOylation, if the SUMO attachment site of a target protein overlaps with the

SUMOylation. Figure 3 SUMOylation affects protein–protein interaction. (a) Masking of an interaction site: The interaction between Target A and a second protein (interactor A) is hindered by SUMOylation, as the modification site is in close proximity to the interaction surface. (b) Formation of a novel site: Interacting protein B contains a weak binding site to Target B and a SUMO interacting motif (SIM). The association between Target B and interactor B is initiated/stabilized upon sumoylation of Target B, since it now involves two sites: a weak binding site and a SIM. (c) Change in structure: SUMOylation of Target C leads to changes in the conformation of the modified target due to intramolecular interactions of an internal SIM with the conjugated SUMO.

interaction surface (Fig. 3a). This has been observed, for example, in modification of the ubiquitin E2 enzyme E2-25K with SUMO, which disrupts the association between E2-25K and the ubiquitin E1 enzyme.

Formation of a novel binding site: novel complexes may be formed between a SUMOylated protein and an effector protein that contains a SUMO-interacting motif (SIM or SBM). Proteins that contain two binding sites, a SIM and a weak binding motif to protein X, will bind more strongly to this protein if it is SUMOylated (Fig. 3b). Short peptides that contain the hydrophobic core motif [V/I]-X-[V/I]-[V/I] or [V/I]-[V/I]-X-[V/I] can act as a SIM and bind to SUMO. This core is often flanked by acidic amino acids and/or serine residues.

NMR studies show that this motif forms a β strand that binds in parallel or antiparallel orientation to the β 2 strand in SUMO. One example for a SIM-mediated interaction is the association of the SIM-containing protein Daxx with sumoylated forms of GR and PML. In addition, SIMs may also play a role in target modification: First, SIMs are found in many of the enzymes involved in SUMO conjugation such as the E1 subunit Uba2, Ubc9, RanBP2, and all PIAS E3 ligases; Second, some targets, such as the transcription corepressor Daxx, need a SIM to be efficiently SUMOylated.

Changes in structure: SUMO modification can induce changes in structure if the target protein contains an internal SIM (Fig. 3c). This change was shown for the DNA excision repair enzyme thymine-DNA glycosylase (TDG): TDG binds to GU or GT mismatches and removes the mutated base. Subsequent sumoylation of DNA-bound TDG is necessary to release the enzyme from the AP site and allow for further repair. Crystallographic structural studies reveal that dissociation is due to a conformational change mediated by interaction of an internal SIM with covalently bound SUMO. Of note, conformational changes have not been observed in three sumoylated targets, RanGAP1, E2-25K, and Ets-1 that lack a SIM motif. Here, SUMO and the target are coupled in what is referred to as a “beads on a string” fashion.

Targets of SUMOylation

Based on a number of recent proteomic studies, several hundred proteins are regulated via sumoylation. They function in nearly every aspect of cell biology, including chromatin structure and function, DNA repair, signal transduction, nucleocytoplasmic transport, mitochondria fission, glucose and potassium transport, as well as basic metabolism. Transcription factors and transcriptional coregulators represent a prominent group of SUMO targets. A common feature of these proteins is that their modification leads to transcriptional repression. Interestingly, the sumoylation site in transcription factors often overlaps with an inhibitory domain known as the synergy control (SC) motif. Removal of the SC motif or conversion of the SUMO acceptor lysine to an arginine activates the transcription factor. In line with the suggestion that it is SUMO that renders these factors inactive is the finding that overexpression of SUMO isopeptidases increases the activity of transcription factors such as Sp3, the Androgen receptor (AR), and Elk1. SUMOylation does not interfere with the ability of these transcription factors to bind to DNA. Rather, the repressive function of SUMO seems to be mediated by its ability to recruit corepressors such as histone deacetylases (HDACs) to the promoter. Interestingly, HDAC1 and HDAC4 are themselves targeted for modification by SUMO. HDAC4 mutants that cannot undergo SUMOylation

display reduced transcriptional repression compared to the wild-type protein. SUMOylation also regulates the subcellular localisation of modified proteins: the cytoplasmic protein RanGAP1 is targeted to the nuclear pore complex upon modification, and PML (promyelocytic leukemia protein) sumoylation is essential for its localization to – and formation of – PML nuclear bodies. Transient recruitment of other proteins such as Sp100, Daxx, and TDG to PML bodies is dependent on their sumoylation or a SIM. Finally, SUMO has been shown to regulate enzyme and channel functions: In addition to the inhibition of E2-25K that was already mentioned above, it has recently been shown that SUMOylation inactivates the ER associated protein-tyrosine phosphatase 1B (PTP1B), alters the RNA editing properties of ADAR, and transiently inactivates potassium channels.

Competition with other Posttranslational Modifiers

Other modifications, such as ubiquitination, acetylation, or methylation, which also target lysine residues, can at least in principle compete with sumoylation. Indeed, acetylation and SUMOylation of the same lysine have been reported, for example, Mef2 or the tumor suppressor HIC1. Moreover, ubiquitin and SUMO target the same lysine residues in e.g. PCNA, I κ B α and NEMO. Phosphorylation of I κ B α leads to polyubiquitination on lysine 21, resulting in its degradation by the 26S Proteasome. SUMOylation of the same lysine residue takes place in the absence of phosphorylation. Thus, it was suggested that the role of I κ B α SUMOylation is to act as an antagonist of ubiquitin and thus protect it from proteasomal degradation. In contrast, SUMOylation of NEMO (NF- κ B essential modulator) seems to play a role in priming it for a phosphorylation-dependent ubiquitination: PIASy catalyzes the modification of NEMO by SUMO1, which in turn leads to phosphorylation by the nuclear kinase ATM. Subsequently, NEMO is deSUMOylated and ubiquitinated. This leads to translocation of NEMO to the cytoplasm, where it participates in the activation of NF κ B.

Regulation of SUMOylation

Many proteins undergo modification by SUMO only upon extra- and intracellular stimuli such as cell cycle position, nutritional state, heat shock, or DNA damage indicating that SUMOylation and/or deSUMOylation is tightly controlled. Substrate phosphorylation can act as both a positive and negative regulator of SUMOylation. Some targets such as Hsf-1, HSF4b, GATA, Mef2, and several others contain a phosphorylation-dependent SUMO modification motif (PDSM). This motif is composed of a classical SUMOylation site and an adjacent serine and proline: ψ KxExxSP. Heat-shock dependent phosphorylation of the PDSM in

Hsf-1 is a prerequisite for its SUMOylation. On the other hand, phosphorylation of proteins such as the transcription factors c-Jun, c-Fos, and p53 reduce their SUMOylation. While not much is known about regulation at the level of the enzymes, selected examples suggest that this may be a common mechanism. The yeast PIAS homolog Siz1 changes its localisation in mitosis from the nucleus to the bud neck, where it sumoylates septins, the mammalian E3 ligase Pc2 was reported to be regulated by phosphorylation, and H₂O₂ has been shown to reversibly inactivate SUMO enzymes. The latter is accomplished by disulfide bond formation between cysteines in the active sites of Uba2 and Ubc9. Depending on the levels of H₂O₂ this leads to global or selective deSUMOylation. A global increase in sumoylation has been observed under heat shock and osmotic stress, but the underlying mechanism is not yet clear.

Pharmacological Intervention

Since the SUMO pathway affects multiple pathways ranging from transcription, DNA repair, and intracellular trafficking over cell signaling and cell cycle control to basic metabolism, it is not surprising that links to diseases and viral assaults are emerging. However, the field is not yet at a stage sufficiently developed for pharmacological intervention. Below we will describe selected examples for links of the SUMO pathway to diseases and viral functions.

SUMO1 haploinsufficiency has been linked to a developmental defect: Based on the finding that a patient with a cleft lip and palate had a mutation in the SUMO1 gene locus, a mouse model was generated that had reduced SUMO1 expression. Increased frequency for a cleft palate or oblique facial cleft was observed in the transgenic mice, suggesting that SUMO haploinsufficiency can lead to developmental defects.

SUMO and neurodegenerative diseases: Like ubiquitin, SUMO was observed to accumulate in cytoplasmic and nuclear inclusions characteristic for diverse neurodegenerative diseases. Two proteins linked to formation of these aggregates, the natively unfolded proteins Tau and α -synuclein, are targets for sumoylation. The meaning of their modification remains however to be shown. A functional link to Huntington's disease has been suggested by the observation that a pathogenic fragment of Huntingtin (Httex1p) can be modified either by ubiquitin or by SUMO1 on identical lysine residues. Ubiquitination leads to aggregation of this fragment, whereas SUMOylation stabilizes it in a soluble state. In a drosophila model, sumoylation of Httex1p seems to exacerbate neurodegeneration.

SUMO and viruses: Different viruses have been shown to interfere with or hijack the SUMO pathway. Most drastic is the action of the CELO adenovirus

protein Gam1, which induces degradation of the SUMO E1 and E2 enzymes. Consequently, global sumoylation is lost. Other viral proteins seem more specific: Expression of the Herpes simplex virus (HSV) ICP0 protein or the Cytomegalovirus immediate early 1 (HCMV-IE1) protein leads to disruption of PML nuclear bodies and to deconjugation of SUMO from PML and Sp100. On the other hand, several immediate-early and early proteins produced by DNA viruses are themselves targets for modification or interact with components of the SUMOylation machinery.

SUMO and Cancer: While many tumor suppressors and protooncogenes can be modified by SUMO, direct links of the sumoylation pathway to cancer development are not yet available. The strongest link exists to acute promyelocytic leukemia (APL), which is caused by a chromosomal fusion between PML and the retinoic acid receptor (RARA). The resulting fusion protein PML–RARA forms homodimers that recruit and tightly bind nuclear receptors and corepressors. Transgenic mice that express a SUMO deficient mutant of the fusion protein PML–RARA do not develop APL. Other evidence is only correlative, such as the observation that SENP1 is overexpressed in human prostate cancer or that transgenic mice overexpressing SENP1 develop carcinomas at an early age.

Superantigen

Bacterial or viral proteins linking T-cell receptors and MHC molecules through simultaneous interaction with the constant domains of all MHC class II molecules and of T-cell receptor β -chains. Hence, superantigens are polyclonal T-cell activators most likely involved in the development of autoimmune diseases.

► Interferons

Supercoils

Bacterial as well as eukaryotic chromosomes contain too much DNA to fit easily into a cell. Therefore, the DNA must be condensed (compacted) to fit into the cell or nucleus. This is accomplished by supercoiling the DNA into a highly condensed form. When relaxed circular DNA is twisted in the direction that the helix turns, the DNA becomes positively supercoiled, if it is twisted in the opposite direction, it is called negatively supercoiled. Bacterial DNA is normally found in a negatively supercoiled state. Supercoiling reactions are catalyzed by topoisomerases.

- Quinolones
- Topoisomerases

Superfamily

The term superfamily is used to include in the classical sequence-based families, proteins with no statistically significant sequence similarities but with similar three-dimensional structures.

Superoxide

Superoxide is a free radical form of oxygen (O_2^-) that is damaging to cells. Superoxide is scavenged by the enzyme superoxide dismutase used by neutrophils to destroy microbes in the body.

S

Superoxide Dismutase

Superoxide dismutase (SOD) enzymes are metalloproteins that detoxify superoxide anions (O_2^-) by converting them to H_2O_2 , which is subsequently reduced to water. SOD enzymes include the manganese (Mn) enzyme in mitochondria (SOD2) and the Cu/Zn

enzyme that is present in the cytosol (SOD1) or on extracellular surfaces (SOD3). As superoxide anions play an important role in a variety of pathophysiological conditions, such as tissue injury and inflammation, the capacity of SOD enzymes may be important for the cause of the disease. SOD mimetics are under investigation for their potential use as anti-inflammatory agents.

Suprachiasmatic Nucleus

Region of the mammalian brain residing in the anterior hypothalamus that functions as the master circadian regulator.

► Circadian Rhythms

Supraventricular Tachycardia

Supraventricular tachycardia is a heart condition characterised by fast arrhythmias involving the atrioventricular (AV) node.

► Antiarrhythmic Drugs

SUR

Sulfonylurea receptor (SUR), a member of the ATP-binding cassette superfamily, is a large molecular membrane protein with 17 putative transmembrane domains. The human *SUR1* gene has 39 exons and encodes the SUR1 that has high binding affinity to sulfonylureas, a class of type 2 antidiabetic drugs such as glibenclamide and glipizide, used to promote insulin secretion. The human *SUR2* gene with 38 exons encodes two types of low-affinity receptors, SUR2A and SUR2B, which are different only in the last exon.

SxxK Acyl Transferases

The acyl transferases of the SxxK superfamily have a specific bar code in the form of three motifs SxxK, SxN or analogue and KTG or analogue (with x denoting a variable amino acid residue). The motifs occur at equivalent places and roughly with the same spacing along the polypeptide chains, and close to each other at the immediate boundary of the catalytic centre. A constellation of bacterial genes code for SxxK acyl transferases of varying amino acid sequences, functionalities and modular designs. They occur as free-standing polypeptides and as protein fusions. Those involved in bacterial wall (4–3) peptidoglycan assembly and metabolism bind penicillin in the form of stable

and inactive penicilloyl derivatives in which the penicilloyl moiety is linked as an ester to the serine residue of the SxxK motif.

► [β-Lactam Antibiotics](#)

SxxK Free-standing Penicillin-binding Protein

SxxK free-standing penicillin-binding proteins (PBPs) are uncoupled SxxK acyl transferases that work mainly as bacterial wall peptidoglycan-hydrolases and function as auxiliary cell-cycle proteins. They are not essential.

► [β-Lactam Antibiotics](#)

SxxK β-lactamases

SxxK β-lactamases are uncoupled SxxK acyl transferases that work as β-lactam antibiotic hydrolases. They represent a mechanism of defence of great efficiency. On good β-lactam substrates, their catalytic centres can turn over 1000 times per second.

► [β-Lactam Antibiotics](#)

SxxK PBP Fusions

Class A penicillin-binding protein (PBP) fusions combine in a single polypeptide chain a class A SxxK acyl transferase linked to a glycosyl transferase module having its own five-motif bar code, itself linked to a membrane anchor. They catalyse the conversion of disaccharide-peptide units, borne by a C₅₅ undecaprenyl carrier, into polymeric (4–3) peptidoglycan. Class B PBP fusions are composed of a class B SxxK acyl transferase, a linker module having its own three-motif bar code and a membrane anchor. They are members of the morphogenetic apparatus. They are implicated in the remodelling of (4–3) peptidoglycan throughout the

bacterial cell cycle. PBP fusions of classes A and B are, globally, the lethal targets of β-lactam antibiotics.

Sympatholytic Drugs

Sympatholytic drugs are a group of drugs, which decrease the activity of the sympathetic nervous system, mainly by blocking the action of adrenaline and noradrenaline at adrenoceptors.

► [α-Adrenergic System](#)

► [β-Adrenergic System](#)

Sympathomimetic Drugs

Direct sympathomimetic drugs act as agonists on adrenergic receptors. In contrast, indirectly acting sympathomimetic drugs act by increasing the concentration of noradrenaline. Indirectly acting sympathomimetics like tyramine, amphetamine or ephedrine are taken up into sympathetic nerve terminals and are transported into the vesicles by the vesicular monoamine transporter in exchange for noradrenaline, which escapes into the cytosol. Most of the noradrenaline in the cytosol escapes via the transporter in the presynaptic membrane in exchange for the indirectly acting sympathomimetic monoamine. By this mechanism as well as by partly inhibiting the reuptake of noradrenaline and partly by inhibiting the degradation of noradrenaline by monoamine oxidase (MAO), they increase the concentration of noradrenaline in the synaptic cleft.

► [α-Adrenergic System](#)

► [β-Adrenergic System](#)

Synapse

A synapse is a contact site between two neurones, where information is communicated from the axon of one neurone (the presynaptic) to the cell body, the dendrites or the axon of the second neurone (the postsynaptic). In most synapses, the information is communicated chemically;

the presynaptic neurone releases a neurotransmitter substance, which then acts on receptors of the postsynaptic neurone. Most chemical synapses are characterized morphologically by an increase in diameter of the presynaptic axon to form a varicosity or bouton, by transmitter-storing vesicles inside the bouton and by a synaptic cleft crossed by cell adhesion molecules. In a relatively few synapses, the information is transmitted electrically. In a wider sense, sites of transmission between neuronal axons and peripheral effector cells, such as smooth muscle cells, are also synapses.

► Synaptic Transmission

Synaptic Plasticity

Any mechanism involved in modulating the strength of synaptic signalling (usually with higher frequency and/or amplitude of both inhibitory and excitatory neurotransmitter release). Both excitatory and inhibitory signalling can be reinforced and for both a relatively short (as in “depolarisation-induced suppression of excitation” or “inhibition”) and a relatively long (as in “long-term potentiation” and “long-term depression”) period of time.

Synaptic Transmission

KLAUS STARKE

Institut für Experimentelle und Klinische Pharmakologie und Toxikologie, Universität Freiburg, Freiburg, Germany

Definition

Synaptic transmission is the transfer of biological information across ►synapses. Drugs that influence synaptic transmission play an eminent role in therapy, for two reasons. First, the nervous system controls all tissues. Second, with few exceptions synaptic transmission is chemical, operating by means of transmitter substances, and synapses therefore provide a large number of drug targets, such as the enzymes that synthesize the transmitter. However, the importance of

synaptic pharmacology extends beyond therapy: many poisons act at synapses, as do the everyday drugs caffeine, ethanol and nicotine.

There are numerous transmitter substances. They include the amino acids glutamate, GABA and glycine; acetylcholine; the monoamines dopamine, noradrenaline and serotonin; the ►neuropeptides; ATP; and NO. Many neurones use not a single transmitter but two or even more, a phenomenon called ►cotransmission. Chemical synaptic transmission hence is diversified. The basic steps, however, are similar across all neurones, irrespective of their transmitter, with the exception of NO: transmitter production and vesicular storage; transmitter release; postsynaptic receptor activation; and transmitter inactivation. Figure 1 shows an overview. ►Nitrgic transmission, i.e. transmission by NO, differs from transmission by other transmitters and is not covered in this essay.

Basic Mechanisms

Transmitter Production and Vesicular Storage

All non-peptide transmitters are produced in the axon terminals, which possess the necessary machinery. Cholinergic terminals contain choline acetyltransferase, which acetylates choline to acetylcholine. Dopaminergic terminals contain tyrosine hydroxylase, which converts tyrosine into levodopa, and aromatic L-amino acid decarboxylase, which decarboxylates levodopa to dopamine. Noradrenergic terminals contain in addition dopamine β-hydroxylase, which oxidizes dopamine to noradrenaline. Following synthesis, the transmitters (except NO) are taken up into ►synaptic vesicles by means of a transport system consisting of two components: an ATP-driven H⁺ pump that generates a proton gradient (ΔpH; vesicle lumen acidic) and a potential gradient (Δψ; vesicle lumen positive); and the vesicular neurotransmitter transporter (VNT) (►Neurotransmitter transporters, ►Vesicular transporters), which exchanges intravesicular H⁺ with axoplasmic transmitter (Fig. 1 inset). There are several VNT families. One is the vesicular monoamine transporter (VMAT)/vesicular acetylcholine transporter (VAChT) family. VMAT is responsible for the vesicular transport of dopamine, noradrenaline and serotonin [1].

In contrast to the small transmitter molecules, the neuropeptides are synthesized in the rough endoplasmic reticulum of the neuronal perikarya. They are enclosed in vesicles in the Golgi apparatus. The vesicles travel down to the terminals by axonal transport.

Transmitter Release

All transmitters (except NO) are released by the following cascade: arrival of the nerve action potential at the terminal – opening of voltage-sensitive Ca²⁺

Synaptic Transmission. Figure 1 Synaptic transmission. The presynaptic terminal contains voltage-dependent Na⁺ and Ca²⁺ channels, vesicles with a vesicular neurotransmitter transporter VNT, a plasmalemmal neurotransmitter transporter PNT, and a presynaptic G protein-coupled receptor GPCR with its G protein and its effector E; the inset also shows the vesicular H⁺ pump. The postsynaptic cell contains two ligand-gated ion channels LGIC, one for Na⁺ and K⁺ and one for Cl⁻, a postsynaptic GPCR, and a PNT. In this synapse, released transmitter is inactivated by uptake into cells.

channels – exocytosis – recycling of the vesicle membrane. The nerve action potential is mainly carried by Na⁺ entry through voltage-dependent Na⁺ channels. Axon terminal voltage-sensitive Ca²⁺ channels are mainly of the N- and P/Q-types.

The action potential-induced increase in axoplasmic Ca²⁺ is the physiological trigger for exocytosis. Exocytosis consists of the fusion of the vesicle membrane with the plasmalemma, the opening of a pore in the fused membranes, and outward diffusion of the neurotransmitter or neurotransmitters. Three proteins, the so-called **SNARE proteins**, are essential in exocytosis (Fig. 1 inset). One, synaptobrevin, is a protein of the vesicle membrane; the other two, syntaxin and SNAP-25 (synaptosome-associated protein of 25 kD), are proteins of the plasmalemma (Fig. 1 inset). Upon an increase in cytoplasmic Ca²⁺ from about 0.1 to about 100 μM, the vesicular synaptobrevin grabs hold of the plasmalemmal SNAREs, and the three proteins intertwine into a complex that then tightens like a zipper. This “zippering” of the SNAREs pulls the vesicle and plasma membranes together so that the lipid bilayers merge. An additional vesicular protein, synaptotagmin, may be the Ca²⁺ sensor that detects the increase in cytoplasmic Ca²⁺. Ca²⁺

channels and SNAREs lie closely together. Syntaxin and SNAP-25 in fact interact physically with the α1 subunit of N- and P/Q-type Ca²⁺ channels. The close neighbourhood permits the quickness of exocytosis; the time from the arrival of the action potential to pore formation is only 100 μs or less.

After exocytosis, the vesicle membrane with its lipids and proteins is recycled, either by immediate re-filling with transmitter or by passing through a vesicle resting pool deeper inside the axon terminal.

Action potential-elicited neurotransmitter exocytosis is variable. Firstly, action potentials trigger release from a given axon terminal only unreliably, with one or two release events per ten action potentials, resulting in a low overall release probability. Secondly, the probability of release is modulated by **presynaptic receptors** in the axon terminal membrane (Fig. 1). Through these receptors, transmitter substances from neighbouring neurones and hormones can increase or reduce the release probability [2]. Axon terminals thus integrate [1] the release command of the action potential and [2] various modulatory chemical messages from the neighbourhood to release an appropriate amount of transmitter.

Postsynaptic Receptor Activation

Of the several classes of receptors for endogenous chemical signals [3], two are used as postsynaptic receptors in synaptic transmission: ligand-gated ion channels (LGICs) and **G protein-coupled receptors** (GPCRs; Fig. 1). Due to the large number of transmitters and the existence of several receptor types for almost all, postsynaptic receptor activation is the most diversified step of synaptic transmission. Table 1 shows selected neurotransmitter receptors.

LGICs are hetero- or homo-oligomeric proteins consisting of 3, 4 or 5 peptide chains, of which each spans the membrane several times. The 3–5 subunits surround a pore, which in the absence of transmitter is closed. The nicotinic receptor for acetylcholine, the GABA_A-receptor, the glycine receptor and the 5-HT₃-receptor for serotonin are pentamers. The ionotropic glutamate receptors are tetramers. The P2X-receptors for ATP are trimers. When transmitter is bound to a ligand-gated ion channel receptor, the open probability of the pore is increased. Ions may then enter or leave the

cell, but a selectivity filter in the channel lets only certain ions pass.

The AMPA receptors for glutamate, the nicotinic acetylcholine receptor and the 5-HT₃-receptor for serotonin are cation channels (Table 1). When they open, the major consequence is a sudden entry of Na⁺, depolarization and an excitatory postsynaptic potential (EPSP; Fig. 1).

The GABA_A-receptor and the glycine receptor are Cl⁻ channels (Table 1). When they open at a resting membrane potential of about -60 mV, the consequence is an entry of Cl⁻, hyperpolarization and an inhibitory postsynaptic potential (IPSP; Fig. 1).

All these postsynaptic events last only for a few milliseconds; synaptic transmission through LGICs is fast. When the postsynaptic cell membrane is sufficiently depolarized, voltage-dependent Na⁺ channels open and an action potential is generated.

GPCRs are proteins that span the postsynaptic cell membrane seven times (heptahelical receptors). Small ligands are usually bound within a pocket formed by the

Synaptic Transmission. Table 1 Selected neurotransmitter receptors

Transmitter	Receptor ^a	Effector mechanisms ^b	Agonists	Antagonists
Glutamate	AMPA (LGIC)	↑ Na ⁺ and K ⁺ conductance	α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)	
GABA	GABA _A (LGIC)	↑ Cl ⁻ conductance	Muscimol	Bicuculline
	GABA _B (GPCR)	G _{i/o}	Baclofen	
Glycine	glycine receptor (LGIC)	↑ Cl ⁻ conductance		Strychnine
Acetylcholine	nicotinic (LGIC)	↑ Na ⁺ , K ⁺ and Ca ²⁺ conductance	Nicotine, suxamethonium	Tubocurarine, α-conotoxins, α-bungarotoxin
	muscarinic M ₁₋₅ (GPCR)	M ₁ , M ₃ , M ₅ : G _{q/11} ; M ₂ , M ₄ : G _{i/o}	Muscarine, carbachol	atropine, scopolamine
Dopamine	D ₁₋₅ (GPCR)	D ₁ , D ₅ : G _s ; D ₂ , D ₃ , D ₄ : G _{i/o}	D ₂ : bromocriptine	D ₂ : Chlorpromazine
				D ₄ : Clozapine
Noradrenaline	α _{1A,B,D} (GPCR)	G _{q/11}	Phenylephrine	Prazosin
	α _{2A-C} (GPCR)	G _{i/o}	Clonidine	Yohimbine
	β ₁₋₃ (GPCR)	G _s	Isoprenaline	Propranolol

	5-HT ₃ (LGIC)	↑ Na ⁺ and K ⁺ conductance		Ondansetron
Opioid peptides	μ, δ, κ (GPCR)	G _{i/o}	μ: Morphine	Naloxone

^aLGIC, ligand-gated ion channel; GPCR, G protein-coupled receptor

^bActivation of G_{i/o} leads to ↓ cyclic AMP (inhibition of adenylyl cyclase) and ↓ Ca²⁺ conductance (N- and P/Q-type Ca²⁺ channels). Activation of G_{q/11} leads to ↑ inositol trisphosphate and ↑ diacylglycerol (stimulation of phospholipase C). Activation of G_s leads to ↑ cyclic AMP (stimulation of adenylyl cyclase)

seven transmembrane helices. The large neuropeptides bind to the extracellular domains. When the receptors are activated, they interact with the appropriate G proteins that are bound to the inner surface of the cell membrane. The G proteins then pass the information on to various effectors (Fig. 1).

The GABA_B-receptors, the muscarinic M₂- and M₄-receptors for acetylcholine, the dopamine D₂-, D₃- and D₄-receptors, the α₂-adrenoceptors for noradrenaline, the 5-HT_{1A-F}-receptors for serotonin, and the opioid μ-, δ- and κ-receptors couple to G proteins of the G_{i/o} family and thereby lower [1] the cytoplasmic level of the second messenger cyclic AMP and [2] the open probability of N- and P/Q-type Ca²⁺ channels (Table 1). The muscarinic M₁-, M₃- and M₅-receptors for acetylcholine and the α₁-adrenoceptors for noradrenaline couple to G proteins of the G_{q/11} family and thereby increase the cytoplasmic levels of the second messengers inositol trisphosphate and diacylglycerol (Table 1). The dopamine D₁- and D₅-receptors and the β-adrenoceptors for noradrenaline, finally, couple to G_s and thereby increase the cytoplasmic level of cyclic AMP.

These cascades of reactions need time in the range of seconds: synaptic transmission through GPCRs is slow. All further postsynaptic changes depend on the type of postsynaptic cell. For example activation of β₂-adrenoceptors causes: in the heart an increase of the rate and force of contraction; in skeletal muscle glycogenolysis and tremor; in smooth muscle relaxation; in bronchial glands secretion; and in sympathetic nerve terminals an increase in transmitter release.

Transmitter Inactivation

Once released, transmitters are inactivated by diffusion into the neighbouring extracellular space, combined with one of two specific pathways: either extracellular degradation by enzymes that face the extracellular space, or uptake into cells.

Extracellular degradation removes acetylcholine, the neuropeptides and ATP. Acetylcholine is rapidly hydrolyzed to choline and acetate by acetylcholinesterase. The enzyme is localized in both the presynaptic and the postsynaptic cell membrane and splits about 10,000 molecules of acetylcholine per second.

Glutamate, GABA, glycine, dopamine, noradrenaline and serotonin are taken up into adjacent cells. The uptake is mediated by plasmalemmal neurotransmitter transporters (PNTs; Fig. 1). The main driving force for all PNTs is the Na⁺ concentration gradient across the axolemma. There are several PNT families. One is the Na⁺/Cl⁻-dependent neurotransmitter transporter (SCDNT) family, which comprises transporters for GABA, glycine, dopamine, noradrenaline and serotonin. The GABA transporters are located partly in the GABAergic, and the glycine transporters are located

partly in the glycinergic terminals themselves. The dopamine, noradrenaline and serotonin transporters are located almost exclusively in the dopaminergic, noradrenergic and serotonergic terminals, respectively. In all these cases, cellular uptake means re-uptake into the presynaptic neurone. Re-uptake by the PNTs may be followed by vesicular re-uptake by the VNTs; an economical way of inactivation, reminiscent of the recycling of the storage vesicle membrane [1].

Pharmacological Interventions

Transmitter Production and Vesicular Storage

Drugs affecting transmitter production and storage include the following, all acting on monoamine neurones. Levodopa is administered as the precursor of dopamine to compensate for the loss of dopaminergic neurones in ►Parkinson's disease. Benserazide is an inhibitor of aromatic L-amino acid decarboxylase that does not pass the blood–brain barrier. It is given together with levodopa in Parkinson's disease to prevent the decarboxylation of levodopa in peripheral tissues. Reserpine specifically blocks VMAT, thus depletes monoamines from the axon terminals, and is occasionally used to treat hypertension.

Transmitter Release

So central is exocytosis from neurones for animal life, that evolution has made it the target of a large number of natural poisons, used by the producing organisms for defence or attack. The puffer fish produces tetrodotoxin and some dinoflagellates produce saxitoxin, both of which occlude voltage-gated Na⁺ channels by binding to the external side of the channel pore. The cone snail *Conus geographus* produces the ►conotoxin 9-conotoxin GVIA, a small cysteine-rich peptide, which blocks N-type Ca²⁺ channels. P/Q-type Ca²⁺ channels are insensitive to 9-conotoxin GVIA but selectively blocked by the funnel-web spider venom 9-agatoxin IVA, also a small cysteine-rich peptide. Tetrodotoxin and 9-conotoxin GVIA are the two most widely used toxins in neuroscience.

The most ingenious exocytosis toxins, however, come from the anaerobic bacteria *Clostridium botulinum* and *Clostridium tetani*. The former produces the seven botulinum neurotoxins (BoNTs) A–G; the latter produces tetanus neurotoxin (TeNT). All eight toxins consist of a heavy (H) chain and a light (L) chain that are associated by an interchain S–S bond. The L-chains enter the cytosol of axon terminals. Importantly, BoNT L-chains mainly enter peripheral cholinergic terminals, whereas the TeNT L-chain mainly enters cerebral and spinal cord GABAergic and glycinergic terminals. The L-chains are the active domains of the toxins. They are zinc-endopeptidases and specifically split the three core proteins of exocytosis, i.e. the SNAREs (Fig. 1 inset). Each of the eight toxins splits a

single SNARE at a single site. Destruction of synaptobrevin, syntaxin or SNAP-25 in cholinergic terminals by the BoNTs leads to cessation of acetylcholine release followed by flaccid paralysis, the main symptom of ►**botulism**. Destruction of synaptobrevin in GABAergic and glycinergic terminals by TeNT leads to cessation of GABA and glycine release followed by spastic paralysis, the main symptom of ►**tetanus**. BoNT and TeNT are the most potent toxic substances known, able to kill vertebrates at a dose of 0.1 to 1 ng/kg body weight [4].

Postsynaptic Receptor Activation

The most diversified step of synaptic transmission is also the target of the greatest variety of drugs. Some are included in Table 1. Many are natural poisons such as muscimol, bicuculline, strychnine, nicotine, tubocurarine, muscarine, atropine, scopolamine, yohimbine and morphine, all of which stem from plants; the α -conotoxins; and α -bungarotoxin from the bungar snake. Tubocurarine, the α -conotoxins and α -bungarotoxin cause flaccid paralysis by blocking the postsynaptic nicotinic receptor of the skeletal muscle endplate – the same symptom that BoNTs produce by preventing the release of acetylcholine.

The therapeutic impact of drugs acting at transmitter receptors is enormous. All volatile and intravenous anaesthetics and also ethanol act primarily on cerebral LGICs, above all GABA_A-receptors. All neuromuscular blocking agents are agonists or antagonists at the skeletal muscle nicotinic receptor. There would be no surgery worth mentioning without these drug actions on neurotransmitter receptors. Morphine and related opioid agonists are the most effective analgesics. The β -adrenoceptor antagonists such as propranolol have become the most successful group of cardiovascular drugs. The benzodiazepine anxiolytics, which promote the effect of GABA on GABA_A-receptors, and the dopamine receptor-blocking ►**neuroleptics** such as chlorpromazine and clozapine are two major drug classes used in psychiatry.

Transmitter Inactivation

The cholinesterase inhibitors are the classical drugs that interfere with transmitter inactivation. The prototype was physostigmine, a plant poison and later a therapeutic agent in ►**myasthenia gravis**. The highly toxic nerve gases such as sarin also are cholinesterase inhibitors. The GABA transporter is blocked by tiagabine, an antiepileptic that owes its effect to the ensuing increase of the concentration of GABA in the synaptic cleft. Cocaine is abused because it blocks the dopamine transporter and, hence, enhances dopaminergic transmission in the mesolimbic dopaminergic

“reward system”. Blockers of the noradrenaline transporter and blockers of the serotonin transporter are the main ►**antidepressant drugs**, i.e. the main members of the third major drug class in psychiatry.

Synaptic Vesicle Neurotransmitter Transporters

► Vesicular Transporters

Synaptic Vesicles

Synaptic vesicles are the organelles in axon terminals that store neurotransmitters and release them by exocytosis. There are two types, the large dense-core vesicles, diameter about 90nm, that contain neuropeptides, and the small synaptic vesicles, diameter about 50nm, that contain non-peptide transmitters. About ten vesicles per synapse are “docked” to the plasma membrane and ready for release, the “readily releasable pool”. Many more vesicles per synapse are stored farther away from the plasma membrane, the “resting pool”. When needed, the latter vesicles may be recruited into the readily releasable pool. Neuronal depolarization and activation of voltage-sensitive Ca²⁺

channels increases intracellular Ca^{2+} levels that promotes exocytosis and fusion of the vesicles with the presynaptic membrane allowing the vesicular neurotransmitter to be released into the synaptic cleft.

- ▶ Synaptic Transmission
- ▶ Vesicular Transporters

Synaptotagmin

Synaptotagmin is an integral type I transmembrane glycoprotein that possesses two C2 calcium-binding domains. C2 domains are present in several other proteins such as the calcium-dependent isoforms of protein kinase C and phospholipase D where they are known to regulate Ca-dependent binding to phospholipid membranes. More than ten different synaptotagmins are known, that are widely expressed in many tissues. Best characterized is synaptotagmin I, a resident of synaptic vesicles and neurosecretory granules. Synaptotagmin I probably functions as an exocytotic Ca-receptor that links the calcium signal to membrane fusion by means of Ca-dependent binding to membranes and (possibly) to SNAREs.

- ▶ Exocytosis

Syndecans

Syndecans are transmembrane proteins, which are modified by the addition of heparan sulphate glycosaminoglycan (GAG) chains and other sugars. Syndecans bind a wide variety of different ligands via their heparan sulphate chains. Binding specificities may vary depending on cell-type specific modifications of the heparan sulphate chains.

Systolic and Diastolic Blood Pressure and Pulse Pressure

Systolic pressure, or maximum blood pressure, occurs during left ventricular systole. Diastolic pressure, or minimum blood pressure, occurs during ventricular diastole. The difference between systolic and diastolic pressure is the pulse pressure. While diastolic blood pressure has been historically been used as the most relevant clinical blood pressure phenotype, it has now been clearly established that systolic blood pressure is the more important clinical predictor for cardiovascular morbidity and mortality. More recently, additional attention is focussed on the importance of pulse pressure, i.e. the blood pressure amplitude, as a predictive factor for cardiovascular disease.

Definition

The T cell receptor is a clonotypic, T cell specific surface receptor that mostly recognizes peptides bound to MHC molecules on antigen-presenting cells.

Basic Characteristics

The immune system of vertebrates has witnessed the evolution of an adaptive arm of the immune response that allows for the specific and persistent response to pathogens. At the heart of this development lies the ability of B and T cells to produce clonotypic receptors (referred to as BCR and TCR from hereon) that constantly monitor the fluidal and cellular composition of the body and potentially elicit an immune response should foreign or danger signals exceed a certain threshold value. Antigen recognition by the heterodimeric BCR and TCR is achieved by loop regions – also called complementarity determining regions (▶CDR's) – of their respective variable domains. However, while the BCR, antibodies and a small subset of TCR's called β - δ -TCR's directly recognize diverse structural features including proteins, RNA, DNA or lipids, the α - β TCR has evolved almost exclusively towards the recognition of peptides derived from proteolytically cleaved proteins. Consequently, while BCRs, antibodies mostly recognize antigens in their native molecular context and conformation, TCRs interact with immunogenic peptides embedded in the binding groove of the bodies own major histocompatibility complex (MHC) molecules. Seminal experiments by Zinkernagel and Doherty in the 1970's, where they analyzed cytolytic T cell responses of mice infected by lymphocytic choriomeningitis virus, introduced this concept of "MHC restriction" [1]. Without detailed knowledge of the structure and composition of the

molecules involved, they hypothesized that a single receptor is responsible for the recognition of a virus-induced modification of the self-MHC. This “altered-self” hypothesis was later proven more directly with the advent of molecular biology and the cloning of individual TCRs [2]. However, the bold interpretation of their intriguing findings won Zinkernagel and Doherty the Nobel Prize in 1996.

Another central aspect of B and T cell immunology has long been the question as to how variability at the level of individual cells and individual molecules could be achieved. The clonal selection theory by McFarlane Burnet set the stage for deciphering the recombination events that govern immunoglobulin and TCR gene rearrangements [3]. Combinatorial recombination events of families of gene segments leads to a very diverse set of B and T cell receptors in somatic cells that are constantly selected on the basis of BCR or TCR activation thresholds matched to distinguish self from non-self. The precursors of T cells, the common lymphoid progenitor cells, are produced in the bone marrow, and they are committed to T cell fate after transport to the **thymus** where they further mature. During thymic development, β chain rearrangements are followed by recombination of the α chains of the TCR. Productive rearrangements are required for thymocyte survival and TCR signaling seems to be pivotal for development. On the one hand, the thymocytes with productively rearranged TCRs need to recognize self-MHC to become “MHC restricted,” while on the other hand the binding to MHC in complex with self-peptide should not lead to a strong response, since this may pose problems after the release of such T cells into the periphery (potentially leading to strong anti-self reactions and autoimmunity).

While the T cell receptor α/β -heterodimer is the central element of receptor adaptivity, there are additional components that non-covalently associate and directly contribute to a functional TCR [4] (Fig. 1). All of these additional components, namely CD3 ϵ , CD3 γ , CD3 δ and the ζ dimer, have cytoplasmic tails that contain so-called immune receptor-tyrosine based activation motifs (**ITAMs**). The ITAMs can become tyrosine phosphorylated upon stimulation, and thereby they act as docking sites for the SH2 domains of the ZAP-70 kinase. Signaling cascades are subsequently initiated that lead to Ca^{2+} mobilization, changes in integrin-mediated cell adhesion, and the transcription of genes [5]. Extracellular binding of components of the CD3 complex, for the purpose of modulating T cell receptor mediated responses, are not only potentially modulating the interaction of the receptor with the MHC:peptide complex. More importantly they elicit or attenuate signaling events mediated by conformational changes or clustering of the receptors and induce the

T Cell Receptors. **Figure 1** Composition of the TCR/CD3 complex. The extracellular domains of the α/β heterodimer are shown in blue and green and the counteracting peptide:MHC is shown in red and yellow, respectively. In this example, the peptide binding groove is represented by a single chain, which is indicative of MHC class I molecules. The additional components of the TCR/CD3 complex, which are critical for intracellular signaling, are depicted as grey ovals, cylinders represent transmembrane domains and the dotted structures stand for the cytoplasmic domains of the complex. Dark blue dots highlight the tyrosine residues of the ITAM motifs that can become phosphorylated upon receptor stimulation.

concomitant post-translational modifications of the cytosolic parts of the CD3 complex.

Drugs

CD3 Specific Monoclonal Antibodies

Introduction/Overview

The first mouse **monoclonal antibody** specific for human CD3 was produced in 1979 and named “orthoclone OKT3.” Aside from its use in the laboratory, OKT3 became the first anti-CD3 antibody to be utilized in transplantation medicine, but its wider application was hampered by its immunogenic and mitogenic properties (reviewed in [6]). Consequently, humanized and engineered anti-CD3 antibodies were developed to circumvent these limitations (Table 1). Since T cells and the TCR are involved in many immunological diseases, it is not surprising that the application of CD3 antibodies is not restricted to the field of transplantation. For example, CD3 antibodies are tested in clinical studies of diseases such as autoimmune diabetes (type 1 diabetes), immune-mediated inflammatory arthritis and inflammatory bowel disease [7].

Side Effects – Immunogenicity and Mitogenicity

In the early phase of application a massive humoral immune response was raised by CD3 antibodies which reduced their potential clinical benefit. Furthermore, 5–7 days after administration of OKT3 CD3 antibodies, OKT3 was neutralized and cleared by the recipient's immune system. Initially, attempts were made to suppress the antibody-induced immune response by co-administration of conventional immunosuppressive drugs like corticosteroids or azathioprine. More recently attempts have been made to reduce the immunogenicity of the CD3 antibodies themselves. “Humanized” CD3 antibodies (Fig. 2) contain the hypervariable region of the parental rodent antibody which are grafted onto a human heavy- and light-chain immunoglobulin. While humanization is intended to attenuate the number of potentially immunogenic epitopes, mutations that abolish Fc receptor binding are able to reduce the negative side effects of the antibody's effector function. In a more radical approach, a fully human framework might be used for selection of the desired anti-CD3

binding specificity, e.g. by phage display, and the corresponding Fab fragments may then be either used directly or combined with a non-mitogenic Fc part of an antibody. In contrast to these modern versions of CD3 antibodies, early CD3 antibodies were mitogenic *in vitro*, inducing T cell proliferation and cytokine production, features typical for activated T cells and an activated immune system in general. Surprisingly, the same antibodies *in vivo* induced immunosuppression which led to the tolerance of transplanted organs. This apparent paradox was the starting point of several interesting studies which sought to shed light on the molecular mechanisms underlying the mode of action of CD3 antibodies [6].

Mode of Action

The current models for the mode of action of T-cell-specific monoclonal antibodies are based on the observation that the administration of CD3 antibodies leads to a significant reduction of the number of CD3-positive T cells. On the one hand, CD3⁺ T cells were

T Cell Receptors. Figure 2 Humanized CD3 antibodies. Starting from mouse monoclonal CD3-specific OKT3 antibodies, so called “humanized antibodies” are designed and produced using recombinant techniques. Mouse hypervariable regions (displayed in red) within the Fab part of the antibody are transferred from the mouse antibody onto a human framework. Certain mutations can be introduced within the Fc region (e.g. the double mutant Leu234Ala/Leu235Ala in OKT3), which act to destroy the antibody's Fc-receptor binding capacity and potentially reduce mitogenicity.

depleted by sustained stimulation and led to activation induced cell death. On the other hand, a substantial number of cells remained physically present but displayed reduced CD3/TCR surface expression while other T cell molecules like CD4 or CD8 were left unaffected (Fig. 3a). These CD3/TCR-negative cells are not susceptible to antigen-specific signals and thereby contribute to an increased immunotolerance. CD3 antibody induced TCR downmodulation is fully reversible. After clearing CD3 antibodies from the blood, expression of the CD3/TCR complexes is fully restored within a few hours [6].

In a mouse model for autoimmune non-obese diabetes (NOD), the full-blown diabetes could be reversed to normoglycaemia by treatment with CD3 antibodies. In these diabetes-tolerant mice, the proportions of CD4⁺ CD25⁺ regulatory T cells were increased. Moreover, the CD4⁺ CD25⁺ regulatory T cells of the tolerant mice produced high levels of

TGF- β . Neutralizing antibodies specific for TGF- β prevented the CD3-specific antibody-induced diabetes remission. These observations led to the hypothesis that CD3 antibodies are acting through cell signaling events, including the generation of CD4⁺ CD25⁺ regulatory T cells and the secretion of TGF- β (Fig. 3b). It will be interesting to see whether the correlation between CD3 antibody administration and the number of regulatory T cells will hold for other disease models as well.

Alternative Approaches to CD3 Antibodies TCR α/β Antibodies

In addition to antibodies targeting the CD3 subunit of the TCR complex, antibodies against the α and β subunits of the TCR have been tested as therapeutic agents. A benefit for the treatment experimental autoimmune encephalomyelitis or collagen induced arthritis could be shown in animal models [8].

T Cell Receptors. Figure 3 Schematic view of the putative mode of action of anti-CD3 antibodies. A, TCR downmodulation. In hosts treated with CD3-specific antibodies special subpopulations of T cells can be detected. These T cells are negative for their CD3/TCR but positive for other T cell markers like CD4. The crosslinkage of several CD3/TCR complexes via the CD3 antibodies leads to a local enrichment of CD3/TCRs complexes (capping). The CD3/TCR complexes are subsequently internalized and either recycled or degraded. B, Antibody-induced production of TGF- β mediated by regulatory T cells. This scheme is based on mouse models that show the administration of CD3 antibodies to correlate with increased number of regulatory T cells and the reduction of autoimmune symptoms. This effect could be reversed by the reduction of TGF- β via administration of TGF- β -neutralizing antibodies.

Soluble T Cell Receptors

In addition to the antibodies described above, latest research considers the TCR α/β heterodimer itself as a promising protein for immunotherapies. Considering the diversity of naturally occurring T cell receptors they might represent interesting scaffolds for the generation of novel, highly specific therapeutics. Utilizing the methods of directed evolution (e.g. DNA shuffling and phage display), artificially modified, recombinant and soluble TCRs can be produced. Thereby, the issues of stability, dissociation rates from the MHC:peptide complex, and peptide specificity can be tackled. Soluble TCRs might also represent interesting therapeutics for cancer immunology. Like therapeutic antibodies, soluble TCRs could be engineered to precisely deliver radionuclids, toxins or immunomodulatory molecules to their intended site of action. Moreover, the application of soluble TCRs for the treatment of autoimmunity (e.g. for targeted delivery of immune-inhibitory lymphokines) or as agents for vaccination in the generation of autoimmunity-suppressing regulatory T cells is possible and first experimental studies have been undertaken [9,10].

Outlook and Risks

The immune system plays a fundamental role in maintaining the physiologic integrity of the human body, and pharmacological immunomodulation is therefore a field of continuous development. With the TCR/CD3 complex as a central player determining the specificity of the immune response, this complex constitutes a prime target for intervention. As an understanding of the general principles governing T cell receptor signaling is being unraveled, it is now time to exploit these features in a more sophisticated manner by addressing various diseases. Recent clinical trials have identified the therapeutic potential of CD3 antibodies and their more advanced derivatives. In this context, CD3 antibodies were tested for treatment of psoriatic arthritis, acute renal allograft rejection, pancreatic islet allograft rejection, Crohn's disease and severe ulcerative colitis. Since immunotherapy always imposes a potential risk to the intricate homeostasis of the patients immune system itself, the success of these approaches is still closely related to an advanced understanding of the underlying molecular mechanisms involved, and will require ongoing basic and preclinical research [11].

Tachykinins and their Receptors

ALESSANDRO LECCI, CARLO ALBERTO MAGGI
Clinical Research Dept (AL) and Direction (CAM) of
Menarini Ricerche, Florence, Italy

Synonyms

Neurokinins (Table 1); Neurokinin receptors (Table 1)

Definition

Except substance P (SP), the first mammalian tachykinin (TK) peptide to be sequenced (by Chang and Leeman in 1970), other peptides belonging to TK family have synonyms. This is due to historical reasons,

in 1983 three different groups (Kimura, Matsuo, Nawa and their respective coworkers) independently identified other TK peptides: these peptides were renamed as neurokinin A (NKA) and neurokinin B (NKB) at the Montreal Symposium in 1986 when a new nomenclature system was proposed (Table 1). Unfortunately, since no general agreement on this nomenclature was reached, these synonyms have been also the basis to define the receptors at which each of the above TK acts as preferential agonist.

Tachykinin Peptides

TKs are a family of peptides widely expressed in the central nervous system and peripheral tissues of vertebrates and invertebrates [1, 5]. All TKs share a common C-terminal amidated amino acid region, Phe-X-Gly-Leu-MetNH₂, which is the minimal sequence for exerting biological activity at TK receptors (Table 2). SP, NKA and its elongated forms, and NKB have conserved amino acid sequences across the mammalian species investigated so far, whereas the rodent (rat and mouse) sequence of hemokinin-1 (HK-1) differs from that found in humans, although the pharmacological profile of rodent and human HK-1 are very similar [1, 4, 5].

Genes for Tachykinin Peptides

All TKs are encoded by three genes called *TAC1*, *TAC3*, and *TAC4* (see Table 1 for synonyms). *TAC* genes are transcribed into primary mRNAs which are then

subjected to alternative posttranscriptional splicing (Table 3). The translation of alternatively spliced mRNAs by ribosomes located on the surface of the rough endoplasmic reticulum produces pre-pro-TK peptides which are then subjected to posttranslational processing to generate pro-TK peptides, through the removal of the signal sequence. Finally, following the removal of spacer sequences of the pro-peptides and the C-terminal amidation of methionine, mature TKs are now ready to be released into the extracellular environment where they exert their biological actions through the stimulation of specific receptors located within the plasma membrane.

Tachykinin Receptors

TKs exert their biological effects through three distinct receptor (r) types termed TK NK_{1r}, NK_{2r}, and NK_{3r} (see Table 1 for synonyms). These receptors belong to the class 1 (rhodopsin-like), seven transmembrane, G-protein-coupled receptors (capability to bind and hydrolyse GTP). Since TK receptors are proteins (i.e., large peptides), the scheme of their biosynthesis is similar to that of TKs (Table 3). The amino acid sequence of TK receptors shows slight species-related variations which account for the species-related differences in the affinity of some receptor antagonists; in contrast, critical residues for the binding and intrinsic activity of TKs are phylogenetically conserved [1, 5].

	beta-TAC3	Neurokinin B
	gamma-TAC3	None
TAC4	alpha-TAC4	Hemokinin-1, hemokinin-1 (4–11), endokinin A, endokinin B, endokinin C
	beta-TAC4	Hemokinin-1, hemokinin-1 (4–11), endokinin B, endokinin D
	gamma-TAC4	Hemokinin-1, hemokinin-1 (4–11), endokinin B
	delta-TAC4	Hemokinin-1, hemokinin-1 (4–11), endokinin B
TACR1	long-TACR1	Long NK ₁ receptor (407 amino acids)
	short-TACR1 (encode for a shorter, 7 amino acids C-terminal intracellular sequence)	Short NK ₁ receptor (311 amino acids)
TACR2	alpha-TACR2 (classic)	Alpha-NK ₂ receptor (398 amino acids)
	Beta-TACR2 (encode for a shorter receptor lacking extracellular (EC3), and intracellular (IC2) loops and a transmembrane domain (TM4))	Beta-NK ₂ receptor (333 amino acids)
TACR3	TACR3 (classic)	NK ₃ receptor (465 amino acids)
	TACR3 variant (encode for a shorter receptor putatively of lacking extracellular (EC2), and intracellular (IC2) loops and a transmembrane domain (TM4))	Protein expression not yet demonstrated

Genes for Tachykinin Receptors

TK NK_{1r}, NK_{2r}, and NK_{3r} are encoded by three genes termed as *TACR1*, *TACR2*, and *TACR3*, respectively. Splice variants of these TK receptors have also been identified (Table 3).

Basic Characteristics

The binding of TKs to their receptors promotes conformational changes enabling the receptors to couple with specific ▶heterotrimeric GTP-binding proteins (made up by alpha, beta, and gamma subunits) which in turn activate enzymes capable of generating second messengers; this process is defined as signal transduction. These second messengers diffuse in the intracellular environment and trigger a cascade of events leading ultimately to the cellular responses [3]. These events include the generation of other mediators like prostanoids and nitric oxide which can diffuse through the plasma membrane, or the extracellular release of other neurotransmitters (i.e., acetylcholine, noradrenaline, dopamine, GABA, glutamic acid) thus affecting the functionality of neighbor cells [5]. Albeit with different relative potency, SP, NKA, NKB, HK-1, elongated forms of NKA (neuropeptide gamma and kappa) and HK-1 (endokinin A and B) act as agonists at NK₁ (NK_{1r}), NK₂ (NK_{2r}), and NK₃ receptors (NK_{3r}), whereas endokinin C and D are virtually inactive at these receptors, or, in some systems, they act as NK_{1r} antagonists. This also applies to TK metabolites, where NKA(3–10) (that can be also directly translated from *beta-TAC1* and *gamma-TAC1*) is a good agonist at TK receptors, whereas the N-terminal metabolite SP(1–7) does not interact with TK receptors, although it exerts several biological activities through a yet unidentified molecular target.

The structure of all TK receptors is similar in terms of expression of *TACR* genes, since all these genes contain five exons intercalated by four introns [1, 5]. Exon I encodes for the N-terminal extracellular tail, the first intracellular (IC1) and extracellular (EC1) loops and the first, second, and third transmembrane domains (TM1, TM2, and TM3). Exon II encodes for the second intracellular (IC2) and extracellular (EC2) loops and the fourth transmembrane domain (TM4). Exon III encodes for the fifth transmembrane domain (TM5) and the third intracellular loop (IC3). Exon IV encodes for the sixth and seventh transmembrane domains (TM6 and TM7) and the third extracellular loop. Exon V encodes for the C-terminal intracellular tail only. A schematic drawing of the amino acid sequences and TK receptor organization is shown in Fig. 1.

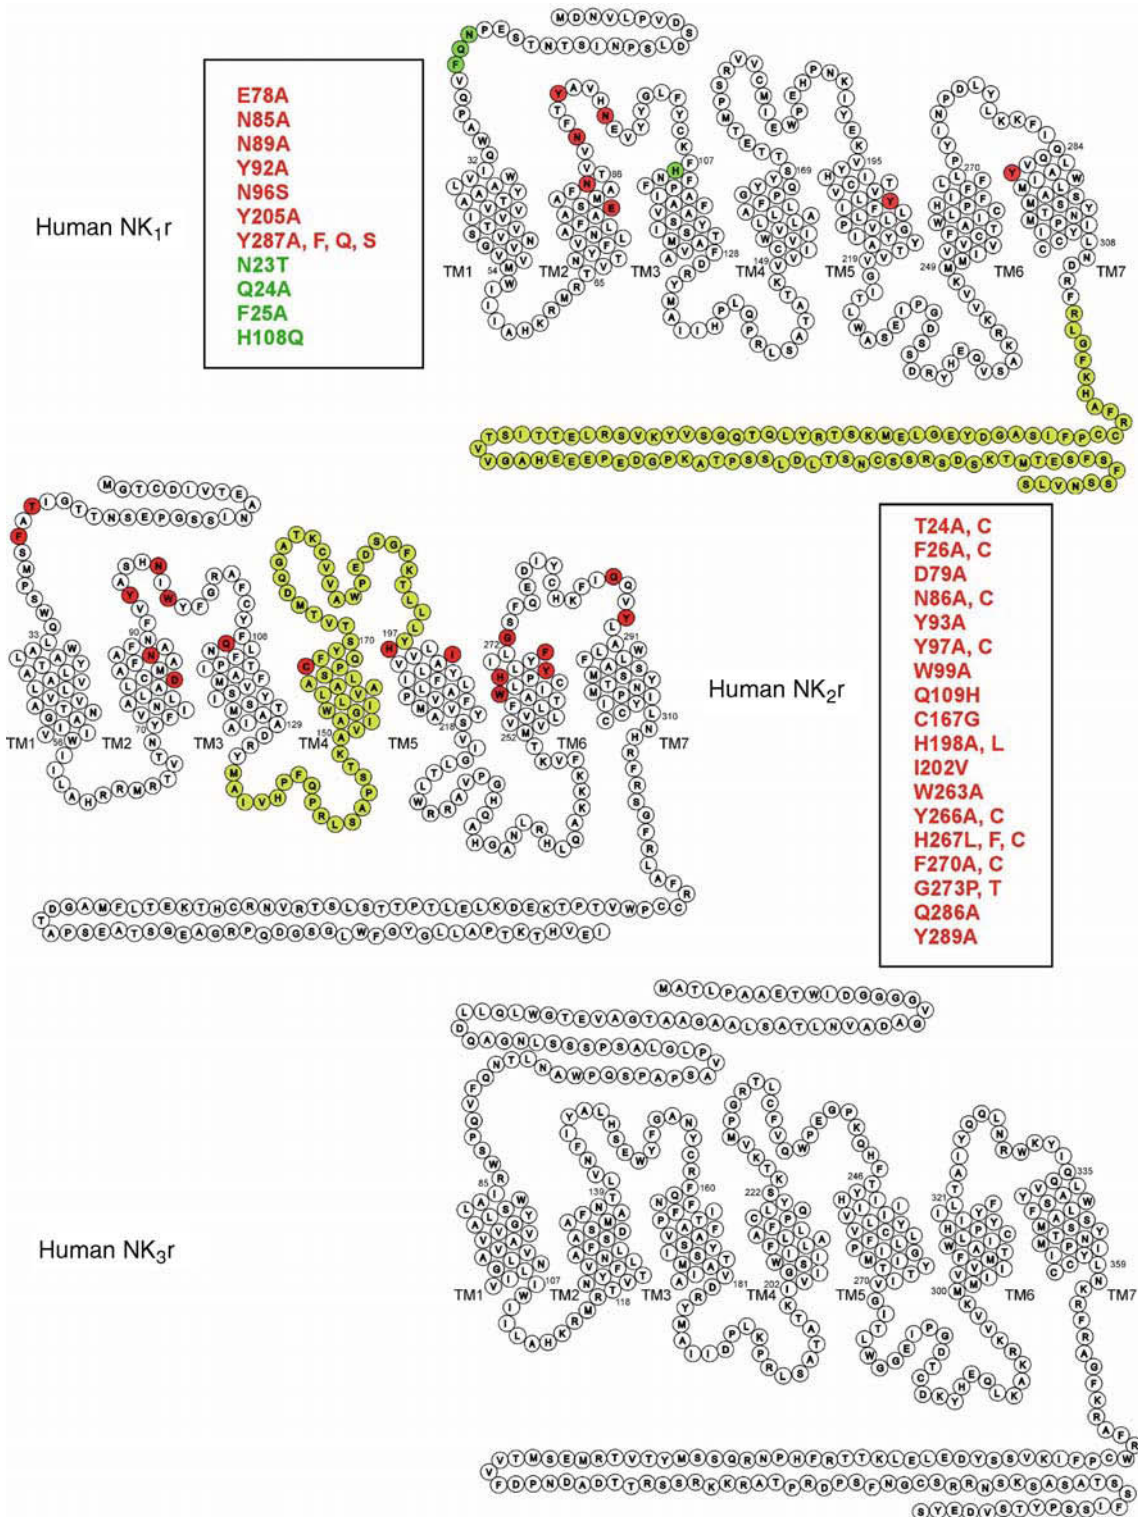

Available evidence indicates that the stimulation of NK_{1r}, NK_{2r}, or NK_{3r} by the respective preferred endogenous agonist, that is, SP, NKA, and NKB respectively, lead to similar basic transduction mechanisms mediated by the coupling with G-proteins such as Galpha-q and Galpha-s [1, 3, 5]. As a consequence,

the respective activation of NK_{1r}, NK_{2r}, or NK_{3r} by SP, NKA, and NKB increases the activity of phospholipase C via Galpha-q and thus promote the hydrolysis of the phospholipid phosphatidyl inositol triphosphate into diacylglycerol and inositol triphosphate which increases intracellular calcium by releasing it from endoplasmic reticulum. Likewise, NK_{1r}, NK_{2r}, or NK_{3r}-mediated activation of Galpha-s stimulates the activity of adenylate cyclase therefore increasing intracellular levels of cAMP. These two transduction pathways can either coexist or be specific for a given cell system. Because of these common transduction pathways, the selective stimulation of either NK_{1r} or NK_{2r} can evoke similar functional responses (e.g., contraction) in cell systems which can express both receptors (e.g., smooth muscle cells). On the other hand, the effects of the stimulation of different TK receptors can diverge when looking at other cell systems or other cellular responses; for instance, the stimulation of NK_{1r} induces the proliferation of hematopoietic stem cells, whereas the stimulation of NK_{2r} inhibits their proliferation. This would imply that along transduction pathways common to all TK receptors there should be other ones that are receptor specific. Moreover, it should be pointed out, that different TKs acting at a single TK receptor have a different probability to induce receptor conformers responsible for a different G-protein coupling [3]. As a consequence, different TK agonists acting through the same TK receptor can generate different cellular or tissue responses. Furthermore, the same agonist can induce different responses by activating the same TK receptor on different cells, since the qualitative or quantitative expression of enzymes transducing the receptor signal can vary from cell type or even within different clones of the same cellular type. Overall, several examples of TK ▶co-transmission have been described in the physiology of both laboratory animals and humans. The vast majority of *TAC1*-expressing neurons (CNS, enteric, sensory) corelease multiple TKs having preferential affinity for NK_{1r} and NK_{2r}. These receptors are often coexpressed on target cells (e.g., smooth muscle, secretory elements) and the contribution of the single receptor to the overall response mediated by the release of endogenous TKs can vary case by case (Table 4).

Basic agonist pharmacology at NK_{1r}, NK_{2r}, or NK_{3r} that is valid for most of bioassay is shown in Table 5.

Tachykinin NK₁ Receptors

Two NK_{1r} splice variants have been identified (Table 3). A NK_{1r} splice variant having a very short C-terminal intracellular tail (7 instead of 96 amino acids), which has been expressed and characterized in recombinant systems (Fig. 1), was found to be expressed at higher level than the long isoform in breast cancer cells. As compared to the long receptor, the short NK_{1r} isoform is less subjected to desensitization and internalization

Tachykinins and their Receptors. Figure 1 Snake plots of human tachykinin NK₁, NK₂, and NK₃ receptors. Amino acid sequences and receptor organisation have been downloaded from www.gpcr.org/7tm/seq/. In yellow are indicated amino acids which lack the short NK₁ and beta-NK₂ receptor isoforms. Amino acids whose substitution can lead to a significant decrease (>10-fold) in SP and NKA binding affinity at NK₁ and NK₂ receptors, respectively, as detected through homologous competition are marked in pink and those detected through heterologous competition (i.e., displacement of the NK₁r antagonist [¹²⁵I]-703606) are marked in green in both the snake plots and in the respective insert within the figure. (Courtesy of Dr. Stefania Meini.)

Tachykinins and their Receptors. Table 4 Examples of tachykinin cotransmission

Type of cotransmission	Examples
Summation	The overall response is the arithmetic sum of the contribution brought by each receptor (e.g., NK ₁ and NK ₂). Capsaicin-induced contraction of rat isolated urinary bladder, electrical field stimulation (EFS)-induced nonadrenergic, noncholinergic contraction of the isolated guinea pig bronchus or renal pelvis when SP metabolism is blocked by peptidase inhibitors are all examples of summation. Both NK ₁ r and NK ₂ r antagonists are required to abolish such kind of response, but each antagonist substantially reduces the response
Cooperation	The overall response is qualitatively different from the response mediated by each receptor. EFS-induced nonadrenergic, noncholinergic contraction in guinea pig or human small intestine circular muscle is associated to the generation of muscle action potentials. Both responses can be blocked by either NK ₁ r or NK ₂ r antagonists indicating that the costimulation of both receptors is required for eliciting these responses
Specialization	Each receptor contributes to morphologically (e.g., phasic vs. tonic) or temporally (early vs. late) distinct components of the overall response. This is the case of prolonged EFS-induced nonadrenergic, noncholinergic contraction the guinea pig colon or rat urinary bladder, where the fast and late components of the contraction are mediated by NK ₁ r or NK ₂ r, respectively
Supra-additivity	This is a special case of cooperation where the blockade of a single receptor is not sufficient to reduce the overall response. Capsaicin-induced nonadrenergic, noncholinergic contraction in the guinea pig ileum or common bile duct can be inhibited only when at least two different TK receptors are blocked (e.g., NK ₁ + NK ₂ , NK ₁ + NK ₃ , NK ₂ + NK ₃)

Tachykinins and their Receptors. Table 5 Order of potency of endogenous human TKs at NK₁, NK₂, and NK₃ receptors and selective TK NK₁, NK₂, and NK₃ receptor agonists

Receptor	Natural agonists (order of potency)	Selective agonists
NK ₁	SP = HK-1 > NKA > NKB	SP-methylester, [Pro ⁹]-SP, [Sar ⁹ , Met(0 ₂) ¹¹]-SP, septide, GR73632
NK ₂	NKA > NKB > SP = HK-1	[βAla ⁸]-NKA(4–10), [Nle ¹⁰]-NKA(4–10), [Lys ⁵ , MeLeu ⁹ , Nle ¹⁰]-NKA(4–10), GR64349
NK ₃	NKB > NKA > HK-1 ≥ SP	[MePhe ⁷]-NKB, [MePhe ⁷]-NKB(4–10), senktide

upon stimulation with SP [3], and thus it produces a more effective stimulus for the autocrine induction of *beta-TAC1* expression and proliferation of these cells. Despite these different characteristics, no major pharmacological differences for the 2 NK₁r splice variants have been reported yet.

Receptor residues critical for the modulation of SP binding have been identified in the extracellular domains, and in particular in the N-terminal tail, EC1 and EC2 loops, and in the outer surface of TM2 and TM7 (see Fig. 1 for critical point mutations) [1]. Although, among natural TKs, SP is the more potent agonist at NK₁r in all systems known so far (or at least equipotent to HK-1), NKA is also a very good agonist when these receptors are coupled to Galpha-q, and there is evidence that NKA is an endogenous NK₁r agonist in some districts (eye, spinal cord) [3]. All NK₁r agonists are relatively less potent to induce cAMP accumulation than inositol phosphates formation [3, 5]. Indeed, NKA and some selective NK1 agonists, such as septide, are

partial agonists at these receptors when they are coupled to Galpha-s; this could be the reason why septide is less effective than other NK₁r agonists in the stimulation of nitric oxide production. G166 and Y167 residues, located on the upper edge of the TM4 domain, play a key role in SP-induced coupling of NK₁r to Galpha-s [1, 5].

At the beginning of 1990s, a discrepancy between the apparent affinity of septide (and other NK₁r agonists) measured through cellular responses or SP displacement emerged: septide potently (nanomolar range) activated NK₁r-mediated cellular signaling (inositol phosphate production, calcium response), whereas it was a weak displacer of SP binding (micromolar range). Furthermore, the apparent affinity of NK₁r antagonists was higher when measured against the responses induced by septide than those induced by SP (or some other NK₁r agonists). These results led to the definition of a septide-sensitive NK₁r. Although the intimate mechanisms underlying these discrepancies have been not completely clarified, it is now assessed that the

behavior of septide-sensitive receptor is not due to different genotypes or phenotypes (intended as amino acid sequence) of NK_{1r}, but rather to a different dynamic of agonist–receptor interactions within a single transduction pathway [1, 3].

NK_{1r} also couple with Go, which increases the activity of phospholipase A2 leading to the formation of arachidonic acid and then prostanoids. SP via NK_{1r} is also known to affect the activity of several ion channels. Although these effects could involve effectors located downstream to the above mentioned transduction pathways, such as protein kinase C (PKC) activation, recent evidence indicates the inhibition of inward rectifier potassium channel by SP would involve a direct interaction of Galpha-q with the channel. A further mechanism through which TKs acting at NK_{1r}s modulate channel activity involves beta/gamma subunits of G-proteins which dissociate from Galpha subunit upon receptor stimulation. This mechanism is responsible for the fast inhibition of R-type calcium channels by NKA (via NK_{1r}) in a recombinant system.

Agonist-triggered events in receptor dynamics have been termed as **▶receptor trafficking**: these events are intimately related to the agonist-induced cellular responses [2]. Beta-arrestins play an important role in tachykinin receptor trafficking (uncoupling, internalization, MAPK activation) but, downstream to beta-arrestins, other proteins are also involved in receptor trafficking, as shown in recombinant or native systems expressing NK₁ receptors [2]. The GTPase dynamin is involved in the formation of early endosomes and resensitization of SP response (calcium mobilization) following an initial SP challenge causing desensitization. Dynamin also plays an essential role in SP-induced MAPK activation. Ras-related 5a (Rab5a) is another GTPase involved in the formation of clathrin-coated endosomes containing NK₁ receptors, in their perinuclear translocation, in the resensitization of SP response, but not in MAPK activation. Neither dynamin, nor Rab5a are involved in NK₁ receptor desensitization (decrease SP-induced calcium mobilization upon repeated stimulation). Following agonist activation, NK_{1r} desensitizes, however, this process is not just the direct consequence of receptor stimulation, since desensitization is regulated by the N-terminal part of NK_{1r} agonists, as determined by structure–activity relationships [3]. Desensitization is mediated by several processes such as receptor phosphorylation, G-protein uncoupling, and receptor endocytosis. Different families of protein kinases are responsible for receptor phosphorylation. G-protein receptor kinases (GRKs) phosphorylate C-terminal threonine or serine residues of the receptor and favor its binding to beta-arrestins, thus promoting receptor uncoupling to G-proteins; since this phosphorylation only occurs when the agonist is associated to the receptor, this process is responsible

for the homologous desensitization. The other families of protein kinases involved in receptor desensitization are those activated by transduction mechanisms such as protein kinase A (PKA, cAMP dependent) and PKC (modulated by calcium and/or diacylglycerol): since Galpha-s and Galpha-q-mediated transduction mechanisms are shared by other kinds of G-protein coupled receptors, a cross-desensitization (heterologous desensitization) can occur through these kinases [2].

Receptor endocytosis is regulated by several mechanisms, one of which is the degree of glycosylation of the receptor itself. A double mutant of N-glycosylation sites in the extracellular tail of NK_{1r} (N14Q and N18Q) transfected in NCM 460 cells had a more rapid internalization kinetics upon SP stimulation as compared to wild type NK_{1r}. The binding affinity of SP and NKA as well as the ability of SP to promote phosphorylation of mitogen-activated protein kinases (MAPK) for the double mutant were not changed but modifications in receptor expression (decreased Bmax) and functional response (interleukin-8 secretion) were observed.

The binding of beta-arrestins to the receptors also induces receptor internalization in clathrin-coated vesicles, however, recent evidence also indicate that beta-arrestins are also involved in G-protein-independent receptor transduction mechanisms. Indeed, the activity of receptor-activated extracellular signal-regulated kinases 1 and 2 (ERK1/2) and MAPK can be increased both by conventional G-protein-mediated transduction mechanisms and beta-arrestin–receptor complexes independently from G-protein-mediated signaling. However, these two modalities of ERK1/2 activation differ in their time course since beta-arrestin-mediated activation is slower in the onset but longer lasting than that mediated by G-protein-mediated transduction mechanisms. Interestingly in a native system (human CaCo-2 cell line), SP increased the phosphorylation of MAPK without increasing intracellular calcium and the effect on MAPK was antagonized by the selective NK_{1r} antagonist CP-96345. In this system, the prototypical antagonist [D-Pro², D-Trp^{7,9}]-SP behaves as biased (or collateral) agonist (**▶biased agonism**), since it increased MAPK phosphorylation through the stimulation of NK_{1r} but it blocks SP-induced inositol phosphate accumulation in other systems [3].

TK NK_{1r} displays a broad distribution in both peripheral tissues and in the central nervous system (CNS). In both CNS and enteric neurons, NK_{1r} stimulation increase their excitability, whereas in trigeminal ganglion neurons SP has no intrinsic electrophysiological effects but is capable to enhance the amplitude of the inward current induced by the stimulation of serotonin 5-HT₃ receptors. This enhancement depends on the activation of PKC via the stimulation of NK₁ receptors. This is an interesting case of **▶receptor cross talk**. Other functions of NK_{1r} have been also highlighted.

SP, by acting through NK₁r located in inflammatory and immune cells, has proinflammatory effects and activate innate immunity. Furthermore, the peripheral release of TKs from ►capsaicin-sensitive primary afferent neurons, at the site of stimulation or at distal sites via an ►axon reflex, also plays a prominent role in initiating ►neurogenic inflammation, where the stimulation of NK₁r produces edema and in some districts participates in vasodilatation [3]. NK₁r located on glandular elements stimulate secretions (salivary and water intestinal secretion). SP acting at NK₁r can promote proliferation on both epithelial cells and fibroblasts, but in specific types of neurons can induce nonapoptotic, programmed cell death.

Tachykinin NK₂ Receptor

Two NK₂r splice variants have been identified (Table 3). Beyond the classic NK₂r, a splice variant (beta-NK₂r) lacking of several domains of the classic NK₂r (alpha-NK₂r) has been also described: however, no TK was capable to activate this splice variant, when transfected in CHO cells, since the receptor architecture was disrupted and the variant lacked domains containing critical amino acid residues for the binding of TKs [1]. NKA binding at NK₂r occurs through an interaction with residues of the N-terminal extracellular tail, the EC1 loop, the outer surface of TM3, TM4, and TM5 as well as aromatic residues of TM6 (see Fig. 1 for critical point mutations). Molecular dynamics of agonist-induced transduction mechanisms mediated by Galpha-q and Galpha-s have been clarified in a recombinant system by using fluorescent NKA and NK₂r labeled with fluorescent protein, thus, allowing simultaneous real time recording of ligand binding and calcium responses in living cells. Two phases of NKA binding to NK₂r were identified: a fast component showed a temporal and spatial correlation with intracellular calcium increase, whereas a slower component was associated with cAMP production and PKC-induced desensitization of the calcium response. In contrast, NKA(4–10) only displayed the fast component of the binding and selectively increased intracellular calcium [3]. An antagonist discriminating these two conformers of NK₂rs has been described: LPI805 behaved as a partial and noncompetitive inhibitor of the binding of NKA, it inhibited NKA-induced cAMP production but slightly enhanced NKA-induced calcium response. Indeed, a cross talk between these transduction pathways was outlined since PKC activation facilitated NKA-induced cAMP increase, whereas activation of PKA provided a feedback inhibition on NKA-induced cAMP increase. As for NK₁r, there is evidence of NK₂r-mediated activation of alternative transduction pathways. NK₂r-mediated synthesis of prostanoids was observed in both recombinant and native systems, and this effect was calcium dependent and SKF96365 sensitive but it was not affected by the phospholipase C

inhibitor U-73122, indicating that neither Galpha-q nor Galpha-s were involved. Interestingly, in a recombinant system expressing both NK₂r and transient receptor potential 3 (TRP3) channels, NK₂r agonists activated an inward cation current that was reduced by SKF96365 suggesting that NK₂r-triggered calcium entry responsible for prostanoid production is mediated by the activation of TRP3 channels. NK₂r stimulation also activated MAPK: this activation was transient and blocked by a cAMP analog, indicating the dependency from Galpha-s-mediated transduction. However, in a truncated form of the receptor lacking the intracellular C-terminal domain, NK₂r-induced MAPK activation was associated with increased DNA synthesis, and morphological changes such as cytoskeleton remodeling, cell growth, and transformation, effects which were not blocked by the cAMP analog. NKA-induced DNA synthesis, but not morphological changes, was reduced by ADP-ribosylation of Rho G-proteins, thus envisaging alternative signaling pathways in this system. It is worth noting that NK₂r-mediated cell proliferation is not restricted to this recombinant system but also occurs through the stimulation of native receptors expressed in breast cancer cell lines. If the stimulation of C-terminal truncated NK₂r induces cell proliferation, the activation of native NK₂r in hematopoietic stem cells inhibits cell proliferation through the activation of p53 protein. Although it is unclear which transduction pathway is responsible for p53 activation, these results highlight how the cellular environment is crucial for the final effect observed.

TK NK₂rs are mainly expressed in peripheral tissues, although a low level of expression has been detected in several CNS areas. The stimulation of these receptors induces contraction of airway, gastrointestinal, and genitourinary smooth muscle [3, 5]. In both airways and urogenital organs, NK₂r mediate muscle contraction that follows the activation of the ►efferent function of sensory nerves. In these systems, functional expression has been detected also in epithelial cells, where NK₂r activation increases the luminal permeability of hollow organs, effect that is probably mediated by nitric oxide. There is also evidence that visceral sensitivity is increased through the peripheral stimulation of NK₂r; since TKs are released from sensory nerves at the peripheral level (see above), this mechanism represents a positive feedback enhancing the afferent function of sensory nerves, a mechanism which is believed to participate in the pathogenesis of visceral pain.

Tachykinin NK₃ Receptors

Beyond the classic NK₃r, an mRNA splice variant has been also recently identified but no data on its expression and function are available yet, although the extensive deletion of critical regions renders unlikely its functionality (Table 3) [5]. NK₃r has been much less

characterized in term of ligand interactions, molecular dynamics, and transduction mechanisms than other TK receptors. Agonist binding at TK NK_{3r} occurs through residues located in EC2 and EC3 loops, TM2, TM4, and TM7 [1]. NK_{3r} stimulation by NKB activates Galpha-s and Galpha-q mediated transduction mechanisms, thus increasing cAMP and inositol triphosphate levels [1, 3, 5]. Like other TK receptors, an increase in intracellular calcium has been described, but it is unclear whether this is only due to Galpha-q coupling or other transduction mechanisms are also involved. In a recombinant system, NK_{3r} stimulation by [MePhe⁷]-NKB induces a rise of intracellular calcium and nitric oxide production via Galpha-q coupling since both effects were inhibited by thapsigargin (that means they are mediated by inositol triphosphate). NK_{3r}-induced phosphorylation of MAP kinases ERK1/2 is mediated by receptor coupling with beta-arrestins. In fact, upon stimulation, NK_{3r}-mediated responses (increase of intracellular calcium) rapidly desensitize and internalize through a beta-arrestins mediated process. However, in recombinant or native systems coexpressing both NK_{1r} and NK_{3r}, the stimulation of NK_{1r} prevents the homologous desensitization and the internalization of NK_{3r} by competing on a common pool of beta-arrestins at which NK_{1r} have a higher affinity than NK_{3r} [2]. This is an interesting example of TK ►receptor cross talk. Molecular basis for cases of tachykinin cotransmission can be identified in tachykinin receptor cross talk.

NK_{3rs} are preferentially expressed in the CNS. At the peripheral level, NK_{3rs} have been localized in the enteric nervous system, nerve terminals, and autonomic ganglia, but also on other tissues. At the peripheral level, it remains to be explained the mismatch between NK_{3r} expression and the apparent lack of expression of NKB: there are, however, physiological conditions

where NKB is expressed and secreted by peripheral organs, such as placenta during pregnancy [1].

Drugs

The first generation of TK receptor antagonists were peptides designed on the backbone of natural TKs [1, 3]. These antagonists had several drawbacks such as low affinity, limited selectivity, metabolic instability, negligible bioavailability, and several of them also displayed nonspecific effects. In the 1990s, a number of selective peptide and nonpeptide antagonists with an improved profile were designed and developed. More recently, because of the frequent coexpression of different TK receptors on the same cell type and the functional interactions between TK receptors, that is, TK ►cotransmission, nonselective antagonists have been also developed (Table 6).

Tachykinin NK₁ Receptor Antagonists

The discovery of nonpeptide NK_{1r} antagonists paralleled that on species-related differences of the affinity of these antagonists which never clearly emerged with peptide NK_{1r} antagonists. In fact, CP-96345, as well as several antagonists listed in Table 5, possesses high affinity at human and guinea pig NK_{1r}, whereas the affinity at rat or mouse NK_{1r} was markedly lower. The opposite pattern was observed with RP-67580 which displays a high affinity at rat or mouse but quite low at both human and guinea pig NK_{1r} [1, 3]. Species-related differences could be attributed to divergent residues in NK_{1r} sequences of these species. In fact, the replacement of rat residues (V116L and I290S) into the human sequence decreased the affinity of CP-96345 and increased that of RP-67580. Critical point mutations for the binding of antagonists to the human NK_{1r} are shown in Table 7 [1].

Tachykinins and their Receptors. Table 6 Examples of selective and non-selective tachykinin receptor antagonists

Receptor selectivity	Antagonist
NK ₁	CP-96345, CJ-11974 (ezlopitant), CP-99994, CP-122721, RP-100893 (dapitant), RP-67580, GR-82334, GR-203040, GR-205171 (vofopitant), L-732138, L-703606, L-733060, L-161664, L-754030 (MK-869, aprepritant), SR-140333 (nolpitantium), SSR-240600, LY-303870 (lanepitant), TAK-637, SDZNKT-343, CGP-49823, MEN-11467, WIN-51708, FK-888
NK ₂	MEN-10376, MEN-10627, MEN-11420 (nepadutant), MEN13918, MEN-15596, L-659877, SR-48968 (saredutant), SR-144190, GR-94800, GR-159897, UK-224671, NK-5807, M-274773, LPI-805
NK ₃	SR142801 (osanetant), SSR-146977, SB-223412 (talnetant), SB-235375, SB-222200, SB-218795, PD-154740, PD-157672
NK ₁ -NK ₂	MDL-105212A, MDL-105172A, DNK-333A, YM-44778, ZD-6021, SCH-205528, AVE-5883

Tachykinins and their Receptors. Table 7 Critical receptor amino acid residues for the binding of selective NK₁, NK₂, or NK₃ receptor antagonists at the respective human TK receptors

Receptor	Antagonist	Critical mutations (>10 times lower affinity)
NK ₁	CP-96345	Q165A, S, N; H197A, Y, S, K; Y272A
	RP-67580	H197K; H265A; Y287A; Y287Q, W, S
	L-161664	Q165A; H265A; Y287S
NK ₂	SR-48968 (saredutant)	H198A; Y266A, S; Y289A, F
	MEN-11420 (nepadutant)	C167G; T171A; Y206A; W263A; Y266A, F; F270A; Y289A, T
	MEN-13918	I202F; W263A; Y266F; F270A; Y289F; Y289T
NK ₃	SR-142801 (osanetant)	M134L; A146R

Critical residues were identified through heterologous competition, or affinity of the radiolabeled antagonist to the point-mutated receptor.

TK NK_{1r} antagonists have displayed potential therapeutic effects in preclinical models of pain (including migraine), depression, anxiety, drug abuse, experimental autoimmune encephalopathy, asthma, pulmonary hypertension, emesis, urinary incontinence, inflammation, cystitis, pancreatitis, and nephritis [3]. The clinical efficacy of NK_{1r} antagonists has been tested in some of the abovementioned diseases. To date, a clinical benefit has been clearly demonstrated in the treatment of emesis which has led to registration of the centrally acting NK_{1r} antagonist aprepitant [3]. This antagonist also showed promising clinical results in bladder overactivity, whereas the same antagonist or other ones displayed inconsistent results in trials for depression and asthma, or they were clearly not effective in trials for pain or migraine.

Tachykinin NK₂ Receptor Antagonists

Although initially interpreted as evidence of expression of NK_{2r} subtypes, the existence of species-related difference in NK_{2r} pharmacology was already emerged during the characterization of peptide antagonists. In fact, it was evident that the affinity of MEN-10207 and MEN-10376 for the rat receptor was lower than that for guinea pig and human receptors, whereas the opposite pattern of affinity was observed for L-659877 [1]. A similar, or even a deeper gap in receptor affinity has been reported for a new series of nonpeptide antagonists such as MEN-13918 and MEN-15596 which possess very high affinity at human and guinea pig NK_{2r} and much lower affinity for rodent receptors, where one important residue for the high-affinity binding at human receptors is F202. Critical point mutations at the receptor protein for the affinity of other NK_{2r} antagonists are shown in Table 7.

TK NK_{2r} antagonists showed interesting activities in preclinical models of depression, anxiety, asthma, gastrointestinal dysmotility and hypersensitivity, and urinary incontinence [1, 3]. In clinical, NK_{2r} antagonists antagonize NKA-induced bronchoconstriction and NKA-induced intestinal dysmotility. However, a pilot trial in asthma failed to show any clinical benefit by

NK_{2r} antagonists. At the CNS level, the efficacy of NK_{2r} antagonists in depression and anxiety is currently being tested.

Tachykinin NK₃ Antagonists

The interest in NK_{3r} as therapeutic target rose later than that for the two other TK receptors. Indeed, a few peptide selective antagonists have been available (R-486, R-487) up to the discovery of nonpeptide antagonists [1, 3]. SR-142801 also displayed species-related affinity, being more active at human and guinea pig NK_{3r} than the rodent counterparts and critical residues for this discrimination were identified in M134, A146 [1]. Preclinical research has not clarified the therapeutic potentials of these antagonists which displayed activity in models of drug abuse, asthma and intestinal dysmotility. SR-142801 and SB-223412 have been subjected to clinical development: no information is available on the latter drug, whereas the former was unsuccessful in a pilot trial on levodopa-induced dyskinesia but showed promising results in schizophrenia.

Nonselective Tachykinin Antagonists

This area represents a new challenge because, if it is true that nonselective antagonists display a broader therapeutic potential than selective drugs, the same concept applies for potential to precipitate adverse events. The dual NK_{1r} and NK_{2r} antagonists DNK-333 or AVE5883 or the pan-antagonist CS-003 have been shown to antagonize NKA-induced bronchoconstriction in asthmatics in a more efficient manner than selective NK_{2r} antagonists. AVE5883 did not reduce antigen-induced bronchoconstriction and methacholine hyper-reactivity in asthmatics, but no other clinical result is known for this kind of antagonists.

Tacrolimus

► FK506

► Immunosuppressive Agents

Tandem Mass Spectrometry

Tandem mass spectrometry (MS/MS) is a method for obtaining sequence and structural information by measurement of the mass-to-charge ratios of ionized molecules before and after dissociation reactions within a mass spectrometer which consists essentially of two mass spectrometers in tandem. In the first step, precursor ions are selected for further fragmentation by energy impact and interaction with a collision gas. The generated product ions can be analyzed by a second scan step. MS/MS measurements of peptides can be performed using electrospray or matrix-assisted laser desorption/ionization in combination with triple quadrupole, ion trap, quadrupole-TOF (time-of-flight), TOF–TOF or ion cyclotron resonance MS. Tandem

mass spectrometry of peptides provides amino acid sequence-specific ions and can be used to identify and characterize proteins.

► Proteomics

Tardive Dyskinesia

Tardive dyskinesia (TD) refers to a neurological syndrome caused by the long-term use of antipsychotic medications. It is characterized by repetitive involuntary movements of the face, limbs, or trunk. The incidence of tardive dyskinesia is greater with conventional antipsychotic drugs than atypical antipsychotic drugs, and clozapine may even have an ameliorative effect on established TD. There is no known treatment for TD, though dose reduction, discontinuation of the offending drug, or substituting with an atypical antipsychotic drug may be beneficial.

Targeted Cancer Therapy

CHRISTOPHE LE TOURNEAU, SANDRINE FAIVRE, ERIC RAYMOND
Department of Medical Oncology, Beaujon University Hospital, Clichy Cedex, France

Synonyms

Molecular cancer therapeutics

Definition

Targeted cancer therapy refers to anticancer treatments that selectively interfere with molecules (► **oncogenes** and ► **antioncogenes**) considered to be important in neoplastic transformation, cell proliferation, invasion

and metastasis, and/or tumor-related angiogenesis [1]. Targeted cancer therapy is intended to spare normal cells, by contrast with “classical” cytotoxic agents that are relatively nonspecific. Targeted cancer therapy is rationally designed, while “classical” cytotoxic agents are usually discovered through the systematic screening of number of substances primarily issued from nature.

Basic Mechanisms

First targets that have been triggered for cancer treatment are estrogens, progesterone, and their receptors, leading to the concept of hormone therapy. Although hormone function was initially unknown, first hormone therapy was used by Sir Georges Beatson in 1896 when he performed a bilateral ovariectomy in five patients with advanced breast cancer and had three tumor shrinkages. Ovariectomy leads to the blockade of estrogen and progesterone synthesis, and thus to the inhibition of tumor progression in hormone receptor-overexpressing breast cancers. Interestingly, 10 years later, targets were identified by Marshall and Jolly who described the hormonal function of ovaries. In 1930, Decourmelle was the first to perform an ovarian irradiation leading also to tumor response. “Medicinal” hormone therapy arised only in the 1960s. Hormone therapy (or antihormone therapy should we say) is the most older targeted cancer therapy used in oncology. A Number of hormone therapies have been developed for hormone receptor-overexpressing breast cancer therapy:

- Chemical ovarian suppression with the use of ►LH-RH agonists.
- Competitive inhibitors of estrogen receptors, including ►selective estrogen receptor modulators, such as tamoxifene, and ►selective estrogen receptor down-regulators, such as fulvestran. The first ones competitively bind to estrogen receptors, whereas the later ones induce estrogen receptor degradation.
- ►Aromatase inhibitors that inhibit the androgen aromatization in estrogens and thus block estrogen synthesis.

Besides the hormone therapy, the notion of targeted cancer therapy is not so new and can be traced back to the 1940’s [2]. Early approaches included the largely unsuccessful use of antibodies, often conjugated with radioisotopes or toxins, directed against tumor-associated antigens.

More recently, novel targets to targeted cancer therapy have emerged and successfully been introduced in clinical practice. These therapies have been designed to target key components of signaling pathways important in malignant cell transformation and proliferation. Number of growth factor receptors, principally receptor tyrosine kinases, located on tumor cell membrane,

such as epidermal growth factor receptor (EGFR) (►epidermal growth factor receptor family), ►epidermal growth factor receptor 2 (HER-2), and KIT; on endothelial cells, such as ►vascular endothelial growth factor receptor (VEGFR); and on pericytes, such as ►platelet-derived growth factor receptor (PDGFR), have been identified. In each case, activation of the receptor tyrosine kinase causes autophosphorylation of the tyrosine kinase within its intracellular domain, which triggers a cascade of intracellular signals that ultimately promote malignant transformation and tumor progression. In addition, intracellular serine/threonine kinases have also been identified as key kinases in signaling pathways leading from receptor tyrosine kinase activation to cell proliferation and other processes important for cancer development and progression. Three major signaling pathways have been identified as playing important roles in cancer, including mitogen-activated protein kinase (MAPK)/Ras, the phosphatidylinositol-3-kinase (PI3K)/AKT, and the protein kinase C (PKC) signaling cascades. A number of drugs in development inhibit multiple receptor tyrosine kinases and/or intracellular serine/threonine kinases at the convergence of multiple signaling pathways. The critical idea underlying targeted cancer therapy is that excessive activity of the receptor tyrosine kinase promotes cancer development and progression, and thereby inhibition of receptor tyrosine kinases may break this pathogenic chain. The beginning of the twenty-first century has been a turning point in oncology with approvals of several targeted cancer therapies for the treatment of patients with solid tumor treatment (Fig. 1).

Targeted cancer therapy that first entered clinical practice were tyrosine kinase inhibitors, including monoclonal antibodies and small-molecule tyrosine kinase inhibitors. These drugs were specifically designed to inhibit one key cellular protein associated with tumor development and progression. Monoclonal antibodies bind either to the extracellular domain of transmembrane tyrosine kinase receptors or directly to their ligands, thereby preventing the endogenous ligand from binding and activating the receptor. Monoclonal antibodies have a single target, and required to be administered intravenously. Three monoclonal antibodies have been successfully introduced in clinical practice for the treatment of solid tumors, including trastuzumab, bevacizumab, and cetuximab (Table 1).

- Trastuzumab specifically binds the extracellular domain of HER-2 that is found overexpressed on the membrane of cancer cells in 15–20% of patients with breast cancer. It has been approved in HER-2 overexpressing (HER-2 +++ or FISH +) breast cancers.

Targeted Cancer Therapy. Figure 1 History of approval of targeted cancer therapy in clinical practice.

Targeted Cancer Therapy. Table 1 Approved targeted cancer therapies in clinical practice

Molecule	Company	Type	Target(s)	Approved indication(s)
<i>Trastuzumab</i> (Herceptin [®])	Roche	mAb	HER-2	HER-2 overexpressing breast cancer in the adjuvant and metastatic settings
<i>Imatinib</i> (Gleevec [®])	Novartis	TKI	KIT, PDGFR, BCR-ABL	KIT overexpressing unresectable or metastatic gastrointestinal stromal tumor
<i>Gefitinib</i> (Iressa [®])	Astra-Zeneca	TKI	EGFR	Metastatic non-small cell lung carcinoma
<i>Bevacizumab</i> (Avastin [®])	Roche	mAb	VEGFR	Metastatic colorectal cancer Metastatic non-small cell lung carcinoma
<i>Cetuximab</i> (Erbix [®])	Merck	mAb	EGFR	Metastatic colorectal cancer Advanced head and neck cancer
<i>Erlotinib</i> (Tarceva [®])	Roche	TKI	EGFR	Metastatic non-small cell lung carcinoma Metastatic pancreatic cancer
<i>Sorafenib</i> (Nexavar [®])	Bayer	TKI	VEGFR, PDGFR, KIT, FTL-3, RAF	Unresectable or metastatic renal cell carcinoma
<i>Sunitinib</i> (Sutent [®])	Pfizer	TKI	VEGFR, PDGFR, KIT, FLT-3, RET	Imatinib-resistant KIT overexpressing unresectable or metastatic gastro-intestinal stromal tumor Unresectable or metastatic renal cell carcinoma

mAb: monoclonal antibody; TKI: tyrosine kinase inhibitor.

- Bevacizumab specifically binds VEGF, present in tumor vasculature, and has been designed to disrupt tumor angiogenesis. Angiogenesis is an ideal anti-cancer target because in healthy adults it is restricted to a few short episodes, so that antiangiogenic therapy tends to spare normal tissues. Moreover, vascular endothelial cells are genetically more stable and less likely to develop rapid resistance to therapy than neoplastic cells. They are also a relatively uniform cell type, so that antiangiogenic therapy is potentially effective across a broad spectrum of tumors. Bevacizumab has been approved in colorectal and non-small cell lung cancers.
 - Cetuximab specifically binds the extracellular domain of EGFR. It has been approved in colorectal and head and neck cancer. However, unlike for trastuzumab, no clear correlation has been demonstrated between EGFR expression in cancer cell and efficacy of cetuximab.
- Interestingly, all these monoclonal antibodies have a poor antitumor activity when used as single agents, with overall response rates of about 10%. Thereby, these monoclonal antibodies have all been approved in combination with “classical” cytotoxic agents or radiation therapy.

Small-molecule tyrosine kinase inhibitors that bind to the intracellular domain of transmembrane receptor tyrosine kinases may have one or several targets and, due to the lack of solubility, are orally administered. Small-molecule tyrosine kinase inhibitors that have been approved in clinical practice include gefitinib, erlotinib, imatinib, sorafenib, and sunitinib, the first two being the only ones that have a single target, and the later being considered as multitargeted agent (Table 1).

- Erlotinib and gefitinib selectively bind EGFR. Gefitinib has been approved in non-small cell lung cancer, while erlotinib has been approved in non-small cell lung and pancreatic cancers. Imatinib that selectively binds ►**BCR-ABL fusion protein**, KIT, and PDGFR, is the first approved targeted cancer therapy that may be considered to be a multitargeted tyrosine kinase inhibitor. BCR-ABL has been linked with chronic myeloid leukemia, while KIT and PDGFR have been associated with gastrointestinal stromal tumors (GIST). Thus, imatinib has been approved in chronic myeloid leukemia and GIST.
- Sorafenib is a multitargeted cancer therapy that inhibits VEGFR, PDGFR, KIT, fetal liver tyrosine kinase 3 (FLT-3), and the serine/threonine kinase RAF. RAF kinase is a key downstream effector of Ras in the MAPK/Ras signal-transduction pathway that has been linked to various cancers. Sorafenib is both a tyrosine kinase inhibitor and serine/threonine signal-transduction inhibitor. Sorafenib has been approved in renal cancer.
- Sunitinib is also a multitargeted cancer therapy targeting VEGFR, PDGFR, KIT, FLT-3, and RET. Sunitinib has been approved in GIST refractory to imatinib and renal cancer.

Main differences between monoclonal antibodies and small-molecule receptor tyrosine kinases are described in Table 2.

In addition to the targeted cancer therapies described above, other agents in development have been designed to target downstream signaling effectors, i.e., molecules downstream from the receptor tyrosine kinase that are part of the signaling cascades leading to cancer development and progression. These latter agents are sometimes referred to as signal-transduction inhibitors. Some of these agents, like the mammalian target of rapamycin (mTOR) inhibitors, have been designed to affect a key molecule at the convergence of signaling cascades generated by various receptor tyrosine kinases. PKC is another important molecule in signal-transduction pathways, and PKC inhibitors are in development as potential new targeted cancer therapy. Both mTOR and PKC inhibitors target serine/threonine protein kinases.

Targeted Cancer Therapy. Table 2 Main differences between monoclonal antibodies and small-molecule tyrosine kinase inhibitors

Monoclonal antibodies	Small-molecule tyrosine kinase inhibitors
Intravenous administration no absorption problem	Oral administration submitted to absorption variations
Few submitted to metabolism variations, in particular to hepatic metabolism	Submitted to metabolism variations, in particular via cytochroms
Long half-life (>1–2 weeks)	Short half-life (<48 h)
Few pharmacokinetic variations	Possible pharmacokinetic variations
Limited tissular penetration	Satisfactory tissular penetration

Pharmacological Relevance

Many of the initial targeted cancer therapies were focused on a single oncogene product that was found important for cancer development and progression, typically focusing on either molecules associated with direct cancer cell proliferation or those associated with tumor angiogenesis. Increasingly, there is an understanding that monotherapy with agents focused on a single target may produce less than optimal results. In 2000, Hanahan and Weinberg published their theory on tumor growth, suggesting that there are six essential processes that play key roles in tumor growth: self-sufficiency in growth signals, insensitivity to anti-growth signals, evasion of programmed cell death (apoptosis), limitless replicative potential, sustained angiogenesis, and tissue invasive and metastasis [3]. Moreover, they noted that malignant tumors are complex tissues that involve interactions between cancer and supporting cells, including vascular endothelial cells, fibroblasts, and immune cells. Pericytes (which express PDGFR) may also play important roles in tumor-related angiogenesis.

For maximal benefit, it seemed logical that more than one cancer-related target may need to be inhibited [4]. This may involve combining targeted therapies with “classical” cytotoxic agents, as it is the case for monoclonal antibodies, or using targeted agents with more than one target. These latter multitargeted cancer therapies have the benefit of minimizing the number of agents that patients would be required to take. Theoretically, multitargeted cancer therapies could also be combined with “classical” cytotoxic agents for maximal benefit. Imatinib, sorafenib, and sunitinib are currently the only members of this class on the market, but a number of investigational products are in development that may soon be available.

There are a number of reasons for expecting multi-targeted cancer therapy to be superior to targeted cancer therapy focused on a single target or to “classical,” nonselective cytotoxic agents.

- For one, cancer development is characterized by multiple abnormalities rather than a single defect, and it is unlikely that a single-target agent will have dramatic effects on both cancer cells and cells supporting tumor development, such as endothelial cells and pericytes. Thus, maximally effective therapy may need to involve a multitargeted therapy or combination of drugs targeting signaling pathways in both tumor cells and endothelial cells or pericytes. Additionally, one may expect that targeting two components in a given cancer-related pathway will have greater effects than targeting a single component in the pathway. This is another potential argument for targeting of multiple molecules important for cancer development.
- Moreover, by the time a tumor has grown to any significant extent, it has become heterogeneous and is likely to contain resistant clones to single-target cancer therapy. Larger tumors contain cells that have undergone several cell divisions, which increase the odds of mutations, including those associated with drug resistance. This is one reason why more advanced solid tumors commonly become refractory to treatment with single-target agents or “classical” cytotoxic agents using a single mechanism of action. Additionally, new resistance-conferring mutations may arise over time. In either case, resistance is less likely to be an issue when therapeutic regimens target multiple molecules involved in cancer development or utilize multiple mechanisms of action. Thus, the other major argument for multitargeted or combination cancer therapy is increased likelihood of sustained effectiveness compared with treatment involving single-target drugs or agents using a single mechanism of action.
- Finally, the effectiveness of “classical” cytotoxic agents may increase when combined with targeted cancer therapies. In the case of agents targeting angiogenesis, the improvement may be attributed, at least in part, to an initial normalization of the tumor vasculature that results in improved delivery of “classical” cytotoxic agents to the tumor target. In some cases, resistance to cytotoxic therapies may be overcome or prevented in the first place when used in combination with targeted cancer therapies.

Many of these strategies, particularly the ones involving different drug combinations, are largely theoretical at this point and require validation of the concept and determination of optimal regimens. Increased understanding of the mechanisms underlying cancer

suggests that an integrated approach to cancer therapy involves inhibition of multiple signaling pathways.

Taste Receptors

Sensory receptors expressed in particular in taste receptor cells of the taste buds that sense the five basic tastes: salt, sour, sweet, bitter and umami (glutamate taste). Sodium type ion channels sense salty taste whereas sour taste is transduced by potassium type ion channels. The underlying cause of sweet, bitter, and umami tastes is the selective activation of different groups of G protein coupled receptors that discriminate between sweet, bitter, and umami tasting molecules.

► Orphan Receptors

TATA Box

Consensus sequence in the promoter region of many eukaryotic genes that bind a general transcription factor and hence specifies the position where transcription is initiated by the RNA polymerase.

► Interferons

Taxanes

Anticancer drugs originally extracted from the cortex of *Taxus brevifolia* or *Taxus baccata*. They block cell division by inhibiting tubulin depolymerization. Two

taxanes, paclitaxel and docetaxel, have been approved for clinical use.

► Antineoplastic Agents

TCR

► T Cell Receptors

TDM

Therapeutic drug monitoring by measurement of concentrations at a defined time related to drug dosing.

► Pharmacokinetics

Temporal Lobe

The temporal lobe is the inferior middle portion of the cerebral cortex of both hemispheres. The temporal lobes are involved in the analysis of visual and acoustic information and in memory formation. The hippocampus is part of the inner, medial side of the temporal lobes.

► Antiepileptic Drugs

Tendinitis

Tendinitis is an inflammatory painful tendon disorder which can be caused by quinolones. Typical cases are characterized by acute onset, palpation and sharp pain mostly of one or both Achilles tendons, but other tendons may also be affected. Magnetic resonance imaging (MRI) is used to support the diagnosis. Estimates for the incidence of quinolone-induced tendinitis range from approximately 1:100 to 1:10,000. The etiology remains unknown, concomitant

use of corticosteroids, end stage renal disease and age older than 60 years are recognized as risk factors. The latency period ranges from 2 to 60 days after start of treatment, but tendon ruptures may occur as late as 6 months after cessation of therapy.

► Quinolones

Teratogen

A teratogen (the word is of Greek origin, meaning the induction of a monster) is a chemical, physical or viral factor causing birth defects. Exposure to teratogens can result in a wide range of structural abnormalities.

► Antimetabolites

Testosterone

► Sex Steroid Receptors: Androgen Receptor, Estrogen Receptors, Progesterone Receptor

Tetanus

Tetanus is a disease caused by the release of neurotoxins from the anaerobic, spore-forming rod *Clostridium tetani*. The clostridial protein, tetanus toxin, possesses a protease activity which selectively degrades the pre-synaptic vesicle protein synaptobrevin, resulting in a block of glycine and γ -aminobutyric acid (GABA) release from presynaptic terminals. Consistent with the loss of neurogenic motor inhibition, symptoms of tetanus include muscular rigidity and hyperreflexia. The clinical course is characterized by increased muscle tone and spasms, which first affect the masseter muscle and the muscles of the throat, neck and shoulders. Death occurs by respiratory failure or heart failure.

Tetracycline

Tetracycline is an antibiotic with a flat structure of four fused rings with hydrophilic groups on one side and hydrophobic groups on the other side. It exhibits a broad spectrum of activity against Gram-positive and Gram-negative bacteria. It has been used widely in human and veterinary medicine until the recent spread of antibiotic resistance. Resistance to tetracycline, unlike many other antibiotics, is not caused by mutation of ribosomal RNA (rRNA) or ribosomal proteins or modification of a rRNA target site. It is rather caused by enzymes that result in (i) efflux of the drug across the cell membrane, (ii) modification of the drug or (iii) mimicry of elongation factors and release of the bound drug from the ribosome.

- ▶ Ribosomal Protein Synthesis Inhibitors

Thioxanthene

Thioxanthenes are a group of antipsychotic drugs (e.g. chlorprothixene).

- ▶ Antipsychotic Drugs

Threading

Threading techniques try to match a target sequence on a library of known 3D structures by “threading” the target sequence over the known coordinates. In this manner, threading tries to predict the 3D structure starting from a given protein sequence. It is sometimes successful when comparisons based on sequences or sequence profiles alone fail due to a too low sequence similarity.

- ▶ Bioinformatics

Thrifty Gene Hypothesis

The thrifty gene hypothesis postulates that specific sets of genes, which optimized energy utilization and storage, prepared our ancestors for “feast and famine” by efficiently protecting energy reserves when supplies

were low and by rapidly replenishing them when supplies increased again. With unlimited food resources, the thrifty gene haplotype is responsible for a metabolic syndrome of obesity, insulin resistance, hypertension, and dyslipidemia. This dependence of the phenotype on “lifestyle” was first observed in Polynesian and American Indian populations.

- ▶ Antiobesity Drugs

Thrombin

Thrombin (factor IIa) is an enzyme of 295 amino acids derived from prothrombin (vitamin K-dependent zymogen) that converts soluble fibrinogen into insoluble fibrin; other procoagulant activities of thrombin include activation of factor XIII to factor XIIIa (which irreversibly crosslinks fibrin polymers) and activation of the nonenzymatic coagulation factors V and VIII to Va and VIIIa, respectively (greatly amplifying thrombin generation). Thrombin also activates platelets. In addition, thrombin binds to thrombomodulin on endothelium, which causes thrombin to lose its procoagulant activities, and instead to convert protein C to activated protein C (APC), which downregulates thrombin generation by proteolyzing factors Va and VIIIa.

Prostanoids.

- ▶ Cyclooxygenase

Thrombus

A thrombus is a mass of cells and protein composed principally of platelets and fibrin, but also containing red and white blood cells. A thrombus which forms in the circulatory system can become occlusive in that the thrombus can physically block flowing blood.

- ▶ Thrombosis

Thymoleptics

- ▶ Antidepressant Drugs

Thymus

The thymus is a lympho-epithelial organ, located within the upper thorax. One of its functions is the conversion of certain lymphoid hematopoietic precursor cells originating from the bone marrow into thymus-derived lymphocytes (T-cells).

- ▶ T Cell Receptors

Thyroglobuline

Thyroglobulin (Tg) provides the matrix for thyroid hormone biosynthesis. It is a dimeric glycoprotein with a molecular weight of 660,000. Most of the thyroglobulin is present in the thyroid follicular lumen. Thyroglobulin contains 0.1–2.0% iodine and, as a glycoprotein, it contains 8–10% total carbohydrate, with galactose, mannose, fucose, *N*-acetyl glucosamine and sialic acid residues. The carbohydrate in the protein is distributed as three distinct units, A, B and C. Tg is synthesized on polysomes on the endoplasmic reticulum near the basal portion of the cell. After phosphorylation and glycosylation it is vectorially transported to

the apical membrane of the cell and deposited into the follicular lumen.

► Antithyroid Drugs

Thyroid Autonomy

Thyroid autonomy appears as a solitary toxic nodule or toxic multinodular goitre. In toxic thyroid, the nodule's synthesis and secretion of thyroid hormones is autonomous from the thyroid-stimulating hormone (TSH), which is produced in the pituitary gland. Accordingly TSH is suppressed and the extranodular thyroid tissue is functionally downregulated. Thyroid autonomy occurs frequently in iodine-deficient countries, whereas it is much less common in iodine-sufficient areas. Constitutively activating mutations in the TSH receptor and in the Gs α protein are the major molecular aetiology of toxic thyroid nodules.

► Antithyroid Drugs

Thyroid Peroxidase

Thyroid peroxidase (TPO) is a membrane-bound, glycosylated, hemoprotein enzyme. It catalyzes iodination of tyrosyl residues and the coupling of iodotyrosyl residues in thyroglobulin to form thyroxine and triiodothyronine. All mammalian peroxidases belong to the same gene family. The human TPO gene consists of 17 exons and 16 introns and covers at least 150 kb pairs. The heme iron in native peroxidases including TPO and LPO, is in the ferric form (Fe III). In model systems, TPO has no catalytic activity in the absence of H_2O_2 and there is little doubt that H_2O_2 production plays an essential role in thyroid hormone formation in vivo. The H_2O_2 generating system is Ca^{2+} dependent and involves a nicotinamide ADPH (NADPH) oxidase.

► Antithyroid Drugs

Thyrotoxicosis

► Hyperthyroidism

Thyroxine

Thyroxine (3',5',3,5-L-teraiodothyronine, T₄) is a thyroid hormone, which is transformed in peripheral tissues by the enzyme 5'-monodeiodinase to triiodothyronine. T₄ is 3–8 times less active than triiodothyronine. T₄ circulates in plasma bound to plasma proteins (T₄-binding globulin, T₄-binding prealbumin and albumin). It is effective in its free non-protein-bound form, which accounts for less than 1%. Its half-life is about 190 h.

► Antithyroid Drugs

TIMP

The matrix metalloproteinases are inhibited by specific endogenous tissue inhibitor of metalloproteinases (TIMPs), which comprise a family of four protease inhibitors: TIMP-1, TIMP-2, TIMP-3, and TIMP-4. Overall, all MMPs are inhibited by TIMPs once they are activated but the gelatinases (MMP-2 and MMP-9) can form complexes with TIMPs when the enzymes are in the latent form.

► Matrix Metalloproteinases

TIR Domain

Toll/IL-1 receptor domain – A domain found on the internal C-terminus of Toll-like receptors involved in binding the adapter proteins to initiate signalling inside the cell.

► Toll-like Receptors

Tissue Factor

Tissue factor (TF) is an integral membrane glycoprotein, which is tightly associated with phospholipid (molecular weight 44 kDa). It is located on most

vascular cells and by functioning as a receptor for factor VII, initiates the extrinsic pathway of the blood coagulation cascade. The formation of a 1 to 1 complex with factor VII in the presence of Ca^{2+} -ions facilitates the conversion of factor VII to factor VIIa by minor proteolysis.

T-lymphocytes

T-lymphocytes are hematopoietic cells belonging to the adaptive immune system. The prefix “T” indicates that immature precursors migrate to the thymus and are released as mature T-cells. During the maturation process in the thymus, a selection process eliminates both inactive and self-reactive cells. Each T-cell displays a specific receptor for antigen. From a functional point of view, T-cells are classified into cytokine-producing CD4^+ or helper T-cells that provide growth and activation factors to neighboring cells, and CD8^+ or cytotoxic T-cells, that specifically attack and kill target cells expressing the specific antigen. The composition of cytokines released by CD4^+ cells allows a classification into Th1 and Th2 populations. The term “Memory cells” describes a population of sensitized T- or B-cells that persist in the host and can rapidly be reactivated upon exposure with the specific antigen.

TNF Receptor Associated Factors

Tumor necrosis factor receptor associated factors are a group of at least 6 proteins (TRAF1-6), which are major signal transducers for the TNF receptor superfamily and the interleukin-1 receptor/toll-like receptor (IL-1R/TLR) superfamily. TRAF proteins are characterized by the presence of the TRAF domain at the the C-terminus,

which mediates self-association and upstream interaction with receptors and other signaling proteins. They function as adaptor proteins, which elaborate receptor signal transduction by serving as both a convergent and divergent platform.

TNF Receptor Superfamily

The TNF receptor superfamily is a group of receptors, which share some structural similarities. Best-studied examples are the receptors for tumor necrosis factor α (TNF α) and the Fas receptor. Binding of the inherently trimeric ligands induces receptor trimerisation and results in the recruitment of several signaling proteins to the cytoplasmic domains of the receptors. TNF receptors recruit the “TNFR1-associated death domain protein” (TRADD), which serves as a platform to recruit several other mediators including “receptor-interacting protein 1” (RIP1), “Fas-associated death domain protein” (FADD) and “TNF-receptor associated factor 2” (TRAF2). TRAF2 plays a central role in the induction of downstream events like activation of I κ B-kinase (IKK) and MAP-kinases. Activation of Fas receptor does not result in the recruitment of TRAF2, but recruits FADD and subsequently leads to activation of caspase 8.

Tocolytics

Tocolytics are drugs such as the selective β_2 -adrenoceptor agonists, e.g. salbutamol or terbutaline, which inhibit both the spontaneous and oxytocin-induced contractions of the pregnant uterus by relaxing

the muscles of the uterus (myometrium). Tocolytics are used in selected patients to prevent premature labor.

Tolerance

The term tolerance is used to describe a gradual decrease in responsiveness to a drug, typically developing over days or weeks. A fast loss of responsiveness developing, e.g., over a few minutes is called desensitization or tachyphylaxis. It is important to note that tolerance does not only develop with drugs of abuse but also after repeated administration of a wide variety with drugs that are not self-administered by animals or used compulsively by man. Examples of the phenomenon of tolerance to opioids are described. Opioid tolerance is not associated with changes in affinity and/or density of opioid receptors. Opioid receptor desensitization is also not associated with receptor internalization but underlies uncoupling of the G protein.

Tolerance and Desensitization

TORSTEN SCHÖNEBERG
Institut für Biochemie, Medizinische Fakultät,
Universität Leipzig, Leipzig, Germany

Definition

▶ **Tolerance** is the reduction in response to a drug after repeated administration. Clinically, a higher dose is required to obtain the original response. The time course and extent of tolerance developments varies between different drugs. At least two types of tolerance, ▶ **pharmacokinetic** and ▶ **pharmacodynamic tolerance**, can be distinguished. Tolerance development is a reversible process. The phenomenon of ▶ **cross tolerance** may develop to the effect of pharmacologically-related drugs, particularly to those acting at the same receptor. Drug tolerance can involve not only physiological but also psychological factors.

► **Desensitization** describes the rapid signal attenuation in response to stimulation of cells by receptor agonists. Changes in the coupling efficiency of receptors to signal transduction pathways and receptor internalization can account for ► **desensitization** and the development of pharmacodynamic tolerance.

Basic Mechanisms Removal of the Agonist

The action of an agonist can be terminated by its removal from the extracellular fluid. This includes simple dissociation and diffusion as well as the reuptake and metabolic inactivation of the agonist. Latter mechanisms are fast and powerful and underlay a fine-tuned regulation that can adapt its capacity to maintain a physiological homeostasis. Many clinically used agonists are inactivated by similar mechanisms as the physiological ligands. Therefore, continued agonist treatment can induce an increased drug degradation. Such mechanisms may contribute to the development of a pharmacokinetic tolerance. For example, barbiturates induce their own metabolic inactivation in the liver, a process that leads to a reversible pharmacokinetic tolerance. Chemical modifications of an agonist that prevent reuptake and metabolic degradation can help to circumvent this form of tolerance.

Receptor Desensitization

Receptor desensitization summarizes pharmacodynamic processes that lead to an inactivation of receptor signaling within seconds to minutes. The rapid attenuation of extracellular signals mediated by G protein-coupled receptors (GPCRs) and their signaling pathways belong to the best-studied systems. The uncoupling of the receptor from its G protein involves receptor phosphorylation by different classes of protein kinases. Two types of receptor desensitization can be distinguished. ► **Homologous desensitization** is mediated by agonist-induced activation of the same receptor, whereas ► **heterologous desensitization** is caused by activation of a different receptor. The so-called ► **G protein-coupled receptors kinases** (► **GRKs**) are responsible for homologous agonist-induced receptor phosphorylation. So far, seven GRKs have been cloned. The expression of GRK1 and -7 is confined to retinal rods and cones, respectively. GRK2, GRK3, GRK5, and GRK6 are the most widely distributed GRKs, but expression and knockout studies also implicate more distinct roles of individual GRKs. Following receptor activation by an agonist, GRKs translocate from the cytosol to the plasma membrane. But there are also GRKs (GRK4, 5, 6) which constitutively associate with membranes. The signal which recruits GRKs to the activated receptor is not fully understood. Changes in the three-dimensional structure of the intracellular receptor surface, exposition of the phosphorylation consensus sites as well as a direct interaction of

GRKs and G proteins are discussed. The sites (mainly serine residues) phosphorylated by GRKs are located within the third intracellular loop and the intracellular C terminus of GPCRs. Once the receptor is phosphorylated, the functional cofactors of GRKs, the ► **arrestins** bind to the GPCR and thereby quench the signal transduction by disrupting the interaction of the receptor and the G protein. At least four arrestins – the visual arrestin 1 and arrestin 4 and the ubiquitously expressed arrestins 2 and 3 (also known as β -arrestin-1 and β -arrestin-2) – can be distinguished. β -Arrestins are essential for ► **internalization** of many GPCRs and some other membrane receptors (TGF- β type III receptor, IGF1 receptor). They act as adaptor proteins that link the receptors to the clathrin-coated pit endocytosis pathway (see Receptor Internalization).

Second messenger-dependent kinases such as protein kinase A (PKA), protein kinase C (PKC) and Ca^{2+} /calmodulin-dependent protein kinase II (CaMKII) are mainly involved in heterologous agonist-independent receptor desensitization. The heterologous desensitization includes receptors that use similar signal transduction pathways and simply depends on the overall kinase activity regulated by many different stimuli. Phosphorylation-induced conformational changes of the receptor reduce the affinity to the G protein, thereby leading to receptor/G protein uncoupling.

Many GPCRs contain one or more conserved cysteine residues within their C-terminal tails, which are modified by covalent attachment of palmitoyl or isoprenyl residues. The palmitoyl moiety is anchored in the lipid bilayer forming a fourth intracellular loop. There is evidence that palmitoylation of a GPCR is a dynamic process and may affect receptor desensitization.

Desensitization is also a general property of other receptor families such as receptor tyrosine kinases and ligand-gated ion channels. For example, receptor tyrosine kinases undergo agonist-induced dimerization and autophosphorylation that initiates receptor internalization (see Receptor Internalization). Phosphorylation of serine and tyrosine residues may also modulate the desensitization of ion channels such as the nicotinic acetylcholine receptor at the neuromuscular junction. Nevertheless, the molecular mechanism that mediates channel opening by agonist binding, and then allows the channel to close (desensitize) even though agonist remains bound, is not understood in detail.

It should be noted that fast inactivation of receptor signaling not only involves the desensitization of the receptor but also the components of the downstream signaling cascade. The deactivation of active $G\alpha$ subunits is controlled by the intramolecular hydrolysis of bound GTP, allowing it to reform the inactive heterotrimer. Termination of G protein-mediated signaling in vivo is 10- to 100-fold faster than the in vitro rate of GTP hydrolysis by $G\alpha$ subunits, suggesting

the existence of GTPase-activating proteins (GAPs). Indeed, so-called “regulators of G protein signaling” (RGS) have been identified as potent GAPs for $G\alpha$ subunits which are required to achieve timely deactivation.

Receptor Internalization

Agonist-induced receptor internalization (also called receptor endocytosis or sequestration) has been observed for many membranous receptors including GPCRs. Following GRK-mediated receptor phosphorylation, arrestins bind to the receptor and recruit other proteins such as AP-2, dynamin, and clathrin. Then, clathrin-coated pits are formed and the receptors internalize. Subsequently, endosomal acidification permits dissoziation of the ligand and dephosphorylation of the receptor by cytosolic phosphatases (Fig. 1). Internalized receptors can recycle to the cell surface or can be degraded in lysosomes, a process known as receptor downregulation (see Receptor Down-Regulation). The predominant pathway for internalization requires a concerted action

of dynamin, arrestin, and clathrin. But there are mechanistic differences in arrestin-mediated receptor trafficking. So-called “class A” receptors (e.g., β_2 -adrenergic receptor) bind to β -arrestin transiently, traffic with it to clathrin-coated vesicles, then dissociate and rapidly recycle. “Class B” receptors (e.g., V_2 vasopressin receptor) bind β -arrestin more tightly and internalize together with it. It should be noted that there are additional pathways of GPCR endocytosis. Internalization of the M_2 muscarinic acetylcholine receptor also requires dynamin, but proceeds in an apparent β -arrestin- and clathrin-independent manner.

In some cases, receptor inactivation, e.g., of the V_2 vasopressin receptor, is mediated by agonist-induced enzymatic cleavage of the GPCR. This nonendocytic proteolysis is promoted by a plasma membrane-associated metalloprotease. Proteinase-activated receptors (PARs) such as the thrombin receptor also follow a distinctly different pathway. PARs require the enzymatic cleavage of their N terminus, and the newly generated N terminus activates the receptor. Once

Tolerance and Desensitization. Figure 1 Agonist-induced internalization of GPCRs (G protein-coupled receptors). The model depicts the agonist-induced regulation of GPCR phosphorylation, internalization, recycling, and degradation. Agonist activation of many GPCRs results in receptor phosphorylation by GPCR-specific kinases (GRK). The phosphorylated GPCR recruits β -arrestin, which initiates receptor targeting to clathrin-coated pits. Endosomal acidification permits dissociation of the ligand. The GPCR is dephosphorylated by a G protein-coupled receptor-specific phosphatase (GRP). Internalized receptors can recycle to the cell surface or are degraded in lysosomes.

activated, PARs are internalized into endosomes and sorted to lysosomes for degradation. Recovery of functional receptors at the plasma membrane requires synthesis of new receptors or mobilization of intact receptors from intracellular pools.

Receptor tyrosine kinases, such as the epidermal-growth factor (EGF) receptor, also undergo agonist-induced endocytosis which is assumed to follow a two-step process. First, the agonist induces receptor dimerization and conformational changes that allow for cross-phosphorylation of tyrosine residues. In a second step, the phosphorylated receptor tyrosine kinase recruits adaptor proteins such as Cbl protein and endophilin, which promote receptor internalization by forming clathrin-coated pits. Receptor activation also induces ubiquitination, a sorting signal for receptor degradation in lysosomes. Interestingly, GPCRs can cross-desensitize receptor tyrosine kinases through clathrin-mediated endocytosis.

Ligand-gated ion channels, such as GABA type A receptor, can also undergo clustering and internalization that is evoked when receptors are occupied by agonists. Internalized receptors can be rapidly recycled to the cell surface, a process that is regulated by PKC. Similar to GPCRs, a portion of the intracellular GABA type A receptors derived from ligand-dependent endocytosis is targeted to degradation pathways.

Receptor Down-Regulation

The decrease in the total cellular receptor number is a process known as receptor downregulation. It is caused by chronic agonist exposure and occurs in hours or days. This process is mainly agonist-mediated but there is also evidence for agonist-independent pathways of cell surface receptor depletion. Recovery from receptor downregulation is reversible but slow. One mechanism of receptor downregulation involves lysosomal targeting and the accelerated degradation of internalized receptors (Fig. 1). The factors that determine the fate of an internalized receptor (recycling pathway vs. degradation) are currently under investigation. Conjugation of proteins with ubiquitin, an abundant intracellular protein, is a signal for the rapid degradation of many cytosolic and membranous proteins. It has been demonstrated that receptor tyrosine kinases and GPCRs undergo agonist-induced ubiquitination. There is evidence that β -arrestins act as obligate adaptors to guide ubiquitin ligases to the receptor. Furthermore, GPCR activation can provoke sustained β -arrestins ubiquitination.

The regulation of receptor synthesis is a second component of receptor downregulation. It involves processes that reduce gene transcription, mRNA stability, and receptor half-life time. It should be noted that mechanisms in addition to the regulation of the receptor number may account for tolerance development. Second messenger levels and enzyme activities that participate in the signaling of a given receptor are

found to be up- or downregulated to compensate for chronic over stimulation of a distinct signal transduction cascade.

Pharmacological Relevance

Desensitization, internalization and downregulation of receptors are mechanisms that eventually lead to a loss of agonist efficacy. These processes together with agonist removal have been implicated in **tachyphylaxis** and in the development of tolerance and drug **dependence**. Vice versa, chronic administration of antagonists and inverse agonists can increase the number of receptors and may account for super sensitivity seen, e.g., after rapid termination of a long-term treatment with β -adrenergic receptor blockers. Understanding the molecular mechanisms of long-term receptor expression regulation may help to influence or even prevent therapeutically undesired effects.

Many mechanistic questions are still puzzling, but recent studies with genetically engineered mice have provided some new insights in the processes of desensitization and tolerance development. The desensitization of the μ -opioid receptor and development of antinociceptive tolerance was abolished in mice lacking β -arrestin-2. As a result of gene deletion, these mice showed a remarkable potentiation and prolongation of the analgesic effect of morphine. Interestingly, the deletion of β -arrestin-2 does not prevent the chronic morphine-induced upregulation of adenylyl cyclase activity, a cellular marker of dependence, and the mutant mice still became physically dependent on the drug. In concert with this finding, several studies indicate that highly addictive opiate drugs such as morphine have a reduced ability to induce the desensitization and endocytosis of opioid receptors. Therefore, the development of physical dependence and addiction appears to be independent from desensitization and endocytosis of opioid receptors. Additional mechanisms of tolerance formation are discussed. These include upregulation of adenylyl cyclase expression and activity, modulation of protein kinase activity as well as upregulation of members of the RGS family.

Agonist-dependent and -independent changes in receptor density can contribute to pathological situations. There is a downregulation of cardiac β -adrenergic receptors in dilated cardiomyopathy, probably as a consequence of increased sympathetic tone. A rapid upregulation of β -adrenergic receptors is characteristic of myocardial ischemia and hyperthyreosis. Blockade of β -adrenergic receptors inhibits the basal receptor activity and action of endogenous catecholamine and may explain part of the beneficial effects of β -blockers in both diseases.

Taken together, the regulation of time course and extent of receptor desensitization and tolerance development involves complex cellular processes. Detailed understanding of the molecular mechanisms of receptor

inactivation may improve the chronic drug treatment of patients and may offer new targets of therapeutic interventions.

Toll-like Receptors

ELAINE F. KENNY, TANYA M. WATTERS,
LUKE A. J. O'NEILL
School of Biochemistry and Immunology, Trinity
College Dublin, Ireland

Definition

Toll-like Receptors (▶TLRs) are type-1 integral membrane glycoproteins with molecular weights of 91–115 kDa. They consist of a Toll/IL-1 Receptor (TIR) domain in their C-terminii and a set of Leucine rich repeats (▶LRRs) in their N-terminii [1]. They are critical receptors in the ▶innate immune system—the body's first defence against pathogens, due to their ability to recognise microbial products and initiate an internal signal cascade to alert the body to attack [1]. To date 10 human TLRs have been discovered each with the ability to recognise a different microbial product.

Basic Mechanisms

Innate Immune System

The innate immune system is found across all organisms and is thought to have originated before the split into animal and plant kingdoms. It is the body's primary response to attack. Receptors used in this system must be capable of recognising a broad range of pathogens. This

works by the recognition of molecules common to the pathogens that are absent in the host. These molecules are recognised by the TLRs. Other important receptors in innate immunity include the secreted mannan-binding lectins and the cytoplasmic NOD like receptors (NLRs).

Discovery

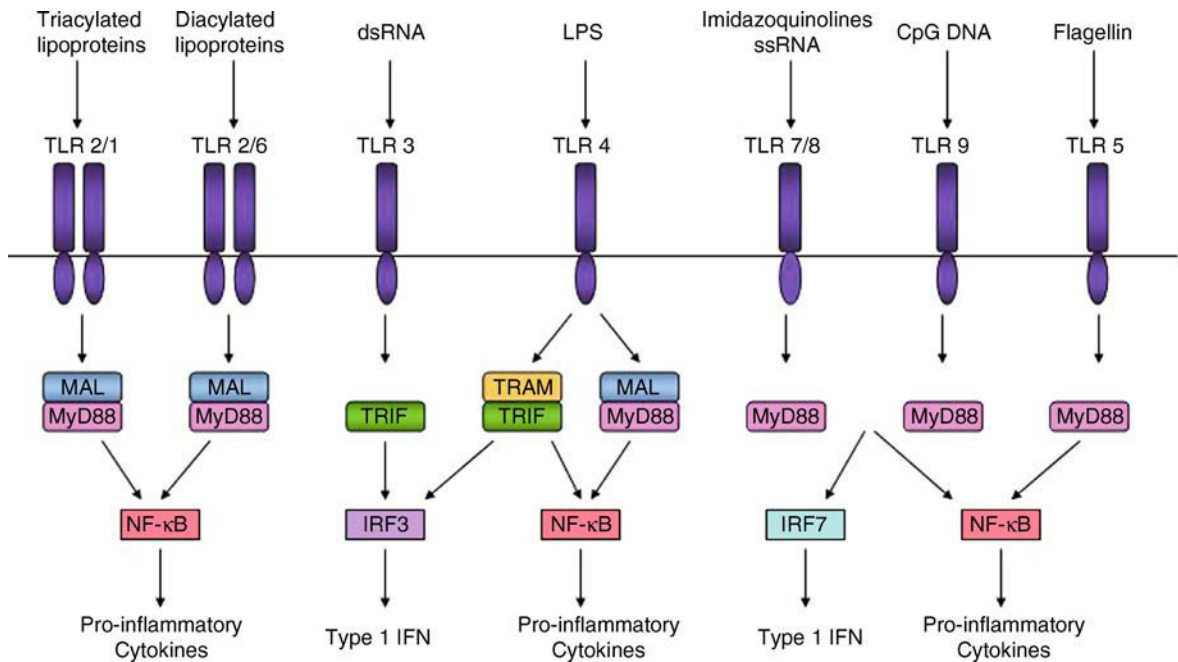

The discovery of TLRs can be traced back to the investigations into the genetics of the fruit fly *Drosophila melanogaster* in the mid-1980s. The Toll receptor in *Drosophila* was shown to be crucial in the establishment of the dorso-ventral pattern during development in flies. It was not until almost 10 years later that it was found that Toll was also important in anti-fungal host defence. Toll consists of an N-terminal leucine rich repeat (LRR) motif and a C-terminal domain highly homologous to the cytosolic domain of the type I IL-1 receptor (IL-1RI) and hence was named the Toll/IL-1R (▶TIR) domain. The homology to IL-1RI indicated that Toll would have a role in host defence, similar to IL-1.

The hunt then began for a mammalian homologue to Toll and in 1997 the first protein similar to Toll was discovered. This protein activated the transcription factor NF- κ B when over expressed. Five human Tolls were then reported and named Toll-like receptors (TLRs). One of these, TLR4, was identical to the first Toll discovered in mammals. Importantly it was then demonstrated that in mice resistant to the Gram negative protein lipopolysaccharide (LPS), termed C3H/HeJ mice, there was a mutation in the *TLR4* gene identifying TLR-4 as the receptor for LPS. Subsequently other TLRs were shown to recognise various microbial products.

What TLRs Recognise

TLRs are transmembrane proteins found on the plasma membrane and on endosomal membranes. The ability of the TLRs to recognise microbial products comes from the 19–25 copies of the LRR motif. The differences in these LRRs are what give the TLRs the ability to bind different components of pathogens.

TLR-1, 2, 4, 5, 6 and 10 are found on the plasma membrane and TLR-7, 8 and 9 are found on the endosomal membranes. TLR-3 has been seen in both depending on the cell line examined. The ligands recognised by the TLRs are outlined in Fig. 1. TLR-2 forms dimers with TLR-1 or 6 to recognise triacylated and diacylated lipopeptides, respectively. All other TLRs probably form homodimers. TLR-4 binds LPS and TLR-5 binds a protein on the flagella of bacteria called flagellin. TLR-3, 7 and 8 are involved in recognition of viral nucleic acids, with TLR-3 recognising double-stranded RNA, and TLR-7 and 8 recognising single-stranded RNA. TLR-7 also recognises the synthetic viral compound imiquimod. TLR-9 is involved in the recognition of unmethylated CpG motifs of pathogens. TLR-10 is found on the same locus as TLR-1

Toll-like Receptors. Figure 1 Overview of TLR signalling pathways. TLRs detect a broad range of conserved microbial structures thereby initiating an immune response against the invading pathogen. Upon activation, the adapter proteins Mal, MyD88, TRIF and TRAM are differentially recruited to the various receptors. MyD88 is utilised by all the TLRs with the exception of TLR3. TRIF is activated downstream of TLR3 and TLR4. Mal and TRAM act as bridging proteins, recruiting MyD88 and TRIF, respectively to TLR4. The recruitment of the adapter proteins leads to the activation of signalling pathways, which culminate in the activation of specific transcription factors, such as NFκB and IRFs. This subsequently leads to the production of proinflammatory cytokines and/or Type 1 IFNs.

and 6 and may in fact interact with them or TLR-2 to signal. At present its ligand remains unclear [1].

Once the TLRs have bound their respective ligand they initiate a signalling cascade to alert the host to the presence of a threat. This signal begins with specific adapter proteins and leads to the activation of transcription factors such as NFκB, IRF-3 and IRF-7 as shown in Fig. 1. These activated transcription factors cause changes in gene expression typically leading to the production of ►cytokines.

Activation of the Signalling Cascade

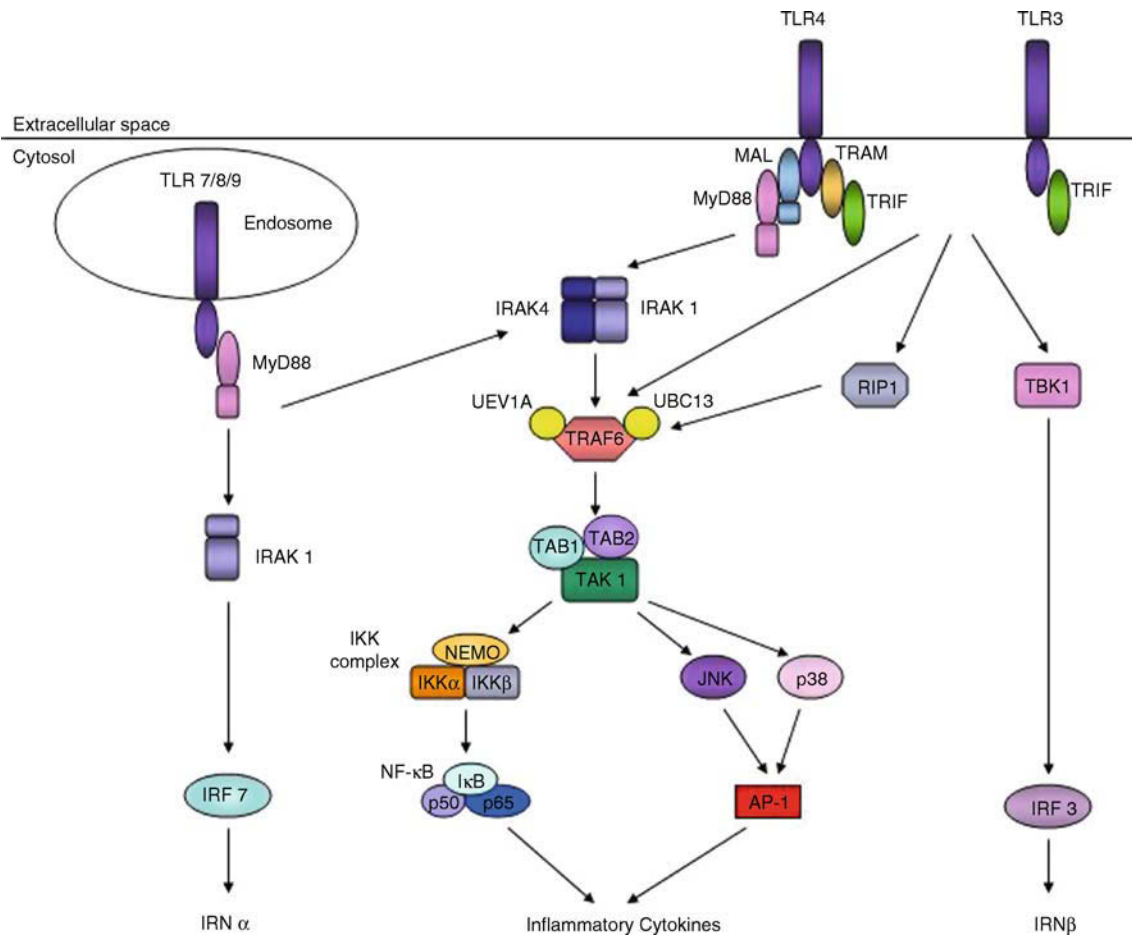

The function of the TIR domain found on each TLR is to allow adapter proteins to bind the TLRs. These adapter proteins then become somehow activated, presumably by conformational changes, and bind other proteins in the signalling pathway. To date five adapter proteins have been discovered four of which aid the signal pathway: Myeloid Differentiation factor 88 (MyD88), MyD88 adapter like protein (Mal), TIR domain containing adapter inducing IFN-β (TRIF) and TRIF-related adapter molecule (TRAM) and one that is inhibitory: SAM and ARM containing protein (SARM) [2]. All the adapter proteins contain a TIR domain allowing them to bind the TIR domain of the activated TLRs.

The MyD88 Dependent Response

MyD88 was the first adapter protein to be discovered. As well as the TIR domain it contains a death domain (DD). MyD88 is used by all TLRs to signal with the exception of TLR-3, which requires TRIF. Its signalling pathway is outlined in Fig. 2.

To begin the signalling cascade MyD88 binds to the TIR domain of an activated TLR through its own TIR domain. This binding leads to the recruitment of IL-1 receptor associated kinase-4 (►IRAK-4) through its death domain. IRAK-1 is also recruited to MyD88 through its interaction with Toll-interacting protein (Tollip).

Hyperphosphorylation of IRAK-1 by itself and IRAK-4 causes IRAK-1 to dissociate from the membrane-bound complex. Tumour necrosis factor (TNF) receptor-associated factor-6 (►TRAF-6), a cytoplasmic protein, is activated by IRAK-1 and with TAB-2, another cytoplasmic protein, activates transforming growth factor-β (TFG-β)-activating kinase (TAK-1). During this process both TRAF-6 and TAK-1 become ubiquitinated. TAK-1 then promotes activation of the IκB kinases, or the ►IKK family, IKKα and IKKβ (found in a complex with NFκB-essential modulator [NEMO]), which phosphorylate the IκB family, notably IκB-α. IκB-α is an inhibitor of NFκB as it sequesters NFκB in an

Toll-like Receptors. Figure 2 MyD88 and TRIF dependent pathways activated by the TLRs. Upon ligand binding, MyD88 is recruited to the receptor and recruits IRAK-4. IRAK-1 is subsequently recruited and activated by IRAK-4. IRAK-1 is responsible for the activation of TRAF-6, which with TAB-2 activates the kinase TAK-1. Substrates for TAK-1 include the IKK complex, JNK and p38. IKK phosphorylates I κ B- α , which induces its ubiquitination and degradation. This allows NF κ B to translocate to the nucleus and induce gene expression. JNK and p38 mediate the activation of AP-1. Both these transcription factors act in concert to produce inflammatory cytokines. Downstream of TLR-7, 8 and 9, MyD88 is also responsible for the activation of IRF7. The TRIF dependent pathway results mainly in the activation of IRF-3 via TBK-1. IRF-3 is involved in the production of type 1 IFNs. TRIF can also mediate the activation of NF κ B via RIP-1 and/or TRAF-6.

inactive form in the cytosol. When it is phosphorylated it is marked for polyubiquitination and ultimately degradation by the 26 S proteasome. This allows NF κ B to translocate to the nucleus and bind transcription start sites on target genes. These genes code for proteins involved in immunity and inflammation.

TAK-1 can also activate c-jun N-terminal kinase (\blacktriangleright JNK) and p38 both of which are MAP kinases. JNK activates the transcription factor AP-1 and p38 is involved in mRNA stabilisation. This pathway is also capable of activating IRF-7 in dendritic cells in response to TLR-7 and TLR-9 ligands.

Mal

Mal was the second adapter to be discovered. It is a bridging adapter connecting MyD88 to TLR-4 and

TLR-2. Evidence for the bridging role of Mal comes from the presence of a phosphatidylinositol 4,5-bisphosphate (PIP2) binding domain at its N-terminus. This domain recruits Mal to areas of the plasma membrane rich in PIP2 and these areas have been shown to contain TLR-4.

There is evidence for another role for Mal besides recruiting MyD88. This is due to the discovery of several other domains in the protein. These include a TRAF-6 binding domain allowing Mal to activate TRAF-6 without MyD88, a PEST domain commonly seen in proteins targeted for ubiquitination and a caspase-1 cleavage site that cleaves Mal into two proteins one of 4 kDa and one of 21 kDa. Mal is also tyrosine phosphorylated by Bruton's tyrosine kinase (Btk) and this phosphorylation targets it for degradation by SOCS-1.

The TRIF Dependent Response

TRIF was the third adapter discovered and is utilised by TLR-3 and TLR-4. It contains a TIR domain and a TRAF-6 binding domain. TLR-3 signalling is entirely through TRIF but in TLR-4 signalling TRAM is also required. An outline of the TRIF pathway is shown in Fig. 2.

To initiate TLR-3 signalling TRIF binds the TIR domain of TLR-3 through its own TIR domain and three signalling pathways are activated. In the first pathway TRIF can recruit TRAF-6 via its TRAF-6 recruitment domain and initiate the same series of events seen in the MyD88 dependent pathway. However, the role of TRAF-6 is still unclear due to different dependencies on it in various cell types. Murine macrophages deficient in TRAF-6 respond normally to TLR-3 ligands but murine embryonic fibroblasts (MEFs) deficient in TRAF-6 do not. This area of TRIF signalling requires further investigation.

TRIF can also activate IRF-3 leading to the production of type I interferons (IFNs).

This second pathway begins with the direct binding of TRIF to TLR-3 and the activation by it of two kinases: inducible IKK (IKK- β also known as IKK- ϵ) and TRAF family member-associated NF κ B activator (TANK)-binding kinase-1 (TBK-1). The activation of these two kinases leads to the phosphorylation of IRF-3 and IRF-7 allowing them to enter the nucleus and induce the expression of IFN- α (IRF-7) and IFN- β (IRF-3 & 7). It has been shown that TBK-1 binds to the N-terminus of TRIF in the same area as TRAF-6 suggesting that in a TLR-3 response either TBK-1 or TRAF-6 bind TLR-3, but never both.

The third signalling pathway of TRIF utilises its C-terminus. This region contains a RIP homology interaction motif (RHIM) that binds RIP-1 and RIP-3. RIP-1 phosphorylates IKK- β and the NF κ B pathway can be activated. RIP-3 is a negative regulator of TRIF competing for RIP-1 [2].

TRAM

TRAM was the fourth adapter discovered and has only been seen to have a role in TLR-4 signalling. It contains a TIR domain and a myristoylation site. When TRAM is myristoylated it becomes bound to the plasma membrane and can bind to TLR-4 through its TIR domain. TRAM then allows TRIF to bind it and activate the pathways associated with TRIF as outlined above for TLR-3.

TRAM is subject to control through phosphorylation by protein kinase C- ϵ . It is phosphorylated on serine 16 which is located close to the myristoylation site which is TRAM cannot signal without this phosphorylation or if the myristoylation site has been mutated.

SARM

SARM was the final adapter to be identified. It contains a TIR domain, two sterile- α (SAM) motifs adjacent to

the TIR domain and HEAT/Armadillo repeats. SARM is a negative regulator of NF κ B and IRF activation in the TRIF pathway alone. Experiments show that the presence of SARM can block the TRIF-dependent pathway while the MyD88 dependent pathway remains functional. It has also been shown that the C-terminus of SARM is sufficient to cause this negative regulation. It is still unclear how SARM inhibits the TRIF pathway.

Cytokine Production

The key end result of TLR signalling is the induction of cytokines. Cytokines are proteins produced during an immune response that allow the maturation, activation and differentiation of effector cells in the immune system. The activation of NF κ B and AP-1 by the MyD88 and the TRIF dependent pathways leads to the production of proinflammatory cytokines such as IL-6, TNF- α and various chemokines. This pathway can also activate IRF-7 via TLR-7 and TLR-9 allowing Type-I interferons to be produced.

The activation of IRF-3 through the TRIF dependent pathway allows for chemokines such as RANTES to be produced. It also leads to the production of IFN- α and IFN- β , which are involved in anti-viral immunity. The TRIF pathway, activated by either TLR-3 or TLR-4, can also induce MHC class-II expression and co-stimulatory molecules, thus leading to T-cell activation. This provides an important link between innate and adaptive immunity.

Pharmacological Intervention

Though TLRs are central to protecting the host they are also linked with disease. They can become over activated during infection, or by the presence of endogenous ligands released from damaged cells and cause inflammation. Examples of the diseases associated with TLRs are shown in Table 1. Several TLRs have been specifically seen to be activated in infectious and inflammatory diseases. The knowledge that TLRs could be involved in disease opened the area of TLR research into drug targeting to counteract the negative effect of TLRs on the host. In addition activation of TLRs will stimulate the immune response and this has potential applications in adjuvants for vaccines, promotion of anti-viral host defence, or the enhancement of anti-tumour immunity. An outline of the compounds that target TLRs can be found in Table 2 [3].

TLR-4

Several TLR-4 adjuvants for vaccines have been developed to date. An example of these is monophosphoryl lipid A (MPL) a modified version of lipid A found in LPS [4]. It has been used extensively in clinical trials as it is far less toxic than LPS. It is hoped to use MPL in vaccines against infectious diseases, allergies and cancer. Derivatives of MPL have now been

Toll-like Receptors. Table 1 Disease Associations of TLRs

TLR	Associated Diseases
TLR4	EAE, Atherosclerosis, Sepsis, Asthma, COPD, RSV bronchitis, Arthritis
TLR2	Candidiasis, Asthma, Arthritis
TLR3	Arthritis, Lethal encephalitis
TLR5	Legionnaire's disease

COPD, chronic obstructive pulmonary disease; EAE, experimental autoimmune encephalomyelitis; RSV, respiratory syncytial virus; SLE, systemic lupus erythematosus.

Toll-like Receptors. Table 2 Therapeutic Targeting of TLRs

TLR	Compound	Action	Indication	Status
TLR4	Supervax™	Agonist	Hepatitis B	Approved (EU)
	Fendrix®	Agonist	Hepatitis B	Approved (Argentina)
	E6020	Agonist	General vaccine adjuvant	Preclinical
	Cervarix®	Agonist	Human papillomavirus	Pre-approval
	Pollinex®Quattro	Agonist	Allergic rhinitis	Marketed (EU)
	Ragweed SC/Pollinex®Quatro	Agonist	Allergic rhinitis (Ragweed)	Phase II clinical trials
	Stimuvax®/BLP25	Agonist	Non-small cell lung cancer	Phase II clinical trials
	TAK-242	Antagonist	Severe sepsis	Phase III clinical trials
	Eritoran	Antagonist	Severe sepsis	Phase III clinical trials
TLR7	Aldara™	Agonist	Basal cell carcinoma Genital warts	Approved
	852A	Agonist	Melanoma	Phase II clinical trials
	ANA975	Agonist	Hepatitis C	Phase I clinical trials
	Resiquimod (R-848)	Agonist	Genital Herpes	Phase II clinical trials discontinued
TLR7/9	IRS 954	Antagonist	Lupus	Preclinical
TLR9	CpG-ODN 7909	Agonist	Melanoma	Phase I clinical trials
	PF3512676	Agonist	Non-small cell lung cancer	Phase III clinical trials
	1808 ISS	Agonist	Colorectal cancer	Phase I clinical trials
	1808 ISS	Agonist	Asthma	Phase II clinical trials
	IMOXine	Agonist	Renal cell carcinoma	Phase II clinical trials
	Second generation CpG-ODN	Agonist	Asthma	Preclinical
	HYB2093 (CpG-ODN)	Agonist	Asthma	Preclinical

produced and have been shown to be effective in vaccines against hepatitis B and human papilloma virus.

TLR-4 has also been targeted in defence against allergy. These compounds also use MPL linked to antigens to prevent allergic reaction specifically against ragweed for example. Anti-tumour peptide vaccines have also been developed again using MPL or its derivatives.

Antagonists of TLR-4 have been developed to prevent an excessive reaction to infection in the body. TAK-242 and Eritoran are both in phase III trials to help combat

severe sepsis due to Gram negative bacteria. Both are lipid A analogues and prevent LPS binding to TLR-4.

TLR-7/8

TLR-7 and 8 have also been investigated as a way of enhancing the body's response to viral attack. This has been used to target cancer and infectious diseases. Treatment of basal cell carcinoma using an imiquimod cream has been approved and meloma targeting drugs are in phase II trials. Imiquimod is also approved for use against papilloma-induced genital warts [4].

In infectious disease compounds such as ANA975 (phase I trials) and Resiquimod (phase II trials) have been developed to target Hepatitis C and genital herpes, respectively. IRS954 is a TLR-7 and 9 antagonist in pre-clinical trials for Systemic Lupus Erythematosus (SLE).

TLR-9

CpG-ODN7907 is a TLR-9 agonist, which has been developed to target melanoma by attaching it to the melan-A peptide and is in phase I clinical trials. Other examples include PF3512676 used in combination with chemotherapy to treat non-small cell lung cancer, which is in phase III trials. 1018 ISS is a TLR-9 agonist being tested in combination with Rituxan to treat non-Hodgkins lymphoma [3].

TLR-9 has also been used to target asthma with several compounds in preclinical trials such as second generation CpG-ODNs and HYB2093. 1018 ISS has also been tested in asthma. Defence against infectious disease is also enhanced through TLR-9. CpG10101 was in phase II trials as a Hepatitis C target but has been discontinued.

These compounds represent only some of the efforts being made to target the TLRs and their signalling pathways. Targeting TLRs holds great promise in the effort to find new therapies for infectious, allergic and inflammatory diseases, and cancer.

Tonic-clonic Convulsions

Tonic-clonic convulsions are abnormal motor behavior during a seizure characterized by slow movements with high muscle tension (tonic phase) and subsequent repetitive oscillating movements of limbs (clonic phase).

- ▶ Antiepileptic Drugs

Topoisomerase

Topoisomerase enzymes control and modify the topologic states of DNA. The mechanisms of these enzymes involve DNA cleavage and strand passage through the break, followed by religation of the cleaved DNA. Two main forms of topoisomerase exist. The type I topoisomerase of mammals is a 100 kD monomeric protein whose activity is ATP-independent. This enzyme binds to double-stranded DNA and cleaves one of the DNA strands of the duplex, simultaneously forming an enzyme-DNA covalent bond between a tyrosine residue and the 3'-phosphate of the cleaved DNA. The type II topoisomerases are dimeric enzymes, which are ATP-dependant. Two isoforms of topoisomerase II exist, topoisomerase α and β , with apparent molecular weights of 170 and 180 kD. Topoisomerase II cleaves the two complementary strands of DNA four base pairs apart and the resulting 5'-phosphoryl groups become covalently linked to a pair of tyrosine groups, one in each half of the dimeric topoisomerase II enzyme. Several groups of drugs are known that selectively inhibit topoisomerases in bacteria (quinolones) or mammalian cells (etoposide, tenoposide). Quinolones are used to treat bacterial infections; inhibitors of mammalian topoisomerases are cytostatic drugs used for the treatment of cancer.

TOR Signalling

ROBBIE LOEWITH
Département de Biologie Moléculaire, Université de Genève, Switzerland

Synonyms

Target of Rapamycin encoded by: *TOR1* and *TOR2* in yeast; *mTOR*, replaces *FRAP*, *RAFT*, *RAPT* or *SEP* in mammals

Definition

Very large Serine/Threonine kinases and the molecular Target of Rapamycin, a naturally occurring secondary metabolite, TOR proteins function within multiprotein complexes to couple cell growth and stress responses to environmental and developmental cues.

Basic Mechanisms

TOR genes were originally described genetically in *Saccharomyces cerevisiae* as the targets of the antifungal and immunosuppressive compound, rapamycin. Subsequent to their discovery in yeast, TOR genes have been found in all eukaryote genomes examined. Eukaryote TOR proteins share 40–60% identity and belong to a group of kinases known as phosphatidylinositol kinase-related and kinases (PIKKs). PIKKs are very large (~280 kDa) have a characteristic domain structure as diagrammed for TOR in Fig. 1.

Rapamycin is a macrocyclic lactone produced by *Streptomyces hygroscopicus*. This bacterium was originally cultured from a soil sample collected on Easter Island (known locally as Rapa Nui; hence the name rapamycin). Parenthetically, rapamycin shares an interesting mode of action with two other antifungal and immunosuppressive compounds, ▶FK506 and ▶cyclosporin A. Inside cells, rapamycin first binds to FKBP12, a small protein receptor known as an ▶immunophilin. FKBP12 is not an essential protein but is an important cofactor required for rapamycin to bind and inhibit TOR.

Two TOR Complexes

Biochemical purification of TOR demonstrated that this protein functions as the catalytic component of two distinct multiprotein complexes known as TOR complex 1 (TORC1) and TOR complex 2 (TORC2). Like TOR, these complexes appear to have been structurally and functionally conserved from yeast to man. The mammalian equivalents are known as mTORC1 and mTORC2.

TOR Signalling. Figure 1 Domain structure of TOR and related PIKKs. HEAT: a domain first identified in huntingtin, elongation factor 3, the PR65/A subunit of protein phosphatase 2A (PP2A), and TOR; thought to mediate protein–protein interactions. FAT: a modified HEAT repeat found in FRAP, ATM, and TRRAP. FRB: where FKBP12–rapamycin binds, a domain specific to TOR. Kinase: although it resembles a lipid kinase, this domain phosphorylates serine and threonine residues. FATC: a small, essential domain found at the carboxy-terminus. This domain is always found in conjunction with the FAT domain suggesting that these two domains interact.

As illustrated in Fig. 2, these complexes are likely dimeric. Curiously, only when in TORC1 is TOR/mTOR bound and inhibited by the rapamycin–FKBP12 complex. Rapamycin has been an incredibly important tool to dissect the molecular function of TORC1/mTORC1 and as outlined below, rapamycin and related derivatives have ever-increasing clinical potential. No small molecule inhibitor of TORC2/mTORC2 has been identified and consequently understood the functions of this complex is relatively less well developed.

Physiological Roles of TORC1 and TORC2

Studies in yeasts (*Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*), slime mould (*Dictyostelium discoideum*), worm (*Caenorhabditis elegans*), fly (*Drosophila melanogaster*) and mammalian systems have all contributed to our understanding of TOR signalling.

TORC1 Regulates Cell Growth and Stress Responses

The processes regulated by TORC1 are still best defined in budding yeast. Studies with rapamycin have demonstrated that TORC1 controls cell ▶growth, or said more precisely, the accumulation of mass, in a number of ways. For example, TORC1 enhances translation initiation, expression and assembly of the protein translation machinery, mRNA stability and the activities of permeases that import amino acids. TORC1 additionally blocks turnover of existing mass by inhibiting a nutrient recycling programme known as ▶macroautophagy. Although the mechanisms by which TORC1 regulates these processes are only beginning to be defined, many of these rapamycin-sensitive readouts are conserved in mammals. Indeed, mTORC1 regulates translation initiation via its two well-documented substrates, 4E-BP1, a negative regulator of translation initiation that is inhibited by mTORC1, and S6K1, a positive regulator of translation initiation that is activated by mTORC1 (Fig. 3). TORC1 in yeast is essential for viability. Similarly, exposure of early mouse embryos to rapamycin also arrests cell proliferation indicating that mTORC1 performs an essential function at this point of development. In metazoans, most “growth” takes place during development; adults in contrast, have largely stopped growing. Consistently, although certain cell types still respond, systemic rapamycin treatment is generally well tolerated in adults (see below).

Yeast cells exposed to noxious stress arrest their growth and increase expression of ▶stress response genes. Thought of another way, “growth” and “stress response” appear to be mutually exclusive states. Consistently, TORC1 also promotes growth by antagonizing the nuclear accumulation and activity of a number of stress-activated transcription factors. Indeed, ▶transcriptome profiling in yeast indicated that

TOR Signalling. Figure 2 Dimeric structure of mTORC1 and mTORC2. mTORC1 contains mTOR, raptor and mLST8. Raptor binds the HEAT repeats of mTOR, mLST8 binds the kinase domain of mTOR. mTORC2 contains mTOR, rictor, Sin1 and mLST8. Rictor and Sin1 cooperatively bind the HEAT repeats of mTOR.

TOR Signalling. Figure 3 Simplified schematic of the mTOR signalling network. Arrows and bars indicate positive and negative signals respectively. Dashed lines indicate that signalling details are not understood. PKB and S6K1 have many more substrates than indicated. See text and [Table 1](#) for details.

rapamycin treatment, nutrient withdrawal, and application of noxious stress all elicit very similar transcriptional programmes. Based on such correlative observations it is hypothesized that nutrient abundance is a physiological activator of TORC1 while noxious stress is a physiological inhibitor of TORC1, however, detailed signalling mechanisms are not known. In contrast to unicellular organisms, metazoans must coordinate cell growth with both organ and organismal growth and this is accomplished via circulating growth factors. As described below, recent studies have elucidated much of the signalling pathways that couple growth factor receptors to mTORC1.

The Physiological Roles of TORC2 are Still Being Elucidated

Since no rapamycin-equivalent exists with which to inhibit TORC2, the functional interrogation of this complex has relied mainly on mutational studies. In *S. cerevisiae*, characterization of cells possessing diminished TORC2 activity demonstrated that TORC2 regulates endocytosis, **actin polymerization** and consequently cell polarity. Recent studies in the slime mould *Dictyostelium discoideum* also support a role for TORC2 in regulating cell polarity, but curiously, studies in the fission yeast *S. pombe* have not established a link between TORC2 and actin/cell polarity but rather suggest that TORC2 in this organism is required for proper stress responses. mTORC2 probably regulates both cell polarity and stress response via its direct pleiotropic substrate PKB/akt (Fig. 3).

Like TORC1, TORC2 is also essential for viability in yeast. Constantly, Homozygous ablation of mTORC2-specific components (e.g., *riCTOR^{-/-}* and *sin1^{-/-}*) results in early embryonic lethality indicating that mTORC2 also performs an essential function at this point of development. The functional requirement of mTORC2 in adults has not yet been evaluated and in no organism are the upstream regulators of TORC2 known.

► **Growth factor** and hormone signalling cascades link mTORC1 dysregulation to cancer and Hamartoma syndromes.

Although the mechanisms by which nutrient and stress cues regulate mTORC1 are not yet clear, as diagrammed in Figure 3 we now know a great deal regarding the regulation of mTORC1 by circulating growth factors and hormones. At the heart of these signalling pathways lie the tuberous sclerosis proteins, TSC1 (hamartin) and TSC2 (tuberin). These proteins function together in a complex and act as a GAP (GTPase-activating protein) for the small GTPase Rheb. Although the details are still debated, GTP-loaded Rheb is thought to bind and activate mTORC1. TSC2 is phosphorylated by several kinases and these phosphorylation events either activate or inhibit its GAP activity. In this manner, TSC2 integrates signal

inputs from several upstream regulators to generate an environmentally appropriate level of mTORC1 activity.

Although potentially many membrane receptors act upstream of TORC1, signalling pathways emanating from the ► **insulin receptor** are illustrated here (Fig. 3). Insulin receptor ligation results in the binding and phosphorylation of insulin-receptor substrate (IRS). Phosphorylated IRS subsequently recruits additional signalling molecules which ultimately results in the activation of ► **phosphatidylinositol 3 kinase (PI3K)** and the ► **small GTPase Ras**.

Activated Ras triggers signalling down the Raf-MEK1/2-Erk1/2-RSK1 ► **MAP kinase cascade**. This process is inhibited by the RasGAP neurofibromin (NF1). Both Erk1/and RSK1 can directly phosphorylate TSC2 and these phosphorylation events inhibit the GAP activity of TSC2 and thus ultimately promote mTORC1 activity.

Activated PI3K converts phosphatidylinositol-4,5-phosphate (PIP₂) to phosphatidylinositol-3,4,5-phosphate (PIP₃). Accumulation of this lipid recruits two kinases, PDK1 and PKB/akt to the plasma membrane. This process is antagonized by the lipid phosphatase PTEN. At the plasma membrane, PKB is activated via phosphorylation by both PDK1 and mTORC2. PKB has many roles in the cell and there are several mechanisms by which PKB-derived signals can inhibit TSC2. (i) Like Erk1/2 and RSK1, PKB can directly phosphorylate and inhibit TSC2. (ii) PKB also promotes nutrient import and thus is required to maintain cellular energy levels. High cellular energy levels (i.e., a high ATP:AMP ratio) blocks activation of the ► **AMP-dependent kinase, AMPK**. AMPK is itself activated by an additional kinase, LKB1, and when active, AMPK phosphorylates TSC2 at a residue that stimulates its GAP activity. (iii) PKB can also phosphorylate and inhibit glycogen synthase kinase 3 (GSK3). GSK3 is a component of the ► **Wnt signalling pathway**. When active, GSK3 can phosphorylate TSC2 that has been 'primed' by previous phosphorylation by AMPK. Phosphorylation by GSK3 further activates TSC2 GAP activity.

As summarized in Table 1, an important theme has emerged from these recent studies: many negative regulators of mTORC1 are known tumor suppressors while many positive regulators of mTORC1 are known proto-oncoproteins. Importantly, genes encoding many of these negative regulators are found mutated in patients suffering from ► **hamartoma syndromes**. These patients suffer from benign tumors that on occasion progress to malignant disease. These observations suggest that mTORC1 may be a good target to treat hamartoma syndromes and possibly certain ► **cancers**.

Pharmacological Intervention

Although novel mTOR inhibitors are in development, to date, only the mTORC1-specific inhibitor rapamycin (and closely related derivatives that improve

TOR Signalling. Table 1 Protooncogenes and tumor suppressors in the mTOR signalling network

Protooncogenes	Evidence
PI3K	Elevated PI3K has been observed in a variety of human cancers and is implicated in transformation and tumor progression
PKB/akt	Akt is amplified in a subset of human cancers
Ras	Mutations yielding hyperactive Ras protein are frequent in human cancers
Rheb	Elevated in many tumor cells, Rheb may be the critical target by which farnesyl transferase inhibitors inhibit tumor growth
S6K1	S6K1 is overexpressed in many breast cancers and this is correlated with poor prognosis
Wnt	Wnts are secreted signalling molecules best characterized for their roles in development. The Wnt signalling pathway is also implicated in cancer
Tumor suppressors	Name and description of corresponding hamartoma syndrome
NF1	neurofibromatosis type 1; benign and malignant peripheral nerve sheath tumors
PTEN	Cowden disease, Bannayan–Riley–Ruvalcaba syndrome, Proteus syndrome, Lhermitte–Duclos disease; overgrowths of various organs, hamartomas of the skin, mucosa, cerebellar cortex; high risk of developing several types of cancer. Spontaneous pten mutations found frequently in human cancers
LKB1	Peutz–Jeghers syndrome; hamartomas in the gastrointestinal tract
TSC1,2	Tuberous sclerosis complex; hamartomas of the brain, heart, kidneys, skin, lungs, and eyes

pharmacokinetic properties) are used clinically or are being evaluated in clinical trials. Rapamycin analogs (▶*rapalogs*) under evaluation include: CCI-779, Wyeth; RAD001, Novartis; and AP-23573, Ariad. These drugs are not without side effects. Oral mucositis often limited the dose that could be administered in phase I trials. Other side effects include metabolic malfunction leading to deviations from normal serum cholesterol and triglyceride levels, anemia and diarrhea. At present, it appears that mTORC1 inhibitors work most effectively when used in combination with other compounds as discussed below. Although not discussed here, it is clear from [Figure 3](#) that there are many additional drug nodes, particularly upstream of mTORC1, which could be targeted for potential clinical benefit. Also, as noted below, compounds that directly or indirectly activate mTORC1 may in some circumstances have clinical value.

Clinical Uses of Rapamycin and Rapalogs Allograft Rejection and Autoimmune Disorders

Rapamycin has been known for many years to possess immunosuppressive activity by interfering with the activation of B- and T-cells by ▶*interleukin-2*. Indeed the first clinically approved indication for rapamycin was renal transplantation. Currently, rapamycin and RAD001 also show promise in liver transplantation and cardiac transplantation, respectively. Generally, treatment protocols utilize a combination of an mTORC1 inhibitor, a ▶*calcineurin* inhibitor and steroids to optimize immunosuppression and minimize nephrotoxicity and other side effects. Rapalogs are also

being evaluated as agents to treat autoimmune diseases including rheumatoid arthritis, psoriasis, multiple sclerosis, and Parkinson's disease.

Cancer and Hamartoma Syndromes

The recent links made between mTORC1 and tumor suppressors/oncoproteins suggests that aberrantly high mTORC1 activity may be the underlying cause of hamartomas and perhaps some cancers. Based on this, many clinical trials are underway to determine the efficacy of rapalogs as anti-cancer agents. Current phase III clinical trials include:

CCI-779 – renal carcinoma, lymphoma

AP23573 – sarcomas

RAD-001 – pancreatic cancer

Again, several preclinical studies suggest that rapalogs will have synergistic effects when used in combination with other chemotherapeutics.

Cardiovascular Disease

At present, the most widespread clinical use of rapamycin is in the prevention of in-stent restenosis. Following balloon angioplasty, stents (an expandable metal coil) are often inserted into the coronary artery. Stenting improves outcome, but in a significant percentage of patients, smooth muscle cells may eventually invade and proliferate within the stent resulting in a reblockage of the artery (in-stent restenosis). Since their approval in 2003, rapamycin-eluting stents are now commonly used to stop the growth/proliferation of invading smooth muscle cells and thus prevent this form of in-stent restenosis.

Muscle Hypertrophy/Atrophy

mTORC1 signalling plays a critical role in the regulation of postnatal muscle size. Both muscle hypertrophy and muscle atrophy can have pathophysiological consequences. For example, cardiac hypertrophy is a major risk factor for heart failure. Interestingly, due to an inherited defect in APMK, persons suffering from Wolff–Parkinson–White syndrome present with hypertrophic cardiomyopathy. Presumably, this defect results in hyperactivation of mTORC1 in cardiac tissue. Conversely, many diseases, for example cancer and HIV/AIDS, or simply a sedentary lifestyle, can lead to muscle atrophy. In extreme cases, such as cancer ►cachexia, patients are physically weakened to a state of immobility. Thus rapalogs may have potential in treating muscle hypertrophic disorders while mTORC1 agonists (or a TSC2 GAP inhibitor) could have clinical value in treating muscle atrophic disorders.

Metabolic Disorders

Recently, a ‘feedback loop’ in mTORC1 signalling has been described. As shown in Figure 3, the mTORC1 substrate S6K1, in addition to regulating translation, also phosphorylates and thus antagonizes the function of IRS. Inhibition of IRS function reduces insulin response. A reduction in insulin response, also known as insulin resistance is typically associated with both type 2 ►diabetes and obesity. Thus, although not yet tested, rapalogs may in the future be useful reagents to treat metabolic disorders involving insulin resistance.

Torsade de Pointes

Torsade de pointes is a life-threatening polymorphic ventricular tachycardia, which occurs in inherited long

QT syndrome and as a side effect of the action potential prolonging drugs.

►Antiarrhythmic Drugs

Total Sleep Time

Synonyms

TST

Definition

The sum of all periods of sleep throughout the night. Used as a measure of diagnosing and recovery following treatment for *insomnia*.

►Sleep

Toxicogenomics

Toxicogenomics is a form of analysis by which the activity of a particular toxin or chemical substance on living tissue can be identified based upon a profiling of its known effects on genetic material. Toxicogenomics may also be of use as a preventative measure to predict adverse “side”, i.e. toxic effects, of pharmaceutical drugs on susceptible individuals. This involves using genomic techniques such as gene expression level profiling and single-nucleotide polymorphism analysis of the genetic variation of individuals.

Trace Amines

LOTHAR LINDEMANN, MARIUS C. HOENER
F. Hoffmann-La Roche, Pharmaceuticals Division,
Discovery Neuroscience, Basel, Switzerland

Synonyms

Biogenic amines

Definition

Trace amines are a family of endogenous monoamine compounds including β -phenylethylamine (PEA), p-tyramine (TYR), tryptamine (TRP) and octopamine (OCT). The trace amines share close structural similarity with the well known classical monoamine neurotransmitters such as dopamine (DA), norepinephrine (NE) and serotonin (5-HT). As their name suggests, trace amines occur in comparably much lower abundance than monoamine neurotransmitters. For historical reasons, other endogenous amine compounds which might share some structural similarities with PEA, TYR, TRP or OCT are not referred to as trace amines.

Basic Characteristics

The synthesis and metabolism of trace amines and monoamine neurotransmitters largely overlap [1]. The trace amines PEA, TYR and TRP are synthesized in neurons by decarboxylation of precursor amino acids through the enzyme aromatic amino acid decarboxylase (AADC). OCT is derived from TYR by involvement of the enzyme dopamine β -hydroxylase (Fig. 1; DBH). The catabolism of trace amines occurs in both glia and neurons and is predominantly mediated by monoamine oxidases (MAO-A and -B). While TYR, TRP and OCT show approximately equal affinities toward MAO-A and MAO-B, PEA serves as preferred substrate for MAO-B. The metabolites phenylacetic acid (PEA), hydroxyphenylacetic acid (TYR), hydroxymandelic acid (OCT), and indole-3-acetic (TRP) are believed to be pharmacologically inactive.

The rate of synthesis is similar for trace amines and monoamine neurotransmitters, however, trace amines undergo a more rapid turnover due to their higher affinity to MAO and the lack of comparable cellular storage. Thus, the tissue concentration of trace amines in the vertebrate central nervous system is estimated to be in the range of 1–100 nM, depending on the trace amine and brain area, in contrast to micromolar concentrations of classic monoamine neurotransmitters.

Due to their physicochemical properties trace amines can pass the cell membrane to a limited extent by passive diffusion, with the more lipophilic PEA and TRP crossing membranes more readily than the more polar amines TYR and OCT. In spite of these features, trace amines show a heterogeneous tissue distribution in the vertebrate brain, and for TYR and OCT storage in synaptic vesicles as well as activity-dependent release have been demonstrated. So far, trace amines have always been found co-localized with monoamine neurotransmitters, and there is no evidence for neurons or synapses exclusively containing trace amines.

Trace Amine-Associated Receptors

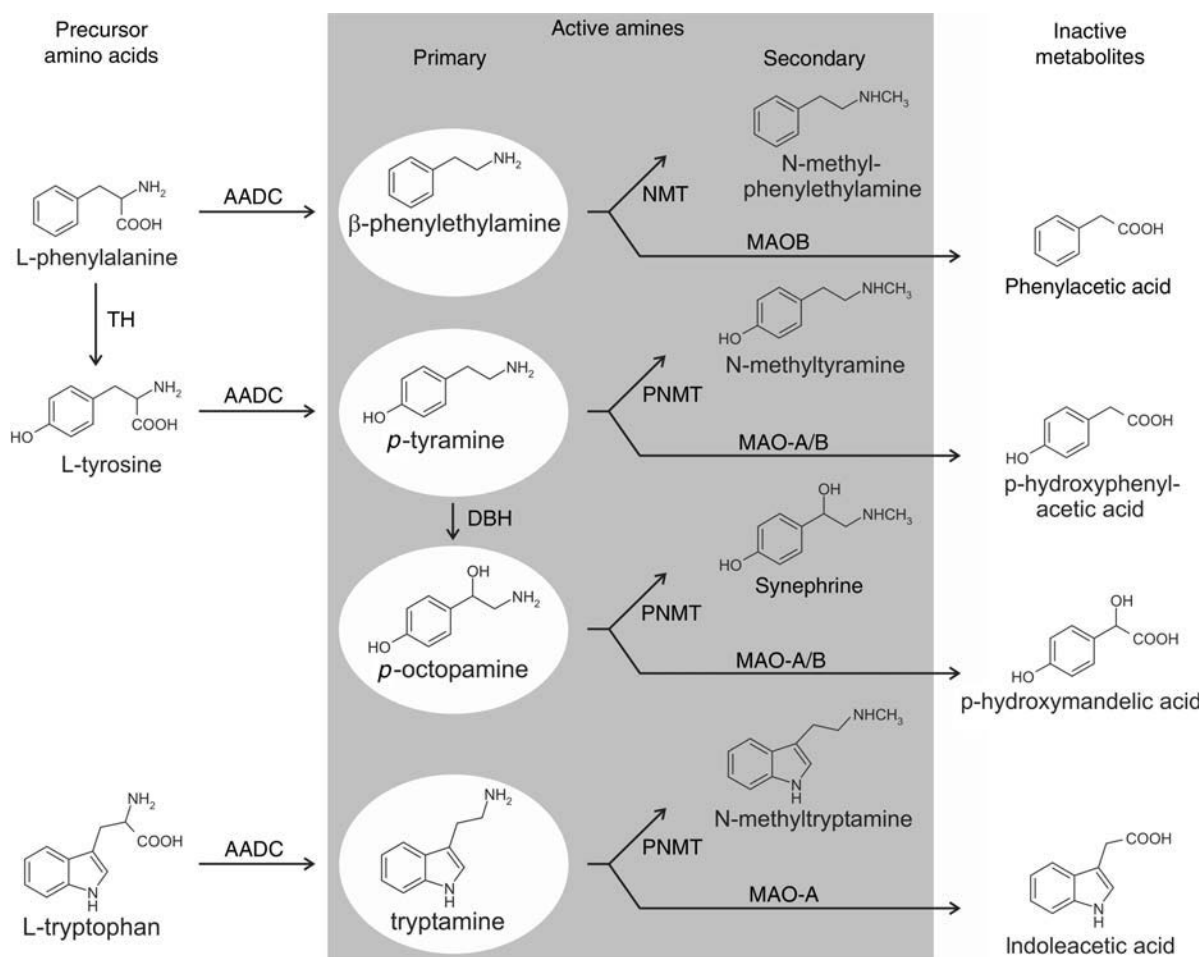

Although trace amine-selective receptors had been hypothesized for several decades and trace amine binding sites had been reported earlier, it was only

in 2001 that the first members of the Trace Amine-Associated Receptor (TAAR) family were identified [2]. While only two members of the TAAR family were confirmed trace amine-sensitive and synthetic ligands for two additional receptors were recently reported (Table 1) [4], the majority of TAARs are currently orphan receptors. As recent data suggest that not all TAARs are sensitive to trace amines, and as some TAARs respond to a range of compounds different from trace amines, the receptor family has been officially designated as Trace Amine-Associated Receptors [3].

Phylogenetically, the TAARs most likely evolved from a common single ancestor gene through sequential **gene duplication** and speciation (Gene specification refers to the mutational events underlying the divergence of orthologous genes, i.e., two gene counterparts present in two different species which are derived from a single ancestral gene.) events, which occurred independently from other GPCR families (Fig. 2). By comparison to other monoamine-sensitive receptors such as the 5-HT sensitive GPCRs, individual *TAAR* genes show a high degree of sequence identity between species. However, the TAAR family reveals pronounced species differences with respect to the total number of *TAAR* genes and the proportion of **pseudogenes** in each species [3]. While there are 19 and 16 *TAAR* genes including 2 and 1 pseudogenes in rat and mouse, respectively, only 9 TAAR genes are represented in the human and chimpanzee genomes, out of which 3 (human) and 6 (chimpanzee) are pseudogenes. It is believed that the difference with respect to the total number of genes and the degree of pseudogenization reflects the species-specific physiological roles of the receptors. All *TAAR* genes map to a single, narrow chromosomal region of ~100–200 kb, and the orientation of the *TAAR* genes on the chromosomes is conserved between human, chimpanzee and rodents. This pattern as well as **pharmacophore modeling** studies, suggests the existence of three receptor subfamilies of so far unknown functional relevance.

Trace amine-sensitive receptors also occur in invertebrates such as the fruitfly (*Drosophila melanogaster*) or the nematode *Caenorhabditis elegans* and in both cases are activated by TYR and OCT. However, these invertebrate trace amine receptors evolved independently, are phylogenetically not related to the TAAR family, and show more similarity to the vertebrate 5-HT, DA and **adrenergic receptors**. In zebrafish (*Danio rerio*) 57 *TAAR* genes and 40 pseudogenes have been reported. The evolution of *TAAR* genes in zebrafish through tetraploidization, block duplication and local duplication events is more complex than for most other GPCR families studied so far.

With respect to tissue distribution, the available data is limited to mRNA transcripts which, for all TAARs studied so far, are present at generally low levels when compared to e.g., 5-HT and DA receptors. The most

Trace Amines. Figure 1 The main routes of trace amine metabolism. The trace amines β -phenylethylamine (PEA), *p*-tyramine (TYR), octopamine (OCT) and tryptamine (TRP), highlighted by white shading, are each generated from their respective precursor amino acids by decarboxylation. They are rapidly metabolized by monoamine oxidase (MAO) to the pharmacologically inactive carboxylic acids. To a limited extent trace amines are also *N*-methylated to the corresponding secondary amines which are believed to be pharmacologically active. **Abbreviations:** AADC, aromatic amino acid decarboxylase; DBH, dopamine β -hydroxylase; NMT, nonspecific *N*-methyltransferase; PNMT, phenylethanolamine *N*-methyltransferase; TH, tyrosine hydroxylase.

detailed information is available for TAAR1 which for human was detected in several brain areas involved in mood regulation and memory formation such as the amygdala, hypothalamus, hippocampus and cerebellum, as well as in several peripheral tissues including liver, pancreas, lung, kidney and skeletal muscle [2]. Recently, the expression of TAAR2–9 in the mouse \blacktriangleright olfactory epithelium was described. The presence of at least three TAARs sensitive to volatile amines (Table 1) present in urine suggests a role of TAARs for social interaction in rodents [4].

Function of Trace Amines

Prior to the identification of specific receptors, the understanding of trace amine functions on the molecular level was limited to hypotheses mainly considering the following possibilities [1]: (i) trace amines may serve

as co-transmitters to monoamine neurotransmitters such as DA, NE or 5-HT and, linked to this assumption, (ii) trace amines may function as so-called false neurotransmitters by interfering with the well known receptor systems and transporters of monoamine neurotransmitters; alternatively, (iii) trace amines may function as neurotransmitters or neuromodulators independently of catecholamines through an independent receptor system which at that time remained to be identified. Currently, three modes of action for trace amines can be distinguished: (i) amphetamine-like activities linked to the monoamine neurotransmitter system (e.g., interaction with DA transporter), (ii) TAAR-dependent function (s) of trace amines as neuromodulators, and (iii) the TAAR-dependent role of trace amine-like compounds in the context of olfaction and social communication in rodents.

Trace Amines. Table 1 The trace amine-associated receptor (TAAR) family

Subgroup	Unified nomenclature	Previous name(s)	Selected ligands
1	TAAR1	TA1 ^{a,b} , TRAR1 ^{a,b,c} , TAR1 ^{a,b,c}	PEA, TYR, TRP, OCT, synephrine, amphetamine, 2-methylbutylamine
	TAAR2	GPR58 ^{a,c}	–
	TAAR3	GPR57P ^a , GPR57 ^c	Cyclohexylamine, 2-methylbutylamine, isoamylamine

The amphetamine-like properties of trace amines are best described for PEA which shares close structural similarity to amphetamine and can displace monoamine neurotransmitters from ►synaptic vesicles and trigger their release into the synaptic cleft by acting on the dopamine transporter. However, this effect is only observed at high, supra-physiological PEA concentrations and thus might not occur under physiological conditions.

The role as neuromodulators is supported by observations that trace amines at physiological concentrations on their own do not alter the electrical excitability of neurons but instead modulate the neuronal response to catecholamine neurotransmitters. Further insight into this mode of action comes from a recent study involving a TAAR1-deficient mouse mutant [5]. These mice display a grossly normal behavioral profile in the absence of pharmacological or behavioral challenges, but the psychostimulant and TAAR1 agonist amphetamine triggers a much stronger increase in the locomotor activity and extracellular DA levels in certain brain areas in TAAR1-deficient as compared to wild-type mice. This

phenotype relates to neurochemical observations from these mutant mice indicating that TAAR1 negatively modulates the release of dopamine from neurons and possibly also the signaling of dopamine receptors. So far, it is not known which molecular mechanisms link TAAR1 to dopamine release and signaling, and whether TAAR1 or maybe also other TAARs are linked only to dopamine or also to other neurotransmitters (Fig. 3).

The relevance of the TAAR receptor system for olfaction and social communication in rodents is supported by the reported expression of several TAARs in olfactory sensory neurons and their sensitivity towards volatile amine compounds which are present in urine [4]. Notably, sensitivity of the TAARs expressed in the olfactory epithelium towards the traditional four trace amines has not been observed, except for TAAR4 and expression data suggest that the trace amine-sensitive TAAR1 is not expressed in the olfactory epithelium. The role of TAARs in the context of olfaction in rodents is only beginning to emerge and so far, there are no data on the exact physiological impact of these mechanisms in the living animal.

Trace Amines. Figure 3 Modulation of dopaminergic neurotransmission through TAAR1. An amphetamine challenge applied to mice triggers the release of dopamine (DA) which is reflected in a transiently increased locomotor activity. This behavioral effect is mediated by the increased activation of DA receptors on neurons, notably of the D₂ receptors which is the overall most abundant of the DA receptors in the brain. In TAAR1 deficient “knock-out” mice the same amphetamine challenge triggers a much stronger DA release corresponding to a much stronger increase in locomotor activity as compared to the wild-type animals. These observations have prompted the conclusion that TAAR1 provides a generally negative modulation to DA signaling in the rodent central nervous system. The exact mode of interaction between TAAR1, the D₂ and potentially other DA receptors, the DA transporter or any downstream signaling element is currently not known. Abbreviations: DA: dopamine; D₂: D₂ dopamine receptor; DAT: dopamine transporter; K⁺: potassium channel; TAAR1: trace amine-associated receptor 1.

from studies on TAAR1 in rodents and recombinant systems. Basic information such as the tissue distribution in human, rodents or other species is not yet available for the majority of TAARs, and there is no data on a possible function of TAARs outside the nervous system. Thus, the current understanding of the TAAR receptor family and the TAAR-dependent functions of trace amines is incomplete and can not be extrapolated to the TAAR/trace amine system as a whole.

Trace Amines and Diseases

Based on several observations linking trace amines to the modulation of catecholamine neurotransmitter systems it is not surprising that trace amines have been implicated in most neuropsychiatric disorders that are associated with these systems. Alterations in trace amine function are thought to be involved in the etiology of a variety of neuropathological conditions, including major depression, stress/anxiety disorders, schizophrenia, bipolar disorder, anorexia/eating disorders, attention deficit hyperactivity disorder (ADHD), drug abuse/dependence, migraine/cluster headache, epilepsy, and Parkinson’s disease. As the link to trace amines for some indications is predominantly indirect, the discussion in this context is focused on depression and schizophrenia.

Trace amines, most notably PEA, have been implicated in the etiology of depression. It has been suggested that trace amines stabilize mental functions within physiological limits, a hypothesis which might be in line with the assumed role of trace amines as

neuromodulators on the cellular level. Earlier studies examining the levels of PEA in a variety of body fluids have in general supported this so-called PEA hypothesis, which postulates that a deficit in the level or turnover of PEA is underlying the etiology of depression, while an excess might result in manic episodes. The PEA hypothesis receives support from clinical observations that administration of PEA or its precursor L-phenylalanine produces a relief from depression symptoms in depressed patients. Furthermore, a reduction of PEA levels in cerebrospinal fluids of depressed patients as compared to healthy subjects has been reported to correlate with the disease state. It is believed that the increase in trace amine levels triggered by the application of MAO inhibitors is an important molecular mechanism underlying the antidepressant effect of these inhibitors. Moreover, MAO-B deficient mouse mutants, which show increased PEA levels in the central nervous system, display a behavioral profile reminiscent of animals treated with traditional antidepressants. Taken together, these observations support a significant role of trace amines in the regulation of affect and mood.

The postulation of a possible role of trace amines in the context of schizophrenia was kindled early on by the structural similarity between PEA and amphetamine. Symptoms such as hallucinations and paranoid episodes caused by a prolonged amphetamine intoxication are reminiscent of patients suffering from acute schizophrenia. Further support for a role of trace amines in the context of schizophrenia comes from clinical studies

reporting increased PEA plasma levels in patients suffering from acute schizophrenia, as well as elevated urinary excretion of PEA in paranoid schizophrenics. Moreover, several studies identified a chromosomal region comprising the TAAR genes as schizophrenia susceptibility locus. These findings from human subjects are in agreement with the observation that TAAR1-deficient mice reveal a deficit in a rodent behavioral model for schizophrenia symptoms known as ▶ [prepulse inhibition of the startle response](#) [5].

The knowledge of the potential link between trace amines and pathological conditions is only beginning to emerge. The understanding of the physiological roles of trace amines and TAARs in vivo will much depend on the arrival of powerful pharmacological tools such as highly specific TAAR agonists and antagonists.

Transcription Factor

Transcription is the process by which information encoded in DNA is “transcribed” into RNA, another form of genetic information. The enzyme RNA polymerase (RNA Pol) catalyzes the synthesis of RNA from the DNA template. In prokaryotes there is only one RNA pol, while there are three distinct RNA pol enzymes in eukaryotes. A general or basal transcription factor (TF) is a protein that mediates the binding of RNA pol and the initiation of a basal level of transcription. The complex consisting of RNA POL and the associated general transcription factors required for a basal level of transcription is called the basal transcription machinery. A regulatory transcription factor typically binds DNA regions distal (5′) to the site of initiation of transcription. These factors modulate basal levels of transcription (positively or negatively) by a mechanism thought to involve DNA bending or looping such that the regulatory TFs bound at sites distal to the site of initiation interact with the basal transcription machinery to affect transcriptional activity of the gene.

Transcriptional Coactivators

Transcriptional co-activators form a bridge between transcription factors, such as NF- κ B and AP-1 and general transcription factors (GTFs), and RNA polymerase II. They do not bind DNA themselves but enable the transduction of the regulatory signal (e.g. NF- κ B) to the basal transcriptional complex, enabling initiation of gene transcription. There are two types of coactivators, ubiquitous or general coactivators and more specialised coactivators that are tissue-specifically expressed and/or specifically bind to certain transcription factors. Co-activators contain histone acetyltransferase activity.

Coactivators enhancing the transcriptional activity of steroid hormone receptors activators include SRC-1 (steroid-receptor co-activator 1) or TIF2 (transcriptional intermediary factor 2), which are recruited by the DNA/steroid hormone receptor complex. Their main role is to attract other transcriptional coactivators with histone acetyltransferase activity in order to decondense chromatin and allow for the binding of components of the general transcription apparatus.

Synonyms

Regulation of mRNA synthesis; Regulation of gene expression

Definition

Transcriptional regulation encompasses the modulation of the synthesis rate of mRNA due to cell type specific factors that may be triggered by external stimuli.

Basic Mechanisms

Background

Cellular phenotypes and their responses to environmental, hormonal, and growth-promoting stimuli depend

on changes of protein function. The functional properties of proteins can be modulated by chemical modifications. Equally important is the composition of the protein mix of a cell due to alteration in their abundance. Abundance is determined by the balance of new synthesis and turnover. Both synthesis and turnover are regulated and changed under the influence of extracellular stimuli. The rate of protein synthesis can be influenced on several levels: the gene encoding the protein is controlled during the process of transcriptional initiation and elongation. The mRNA thereby synthesized is subjected to turnover, which again can be differentially regulated. Most pre-mRNAs carry intron sequences that need to be excised from RNA before translation. The excision of some introns is not obligatory but is regulated (alternative [▶ splicing](#)) and can generate different RNA-species from a single gene. Finally the rate of translation can be modulated. All these options coexist in cells of the organism. It is impossible to say at this time which type of regulation of gene expression predominates as most recent discoveries have revealed new regulatory steps, e.g. by microRNAs, and additional features are likely to be revealed in the future. We restrict the discussion here to transcriptional initiation because its complexity is best studied and most extracellular stimuli affect transcriptional initiation at the promoters of genes. Promoters assemble numerous regulatory proteins, which integrate the input of different stimuli.

The history of transcriptional regulation reaches back to 1961 when the first regulatory proteins were proposed on the basis of genetic experiments with bacteria. Nutrients stimulate bacterial gene expression. It took 20 additional years to discover regulatory components in mammalian cells, which select genes and regulate transcription in response to hormonal and other extracellular stimuli. The mechanistic role of chromatin in transcriptional regulation has been recognized much more recently and still is a matter of intensive research. Most recent and ongoing work aims at unravelling the enormous network of protein–protein interactions and their dynamic nature, which determine gene expression. To present a taste of the complexity of transcriptional regulation we choose here interleukin-6 (*IL-6*) gene activity, which is increased upon inflammatory stimuli and downregulated by anti-inflammatory drugs.

Transcriptional Initiation

A specialized multi-subunit enzyme, [▶ RNA polymerase II](#), catalyzes transcription of mammalian coding genes such as that for *IL-6*. The resulting messenger RNA is complementary to one strand of the double-strand DNA molecule. To be able to assemble the nucleotide building blocks according to the base pairing rules, the double strand must be locally unwound to expose the coding strand. This is one of the functions

exerted by RNA polymerase II. Upon proper alignment of the nucleotides in the form of highly energized triphosphates, they are coupled to each other in the process of phosphodiester formation. The RNA polymerase moves in a step-wise fashion releasing the single-stranded RNA as RNA-polymerization grows in the 5' to 3' direction. Several RNA polymerase molecules can travel along the gene at the same time, one after the other.

Although we will stick to the *IL-6* ►gene, it should be mentioned at the side that two other RNA polymerases exist in mammalian cells responsible for the synthesis of ►RNA molecules, which are not translated into proteins: ribosomal (rRNA), transfer (tRNA), small nuclear (snRNA), small nucleolar (snoRNA), and some of the recently discovered microRNAs and piRNAs. These RNA molecules act in the process of translation and mRNA turnover. Micro and piRNAs are probably extremely important in the definition of stem cells and of differentiation programs. Some of them are synthesized by RNA polymerase II.

Protein-encoding genes are dispersed in an excess of noncoding DNA. An important question is therefore, how does RNA-Polymerase II find a gene and, once found, how does it know where to start. The start site of transcription was discovered by comparing sequences upstream of many coding genes. In defined distance 5' of the first coding nucleotide, most genes carry a sequence resembling TATA where RNA polymerase II binds. So-called ►general transcription factors guide the RNA polymerase to this site, e.g. the TATA binding protein TBP, which is associated with numerous cofactors, so-called TBP associated factors (TAFs). One of the TAFs with a molecular weight of 250 kDa (TAFII250) appear to be a jack-of-all-trades in that it organizes many steps: assembly of other TAFs, catalyzing the formation of the general transcription factor of polymerase II D (TFIID), which comprises the TBP, interaction with acetylated lysine residues in core histones (see later), and exerting enzyme activities (protein kinase, ubiquitin-activating/conjugating, and acetylase activities). The factors involved in transcriptional initiation bind in a sequential order: bound TFIID allows the recruitment of the basal transcription factors TFIIA and TFIIB followed by the binding of RNA polymerase II. All this can take place if the DNA sites are accessible, a problem to be discussed subsequently.

Given that these proteins have properly assembled, the initiation complex is ready to start transcription. How does the enzyme get started? A component of TFIID, again a multi-subunit complex: TFIIH, unwinds the DNA and phosphorylates serine-5 of the C-terminal tail (CTD) of the largest polymerase subunit (Rpb1). Serine-5 phosphorylation and phosphorylation of serine-2 (by pTEFb) are required to release the enzyme from the other components of the initiation complex and to start RNA synthesis.

Regulation of Transcriptional Initiation

If recruitment of polymerase II would just occur in the presence of general transcription factors, transcription should start from all TATA containing promoters at a constant rate which is, however, not the case at all. Of the thousands of genes, the *IL-6* gene is selected for transcription only under conditions of inflammation. These conditions obviously determine at which promoter to start transcription. In addition, transcriptional initiation is not just a TATA finding exercise. Rather, the genes are heavily packed in ►chromatin, which forms an obstacle to proteins searching a DNA sequence. Both, the specific selection of the gene to be transcribed and the “unpacking” (chromatin remodeling), is achieved by proteins called transcription factors or enhancer factors, which recognize so-called “enhancer” sequences. These are specific for the gene, but can be in respectable distance to the TATA sequence. Enhancer-binding proteins recruit the chromatin remodeling enzymes that open the chromatin. One may ask how do enhancer factors themselves get access to the DNA. The basal structures forming the chromatin, the nucleosomes, assembled by histones, are not localized randomly on DNA but are deposited in a manner directed by specific sequence elements. It is believed that unfolding occurs in several steps one of which exposes nucleosome-free sections. The entry of one enhancer factor channels the assembly of others, further modifying the chromatin histones and thereby unfolding the chromatin.

The assembly of the enhancer factor is the essential step at which transcriptional regulation occurs. The factors binding to the enhancer sequences are not necessarily active at all times, but may require an activating modification. Once bound, they can serve to assemble so-called coactivators, necessary to enhance transcription, or they may recruit corepressors, blocking transcription. Enhancer sequences are often assembled in larger conglomerates, which can thus bind several enhancer factors. Several transcriptional activators and repressors can therefore act on one and the same gene. Their integrated activities define the synthesis rate of the mRNA.

Enhancer-Binding Factors in Regulatory Units of the *IL-6* Promoter

The regulatory aspects eluted to above, can be illustrated best by looking at expression of a specific gene. We chose as an example the gene encoding the cytokine *IL-6*. *IL-6* is a peptide that has a wide range of biological activities and regulates a number of important physiological and pathological processes, e.g. the activity of the immune system, but also oncogenesis. The gene can be expressed in many tissues of the body. Whereas under most conditions virtually no *IL-6* mRNA or protein can be detected, *IL-6* production is rapidly induced if cells come

into contact with specific stimuli such as lipopolysaccharides (constituents of the outer cell wall of bacteria), other cytokines (IL-1, TNF, IL-2, IFN β), or growth factors (PDGF). These factors stimulate the activation and binding of sequence-specific enhancer factors, which find their proper (cognate) sequences in the promoter of the *IL-6* gene.

A sequence stretch 300 base pairs upstream of the transcriptional start site suffices for most of the transcriptional regulation of the *IL-6* gene (Fig. 1). Within this sequence stretch several transcription factors find their specific recognition sites. In 5' to 3' direction, AP-1, CREB, C/EBP β /NF-IL6, SP-1 and NF- κ B can bind to the promoter followed by TATA and its TATA binding protein TBP. Most enhancer factors become active in response to one or several different stimuli and the active factors can trigger transcription individually or in concert. For example, AP-1 is active upon cellular stress, or upon stimuli that tell cells to proliferate; CREB becomes also active if cells experience growth signals, but also upon elevation of intracellular levels of cyclic adenosine monophosphate (cAMP), which occurs upon stimulation if so called hormone-activated G protein-coupled receptors.

How do these transcription factors recognize their binding sites? They contact DNA through the major groove where recognition of a specific DNA sequence is provided by interactions of amino acid side chains of α -helical domains or β -sheets of the factor with individual base pairs. The tertiary structures of enhancer factors provide the optimal contact to the major groove. A small number of characteristic domain motifs serve to mediate the specific recognition of DNA sequence: helix-turn-helix motifs, homeodomains, helix-loop-helix domains, and Zn-fingers each consisting of α -helices and/or β -strands that are stabilized by the Zn-ion, which coordinates Cys- and His-residues. The interaction between enhancer factor and DNA can force the DNA into a curved and twisted conformation.

It is believed that many transcription factors bind DNA as dimers (\blacktriangleright dimeric transcription factors) in either the same or opposite orientation. The DNA sites therefore can look like two direct repeat sequences or like palindromes. The interaction of the subunits with each other must obviously be specific and be mediated by \blacktriangleright dimerization domains. Specificity and stability of the dimers (dimeric transcription factors) is mostly promoted by hydrophobic or ionic interphases, e.g. a

Transcriptional Regulation. Figure 1 Schematic representation of the occupancy of the promoter of the *IL-6* gene by sequence-specific transcription factors, coactivators, general transcription factors, and RNA-Polymerase II. Enhancer sequences are shown in boxes such as GRE (glucocorticoid responsive element), AP-1 (AP-1 binding site binding the Jun:Fos AP-1 dimer), CRE (CREB responsive element binding the CREB dimer), C/EBP (binding C/EBP dimers), G/C (GC rich boxes binding SP1), and the NF- κ B (binding dimeric p50:p65 complexes). Sequence-specific transcription factors interact with coactivators (p160, CBP) to facilitate acetylation on the histone tails (Ac) and to interact with general transcription factors (TBP, TFIIA, TFIIB, TFIID), which are sequentially recruited to allow effective binding of RNA polymerase II (Pol II) to the promoter and start with mRNA synthesis. The glucocorticoid receptor (GR) can interfere with the transcription stimulating activity of sequence-specific transcription factors such as AP-1 or NF- κ B.

basic leucine zipper motif oriented to one side of an amphipathic helix, as for the transcription factor complex AP-1. While in this case the hydrophobic amino acid residues stabilize the interaction, polar amino acids of the α -helices determine the interaction specificity. AP-1 turned out to represent a whole family of heterodimeric factors composed of subunits from three protein families, Jun, Fos, and ATF [1]. The polar amino acid code enforces that Fos proteins (c-Fos, FosB, Fra-1, Fra-2) can only heterodimerize with Jun proteins (c-Jun, JunB, JunD) while Jun proteins can also **dimerize** with members of the ATF family: e.g. Fos:Jun; Jun:ATF2. The dimer composition dictates recognition of DNA sequence elements specific for the **dimer**. For instance, Fos:Jun recognizes a DNA sequence element different from that selected by Jun:ATF2. Different dimers (**dimeric transcription factors**) of the same family can exert opposite functions: e.g. Fos:Jun heterodimers activate genes, while cJun:JunB heterodimers usually suppress the same gene.

As mentioned above, many transcription factors are not always active. Rather the activity of transcription factors is often achieved by induced reversible modification. Most frequently is the addition of phosphate groups (phosphorylation) to Ser, Thr, or Tyr residues. For the AP-1 component c-Jun the phosphorylation at Ser63 and Ser73 enhances activity when cells are subjected to stress, e.g. radiation. Phosphorylation is, however, dispensable for c-Jun-dependent tissue homeostasis in the liver, indicating that certain activities do not require the regulatory enhancement. Jun-N-terminal kinase and a kinase called RSK or p38 catalyze the phosphorylation of AP-1.

The cAMP responsive element binding factor (CREB) is also activated by phosphorylation. Depending on the stimuli, CREB is the target of a cAMP dependent protein kinase or of kinases called MAPKs, RSK, and CamKIV. As in AP-1, CREB carries a basic leucine zipper motif (bZIP), which mediates homo- **dimerization** of CREB when bound to the CRE.

Similarly, the CCAAT/enhancer-binding protein beta (C/EBP β) can also form homo- and heterodimers with different other factors.

SP-1 family members bind to a GC rich sequence between the C/EBP and NF- κ B binding sites. SP-1 is important for basal expression of house keeping genes as well as for inducible gene expression.

Essential for induction of the *IL-6* gene in inflammatory reactions is the binding site for nuclear factor kappa B (NF- κ B). NF- κ B responds to cytokines, stress, free radicals, ultraviolet irradiation, and bacterial, viral, or even parasitic antigens [2]. NF- κ B stands for a family of subunits, which form homo-, and heterodimers. All NF- κ B proteins share a highly conserved DNA-binding/dimerization domain called the Rel homology domain (RHD) consisting of two β -strand core domains

connected by a flexible link. NF- κ B is retained in the cytoplasm as long as an internal inhibitor (I- κ B) masks the nuclear uptake signal. The inhibitor is removed by proteasomal degradation, which is triggered by phosphorylation through an I- κ B kinase complex. The extracellular stimuli determine which kinase and which NF- κ B subunits are activated. For instance, the so-called canonical pathway activates NF- κ B consisting of RelA and p50.

The fact that a promoter comprises a given transcription factor recognition sequence, does not prove that this sequence element is of any importance. The IL-6 promoter carries such a putatively irrelevant element. In the most 5' region of the IL-6 promoter sequence two consensus sequences of glucocorticoid responsive elements (GREs) have been described. GREs in principle can bind the glucocorticoid receptor (GR), a transcription factor which, like NF- κ B, is retained before hormonal stimulation in the cytoplasm in association with chaperones and transported into the nucleus upon binding of the ligand, cortisol. The GR belongs to the nuclear receptor super family whose 48 members share a common arrangement of their ligand-binding (LBD), Zinc-finger-motif-containing DNA-binding (DBD), and transactivation domains (Fig. 2) [3].

The strict control of the activity of nuclear receptors by their respective ligands has recently permitted to follow the dynamics of DNA occupancy and to discover a surprising feature, which may be true also for other enhancer-binding factors. During transcriptional activation these transcription factors do not stably reside

Transcriptional Regulation. Figure 2 The action of the glucocorticoid receptor dimer on positive regulated promoters. (a) Schematic representation of the domain structure from the N to C terminus of the glucocorticoid receptor containing activator function 1 (AF-1), DNA-binding domain (DBD), ligand-binding domain (LBD), and activator function 2 (AF-2). (b) The glucocorticoid receptor (GR) binds as a homodimer to the palindromic sequence (glucocorticoid responsive element, GRE) and interacts with chromatin remodeling complexes, which are comprised by CREB-binding protein (CBP) and members of the p160 histone acetylase family. The p160 histone acetylases interact via their LxxLL motifs with the ligand-activated AF-2 domain of the GR.

on their target site, but rather associate and dissociate in a cyclic manner. The hypothesis is that this dynamic behavior is essential for the efficient initiation of transcription.

Instead of activating transcription the cortisol-induced GR represses IL-6 synthesis and, even more surprisingly, repression does not involve the GRE elements, but rather the κ B site (Fig. 1). It appears that of a monomeric GR protein without itself touching the DNA interacts with the RelA component of NF- κ B [3]. As a result GR blocks the action of NF- κ B. The negative interference by this crosstalk is not restricted to NF- κ B, it occurs also with AP-1 and CREB, and with several other transcription factors not relevant for IL-6 expression. A nuclear isoform of the LIM protein Trip6 mediates the interaction between these factors and is required for the inhibitory GR function. This interesting negative crosstalk is part of the immune-suppressive action of cortisol.

Coactivators/Corepressors

We have discussed previously the factors, which select promoters and their enhancer sequences. The critical question, how can the binding of transcription factors to promoters influence transcription, remains to be considered. Most insight came from the analysis of ligand-induced transcription factors such as the GR. The transcription factors assemble large complexes of several proteins, coactivators [4]. They are thought to stabilize the complex transcription machinery or to modify and loosen the local chromatin. Two general classes of chromatin-remodeling factors have been identified, which appear to play critical roles in transcriptional activation: ATP-dependent nucleosome remodeling complexes (exemplified by SWI/SNF), and factors that exert histone acetyltransferase (HAT, e.g. p160) activity. They are addressed by different transactivation domains of the GR, for instance: SWI/SNF by the N-terminal so-called AF-1, p160 by the C-terminal AF-2 domain. AF-2 undergoes enormous conformational changes following ligand binding to the GR and is not accessible without ligand interaction. p160 stands for a family of related **coactivators** (SRC-1, SRC-2/GRIP1/TIF2, RAC3/ACTR/p/CIP), which share a nuclear-receptor interaction motif (LXXLL) (Fig. 2). These coactivators in turn are capable of recruiting additional chromatin-modifying enzymes such as CBP/p300 and the histone arginine methylase CARM1. The two related molecules CBP (first identified as CREB binding protein) and p300 (first identified as interacting protein of the transforming adenoviral oncoprotein E1A) have intrinsic functions involved in transcriptional coactivation: (i) they create a physical bridge from various DNA-bound transcription factors (AP-1, NF- κ B, GR, CREB, C/EBP, p53 and others) and coactivators (p160 family members and others) to the basal transcriptional machinery

(TBP-RNA polymerase); (ii) they are potent **histone acetyl transferases** inducing chromatin remodeling (loosening).

Beside coactivators so-called corepressors exist that are bound to transcription factors such as nuclear receptors and inhibit the initiation of transcription. These factors include the nuclear receptor corepressor (NCoR) and the silencing mediator of retinoic acid and thyroid hormone receptor (SMRT), which interact with nuclear receptors and serve as platforms for complexes containing **histone deacetylases (HDACs)**. These enzymes cause the reversal of histone acetylation of histones leading to a tightening of chromatin and enhancing its inaccessibility for RNA polymerase containing complexes.

Chromatin Modification

The core unit of the chromatin, the nucleosome, consists of histones arranged as an octamer consisting of a (H3/H4)₂-tetramer complexed with two histone H2A/H2B dimers. Accessibility to DNA-binding proteins (for replication, repair, or transcription) is achieved by posttranslational modifications of the amino-termini of the histones, the histone tails: phosphorylation, acetylation, methylation, ubiquitination, and sumoylation. Especially acetylation of histone tails has been linked to transcriptional activation, leading to weakened interaction of the core complexes with DNA and subsequently to decondensation of chromatin. In contrast, deacetylation leads to transcriptional repression. As mentioned above, transcriptional coactivators either possess HAT activity or recruit HATs. HDACs in turn act as corepressors.

The transfer of acetyl groups to lysine residues in the histone tails occurs in a reversible manner allowing quick acetylation and deacetylation and thus rapid changes in transcriptional regulation [5]. **Methylation** of lysine or arginine residues by **methyl-transferases** and the recently demonstrated **demethylation** by histone demethylases involve a higher degree of complexity, since single lysine residues can be mono-methylated, di-methylated, or tri-methylated and arginine residues can carry two methyl groups in a symmetric or asymmetric manner. One modification appears to determine subsequent other modifications. Combinations of the possible histone modifications create a histone code with distinct consequences for transcription. For instance, methylation of histone H3 tail lysine-4 (K4) promotes acetylation of K9, K14, K17, and K23 by CBP. K9 methylation in contrast inhibits acetylation of these lysines probably leading to recruitment of the potent transcriptional repressor heterochromatin protein-1 (HP1).

Other steps of RNA synthesis such as elongation or termination also control the abundance of proteins. These are less well understood than the initiation of transcription described here.

Pharmacological Relevance

As transcription is central to cellular phenotypes, its manipulation could be of therapeutic value for a number of diseases including chronic inflammation and cancer. The use of ligands, which directly interact with a transcription factor and activate or inactivate the factor, is an elegant case of transcriptional interference. Ligands for nuclear receptors have been the first widely applied agents targeting transcription: e.g. estrogens, retinoic acids, and glucocorticoids. More recent pharmaceutical attempts to inhibit the interactions between transcription factors with their coactivators by small molecules have yet been successful in only a few cases. For example, interference with the interaction between the transcription factor p53 and the coactivator CBP hinders the transcriptional activation of p53-dependent target genes, which trigger cell death. As an interesting other approach the abundance of a transcription factor can be modulated by specifically blocking degradation, again exemplified by small molecules inhibiting the binding of Mdm2 to p53, the first step which targets p53 for degradation. Elevated p53 can be desirable if cancer cells are to be destined for cell death.

The modulation of transcription nicely demonstrates how results of basic science can be translated into medical application. These few examples of drugs in successful use stimulate at the same time the intensive study of gaps in our understanding of transcriptional control, hoping to find new specific ways of interference.

Definition

Transforming growth factor-beta (TGF-β) proteins are multifunctional ► [morphogens](#) that control cell proliferation, differentiation and apoptosis, as well as cell migration and immune surveillance. TGF-β acts as a tumor suppressor, but can also act as a tumor promoter in

later metastatic cancers. Additionally, TGF- β signaling plays an important role in wound healing and fibrosis. TGF- β signals are transmitted through type I and II serine/threonine kinase receptors to specific intracellular mediators, known as ▶Smad proteins. Activation of Smads by receptor-mediated phosphorylation results in nuclear translocation and activation of gene expression. Adaptor proteins such as ▶SARA, ▶filamin, Disabled, CrkL, and ▶embryonic liver fodrin (ELF), are important components of the TGF- β signaling pathway. Additionally, E3 ▶ubiquitin ligases including ▶SMURFs, SCF/Roc1, ▶ectodermis, ▶itch, and ▶PRAJA are key regulators of this pathway. In the gastrointestinal system, disruptions and errors in TGF- β signaling lead to tissue-specific cancers such as hepatocellular cancers, gastric adenocarcinomas, and colonic adenocarcinomas. Thus, adaptor protein interactions and ubiquitin-dependent protein degradation in the TGF- β /Smad pathway present important new molecular targets for these difficult-to-treat cancers. Recent research has led to the development of a number of small molecule compounds that target the TGF- β pathway and may offer new therapies for these and other cancers [1–4].

Basic Characteristics

TGF- β signals are conveyed through Type I (T β RI) and Type II (T β RII) serine/threonine kinase receptors to specific intracellular mediators, the Smad proteins. There are at least eight different Smad proteins in vertebrates that fall into three classes: (i) Receptor-activated Smads (R-Smads): Smad 1, Smad 2, Smad 3, Smad 5, and Smad 8; (ii) Co-mediator Smad: Smad 4; and (iii) Inhibitory Smads (I-Smads): Smad 6 and Smad 7. Activation of the TGF- β receptor complex by ligand binding results in the phosphorylation of T β RI by the serine/threonine kinase activity of T β RII. R-Smads, such as Smad 2 and Smad 3, act as direct substrates of specific activated T β RI, and are phosphorylated on the last two serines near the carboxyl terminus. Once phosphorylated, R-Smads associate with the co-mediator Smad, Smad 4, and then translocate into the nucleus. In the nucleus, Smad complexes activate specific genes such as *integrins* and *E-cadherin* through cooperative interactions with other DNA-binding and co-activator proteins. The R-Smads and Smad 4 (predominantly cytoplasmic) are modulated by adaptors such as SARA and ELF. Adaptor proteins play critical roles in controlling Smad access to receptors, to components of other signaling pathways, and possibly for translocation into the nucleus. Subsequently, TGF- β functions, such as growth, differentiation, vascular remodeling, and cell fate specification are facilitated by adaptor protein interactions. Studies are now emerging that demonstrate prominent role of the TGF- β pathway in gastrointestinal cell/progenitor cell

Transforming Growth Factor-Beta. Figure 1

Transforming growth factor- β signaling pathway. The transforming growth factor- β (TGF- β) signaling pathway shown occurs through varying mechanisms, yet the receptor-II/receptor-I-mediated pathway has been the most extensively studied. Signals in this pathway are transmitted through serine/threonine kinase receptors located at the cell surface to the Smad proteins, which are specific intracellular mediators. The activation of these Smad proteins results in their nuclear translocation and consequent gene expression activation. From Kitisin et al, Science STKE (Connections Map, ▶http://stke.sciencemag.org/cgi/cm/stkecm;CMP_17699).

formation as well as its complex role in differentiation, with disruptions resulting in cancer (Fig. 1).

Adaptor and Receptor Interacting Proteins

Smad proteins reside in the cytoplasm, and upon stimulation, translocate to the nucleus as part of an oligomeric complex. Smad 2/3 and Smad 4 are thought to be distributed along the microtubule (MT) network, and MT stability may be involved in Smad inactivation. Thus, microtubules represent a large group of TGF- β signaling adaptor proteins. Additional adaptor proteins include SARA, ELF, Filamin, CrkL, FKBP12, Disabled-2 (Dab2), Drosophila inhibitor of apoptosis (DIAP)-1 and -2, T β RI-associated protein (TRAP)-1 and -2, T β RII binding WD-domain protein (TRIP-1), X-linked inhibitor of apoptosis (XIAP), Daxx, AMSH-2, and CD2-associated protein (CD2AP).

SARA is a scaffolding protein that regulates the subcellular localization of inactivated R-Smads, potentially scaffolding the TGF- β receptor kinase to the Smad 2 substrate. Filamins are a family of actin polymerization proteins that also form scaffolds for a range of signaling proteins including SAP kinases such as MKK-4, small GTPases Rho and Ras, as well as Smad 2 and Smad 5.

ELF, a β -Spectrin, is a key component of TGF- β signaling that functions to recruit Smads to the receptor by controlling the subcellular localization of Smad 3 and Smad 4. Interestingly, ELF does not appear to interact with SARA or filamin, and in *elf* mutants, SARA and filamin distribution is the same as in wild-type mice. Thus, TGF- β signaling through R-Smad/ELF interactions may work by way of a different mechanism than that of SARA and filamin.

Extrinsic regulatory pathways such as the Erk, JNK, and p38 MAP kinase pathways also contribute to Smad regulation. In addition, there is a Ca^{2+} -dependent interaction between calmodulin (CaM) and several Smad family members. CaM binds to the N-terminal half of Smad 2 with subsequent phosphorylation inhibiting TGF- β induced nuclear import and transcriptional activity of Smad 2. Therefore, CaM influences Smad protein function in response to agents that regulate intracellular Ca^{2+} flux. Other TGF- β induced signaling pathways involve activation of Rho-like GTPases, including RhoA, Rac and cdc42 through RhoA-specific guanine exchange factor or Ras activation. Thus, elucidation of ELF phosphorylation by TGF- β receptors as well as cross-talk with the stress activated protein kinases is of great interest.

TGF- β Signaling and Wound-Healing

TGF- β has a significant role in wound healing [5]. As platelets arrive at a wound location, they release cytokines, which recruit inflammatory cells, neutrophils, and macrophages. Through a positive feedback mechanism, these cells proceed to secrete additional cytokines, including TGF- β . In Smad 3 mutant mice, TGF- β signaling is disrupted and there is a reduced recruitment of inflammatory cells at the site of epithelial injury. Macrophages digest the extracellular matrix as part of the wound healing process. TGF- β suppresses the proteases released by macrophages, thus allowing for greater progression of the proliferative phase of wound repair. Angiogenesis is another important aspect of the proliferative phase and is essential to normal wound healing. Angiogenesis is promoted by subcutaneous injection of TGF- β . Fibroblasts also secrete TGF- β using a positive feedback mechanism. TGF- β causes the proliferation of fibroblasts which function in wound healing by producing extracellular matrix. Additionally, TGF- β is a strong chemoattractant. In animal models, topical application of TGF- β to wounds produces mixed results because of the presence of proteases and variability of receptor expression. In some instances, TGF- β has been shown to substantially increase the production of both collagen and fibrinogen. TGF- β signaling through Smad 3 is pivotal for collagen synthesis, myofibroblast activation, wound contraction, and scar formation. Interestingly, Smad 3 null mice

have accelerated wound repair without scar formation. TGF- β is responsible for this conversion, and it does not occur if TGF- β signaling is disrupted. As the role of TGF- β signaling in wound healing continues to unravel, many therapeutic targets for improving wound healing are anticipated.

TGF- β Signaling and Malignancy

Despite the large number of molecules found to interact with the TGF- β pathway, few have been identified as functional tumor suppressors using either mouse or human genetics. The TGF-beta pathway is inactivated in nearly all gastrointestinal cancers, from TBR11, TBR1, Smad 2, and Smad 4. Recent exciting data have revealed the role of ELF, a key TGF- β pathway adaptor, in hepatocellular cancer suppression.

Smad 4 is located within human chromosome 18q21.1 and is deleted or mutated in 40–50% of pancreatic cancers and 30% of colorectal cancers. Heterozygous germline mutations in Smad 4 are also responsible for a subset of familial juvenile polyposis (FJP), a disorder characterized by predisposition to hamartomatous polyps and gastrointestinal cancer. Evidence for the role of haploinsufficiency of Smad 4 was demonstrated by the discovery that tumors in FJP individuals almost always retained the wild-type allele of Smad 4. Although continued expression of Smad 4 was not demonstrated, this prompted analysis of the effects of *Smad 4* haploinsufficiency in a mouse model. *Smad 4*^{+/-} mice were found to develop hyperplasia of the fundus and antrum and interestingly, intercrosses with *elf* mutants exacerbated the phenotype, further highlighting the role of ELF haploinsufficiency in suppression against gastric cancers. Interestingly, \blacktriangleright *elf*^{+/-}/*Smad 4*^{+/-} mutants also develop colonic adenomas. Hence, ELF appears to have a tumor suppressor action on its own in hepatocellular cancer, whereas with Smad 4 presents a synergistic role which is conceivably more akin to the natural development of sporadic gastric cancers in humans, than the total loss of both alleles of one gene.

Growth inhibition by TGF- β , associated with inhibition of c-myc, cdks, reduction in cyclin D1 levels, and inhibition of cdk-4-associated Rb kinase activity, as well as induction of cdk inhibitors p15 and p27, has been noted in intestinal epithelial cells. Loss of responsiveness to growth inhibition from TGF- β occurs in many cell types including: breast, colorectal carcinoma, and pancreatic carcinoma cells. Mutational inactivation of TBR11 represents one mechanism of this process, which in many cases, leads to the development of gastrointestinal cancer. Thirteen percent of colorectal carcinomas are thought to be associated with a replication error (RER) or microsatellite instability phenotype. Subsequent inactivation of TBR11 and

restoration of T β RII results in decreased tumorigenicity. Accordingly, mutations with loss of function of Smad 2 and Smad 4 have been noted in 4% and 30% of human colorectal cancers, respectively. APC Δ ⁷¹⁶ mice intercrossed with mice heterozygous for Smad 4 develop larger and more invasive colorectal tumors. Furthermore, Smad 4 is required for gut endoderm lineage, and *Smad 4*^{+/-} mice develop gastric tumors after 12 months. Also, Smad 2 is needed for gastrulation, and Smad 3 is needed to establish the gastrointestinal mucosal immune response to TGF- β signals. Hence, Smad 3-deficient mice frequently develop gut abscesses and die between 1 and 10 months because of impaired mucosal immunity. Defective liver development with loss of gastrointestinal epithelial cell shape and polarity is also observed in *elf*^{-/-} homozygotes, and *Smad 2*^{+/-}/*Smad 3*^{+/-} double heterozygous mice.

Loss of ELF in human gastric cancer is a significant aspect of gastric tumor suppression by TGF- β . Two lines of evidence indicate that ELF is biologically and functionally important in suppressing gastrointestinal tumors. First, hepatic cancers are only observed in mice with *elf* mutations, and have not been observed in other TGF- β signaling pathway or interacting molecules. Secondly, Smad 3 homozygote knockouts do not develop cancers, and Smad 4 homozygote mutants are early embryonic lethals observed in mutants gastric cells that express normal levels of Smad 3 and Smad 4 do not exhibit E-cadherin localization and substrate independent cell-cell adhesion. Importantly, the RING-H2 domain-containing E3 ubiquitin ligase, PRAJA, is a key regulator of ELF expression, and could represent an oncogenic pathway in gastric and hepatocellular cancer by virtue of PRAJA ubiquitination of ELF and Smad 3.

Drugs

We have gained considerable insight into the therapeutic potential of this protein through the use of TGF- β antagonists and transgenic mice with defective TGF- β signaling and we have evaluated the potential toxicity of TGF- β modulation and its overall efficacy in treating cancer. FC Soluble Type II Receptor

Antagonist (SR2F), a chimeric protein of the Fc IgG and extracellular domain of T β RII, and 1D11, a TGF- β neutralizing antibody, have not demonstrated toxicity. Importantly, SR2F, the T β RII antagonist has revealed strong antimetastatic activity.

The tumor suppressive role of TGF- β has been well documented, and disrupting TGF- β signaling can potentially promote tumorigenesis. On the other hand, TGF- β can also promote tumorigenesis, especially during the later growth and metastatic phases. Because of this, there must be caution taken as to identifying when the tumorigenic role of TGF- β signaling is prevalent. To that end, mouse models of cancer have been developed that allow the tissue-specific conditional knockout of T β RII. Through this animal model, the role of TGF- β in tumor progression can be analyzed, and the development of TGF- β antagonists aimed at treating specific stages of tumor development can be observed.

TGF- β overexpression is especially significant in breast cancer as TGF- β -mediated growth inhibition becomes inactive in breast cancer cells. However, in a mouse model of metastatic breast cancer, it was demonstrated that TGF- β has tumor suppressive characteristics in the primary lesion while promoting metastatic dissemination. Because of this observation, it can be concluded that TGF- β signaling can be altered to influence metastasis and effective therapeutics for inhibiting cancer growth can be generated. Examples are one such the development of TGF- β signaling inhibitors such as antisense oligonucleotides and monoclonal antibodies such as those listed in Table 1.

Current agents have focused on inhibiting TGF- β signaling. Lerdelimumab and Metelimumab are monoclonal antibodies that bind to TGF- β , and are being evaluated for their ability to reduce post-operative scarring and suppress fibrosis, respectively. A novel approach utilizing a vaccine to TGF- β ₂ is being tested as a therapeutic for non-small-cell lung cancer. Likewise, AP 12009, a TGF- β ₂ antisense oligonucleotide, is being evaluated for its ability to suppress a variety of metastatic tumors. Small molecule inhibitors of the TGF- β pathway, such as LY550410 and

Transforming Growth Factor-Beta. Table 1 Agents that target the TGF- β signaling pathway

Agent name	Type	Target	Indications
Lerdelimumab	Monoclonal antibody	TGF- β ₂ and TGF- β ₃	Postoperative scarring in glaucoma patients
Metelimumab	Monoclonal antibody	TGF- β ₁	Renal fibrosis
Belagenpumatucl-L	Anti-TGF- β ₂ vaccine	TGF- β ₂	Nonsmall-cell lung cancer
AP 12009	Antisense oligonucleotide	TGF- β ₂	Glioma, pancreatic carcinoma, melanoma
LY550410	Small molecule	T β RI kinase domain	Preclinical
SB-505124	Small molecule	T β RI kinase domain	Preclinical

SB-505124, both of which target the T β R1 kinase domain, are in preclinical use. An alternative approach to inhibiting TGF- β signaling is to focus on the tumor suppressive function of this pathway. Promising future treatments will focus on pathways that are activated when the TGF- β signaling tumor suppressor pathway is inactivated. Examples are inhibitors to wnt signaling, CDK4 activation and IL-6.

Transforming Oncogenes

The growth of tumours can be regarded as the result of an accumulation of genetic changes in a wide variety of genes, the incorrect activation of oncogenes and the loss of function of tumour suppressor genes. Oncogenes are defined on the basis of their gain of function. The number of oncogenes isolated since about the end of the 1970s has grown to over 250.

► Antisense Oligonucleotides

Transgene

A transgene is an additional extra gene which is introduced into the germline of an animal.

► Transgenic Animal Models

Transgenic Animal Models

UWE RUDOLPH

Definition

Transgenic animals are genetically engineered animals, which allow the functional assessment of specific genes or proteins in health and disease.

Description

It is a major goal in biomedical research to identify control elements that regulate complex physiological functions, such as regulation of blood pressure or behavior. These molecular control elements are of interest since they represent potential therapeutic targets for various disease states. Three different strategies have been employed to assess gene functions in terms of providing the determinants for a particular phenotype: (i) Analysis of naturally occurring mutations in humans and animals, (ii) random chemical mutagenesis with subsequent screening for phenotypes and (iii) the generation of transgenic and targeted mutant animals, which are the subject of this contribution. In these approaches, an additional gene (“►transgene”) is transferred to an animal or an inherent gene is mutated in order to assess the respective phenotypes. For the purpose of clarity, a clear distinction between “transgenic” (i.e., nontargeted) and “targeted mutant” animals is made here, although many scientists use the term “transgenic” in a broader sense to encompass all genetically engineered animals.

Generation of Transgenic Animals

Transgenic animals express a foreign gene, the “transgene,” which is typically introduced into the mouse germline by microinjection of DNA into fertilized eggs. This technique is applicable to mice, rats and other species. The DNA will be integrated at random, frequently as concatamers. The tissue distribution and the level of expression vary between mouse lines depending on integration sites and copy number, even when the same DNA was used for injection. Transgenic mice may constitutively and tissue-specifically overexpress the transgene, or may carry gain-of-function mutations in the transgene. Alternatively, they may also contain dominant negative mutations, ribozyme, RNAi or anti-sense constructs. Thus, both gain-of-function and loss-of-function approaches can be pursued with transgenes.

Generation of Targeted Mutant Animals

For the ►targeted mutant approach, targeting vectors are constructed that contain DNA sequences derived from the gene to be targeted. They are specifically integrated at the desired genomic location by homologous recombination in murine embryonic stem cells. These cells are then injected into ►blastocysts, which in turn are reimplanted into pseudopregnant foster mothers. The embryonic stem cells contribute to the developing embryo, which may carry the mutation in its germ line. This technique is currently available only for mice. The target gene may be disrupted by introduction of a neomycin resistance cassette or by deletion of one or more, or even all, exons (classical or global ►knockouts). Since regulatory elements in the neomycin resistance cassette may affect the expression of neighboring genes, it is advisable to eliminate this cassette e.g., by cre/loxP-mediated recombination. Knockout mutations may also be studied in the heterozygous state to assess potential gene dosage effects [1]. The phenotypic consequences of the knockout mutation are expected to provide information on the normal function of the respective gene in wild type animals. Targeted mutagenesis is not limited to gene knockouts. Virtually any desired subtle mutation, e.g., a point mutation, or replacement of a gene with another gene, can be introduced into the mouse germline in this way (“knock-in”). The potential advantage of introducing a point mutation using a “knock-in” approach, compared to a transgenic approach, is that with a gene-targeted point mutation, the gene harboring the mutation is expressed under the control of the endogenous promoter. In contrast, in transgenic approaches the expression level and expression pattern may be different, making it more difficult to interpret a potential phenotype. In general, targeted point mutations permit more precise modeling of many human disease mutations.

Tissue-Specific and Inducible Transgenes

The expression of transgenes in time and space is dependent on the promoter used in the transgene construct and the site of DNA integration. Many transgenes are expressed constitutively, which may perturb development and even cause lethality. To avoid these problems, transgenes may be expressed in an inducible fashion. Mice carrying an inducible transgene grow up normally. The acute effect of transgene expression can then be reversibly induced in adult animals. The same animal may be studied before and after the expression of the transgene and thus serve as its own control, e.g., in behavioral studies. Several systems have been developed to achieve inducible expression, of which the tet system appears to be the most widely used (Fig. 1). The reverse tetracycline-controlled transactivator (rtTA) consists of a rtTA fusion protein

Transgenic Animal Models. Figure 1

Tissue-specific inducible transgene expression using the rtTA system. To achieve an inducible tissue-specific expression of a transgene, a mouse carrying two transgenes may be generated: Transgene 1 codes for rtTA, driven by a promoter expressed in tissue A ($P_{\text{tissue A}}$). Transgene 2 contains the open reading frame (ORF) of the gene that is to be expressed inducibly, preceded by a CMV minimal promoter (P_{minCMV}) and a tet operator (*tetO*). Only when doxycycline is present, rtTA binds to *tetO* and the ORF of interest is expressed in tissue A.

composed of the mutant version of the Tn10 tetracycline-resistance operon of *Escherichia coli* and a C-terminal portion of protein 16 of herpes simplex virus, which functions as a strong transcriptional activator. The rtTA is placed under the control of a tissue-specific promoter. Only in the presence of doxycycline, rtTA binds to the tet operator (*tetO*) that is placed on a separate construct and activates transcription from a minimal CMV promoter, which itself is inactive. This minimal promoter drives the expression of the desired gene. In summary, when doxycycline is added to the food, the transgene is expressed in a tissue-specific fashion. Conversely, it is also possible to shut down the expression of a transgene, using the tetracycline-controlled transactivator (tTA) system [2]. A refined system by which two genes can be simultaneously regulated in opposite directions is provided by a recent extension of this strategy [3]. More recently, a *lac* repressor transgene was developed which resembles a typical mammalian gene both in codon usage and structure and expresses functional levels of repressor in the mouse. This repressor was used to regulate the expression of a mammalian reporter-gene containing *lac* operator sequences. The *lac* repressor can repress the activity of a reporter-gene, which can subsequently be derepressed by the lactose analog IPTG [4].

Tissue-Specific and Inducible Knockouts

Classical global knockouts may have a developmental or lethal phenotype and thus preclude the analysis of the phenotypic consequences of the lack of a gene in specific tissues in adult animals. With the development of the ►cre/loxP and ►flp/FRT systems, it has become possible to excise defined DNA fragments from the genome of specified cells. Cre and Flp are bacterial and yeast recombinases, respectively, which recognize loxP and FRT sequences, respectively. The most common

application is where the DNA fragment to be deleted is flanked by two parallel loxP or FRT sites. Expression of cre or flp, respectively, then leads to the excision or loss of the flanked fragment. This expression can be achieved in cell culture or in mice. In order to get rid of the neomycin resistance marker, this marker may be flanked by two FRT sites. Flp expression in embryonic stem cell culture or in mice expressing an appropriate flp transgene will eliminate the neo marker. In a typical example, essential exons of a gene are flanked by loxP sites (“floxed”) (Fig. 2). These loxP sites most likely do not have a functional activity on their own, so that the “floxed” mice can be considered functional wild type mice (which, however, may have to be confirmed in each case). Crossing the “floxed” mouse with a transgenic mouse carrying a cre transgene that is expressed in tissue A will result in some mice carrying both the targeted “floxed” allele and the cre transgene. Only in tissue A will the cre transgene be expressed and the exons flanked by loxP removed. In all other tissues, the loxP-flanked DNA fragment will be retained.

One major problem with this strategy is that the cre expression has to be strong enough and highly tissue- or even cell type-specific. Many cre transgenes currently in use have been constructed as standard transgenes using promoter elements of limited size via pronucleus injection, with the expression level and pattern being dependent on the integration site. Frequently, these transgenes lack the specificity of cre expression that

Transgenic Animal Models. Figure 2

Tissue-specific knockout using the cre/loxP system. To achieve a tissue-specific knockout, mice carrying a cre transgene (“Transgene”) and a targeted allele characterized by a “floxed” exon in the gene of interest are generated. In this example, the cre transgene is expressed under the control of a promoter that is expressed in tissues A ($P_{\text{tissue A}}$). The Cre protein is synthesized in tissue A, recognizes the two parallel loxP sites and excises the exon that is flanked by the two loxP sites. If the floxed and later deleted exon is essential for gene function, the mouse will display a tissue-specific gene knockout.

would be expected from the respective promoter that was used; in other words, the expression pattern of the cre transgene frequently does not match the expression pattern of the endogenous gene from which the promoter was isolated. It may be preferable to “knock-in” the cre-cDNA into the gene whose expression pattern one wants to replicate; potential disadvantages of this approach are that the cre expression via the endogenous promoter may be too weak for complete excision of flanked sequences and that it is experimentally the most time-consuming one. An alternative approach to achieve cre expression from endogenous promoters utilizes bacterial artificial chromosomes (BACs). BACs contain e.g., 150–200 kb genomic DNA fragments. BAC libraries spotted on nylon membranes are commercially available. Clones hybridizing to a probe of interest can then be purchased individually. Positive clones are mapped to determine the approximate position of the gene of interest in the BAC. A BAC can then be selected which contains the gene of interest roughly in the center and >50 kb of upstream sequence. Via homologous recombination in *E. coli*, the cre cDNA, can be introduced into the ATG start codon of the respective gene of interest. The BAC is then injected into a fertilized mouse egg and frequently integrated as a single copy. The integrity of the BAC ends can be confirmed e.g., by polymerase chain reaction. Though the integration occurs at a random position in the genome, it is hoped that the BAC contains all regulatory elements of the gene of interest [5]. In contrast to the “knock-in” approach, the BAC transgene typically does not change the function of endogenous genes. Other genes present in the BAC may be overexpressed. The BAC approach has the advantage of being usually much less time-consuming than the “knock-in” approach.

Transgenic and Knockout Mice in Functional Genomics Approaches

The linking of genomic sequence information to biological function is of major relevance for the identification of novel drug targets. Instead of analyzing the function of one gene at a time, entire sets of genes can be analyzed by multiplexing genes using “in vivo libraries.” In this approach, overlapping yeast artificial chromosomes (“YACs”) covering a specific chromosomal region, which has been implicated in a specific biological function, are introduced into the mouse germline. The resulting mouse lines will be analyzed with respect to the phenotype in question, which has to be sensitive to gene dosage. The presence or absence of the phenotype in various mouse lines permits functional mapping of the gene of interest. In another approach, cDNAs of unknown function can be overexpressed in mice. However, a gene inactivation approach may frequently reveal more about the normal function of genes than the overexpression of cDNAs.

ES Cell Libraries

In the private and the public sectors, projects are ongoing in which random mutations are generated in murine embryonic stem cells on a large scale (ES cell libraries). Tagged and presumably inactivated genes are easily identified by sequencing. These stem cells can be used to generate the respective knockout mice.

Pharmacological Relevance

Transgenic and gene-targeted animals have a significant impact in providing fundamental insights into biological systems and their pharmacological regulation. They provide valuable information, relevant for target discovery and validation, e.g., by clarifying the functional roles of potential drug targets or by generating animal models for human diseases that allow testing potential therapeutic strategies. Genetically modified animals may also be useful for the development of novel assays for toxicological testing. Tissue-specific and inducible gene expression greatly increases the selectivity with which these analyses can be performed.

Transient Receptor Potential

The founding member of the TRP channel family, TRP, was identified as the product of a gene locus, which was referred to a transient receptor potential (TRP), because TRP mutant flies display a defect in light induced Ca^{2+} influx.

► TRP Channels

Transition State

A transition state is an unstable, high-energy configuration assumed by reactants in a chemical reaction on the way to making products. Enzymes can lower the activation energy required for a reaction by binding and stabilizing the transition state of the substrate.

Translation Inhibitors

► Ribosomal Protein Synthesis Inhibitors

Translocon

Multifunctional protein complex in the ER membrane. It translocates secretory proteins across and integrates membrane proteins into the ER membrane. The protein-conducting channel protein Sec61p is the most important component of the translocon.

Membrane signal transduction

Definition

Cellular functions are controlled by extracellular signals such as hormones, neurotransmitters, odorants, light and other chemical or physical stimuli. Only a few of these signal molecules, e.g., the highly lipid-soluble steroids or thyroid hormones, can diffuse across the

plasma membrane to interact with their intracellular receptors. Most regulatory factors are water-soluble and interact with membrane receptors to induce a signal transduction process that leads to the formation of intracellular signals or to the activation of and further integration within signaling cascades.

Basic Mechanisms

Transmembrane signaling processes involve the recognition and binding of an extracellular signal by an integral membrane receptor protein and the generation of intracellular signals by one or more effector proteins. Receptor and effector functions can be intramolecularly coupled by functional domains of the transmembrane protein or can be located on separate protein entities (intermolecular coupling). On the basis of intermolecular or intramolecular interactions of the signal-receiving receptor to the intracellularly located effector protein or protein domain, receptors can be divided into two groups.

Receptor Classification

Receptors that Couple to an Intramolecularly Linked Effector Domain

Receptors permanently linked to an effector consist of proteins with an extracellular ligand-binding receptor domain and a signal-generating effector domain (Fig. 1). Most of these receptors are composed of two to five structurally related or identical subunits. Effectors can be enzymes or ion channels whose activities are stimulated by agonist binding without significant delay.

1. *Enzyme-linked receptors* possess an extracellular domain with receptor function, a single transmembrane-spanning segment and an intracellular domain possessing catalytic activity. Ligand binding is typically decoded by receptor dimerization or by allosteric rearrangement of a preformed receptor oligomer. ▶ **Receptor tyrosine kinases**, which form the largest family of enzyme-linked receptors, bind various peptides such as growth factors or insulin and act, among others, through the canonical Ras/Raf/MEK/ERK class of ▶ **MAP kinase cascades**. Members of the ▶ **transforming growth factor β** (TGF β) receptor family bind TGF β , bone morphogenic proteins or activin, feature an intracellular serine/threonine kinase activity and act via SMADs [1]. The receptor-linked ▶ **guanylyl cyclases** are receptors for natriuretic peptides and guanylin. Their activation results in an increased intracellular formation of the second messenger ▶ **cGMP**. Some of these enzyme-linked receptors form homodimers, e.g., the receptor tyrosine kinases and the guanylyl cyclases. Receptor-type protein-tyrosine phosphatases (RPTPs) exhibit adhesion protein-like extracellular domains, but their ligands

and specific downstream targets are only poorly defined.

2. ▶ **Ligand-gated ion channels** consist of several identical or related subunits which together form a central pore acting as the regulated effector. The ligand binding domain is typically located on or between the pore-forming subunits, but may also involve accessory subunits such as the sulfonyleurea receptor (SUR) subunit, which is associated with ▶ **ATP-dependent K^+ channels**. The ▶ **nicotinic acetylcholine receptors** and the 5-HT $_3$ ▶ **serotonin receptors** (both consisting of five structurally related subunits with four transmembrane domains each), ▶ **ionotropic glutamate receptors** (consisting of four structurally related subunits with three transmembrane domains each), some ▶ **transient receptor potential (TRP) channels** (consisting of four structurally related subunits with six transmembrane domains and a pore loop domain each) and the P2X ▶ **purinergic receptors** (consisting of three subunits with two transmembrane domains each) are members of this family; they are connected to a cation channel. On the other hand, ▶ **GABA $_A$ receptors** and glycine receptors (consisting of five structurally related subunits with four transmembrane domains each, similar to the nicotinic acetylcholine and the 5-HT $_3$ serotonin receptors) are members that are connected to anion channels.

Receptors Associated with an Effector System

Receptors that are intermolecularly coupled to an effector system consist of two or more protein components providing the ligand-binding site, transducer and effector functions (Fig. 2).

1. ▶ **G-protein-coupled receptors** (GPCRs, seven-transmembrane, 7TM or heptahelical receptors) interact with and activate regulatory heterotrimeric G-proteins and thereby regulate a variety of signal-generating enzymes and ion channels [2]. These receptors represent the largest family of receptor proteins. For about 270 of them, the ligands are known, another 140 are ▶ **orphan receptors** with unknown ligands, and about 900 are olfactory receptors (but two thirds of the human olfactory receptor genes are pseudogenes). Activated GPCRs interact with membrane-attached ▶ **heterotrimeric GTP-binding proteins** (G-proteins), consisting of one α -, β - and γ -subunit each. The β - and γ -subunits form a functional complex (G $\beta\gamma$), which is released from the GTP-bound α -subunit within the receptor-mediated activation process. G α_{GTP} and free G $\beta\gamma$ regulate the activity of effector proteins such as enzymes (e.g., adenylyl cyclases, phospholipases C β , phosphatidylinositol 3-kinases, guanine nucleotide exchange factors of Rho GTPases, and, in the retina, the cGMP ▶ **phosphodiesterase type 6**) and

Transmembrane Signaling. Figure 1 Membrane topology of ligand-gated ion channels and of transmembrane receptors which are intramolecularly linked to an effector domain. Shown are single subunits of ligand-gated ion channel complexes, which are composed of three (P2X receptors), four (ionotropic glutamate receptors, TRP channels) or five (others) identical or structurally related subunits. Transmembrane segments or recursive loops aligning the ion-conducting pore are highlighted. Likewise, catalytically active cytosolic domains of enzyme-linked receptors are indicated (red).

ion channels (e.g., ►voltage-gated Ca^{2+} channels and ►inwardly rectifying K^{+} channels).

G-proteins are subdivided into four G-protein subfamilies according to structural similarities of their α subunits. The G_s subfamily (including G_s and G_{olf} proteins) is involved in ►adenylyl cyclase stimulation, whereas the activated $G\alpha$ and $G\beta\gamma$ subunits of the $G_{i/o}$ subfamily (including the G_i , G_o , G_z , transducin and gustducin isoforms) mediate adenylyl cyclase inhibition (G_i), cGMP ►phosphodiesterase type 6 stimulation (transducin), calcium channel inhibition ($G\beta\gamma$ from G_o) and potassium channel stimulation ($G\beta\gamma$ from G_i). Beside $G\beta\gamma$, members of the G_q subfamily (largely G_q and G_{11} , but in some cellular systems also G_{14} and $G_{15/16}$) by their activated α -subunits cause activation of phospholipase $\text{C}\alpha$ isoforms, thereby inducing a ►PI response. The α subunits of the G_{12} subfamily, consisting of G_{12} and G_{13} , can stimulate guanine nucleotide exchange factors (GEFs) of Rho, thereby mediating ►cytoskeletal rearrangements and, via Rho-dependent kinase (ROCK), Ca^{2+} -independent cellular contraction, e.g., of ►vascular smooth muscle.

Most GPCRs interact with and activate more than one G-protein subfamily, e.g., with G_s plus $G_{q/11}$ (histamine H_2 , parathyroid hormone and calcitonin receptors), G_s plus G_i (luteinising hormone receptor, β_2 -adrenoceptor) or $G_{q/11}$ plus $G_{12/13}$ (thromboxane A_2 , angiotensin AT_1 , ►endothelin ET_A receptors). Some receptors show even broader G-protein coupling, e.g., to G_i , $G_{q/11}$ plus $G_{12/13}$ (►protease-activated receptors, lysophosphatidate and sphingosine-1-phosphate receptors) or even to all four G-protein subfamilies (thyrotropin receptor). This multiple coupling results in multiple signaling via different pathways and in a concerted reaction of the cell to the stimulus.

2. ►Cytokine receptors that couple to the ►JAK-STAT Pathway decode the signaling through hematopoietic cytokines (erythropoietin, thrombopoietin, colony-stimulating factors), prolactin, growth hormone, the α -, β - and γ -►interferons, and a number of immunomodulatory interleukins [3]. They form homodimeric or heterodimeric receptor complexes, which after ligand binding recruit and activate isoforms of Janus kinases (JAKs). Activated JAKs in turn

Transmembrane Signaling. Figure 2 Membrane topology of receptors that are associated with effector proteins. Upon binding to their cognate ligands (cyan), receptor proteins without intramolecularly linked effector domain couple via transducer proteins (yellow) to or directly recruit and activate effector proteins (red). Notch receptors release their transducer domains upon proteolytic cleavage. α , β and γ stand for G-protein α -, β - and γ -subunits, respectively.

phosphorylate a subset of STAT proteins. Phosphorylated STAT proteins dimerize and translocate to the nucleus where they act as transcription factors. Other receptors that recruit nonreceptor tyrosine kinases to exert downstream signaling include the B cell receptor, the T cell receptor and the Fc ϵ receptor.

3. **TNF receptors** constitute a family of transmembrane receptors that share homology with the tumor necrosis factor α (TNF α) receptor and contain a highly conserved stretch of 80 amino acids that has been coined the death domain. Ligands that bind to and activate receptors of the TNF receptor superfamily include several cytokines, inducers of apoptosis and lymphotoxins. Upon ligand binding, TNF receptor-related proteins oligomerize and recruit TNF receptor-associated death domain protein (TRADD), Fas-associated death domain proteins (FADD), TNF receptor-associated factors (TRAFs) and receptor-interacting protein (RIP), a serine-threonine kinase. Downstream signaling pathways of TNF receptors include the initiation of the caspase 8-dependent proapoptotic pathway, the regulation of gene transcription via the IKK/I κ B/NF- κ B pathway, leading to a disinhibition and nuclear translocation

of **nuclear factor- κ B** and the activation of the JNK and p38 classes of **MAP kinase cascades**.

4. **Toll-Like receptors** (TLR) and the interleukin-1 receptors (IL-1R) constitute a superfamily of cell surface receptors that mediate the recognition of specific patterns of pathogens and thereby play a key function in triggering adaptive immune responses. The TLR isoforms bind bacterial membrane components such as lipopolysaccharides, lipoproteins and peptidoglycans, but also double-stranded viral RNAs or unmethylated CpG motifs, which are especially abundant in prokaryotic genomes. The IL-1 family of IL-1R ligands comprises IL-1 α , IL-1 β , IL-18 and IL-1RA. Intracellular responses that are triggered by TLRs and interleukin-1 receptors are initiated by formation of a complex between the respective receptor, a TIR domain-bearing adaptor protein (e.g., MyD88) and IL-1R-associated serine/threonine kinases (IRAKs). Via binding and phosphorylation of TRAF proteins, the IRAK-mediated signaling feeds into the IKK/I κ B/NF- κ B and JNK/p38 pathways.
5. **Notch receptors** are especially important during developmental stages by mediating lateral inhibition,

lineage decision and cellular segregation. The Notch family of cell surface receptors shares an architecture with an extracellular domain consisting of multiple EGF-like repeats, a single transmembrane-spanning segment and an ankyrin repeat-bearing Notch intracellular domain (Nidc). Binding of the ligands Delta or Jagged to Notch receptors triggers sequential proteolysis involving extracellular shedding by ADAM-type metalloproteases and subsequent intramembrane cleavage by γ -secretase, resulting in the release of the Notch intracellular domain (Nidc) into the cytosol. Nuclear targeting of Nidc and interaction with coactivators (Mastermind 1–3) or the corepressor SMRT together with DNA-binding proteins of the Csl family mediate regulation of gene transcription.

6. ► **Cell adhesion molecules** such as integrins, cadherins, claudins and selectins do not only act as transmembrane proteins involved in cell–cell or cell–matrix interactions but are also involved in signal transduction processes (e.g., the collagen-induced platelet adhesion and aggregation). Integrins even mediate inside-out signaling by adopting inactive and active conformations.

Besides classical receptor classes that bind endogenous or naturally occurring ligands and act via prototypical intracellular signaling cascades, a considerable number of transmembrane proteins are referred to as “receptors” albeit their natural ligands are unknown or they do not

initiate a characteristic downstream signaling cascade. These proteins include low density lipoprotein (LDL)-like receptors, the transferrin receptor, receptors for toxins or viruses as well as some target proteins for nonnatural chemical ligands (e.g., the dihydropyridine receptors, the sulfonylurea receptor).

Receptor Transactivation

Transmembrane signaling by one type of receptor may affect signaling pathways that are primarily used by other receptor types. Transactivation of receptor tyrosine kinases downstream of G-protein-coupled receptors is a common phenomenon leading to the activation of the Ras/Raf/MEK/ERK cascade and nuclear transcription events downstream of G-protein signaling. Receptor transactivation means that the signaling of one receptor class cannot be seen as an event separate from other regulations but has to be considered as part of a signaling network within the cell. Long-term changes of cellular responses and tissue functions in response to rapidly and transiently acting agonists may, therefore, result from transactivation of receptor classes that are coupled to transcriptional regulation.

A specific form of transmembrane signaling is given by receptor tyrosine kinase transactivation via the triple membrane-spanning (TMS) pathway [4] (Fig. 3). A GPCR ligand-induced shedding of membrane-bound growth hormone precursors such as pro-EGF, pro-HB-EGF, pro-Epiregulin or pro-Amphiregulin has been

Transmembrane Signaling. Figure 3 Triple membrane-spanning pathway. Control of growth and differentiation downstream of G-protein-coupled receptors often involves transactivation of receptor tyrosine kinases to induce activation of the canonical Ras/Raf/MEK/ERK pathway, nuclear translocation of activated ERK1/2 and subsequent regulation of gene transcription. Cyan: receptor ligands; yellow: transducer proteins; red: catalytically active effectors; green: active cofactors.

recognized to form a variant of transmembrane signaling, in which the signal enters the cell through GPCR activation, exits the cell again by an as yet unresolved mechanism to secrete or activate matrix metalloproteinases and reenters the cell by the autocrine or paracrine action of released mature growth factors that bind to and activate their cognate receptor tyrosine kinases. Besides direct actions of GPCR effectors and intracellular transactivation modules, the TMS pathway appears to be an important mechanism to mediate mitogenic or comitogenic responses to GPCR stimulation.

Quantitative Aspects

The number of receptor molecules is typically restricted to a few thousands per cell, and ligands are in most cases bound with nano- to low micromolar affinities. The effectors coupled to a receptor, independently of being an enzyme or ion channel, amplify the signal either by their catalytic activity or by allowing thousands of ions to flow through an activated ion-conducting pore. In G-protein-coupled receptors, signal amplification is accomplished by the fact that a single active receptor can mediate GDP/GTP exchange of multiple G-proteins. Activated receptor tyrosine kinases typically expose several phosphotyrosines and thereby recruit more than one SH2 domain-bearing adapter or downstream signaling protein. By using whole cascades of transducer molecules and enzymes or by expressing additional amplifying systems, specialized cells are capable of recognizing a very low number of agonist molecules and convert even tiny input signals into robust cellular events such as exocytosis, depolarization or transcriptional regulation.

Spatial Aspects

To ensure a tight control of signaling strength and fidelity, to accelerate the signal propagation or to restrict signaling processes to certain cellular compartments, some transmembrane signaling pathways are highly organized and physically concentrated in higher order molecular networks. Such clustered structures have also been referred to as transducisomes or signalplexes. Higher order signaling complexes can be formed by means of scaffolding proteins such as PDZ domain-bearing proteins or ►AKAPs, by segregating into membrane subdomains including caveolae or rafts, or by clustering within cellular protrusions (e.g., focal adhesions, filopodia, lamellipodia, membrane ruffles, axonal growth cones or primary cilia). Often, disruption of the respective clustering mechanism severely disturbs transmembrane signaling.

Temporal Aspects

Ligand-induced signal transduction processes that are mediated by a ligand-operated ion channel, e.g., by the nicotinic receptor in muscle, result in an almost

immediate (msec scale) cellular response as the number of components is very small and no enzymatic step is involved. In comparison, the onset of cellular responses to ligands interacting with GPCRs and inducing the formation of intracellular signals that stimulate protein phosphorylation is slower (sec). Cellular responses induced by growth factors or cytokines acting via phosphorylation cascades on transcription factors typically occurs after several minutes. Receptor classes that couple to gene transcription events and subsequent changes of protein expression typically exhibit lag times of 30 min to several hours until the cellular response can be seen.

Pharmacological Intervention

The naturally occurring ligands of membrane receptors, i.e., hormones, neurotransmitters, growth factors and cytokines, act as ►agonists, i.e., upon binding they induce the generation of intracellular signals leading to a cellular response [5]. Partial agonists are compounds that activate a certain receptor, but with less than the full intrinsic activity of the natural agonist. For receptors coupling to more than one effector molecule and signaling cascade, the development of pathway-selective agonists may become possible. ►Antagonists that act as blockers of the agonist effects have been developed as drugs.

The pharmaceutical industry has developed drugs that act as ►inverse agonists, i.e., these compounds through the same receptor cause opposite cellular reactions. Agonists are supposed to shift the equilibrium between the inactive and active (effector-coupled) forms towards the latter one, inverse agonists do the opposite; they can be used to silence a constitutively active receptor. Histamine H₂, H₃ and H₄ receptors are examples for receptors with high constitutive activity, and H₂ blockers such as cimetidine and ranitidine actually are powerful inverse agonists. Similarly, naloxone acts as an inverse agonist at μ -opioid receptors.

Most hormones and neurotransmitters act via more than one ►receptor subtype. Receptor subtypes often act on different effectors, thereby allowing complex, and in some cases opposite responses of certain tissues to a systemically distributed hormonal regulator (e.g., adrenaline-mediated vasodilatation via β_2 adrenoceptors and vasoconstriction via α_1 adrenoceptors). Receptor subtypes can show differences in agonist and antagonist binding, a property that can be employed to achieve cell- or tissue-specific action of synthetic subtype-specific agonists or antagonists. Accordingly, the pharmaceutical industry has developed numerous compounds discriminating between receptor subtypes, thus providing higher selectivity for certain receptors than the naturally occurring agonists. Among neurotransmitter receptors, the coexistence of ►ionotropic receptors (linked to ligand-gated ion channels) and of ►metabotropic receptors (i.e., G-protein-coupled

receptors) is most striking, i.e., ►[nicotinic](#) versus ►[muscarinic acetylcholine receptors](#), 5-HT₃ versus the other ►[serotonin receptors](#), ►[GABA_A](#) versus ►[GABA_B](#) receptors and ►[P2X](#) versus ►[P2Y](#) purinergic receptors.

Transporter

► [Table appendix: Membrane Transport Proteins](#)

Transposon

Transposons are mobile DNA elements (sizes ~2.5–23 kbp) that move from one place to another in the chromosome or onto extrachromosomal genetic elements within the same cell. They are flanked by inverted repeats at their ends and encode among other proteins a transposase that is needed for the transposition process. Resistance genes in the transposon are often parts of integrons. These are structures that carry an integrase responsible for the insertion of the resistance gene cassettes into the integron.

Transverse Tubule

Synonyms

T-Tubule

Definition

T-tubule is a transverse invagination of the plasma membrane, which occurs at the specified sites characteristic to animal species and organs, i.e. at the Z-line in cardiac ventricle muscle and non-mammalian vertebrate skeletal muscle and at the A-I junction in mammalian skeletal muscle. It is absent in all avian cardiac cells, all cardiac conduction cells, many mammalian atrial cells and most smooth muscle cells. T-tubule serves as an inward conduit for the action potential.

Triiodothyronine

Triiodothyronine (3',5,3-L-triiodothyronine, T₃) is a thyroid hormone. It is produced by outer ring deiodination of thyroxine (T₄) in peripheral tissues. The biologic activity of T₃ is 3–8 times higher than that of T₄. T₃ is 99.7% protein-bound and is effective in its free non-protein-bound form. The half-life of triiodothyronine is about 19 h. The daily turnover of T₃ is 75%. Triiodothyronine acts via nuclear receptor binding with subsequent induction of protein synthesis. Effects of thyroid hormones are apparent in almost all organ systems. They include effects on the basal metabolic rate and the metabolisms of proteins, lipids and carbohydrates.

TRP Channels

VEIT FLOCKERZI

Institut für Pharmakologie und Toxikologie, Universität des Saarlandes, Homburg, Germany

Definition

A superfamily of cation channels conserved in mammals, flies, worms and yeast. The various TRP-proteins bear sequence and predicted structural similarities to the founding member of this superfamily, ► **transient receptor potential (TRP)**, a light activated cation channel in the *Drosophila* photoreceptor.

Basic Characteristics

So far, more than 20 TRP genes have been identified in mammals [1, 2]. Almost all TRPs are supposed to form ion channels that are widely expressed in the nervous system, and which may be the primary site of Ca²⁺ entry in nonexcitable cells. A TRP protein contains six segments, predicted to cross the cell membrane, and a putative pore loop within the extracellular linker separating the fifth and sixth transmembrane segments (Fig. 1, top left), but lacks the voltage-sensing element (S4) present in voltage-gated channels. Almost all TRPs are activated by as yet unclear mechanisms (see below) involving phospholipase C (PLC) and phosphatidylinositol pathways. Four or five TRP proteins form homooligomeric and heterooligomeric channels (Fig. 1, top right) and evidence is steadily emerging that these

TRP Channels. Figure 1 TRP protein topology and pore loops of the members of the TRPV subfamily. Top, left: TRP proteins comprise six predicted transmembrane segments linked by extracellular and cytosolic protein domains. The pore loop resides within the extracellular linker separating the fifth and sixth transmembrane segments. Top, right: View perpendicular to the surface of the plasma membrane. Four TRP proteins assemble to form an ion channel. The four pore loops line the ion permeant pathway. Circles represent transmembrane segments. Bottom: Amino acid sequence alignment of the pore loops of the members of the TRPV subfamily. The D shown in bold represents the negatively charged aspartic acid residue responsible for the high Ca^{2+} selectivity of channels formed by TRPV5 and, presumably, TRPV6. P_{Ca} and P_{Na} , relative permeability to Ca^{2+} (P_{Ca}) and to Na^{+} (P_{Na}).

channels are integrated into signal transduction complexes by ► **scaffolding proteins**. Based on their structural similarities the TRP proteins fall into three subfamilies of channels, TRPC, TRPV and TRPM (Table 1). Two additional subfamilies, TRPP and TRPML, which are more distantly related to TRP, include ► **PKD2** and ► **mucolipin**.

Ion Channel Properties

Essential molecular determinants of ion permeation through TRP channels should reside within a protein domain, which participates in the formation of the ion permeable pathway of the channel. This domain is therefore called the pore loop. So far this region has only been characterized for TRP channels formed by members of the TRPV group. Here, ► **TRPV1**, TRPV2, TRPV3 and ► **TRPV4** channels do only poorly discriminate between monovalent and divalent cations, especially Na^{+} and Ca^{2+} , and accordingly, are called “nonselective” cation channels. In contrast, ► **TRPV5** and ► **TRPV6** form highly selective Ca^{2+} channels. Thus the relative permeability to Ca^{2+} (P_{Ca}) is more than 100-fold higher than to Na^{+} (P_{Na}) in these two channels. A single negatively charged aspartic acid residue

TRP Channels. Table 1 The superfamily of mammalian TRP channels

TRPC subfamily	TRPV subfamily	TRPM subfamily

TRPC5	TRPV5	TRPM5
TRPC6	TRPV6	TRPM6
TRPC7		TRPM7
		TRPM8

(D, shown in bold in Fig. 1 bottom) in the pore loop of TRPV5, which is conserved in TRPV6, but not in the other members of the TRPV subfamily, has been shown to be responsible for the high Ca^{2+} selectivity of channels formed by TRPV5 [3].

For all other members of the TRP family it still has to be shown whether the presumptive pore loop or other protein domains actually line the ion conducting pathway of the channel. Based on the results showing that expression of most TRPC channels yields currents carried by Na^{+} and Ca^{2+} , and that expression of ► **TRPM4** and ► **TRPM7** channels yields currents carried by Na^{+} but not by Ca^{2+} (TRPM4) or even currents carried by Mg^{2+} or Ca^{2+} (TRPM7), it seems likely that the pore structures of these channel proteins vary considerably.

Modes of Activation

TRP channels vary significantly in their modes of activation [4]. Given that *Drosophila* TRP requires PLC for activity *in vivo*, mammalian TRPs were predicted to be PLC-dependent ion channels. Activation of PLC could be coupled to TRP channel activation via relief of phosphatidylinositol-4,5-bisphosphate (PIP_2)-mediated channel repression and/or production of inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). According to one mechanism, referred to as ► **store-operated Ca^{2+} entry**, transient IP_3 induced release of Ca^{2+} from intracellular stores induces sustained Ca^{2+} influx by activation of a plasma membrane Ca^{2+} entry channel. Leading contenders for channels activated by the latter mechanism are TRPC1, TRPC3, TRPC4 and TRPC5, although none of the published reports have unequivocal evidence for such a mechanism. In addition, members of the TRPC subfamily could be activated by diacylglycerol (TRPC3, TRPC6), by direct interaction with the IP_3 receptor (TRPC3), and – like TRPV1 and TRPM7 – by relief of (PIP_2)-mediated repression of the channel, to mention a few.

Members of the TRPV subfamily are activated by a broad range of stimuli including heat (TRPV1, TRPV2, TRPV3 and TRPV4), ligands such as ► **capsaicin**

(TRPV1) and ►endocannabinoids (TRPV1, TRPV4, see below), osmolarity and cell volume (TRPV4), hydrolysis of PIP₂ and protons (TRPV1). So far, TRPV5 and TRPV6 channels are unique in that they represent the only highly Ca²⁺-selective channels within the TRP superfamily (see above) and are activated by low intracellular Ca²⁺.

Three TRPM proteins, ►TRPM2, TRPM6 and TRPM7, are distinguished from other TRPs and other known ion channels, in that they consist of enzyme domains linked to the C termini of the ion channel domains resulting in “Chanzymes” TRPM6 and TRPM7 encode TRP proteins linked to functional atypical protein kinases; however, at least TRPM7 channel activity does not require the kinase domain for activation [5]. Currents through channels formed by TRPM6, TRPM5, TRPM1 and TRPM3 have not been identified electrophysiologically so far. Currents through TRPM2 channels are activated by ADP-ribose and changes in the redox status within the cell. TRPM4 is a Ca²⁺-activated channel (EC₅₀~0.3–0.4 μM), nonpermeant for Ca²⁺, whereas ►TRPM8 can be activated by a drop in temperature below 26°C or by agents, such as menthol and icilin, that evoke a cool sensation.

Pharmacological Relevance

A clear limitation of studies on TRP channels is the lack of specific channel blockers. Organic compounds (e.g., ruthenium red, econazole, miconazole, SK&F96365) and anorganic blockers (e.g., La³⁺, Gd³⁺) have generally found to be of insufficient potency and specificity. The few exceptions include compounds such as capsaicin (EC₅₀~0.7 μM) and ►resiniferatoxin (EC₅₀~0.04 μM) as activators and capsazepine (IC₅₀~0.3 μM) as blockers of the TRPV1 currents, the endogenous cannabinoid receptor agonist anandamide (EC₅₀≥4.9 μM) and related endocannabinoids as activators of TRPV1 and TRPV4 currents and 4α-PDD, a phorbol derivative, as activator of TRPV4 currents (EC₅₀~0.2 μM).

Biological Relevance and Emerging Roles for Mammalian TRP Channels

Most of the TRP channels have only been characterized in recombinant systems but not as functional channels in a physiological context; still others have not even been characterized as functional channels. Firm data on their biological relevance will emerge basically by the combination of three routes: (i) By the development and identification of toxins and agents that can be used to specifically block currents through a given TRP channel in primary cells and tissues (see above “Pharmacology”). (ii) By linking diseases to mutations in TRP genes; e.g., familial hypomagnesemia with secondary hypocalcemia is caused by mutations in TRPM6, implicating a role for TRPM6 in renal Mg²⁺ uptake. Other examples are mucopolidosis type

IV, a neurodegenerative disease caused by disruption of the mucopolin gene, a TRP of the TRPML subfamily, and common causes of polycystic kidney disease are mutations within PKD2, a TRP of the TRPP subfamily. (iii) By transgenic mice with targeted disruption of single TRP genes or a combination of TRP genes; so far three TRP-deficient mice have been described that underline the biological roles of TRPC2, TRPC4 and TRPV1 in social and sexual behavior (TRPC2), vasorelaxation and microvascular endothelial permeability (TRPC4) as well as nociception and thermal hyperalgesia (TRPV1). There are suggestions that a number of TRP-related proteins may also have roles in growth control, and changes in the expression of these channels may contribute to certain forms of cancer. A decrease in expression of TRPM1 appears to be a prognostic marker for metastasis in patients with localized malignant melanoma. Alterations of TRPM5 may be associated with Beckwith–Wiedemann syndrome, a predisposition to a variety of neoplasms, whereas expression of TRPM8 and TRPV6 appears to be upregulated in prostate cancers; these two TRPs may represent prognostic markers for prostate cancer and targets for new drugs to treat this disease.

TRPM4

TRPM4 also known as the Ca²⁺-activated nonselective cation (CAN-) channel, mediates cell membrane depolarization in many excitable and nonexcitable cells.

►TRP Channels

TRPM7

TRPM7, also known as mTRP-PLIK, ChaK1 or LTRPC7, is a Mg^{2+} -permeable, nonselective cation channel, expressed in kidney, placenta, heart and seemingly, every cell examined, including blood cells and cell lines commonly used for expression studies. The monovalent current is inhibited by Mg^{2+} ($IC_{50} \approx 0.6$ mM) – hence MagNum (magnesium- and nucleotide-regulated metal current) or MIC (Mg^{2+} -inhibited current) – whereas activation involves reduction of local phosphatidylinositol 4,5-bisphosphate (PIP2) concentrations. TRPM7 has been identified as a protein interacting with phospholipase C β 1 (PLC β 1) and has, like TRPM6, the unique feature of being an ion channel and a protein kinase, although TRPM7 channel activity appears not to require the kinase domain for activation.

► TRP Channels

TRPM8

TRPM8 is also known as TRP-P8 or the cold receptor.

► TRP Channels

TRPV1

TRPV1, also known as the capsaicin- or vanilloid-receptor, is a nonselective cation channel expressed e.g., in neurons of the dorsal root and trigeminal ganglions, which integrates multiple pain-producing stimuli including heat, protons, capsaicin, and resiniferatoxin. In addition, TRPV1 currents can be activated by anandamide, protein kinase C (PKC), and by hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP2).

- TRP Channels
- Analgesics

TRPV4

TRPV4, also known as TRP12, OTRPC4 or VROAC, is a nonselective cation channel, predominantly

expressed in endothelium, kidney, heart and brain. It is activated by a decrease in extracellular osmolarity, by cell swelling, arachidonic acid, anandamide, and by 4 α -PDD, a phorbol derivative.

► TRP Channels

TRPV5 and TRPV6

TRPV5 and TRPV6, also known as the epithelial Ca^{2+} channel or ECaC (TRPV5) and Ca^{2+} transporter 1 or Ca^{2+} transporter-like (TRPV6), are the only two Ca^{2+} -selective TRP channels identified so far. They may function in vitamin D-dependent transcellular transport of Ca^{2+} in kidney, intestine and placenta. TRPV6 is also expressed in pancreatic acinar cells, and in prostate cancer, but not in healthy prostate or in benign prostate hyperplasia.

► TRP Channels

True ChE

► Cholinesterases

Trypsin

Trypsin is a major proteolytic digestive enzyme and the identified endogenous ligand for proteinase-activated receptor 2 (PAR 2).

► Proteinase-activated Receptors

Trypsin-like Proteinases

Trypsin-like proteinases are serine proteinases that recognized peptide residues with positively charged side chains (arginyl or lysyl residues) and that effect

hydrolysis of the polypeptide chain on the carboxy-terminal side of these residues. All clotting and complement cascade proteinases are trypsin-like.

► Non-viral peptidases

TSH Receptor

Thyrotropin (TSH) regulates the production and secretion of thyroid hormones as well as thyroid epithelial cell growth via the TSH receptor. The TSH receptor belongs to the family of G protein-coupled receptors. It is composed of 764 amino acids. The receptor contains a long hydrophilic region orientated towards the exterior of the cell (ectodomain), 7 hydrophobic transmembrane domains and a short cytoplasmic region.

► Antithyroid Drugs

T-tubule

A T-tubule is a transverse invagination of the sarcolemma, which occurs at characteristic sites in animal species and organs, i.e. at the Z-membrane in cardiac ventricle muscle and non-mammalian vertebrate skeletal muscle and at the A-I junction in mammalian skeletal muscle. It is absent in all avian cardiac cells, all cardiac conduction cells, many mammalian atrial cells and most smooth muscle cells. It serves as an inward conduit for the action potential. The surface area in the skeletal muscle can reach 6–8 times that of a cylinder with the same radius. In the T-tubule, Na-channel, Ca-channel and other important channels and transporters can be detected.

► Ryanodine Receptor

TTX

► Tetrodotoxin

Tubulin

Tubulin is a major component of the cellular cytoskeleton. Tubulin polymers (microtubules) are important for cell division (mitotic spindle) and the chemotaxis and phagocytosis of neutrophils. Prevention of tubulin polymerisation by colchicine accounts for the therapeutic effects of this drug in acute gouty arthritis and its anti-mitotic effects.

► Anti-gout Drugs

► Cytoskeleton

α and β Tubulin

α and β tubulins associate into heterodimers to form microtubules. Both tubulins have molecular weights of about 50 kD and bind GTP. In higher eukaryotes, there are up to 7 isoforms of α and β tubulin, respectively, which are encoded by different genes.

► Cytoskeleton

Tumor Necrosis Factor

Definition

Human tumor necrosis factor (TNF) (Fig. 1) is a hormone-like proinflammatory peptide belonging to the group of ► cytokines. It is mainly produced by cells of the immune system in response to infection, ► inflammation, or cell damage. Disregulated TNF is an important factor in many pathological situations, like sepsis, rheumatoid arthritis, inflammatory bowel disease (Crohn's disease), and Cachexia. The cytotoxic activity of TNF is of interest in development of new antitumoral strategies.

Tumor Necrosis Factor. Figure 1 Homotrimeric structure of soluble TNF (51 kDa). TNF monomers (17 kDa) in individual subunits fold into a jelly roll pattern that is composed of anti-parallel β strands separated by intervening loop regions, which are represented by green, red, or blue color.

Basic Characteristics

The antitumoral effects of TNF had been first noted in the late nineteenth century by W.B. Coley, a New York surgeon. Coley realized that bacterial infections can cause an antitumoral response in cancer patients. Consequently, he produced preparations of Gram-negative bacteria to treat patients with tumors. About 80 years later, a single, inducible serum protein was discovered that can induce hemorrhagic necrosis of tumors. TNF was molecularly cloned in 1984. Today, TNF is considered as the representative member of a large family of **cytokines** consisting of 19 identified ligands so far [1]. TNF exerts fundamental effects on cell proliferation and death, *inflammation*, and immunological and neuronal cell functions.

TNF is expressed as a 26 kDa **type II transmembrane protein** of 233 amino acids. A soluble form of TNF is generated by proteolytic cleavage close to the transmembrane region releasing the 17 kDa C-terminal extracellular region of the molecule consisting of 157 amino acids. **Metalloproteinases** like TACE (TNF α converting enzyme) convert the membrane bound form to the soluble form of TNF. Both forms confer bioactivity as self-assembled, noncovalently bound homotrimers (Fig. 1) interacting at hydrophobic interfaces. TNF binds to two cellular membrane receptors, TNFR1 (CD120a, TNFR55) and TNFR2 (CD120b, TNFR80) [2].

Both tumor necrosis factor receptors (TNFR) are **type I transmembrane proteins**, also belonging to a large family of proteins, the TNFR superfamily

comprising 29 receptors up to now [1]. TNFR1 and TNFR2 are characterized by four well-conserved cysteine-rich domains in their extracellular parts, a hallmark of the whole TNFR superfamily. Intracellularly, the TNF receptors are distinct. TNFR1 carries a so-called **death domain** that is shared by seven other members of the TNFR superfamily, that is, Fas, DR3 (TRAMP), DR4 (TRAILR1), DR5 (TRAILR2), DR6, EDAR, and NGFR, whereas TNFR2 contains a TNFR-associated factor (TRAF) binding domain, marking also most of the residual members of the TNFR superfamily. Although the amino acid sequences of TNFR1 and TNFR2 are similar in length, the apparent molecular weight is different, about 55–60 kDa and 70–80 kDa for TNFR1 and TNFR2, respectively. This difference is mainly caused by variations in **glycosylation**, as TNFR2 is highly *O*-glycosylated in the so-called stalk region, that is, between the fourth cysteine-rich domain and the transmembrane part. The stalk regions of both TNFR1 and TNFR2 contain proteolytic cleavage sites. Activation of metalloproteases (e.g., TACE) results in cleavage of TNFR1 and TNFR2, leading to the release of the respective extracellular domains. These are still capable of binding to TNF, although with lower affinity, as compared to the full-length transmembrane TNFR. Under many pathological conditions, the levels of soluble TNFR are elevated in patients. In general, higher levels of soluble TNFR2 (2–4 ng/ml) are found in normal sera as compared to soluble TNFR1. The physiological function of shed TNFR are not fully understood; neutralization of the ligand and/or formation of storage pools are plausible.

The main sources of TNF synthesis are monocytes and macrophages, although many other cell types are also able to produce TNF upon stimulation. Many proinflammatory activities of TNF are mediated by TNFR1, which is ubiquitously expressed. In contrast, TNFR2 is highly regulated in its expression and mainly found on immune cells, endothelial cells, and neurons. TNF strongly induces gene expression, although, dependent on the cellular environment, it is also capable of initiating apoptosis as well as necrosis. Whereas TNFR1 is fully activated by both TNF forms, that is, soluble and membrane bound TNF, TNFR2 can be efficiently activated only by membrane bound TNF. Crystal structure analysis of lymphotoxin α (LT α), another ligand of both TNFR, in complex with the extracellular domain of TNFR1 revealed that the homotrimeric ligand binds three receptors. However, further oligomerization of TNFR/ligand complexes is essential for efficient signaling. Upon appropriate activation, both TNFR initiate a complex series of signaling pathways (Fig. 2), including the activation of c-jun N-terminal kinase (JNK), mitogen activated protein (MAP) kinases, and the transcription factor nuclear factor- κ B (NF- κ B) [2]. Additionally, TNFR1

Tumor Necrosis Factor. Figure 2 Schematic representation of TNFR1- and TNFR2-mediated signaling. Activation of TNFR1 and TNFR2 by TNF regulates the expression of a number of genes affecting cellular responses to TNF. Although TNFR2 is not capable to induce the apoptotic pathway directly, the internalization of the TNFR1 signaling complex can lead to the recruitment and activation of caspases, resulting in the induction of apoptosis. Alternatively, TNFR1 can induce cell death by the induction of necrosis (not depicted here). A large number of different signaling molecules as well as kinases are involved in TNFR-mediated signaling. FADD, Fas-associated death domain; JNK, c-jun N-terminal kinase; IKK, IκB kinase; MAPKKK, mitogen-activated protein kinase kinase kinase; MAPKK/MKK, mitogen-activated protein kinase kinase; NF-κB, nuclear factor kappa B; RIP, receptor-interacting protein; TAK1, TGF-beta-activated kinase 1; TRADD, TNFR1-associated death domain; TRAF2, TNFR-associated factor.

activates protein kinase C (PKC) as well as sphingomyelinases that lead to the production of the lipid second messenger ceramide. After ligand binding, two different and sequential signaling pathways are activated. First, the membrane-expressed signal complex induces activation of MAPK, JNK, and NF-κB. After internalization of the complex, a second signal pathway is initiated, leading to the induction of apoptosis. Activation of the latter is initiated by the proteolytic activation of the ▶caspase cascade. Importantly, TNFR2 is a mere gene-inductive receptor that is able to antagonize TNFR1-mediated apoptotic signaling by upregulation of the expression of antiapoptotic factors. However, in some cellular systems TNFR2-mediated signaling can lead to the expression and production of TNF that in turn is capable to activate TNFR1, thereby enhancing the proapoptotic effect of this receptor. Taken together, TNF signaling via the two TNFR, TNFR1 and TNFR2, and the crosstalk between these receptors are complex and cell-type dependent [2].

Drugs

TNF is a pleiotropic ▶cytokine exerting a wide range of cellular responses, that affect biological processes such as lipid metabolism, coagulation, and insulin resistance and the function of endothelial cells. As a major proinflammatory ▶cytokine TNF is also involved in progression of diseases like cancer, Alzheimer, Diabetes type II, cardiovascular, pulmonary or neurological disorders, and many autoimmune diseases. Blocking the action of TNF clearly reduces its inflammatory potential on various autoimmune disorders like Crohn's disease, rheumatoid arthritis (RA), and psoriasis.

Commercially available drugs used for therapeutic therapy comprise up to date mainly injectable monoclonal antibodies like Infliximab (Remicade®) and Adalimumab (Humira®) or TNF-receptor derivatives like Etanercept (Enbrel®) (Fig. 3). One possible way of action of these reagents is the neutralization of TNF, thereby blocking its inflammatory effects and dampening (auto)immune responses [3, 4].

Tumor Necrosis Factor. Figure 3 Anti-TNF drugs. Secreted soluble TNF binds to target cells via transmembrane receptors. Upon binding of TNF to TNFR1, TNF is able to induce inflammation, which may enhance pathological symptoms and tissue damage. TNF-specific monoclonal antibodies, PEGylated anti-TNF Fab fragments or TNF receptor fusion proteins are able to bind TNF, thereby blocking the accessibility of TNF to TNF receptors on target cells, resulting in the neutralization of the proinflammatory potential of TNF (modified from Ref [4]).

Neutralizing Anti-TNF Drugs

Infiximab is mainly used in treatment of psoriasis and arthritis of psoriasis. Infiximab is a chimeric monoclonal antibody consisting of 75% human IgG1 Fc and 25% mouse IgG1 containing the TNF-binding domain. Infiximab binds and neutralizes both secreted TNF and transmembrane TNF, the latter inducing reverse signaling into the TNF-secreting cells. Additionally, there are approved concepts applying the combination of Infiximab with antimetabolite drugs, such as ►methotrexate (Rheumatrex, Trexall) [4]. The precise mechanism of action of this combined therapy in diseases is currently unknown and has to be elucidated. As a result of its potentiating effects, ►methotrexate has been found helpful in treating certain diseases associated with abnormally rapid cell growth, such as cancer of the breast and psoriasis. Furthermore, infiximab alone has been reported to be helpful in decreasing the severity of symptoms of Crohn's disease, the joint ►inflammation of juvenile RA, ankylosing spondylitis, uveitis, and sarcoidosis, all known to be rather unresponsive to traditional therapies. However, it has to be kept in mind that infiximab is mainly easing and not curing these diseases.

Adalimumab (Humira[®]) is a fully human anti-TNF monoclonal antibody that is mainly used in combination with ►methotrexate to treat rheumatoid arthritis in adults [3]. Meanwhile, it is also used against arthritis of psoriasis and ankylosing spondylitis. Its therapeutic value in Crohn's disease is under clinical trial.

Etanercept (Enbrel[®]) is a chimeric TNF receptor 2 (TNFR2/p75/CD120b) IgG fusion protein consisting of two extra cellular domains of TNFR2 for ligand binding fused to the Fc-part of human IgG1. It is used to reduce the signs and symptoms of moderately to severely active juvenile RA in patients, who had shown an inadequate response to other disease-modifying medications [3]. Etanercept is further approved for the treatment of ankylosing spondylitis and the arthritis of psoriasis. It can prevent the progressive destruction of the joints in patients with psoriatic arthritis. Therefore, Etanercept can improve physical function in patients that are restrained by psoriatic arthritis. It has also been reported to benefit in psoriasis and uveitis. However, there are restrictions that Etanercept is not recommended for patients with preexisting disease of the CNS (central nervous system) or for those with MS (multiple sclerosis), myelitis, or optic neuritis.

In addition to therapeutics in use already, there is a fourth upcoming anti-TNF drug, called the TNF-neutralizing drug Certolizumab pegol (CDP870). It is a ►PEGylated Fab fragment of a humanized anti-TNF monoclonal antibody (Fig. 3). At present, it is being tested in clinical phase III trials for both Crohn's disease and RA. Previous studies suggest that it is well tolerated by patients.

In addition to the alleviation of symptoms, the therapeutic use of these drugs results in some side effects. Often, depending on the setup of treatment, flu-like symptoms such as shivering, fever, aching muscles,

weakness, loss of appetite, nausea, vomiting, and diarrhea are observed. Some patients show a breakout of a rash around the area of injection, others tend to bleed or bruise easily. Depending on how severe these problems are, patients may need to stay in hospital during the period of treatment. These side effects usually occur short-term and they gradually reduce after treatment stops.

Furthermore, it also has to be considered that TNF-neutralizing drugs may weaken the innate immune system. In fact, there exists the risk of contracting other diseases, such as tuberculosis. Especially, latent infections may become active, often leading to an atypical clinical presentation of the disease. Infliximab and Adalimumab have label warnings which state that patients should be evaluated for latent tuberculosis infection and treatment should be initiated prior to starting therapy with these medications. Additionally, anti-arthritis drugs like TNF blockers might also allow cancer to occur as they suppress the immune system's ability to fight off tumors.

The Antitumoral Activity of TNF

TNF was originally identified because of its cytotoxic activity against some tumor cell lines and its ability to induce hemorrhagic necrosis of solid tumors in various animal models. However, the clinical use of TNF as an anticancer drug has been so far limited by its severe cardiovascular side effects. Therefore, TNF treatment is limited to regional and local administration of high doses of TNF, often in combination with chemotherapy, as accomplished in isolated limb and isolated hepatic perfusion (ILP and IHP, respectively) [5]. In the case of ILP, typically metastases are treated, patients benefit from this procedure by salvage of limbs from a loss by amputation.

TNF Prodrugs as Antitumoral Medication

A different upcoming approach is the use of TNF ►prodrugs. Thereby, the properties of TNF and TNF receptors are used to achieve a direct targeting via a fusion protein construct. An agonistic peptide consisting of 11 amino acids, comprising the TNF binding site of TNFR1, has been shown to possess many of the leukocyte-activating properties of TNF without the associated toxicity when administered locally or systemically in an animal model.

In a different approach, a TNF fusion protein designated TNF-Selectokine has been described [5]. This TNF ►prodrug is comprised of a trimeric scFv-TNF fusion protein to which a TNFR fragment has been fused at the C-terminal. A flexible peptide linker between TNF and the blocking receptor domain is comprised of sequences specifically recognized by tumor associated proteases such as tissue plasminogen activator, urokinase type plasminogen activator or

matrix metalloproteinase-2 (MMP2). The TNF-Selectokine exerts high bioactivity toward the targeted and adjacent antigen negative cells [5]. Unfortunately, available data are so far from animal studies, clinical trials have to be performed to verify these effects in humans.

Tumor Suppressor Genes

In multicellular organisms, the proteins encoded by tumor suppressor genes exert protective effects against malignant transformation. Their main functions are (i) inhibition of cell cycle leading to reduced proliferation, (ii) promotion of apoptosis, (iii) coordination of the cellular response to DNA damage. A large number of tumors show loss or inactivation of both alleles of a given tumor suppressor gene.

TUNEL

TUNEL is the name given to the in-situ DNA end-labelling technique which serves as a marker of apoptotic cells. This method is based on the specific binding of terminal de-oxy nucleotidyl transferases to the 3-hydroxy ends of DNA. The technique is normally used for examination under the light microscope but can also be adapted for examination under the electron microscope.

- Apoptosis

Turing Machine

The Turing machine is one of the key abstractions used in modern computability theory. It is a mathematical model of a device that changes its internal state and reads from, writes on, and moves a potentially infinite tape, all in accordance with its present state. The model of the Turing machine played an important role in the conception of the modern digital computer.

► Bioinformatics

Twitch/Tetanus

Twitch is a muscle contraction caused by a single action potential, whereas tetanus is a sustained muscle contraction caused by a series of repetitive action potentials. The amplitude of tetanus contraction is larger than that of twitch, due to mechanical summation.

► Ryanodine Receptor

Two-dimensional Gel Electrophoresis

Two-dimensional gel electrophoresis (2DE) is a two-dimensional technique for protein separation, which combines isoelectric focusing and sodium dodecyl sulphate (SDS) electrophoresis. The high resolving power results from separation according to charge (isoelectric point) in the first dimension and size (mobility in a porous gel) in the second dimension. Depending on the gel size, from several hundred to more than 5,000 proteins can be separated.

Type I Allergic Reaction

Type I allergic reactions are inappropriate immune responses to an allergen with preferential synthesis of immunoglobulin E (IgE), a special antibody class, which binds to mast cells and basophilic granulocytes via Fc ϵ receptors. Binding of the allergen to the cell-bound IgE initiates the rapid release of allergic mediators, most prominently histamine, and the de novo synthesis of arachidonic acid metabolites and cytokines, which are responsible for the clinical symptoms.

► Allergy

Type I Transmembrane Proteins

Cell membrane spanning proteins contain a luminal/extracellular domain, a transmembrane region and a cytosolic domain. In a type I transmembrane protein the N-terminus is the extracellular/luminal part of the protein, whereas the C-terminus comprises the cytosolic region of the membrane protein.

► Tumor Necrosis Factor (TNF)

Type II Allergic Reaction

A Type II allergic reaction occurs when antibodies specific for foreign substances recognize the body's own cells after they have firmly bound these foreign substances and initiate the cell's destruction by immune mechanisms.

► Allergy

Type II Transmembrane Proteins

Cell membrane spanning proteins contain a luminal/extracellular domain, a transmembrane region and a cytosolic domain. In a type II transmembrane protein the C-terminus is the extracellular/luminal part of the protein, whereas the N-terminus comprises the cytosolic region of the membrane protein.

► Tumor Necrosis Factor (TNF)

Type III Allergic Reaction

A Type III allergic reaction occurs when antibodies of the immunoglobulin G class (IgG) form immune complexes which are slowly eliminated and thus may elicit an inflammatory reaction by binding to the Fc γ receptors of leukocytes resulting in their activation.

► Allergy

Type IV Allergic Reaction

Type IV allergic reactions are cell-mediated hypersensitivity reactions which are characterized by the expansion of T lymphocytes specific for foreign substances exposed on cell surfaces. In type IVa allergic reactions, this results in the cell-mediated destruction of the cells, whereas in type IVb allergic reactions an

inflammatory reaction results after release of cytokines (delayed-type hypersensitivity reaction, DTH).

Tyrosine Kinase Inhibitors

ANDREE BLAUKAT
TA Oncology, Merck Serono Research, Merck KGaA,
Darmstadt, Germany

Synonyms

TKIs (tyrosine kinase inhibitors); Kinase inhibitors; Monoclonal antibodies

Definition

Tyrosine kinase inhibitors interfere with the function of tyrosine kinases that catalyze the transfer of the γ -phosphate group of ATP to tyrosine residues of protein substrates. Tyrosine kinases can be subdivided into two large families, receptor tyrosine kinases (RTKs) and non-receptor tyrosine kinases (NRTKs; see corresponding chapter). The human genome

encodes for a total of 90 tyrosine kinases that have been implicated in the regulation of a variety of biological responses such as cell proliferation, migration, differentiation and survival. There is evidence that they are involved in the development of many diseases, including immunodeficiency, inflammation, ►atherosclerosis, psoriasis, ►osteoporosis, diabetes and cancer.

Mechanism of Action

Tyrosine kinases can be targeted by different pharmacological strategies. Both, RTKs and NRTKs are accessible to small molecule inhibitors directly interfering with ATP binding and to Hsp90 ►chaperone inhibitors that affect maturation of several kinases following their synthesis. Furthermore, they can be equally addressed by mRNA directed approaches, such as anti-sense therapy (►antisense oligonucleotide) and ►RNA interference (RNAi). In addition, RTKs are targeted by monoclonal antibodies, “ligand traps” and ►aptamers that block binding of activating ligands, interfere with dimerization that is part of the activation process, or induce down-regulation of the receptor protein (Fig. 1). Furthermore, some anti-RTK antibodies may also trigger ►antibody-dependent cellular

cytotoxicity (ADCC) that can contribute to their therapeutic activity.

Antibodies

The first drug targeting a tyrosine kinase approved for clinical use was the anti-ErbB2/Her-2 antibody trastuzumab (Herceptin) that is successfully applied for the treatment of Her-2 positive breast cancers. Her-2 expression is assessed in tumor biopsy material prior to treatment either by immunohistochemistry or ►fluorescence in situ hybridization (FISH). Current data support the hypothesis that trastuzumab exerts its therapeutic effects by inhibition of ErbB2/Her-2 shedding and induction of receptor down-regulation. A second anti-Her-2 antibody that is currently tested in clinical studies is pertuzumab (Omintarg). This antibody is directed against the dimerization domain of Her-2 and inhibits homo- and heterodimerization.

A variety of antibodies has been developed against the epidermal growth factor receptor (EGFR), another ErbB family member that is overexpressed in a several human cancers, but has also been implicated in other diseases like psoriasis. The chimeric antibody cetuximab interacts with domain III of EGFR, prevents binding of activating ligands and can as an IgG₁ elicit

Tyrosine Kinase Inhibitors. Figure 1 Pharmacological strategies to target tyrosine kinases.

ADCC. Cetuximab is approved for treatment of metastatic colorectal cancer (CRC) and squamous cell carcinoma of the head and neck (SCCHN). Interestingly, an adverse event, acneiform rash seems to correlate with a better response to cetuximab, while there is no such correlation with expression levels of EGFR assessed by immunohistochemistry. Further side effects are rare infusion reactions and hypomagnesia. Two other anti-EGFR antibodies approved for clinical use are the fully human antibody panitumumab (Vectibix)

that has been generated in mice transgenic for human IgGs and the humanized antibody nimotuzumab (TheraCIM) (Table 1). Remarkably, nimotuzumab seems to be the only EGFR-targeting drug without reports about skin rash. Additional anti-EGFR antibodies in clinical trials are the fully human IgG zalutumumab (HuMax-EGFR), the humanized matuzumab (EMD72000) and the chimeric antibody ch806. While all other antibodies bind with high affinity to wildtype EGFR, ch806 seems to recognize only a

Tyrosine Kinase Inhibitors. Table 1 Tyrosine kinase inhibitors approved for clinical use (by July 2007)

Drug name	Drug format	Main target(s)	MoA	Indication*
Trastuzumab (Herceptin)	Humanized antibody, IgG ₁	ErbB2/Her-2	Receptor down-regulation	Breast cancer
Cetuximab (Erbix)	Chimeric antibody, IgG ₁	EGFR	Ligand competition ADCC ?	CRC SSCHN
Panitumumab (Vectibix)	Fully human antibody, IgG ₂	EGFR	Ligand competition	CRC

*Note that application in the particular indications is usually restricted either to patients expressing the target (e.g. trastuzumab, cetuximab, lapatinib, imatinib) and/or after failure of prior therapies (e.g. cetuximab, erlotinib, lapatinib, sutinib, dasatinib). Furthermore, for cancer treatment most tyrosine kinase inhibitors are applied in combination with conventional chemotherapeutic drugs, such as fluorouracil, taxanes, platin-based regimens, anthracyclines and irinotecan or radiotherapy.

fraction of EGFR on cells highly overexpressing the receptor and a particular EGFR mutant called variant III that is frequently found in brain tumors. Whether this property translates to an improved safety profile by retaining similar efficacy than approved anti-EGFR antibodies remains to be demonstrated in clinical trials.

Another antibody-based approach targets vascular endothelial growth factor (VEGF) that has been implicated in tumor angiogenesis and other pathological neovascularization processes. In contrast to anti-EGFR strategies, RTK activation is in this case prevented by interference with the ligand and not with the RTK. Bevacizumab (Avastin) has changed the standard of care for patients with metastatic CRC by significantly increasing their survival. It has also been approved for non-small cell lung cancer (NSCLC) and due the fundamental mechanism of action an impact on other cancer treatments can be expected. Bevacizumab is generally well tolerated, though, some serious and unusual toxicities were reported (e.g. gastrointestinal perforations, wound healing complications, hypertension, bleeding and proteinuria). Ranibizumab (Lucentis) is a fragment of bevacizumab engineered specifically to penetrate the retina and is approved for the treatment of ►age-related macular degeneration (AMD) where it stabilizes vision in more than 90% of wet AMD patients.

Given the success of this class of therapeutics a number of antibodies directed against RTKs (e.g. fibroblast growth factor receptors (FGFRs), insulin-like growth factor 1 receptor (IGF1R) and VEGFR) and RTK ligands (e.g. hepatocyte growth factor) are being developed.

Kinase Inhibitors

Though a large number of small molecule inhibitors against a variety of tyrosine kinases are being developed, the most advanced drugs can be roughly classified as (i) Bcr-Abl/Src family kinase inhibitors, (ii) ErbB inhibitors and (iii) broad spectrum TKIs with an anti-angiogenic component.

Among the Bcr-Abl inhibitors is *the* forerunner for the TKI approach, imatinib (STI-571, Gleevec) that shows remarkable clinical activity in patients with chronic myelogenous leukemia (CML) and in a subset of acute lymphoblastic leukemia (ALL). In both diseases Bcr-Abl, a fusion protein of the NRTK c-Abl and the breakpoint cluster region (bcr) with elevated kinase activity is the causative molecular abnormality. Imatinib is in general well tolerated, though, more recently a cardiotoxic potential has been described. As with almost all anti-cancer drugs, primary and acquired resistance to imatinib is observed. Most important mechanisms for resistance are Bcr-Abl amplifications and mutations in the kinase domain that reduce affinity for the drug. Imatinib resistance in CML and ALL is addressed by second generation c-Abl inhibitors

like nilotinib (AMN-107, Tassigna) and dasatinib (BMS-354825, Sprycel). Imatinib is also used for the treatment of gastrointestinal stroma tumors (GIST), dermatofibrosarcoma protuberans (DFSP), myelodysplastic/myeloproliferative diseases (MDS/MPD), aggressive systemic mastocytosis (ASM) and hyper-eosinophilic syndrome/chronic eosinophilic leukemia (HES/CEL). The clinical activity of Imatinib in GIST is based on its ability to inhibit c-Kit, which is frequently mutated in this disease. Other indications, such as DFSP, HES/CEL and a certain proportion of CML involve aberrant PDGF receptor signaling that is blocked by imatinib.

Several TKIs against the ErbB family members EGFR and ErbB2/Her-2 have been generated. While gefitinib (ZD1839, Iressa) and erlotinib (OSI-774, CP-358774, Tarceva) are relatively selective for EGFR, lapatinib (GW572016, Tykerb) was designed as a dual EGFR and ErbB2/Her-2 inhibitor. Gefitinib and erlotinib are used for the treatment of NSCLC and recent data suggest that patients with certain somatic EGFR kinase domain mutations have a particular benefit from this regimen. Lapatinib is approved for the treatment of patients with Her-2 overexpressing metastatic breast cancer who have received prior therapies including trastuzumab.

Examples for the ever-growing class of multi-kinase inhibitors with anti-angiogenic activity are sunitinib (SU11248, Sutent), sorafenib (BAY 43-9006, Nexavar), vandetanib (ZD6474, Zactima), cediranib (AZD2171, Recentin), vatalanib (PTK787), pazopanib (GW786034) and axitinib (AG013736). A common feature of all these TKIs is their activity against one or several RTKs involved in angiogenesis, such as VEGFR1, VEGFR2 and PDGFR. This property may translate to a wide spectrum of cancer indications and first remarkable results led to the approval of sunitinib and sorafenib in renal cell cancer (RCC). This clinical activity may be explained by the frequent loss of the Van Hippel Lindau (VHL) gene in RCC that results in the accumulation of hypoxia-induced factor (HIF) and subsequent activation of HIF-inducible pro-angiogenic proteins, such as VEGF and PDGF. Interestingly, sorafenib was originally developed as a Raf serine/threonine kinase inhibitor, but initially failed in clinical studies in melanoma that frequently express a mutant, activated variant of B-Raf. In addition, many of these TKIs share activity against c-Kit predestining them for the treatment of GIST with activating c-Kit mutations. Again, these TKIs are relatively well tolerated despite their broad target profile.

More TKIs directed against other tyrosine kinases, like c-Met, IGF1R, Flt-3, FGFRs, Tie-2, Axl or Ron are at earlier stages of development with the most advanced candidates having entered phase II studies in different types of cancers.

Hsp90 Inhibitors

Hsp90 is a heat-shock protein that functions as molecular chaperone guiding normal protein folding, intracellular deposition and proteolytic turnover of many key regulators of cell growth and survival. Among the client proteins of Hsp90 are several tyrosine kinases, such as Her-2, c-Kit, Flt-3, Bcr-Abl and mutated Src that are involved in oncogenesis. Therefore, Hsp90 inhibitors are clinically tested for the treatment of cancers, but preclinical data also suggest a potential use in arthritis and neurodegenerative disorders, like Parkinson and Alzheimer disease. The most advanced compounds, 17-AAG (Tanespimycin) and 17-DMAG are derived from natural products and target the N-terminal ATP-binding pocket of Hsp90. While there were initial concerns about severe side effects due to impairment of normal cell function, clinical phase I studies point to an acceptable safety profile of these drugs. Recognized as an attractive target, several fully synthetic small molecule Hsp90 inhibitors suitable for oral application are approaching clinical phase I.

Others

Among the alternative approaches to target tyrosine kinases only pegaptanib (Macugen), an RNA aptamer that binds to VEGF-165, the VEGF isoform primarily responsible for pathological ocular neovascularization and vascular permeability has gained approval for the treatment of AMD.

Another strategy to interfere with the biological actions of tyrosine kinase activating growth factors is based on so called decoy receptors. These are soluble receptor proteins that contain a native ligand binding domain able to capture the growth factor and thereby prevent activation of its cognate transmembrane receptor(s). An example for such as “ligand trap” is the VEGF trap (Aflibercept), a genetically engineered fusion protein of the extracellular domain of VEGFR1 and the constant region of human IgG₁. This construct binds all forms of VEGF-A with high affinity and shows promising clinical activity in the treatment of several cancers as well as in AMD.

Furthermore, peptidomimetic SH2 domain inhibitors for Src, such as AP-22408 have been designed that interfere with effector binding and thereby disrupt signal transduction. AP-22408 decreases bone resorption in animal studies and may be a promising drug to treat osteoporosis and other bone diseases, such as Paget's disease and osteolytic bone metastasis.

Other approaches directed to the mRNA of tyrosine kinase and thereby interfering with their translation to proteins, such as anti-sense therapy and RNA interference (RNAi) are less advanced and currently limited to laboratory studies.

Clinical Use

Tyrosine kinase inhibitors that are currently in clinical use either target ErbB family members, VEGF and its receptors or Bcr-Abl (Table 1). They are applied for the treatment of different types of cancers and for AMD. While antibody-based therapeutics and aptamers are highly selective for their primary target, most small molecular kinase inhibitors have a broader profile ranging from a few additional kinases that are affected (e.g. imatinib and gefitinib) to a significant promiscuity (e.g. sunitinib and sorafenib). Main reason for limited selectivity is that most TKIs are directed against the ATP binding pocket that is to a certain degree conserved throughout the kinome. While this initially raised concerns about potential side effects, hitting several kinases with a single drug can allow the exploration of additional indications (e.g. imatinib for GIST due to its activity against c-Kit) or may even provide a general advantage for a multi-causal disease like cancer. Clinical studies in other indication will show whether the lack of selectivity of many TKIs is an obstacle for the treatment of less life-threatening diseases than cancer.

Protein tyrosine kinases; Nonreceptor tyrosine kinases; Cytoplasmic tyrosine kinases; Tyrosylprotein kinase; Hydroxyaryl-protein kinase

Definition

Protein tyrosine kinases (PTKs) are enzymes (EC 2.7.1.112) that catalyze the transfer of the γ -phosphate group of ATP to tyrosine residues of protein substrates. The activity of PTKs is controlled in a complex manner by posttranslational modifications and by inter- and intramolecular complex formations.

Basic Characteristics

PTKs have been implicated in the regulation of a variety of biological responses such as cell proliferation, migration, differentiation, and survival. They have been demonstrated to play significant roles in the development of many disease states, including immunodeficiency, **atherosclerosis**, **psoriasis**, **osteoporosis**, diabetes, and cancer. In recent clinical trials impressive antitumor effects of PTK inhibitors have been observed. In future, PTK inhibitors may therefore become important drugs for the treatment of specific cancers.

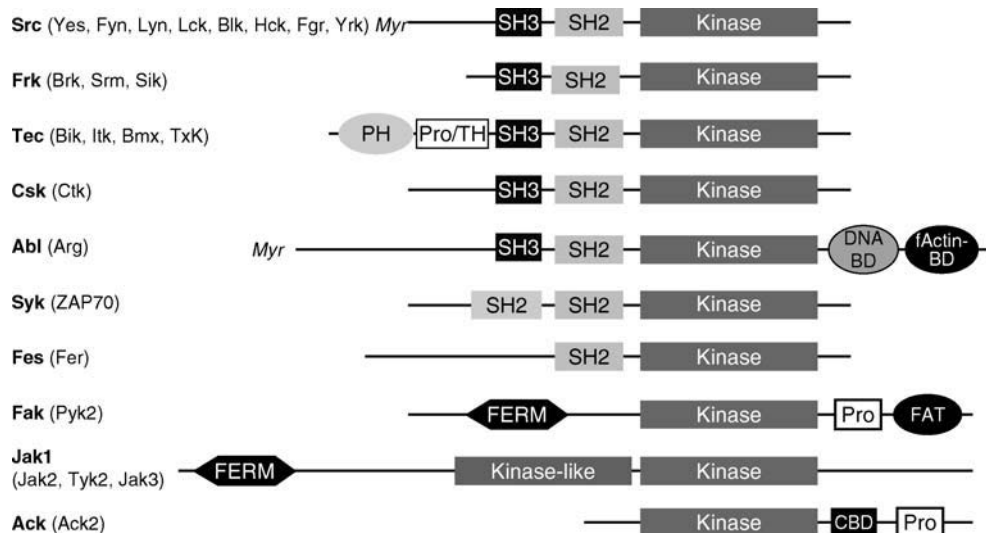

PTKs can be subdivided into two large families, receptor tyrosine kinases (RTKs) and non-RTKs. The human genome encodes for a total of 90 tyrosine kinases of which 32 are nonreceptor PTKs that can be placed in 10 subfamilies (Fig. 1). All nonreceptor PTKs share a common kinase domain and usually contain several additional domains that mediate interactions with protein-binding partners, membrane lipids, or DNA (Table 1). These interactions may affect cellular localization and the activation status of the kinase or attract substrate proteins for phosphorylation reactions.

c-Src

c-Src was the first cellular homologue of a viral oncoprotein (v-Src from the Rous sarcoma virus) to

be discovered. It is involved in mitogenic signaling from many types of transmembrane receptors and has been implicated in a variety of cancers. c-Src and the Src-like kinases Fyn and Yes are expressed in most tissues and are at least partially redundant in their function. Hck, Fgr, and Blk are primarily found in hematopoietic cells, whereas Lyn and Lck are also expressed in neuronal cells.

The inactive, closed conformation of Src is maintained by intramolecular interactions of the SH2 and SH3 domains (Fig. 2). The N-terminal SH3 domain binds to a proline-rich sequence in the linker region between the SH2 and the kinase domain. In addition, the SH2 domain binds to a phosphorylated tyrosine residue (Y527 in chicken, Y530 in human) in the C-terminal part of the protein. The kinase executing this phosphorylation is called Csk (C-terminal c-Src kinase) and is member of a distinct PTK family (Fig. 1). Both intracellular interactions together repress Src kinase activity by blocking access to the active site. Src can be activated by dephosphorylation of pY527 and by intermolecular interactions with SH2 and SH3 binding partners. A variety of cytosolic and receptor-type protein tyrosine phosphatases (PTPs), such as PTP α , PTP1B, and SHP-1/2 has been shown to dephosphorylate pY527 and subsequently activate c-Src. Among the SH2 ligands that can activate Src are autophosphorylated RTKs (e.g., epidermal growth factor (EGF) and platelet derived growth factor (PDGF) receptors) and nonreceptor PTKs (e.g., Fak and Pyk2) as well as tyrosine phosphorylated adaptor proteins (e.g. Shc). For full activation of Src a transautophosphorylation of a conserved tyrosine residue in the activation loop (Y416) has to occur. This model is supported by the elevated Src activity in transformed cells with

Tyrosine Kinases. Figure 1 Tyrosine kinases.

Tyrosine kinases. Table 1 Tyrosine kinases

Domain		Function
CBD	Cdc42-binding domain	Binding to the small G protein Cdc42
DNA-BD	DNA-binding domain	Binding to DNA
fActin-BD	f-Actin-binding domain	Binding to F-Actin
FAT	Focal adhesion targeting domain	Binding to focal adhesions complexes
FERM	4.1/ezrin/radixin/moesin domain	Binding to cytoplasmic regions of transmembrane proteins
Myr	Myristoylation site	Tethering to membranes
PH	Pleckstrin homology domain	Binding to membrane phospholipids, such as phosphoinositides
Pro	Prolin-rich sequences	Binding to SH 3 domains
PTB	Phospho-tyrosine binding domain	Binding to phosphorylated tyrosine residues
SH1	Src homology 1 domain, Kinase domain	Kinase activity
SH2	Src homology 2 domain	Binding to phosphorylated tyrosine residues
SH3	Src homology 3 domain	Binding to prolin-rich sequences
TH	Tec homology domain	SH3-binding prolin-rich sequences and Zn ²⁺ -binding motif

increased PTP activity; a Src mutant with truncated C-terminus lacking Y530 that has been found in human colorectal cancers and is constitutively activated, and v-Src, which in addition to several point mutations lacks a large part of the C-terminal domain, has transforming potential.

Among the substrates of Src are other nonreceptor PTKs (e.g., Fak, Syk, and Tec kinases), RTKs (e.g. EGF and PDGF receptors), phospholipase C γ , PI3-kinase, phosphatases (e.g., SHP-2 and PP2A), and adaptor (e.g., Shc and Cbl) as well as focal adhesion proteins (e.g., paxillin, p130^{Cas} and tensin). Src-mediated phosphorylation either modulates enzymatic activity of

target proteins or creates docking sites for SH2 or PTB domain containing proteins promoting the assembly of multimeric protein complexes that function in cellular signaling.

Given its involvement in many receptor-mediated signaling pathways, Src was thought to be an important regulator of cell proliferation, migration and adhesion. However, the most striking phenotype of c-Src deficient mice is an osteopetrosis suggesting a role for c-Src in bone remodeling and a compensation of c-Src-deficiency by other Src family members in other organs. Indeed, combined deletion of c-Src, Yes and Fyn in mice results in a lethal phenotype.

c-Abl

c-Abl was first identified as the cellular homologue of the transforming gene product of the Abelson murine leukemia virus (v-Abl) and found to encode a nonreceptor PTK. Mammalian c-Abl is expressed ubiquitously and in most cells is primarily localized in the nucleus where it has a role in DNA damage-induced apoptosis.

c-Abl is activated by ionizing radiation in a manner dependent on phosphorylation by ATM (ataxia telangiectasia-mutated), a nuclear protein serine/threonine kinase. c-Abl kinase activity in G0 and G1 phase of the cell cycle is repressed by binding of Rb (retinoblastoma protein) to the activation loop, which is released during S-phase when Rb becomes hyperphosphorylated by cyclin-dependent kinases. Furthermore, c-Abl is negatively controlled by intramolecular SH3 domain interactions and by SH3-binding proteins, such as Pag/MSP23 (human proliferation-associated gene/macrophage 23-kD stress protein).

Nuclear substrates of c-Abl include DNA-PK (DNA-dependent protein kinase, an enzyme critical for DNA repair), Rad51 (a homologue of bacterial RecA involved in recombination/repair by catalyzing strand exchange between homologous DNAs), the tyrosine phosphatase SHPTP1 and the p85 subunit of PI3-kinase, negatively regulating their respective activity. In contrast, c-Abl activates JNK (c-Jun N-terminal kinase) and p38 mitogen-activated protein kinases (MAPKs). c-Abl also functions in the cytoplasm, where it is involved in PDGF-induced motility responses and cell adhesion. In chronic myelogenous leukemia (CML) as well as in a subset of acute lymphoblastic leukemia (ALL) Bcr-Abl, a fusion protein of c-Abl and the breakpoint cluster region (bcr), is expressed in the cytosol of leukemic cells. This fusion protein forms homo-oligomeric complexes that display elevated kinase activity and is the causative molecular abnormality in CML and certain ALL. The transforming effect of Bcr-Abl is mediated by numerous downstream signaling pathways, including ►protein kinase C (PKC), Ras-Raf-ERK MAPK, JAK-STAT (see below), and PI3-kinase pathways.

Fak

Fak (focal adhesion kinase) is expressed in most tissues and is evolutionary conserved across species. It is activated by integrin clustering and by stimulation of several G protein-coupled receptors and RTKs. Fak is associated with focal adhesions and regulates cell spreading and migration. The kinase is essential for embryonic development since the homozygote Fak knockout is embryonic lethal. Pyk2 (proline-rich tyrosine kinase 2), the second member of the Fak kinase family has a more restricted expression pattern (primarily neuronal and hematopoietic cells) and does not localize to focal adhesions.

An early step in Fak activation is a high stoichiometry autophosphorylation of a tyrosine residue (Y397)

proximal to the kinase domain. Phosphorylated Y397 is a high affinity ligand for the SH2 domain of Src, thereby recruiting Src kinases and stimulating their catalytic activity. In a second step, several other tyrosine residues in Fak become phosphorylated, either by Fak itself or by recruited Src. As a consequence, Fak kinase activity is further increased or docking sites for SH2 domain-containing proteins are created, e.g., for Grb2-Sos complexes that link Fak to the Ras-Raf-►MAPK cascade. N-terminal sequences containing the FERM domain anchor Fak to integrins or RTKs and the C-terminal FAT domain mediates binding to cellular focal adhesions. Among the substrates of the Fak/Src complex are the adaptor proteins paxillin and p130^{Cas} and the focal adhesion-associated protein tensin that bind to C-terminal sequences of Fak and, after their phosphorylation, promote the assembly of signaling complexes at discrete sites within cells.

Fak kinases could be modulators of some aspects of human cancers and may also contribute to the development of vascular diseases involving hyperproliferation and migration of vascular smooth muscle cells.

Jak

Jak1 and 2 were identified, among others, by PCR using degenerate oligonucleotides spanning the conserved kinase domain of Src and therefore initially named Jak, for "Just another kinase." When full length clones were isolated it was recognized that they differ markedly from other PTKs by the presence of an additional (pseudo)-kinase domain of unknown function. To denote this unique feature they were renamed as "Janus kinases" in reference to the ancient two-faced Roman god. Jak1, 2, and Tyk2 are ubiquitously expressed, whereas Jak3 is predominantly found in hematopoietic cells. Jak family PTKs mediate signaling primarily downstream of cytokine receptors. In response to ligand stimulation, cytokine receptors oligomerize and recruited or constitutively bound Jak kinases become activated and phosphorylate receptors. Some of the receptors' phosphotyrosine residues subsequently bind to SH2 domains of STATs (signal transducers and activators of transcription), which are then phosphorylated by Jaks on a C-terminal tyrosine residue. This leads to STAT oligomerization through a reciprocal interaction between SH2 domains and phosphotyrosines. Dimeric STATs translocate to the nucleus where they initiate transcription of target genes. Alternatively, STATs can be activated by Src kinases that are recruited to Jak-phosphorylated cytokine receptors via their SH2 domain. Jak kinase signaling is negatively regulated by PTPs and by SOCS (suppressors of cytokine signaling) proteins that inhibit Jaks by binding to the activation loop and by targeting the kinases for protein degradation.

STAT 3 and 5 are overexpressed and/or overactivated in several human malignancies, such as breast,

non-small cell lung cancer and head and neck cancer. An aberrant activation of Jak kinases by fusion with the TEL transcription factor and subsequent constitutive dimerization has been observed in T-cell acute lymphocytic leukemia.

Tec

Tec family kinases participate in signal transduction in response to virtually all types of extracellular stimuli that are transmitted by growth factor receptors, cytokine receptors, G protein-coupled receptors, antigen-receptors, and integrins. Tec kinases are involved in the regulation of growth, differentiation, apoptosis, and cell motility. They are primarily found in hematopoietic lineages but some family members (Btk, Etk/Bmx) have a somewhat broader expression pattern. The defining feature of Tec family kinases is the presence of a PH domain at their N-terminus. The PH domain has a broad binding capacity ranging from lipid products of PI3-kinase, heterotrimeric G protein subunits ($\beta\gamma$ as well as $G\alpha_q$ and $G\alpha_{12}$), PKC isoforms (βI and δ) to STATs, and Fak kinases. These interactions may either be involved in Tec activation (phospholipids and G proteins) or recruit potential substrates of Tec kinases (PKC and STATs).

The current understanding on activation of Tec kinases fits into a two-step model. In the first step an intramolecular interaction between the SH3 domain and a proline-rich region in the TH domain is disrupted by binding of the PH domain to phosphoinositides, G protein subunits, or the FERM domain of Fak. These interactions lead to conformational changes of Tec and translocation to the cytoplasmic membrane where, in a second step, Src kinases phosphorylate a conserved tyrosine residue in the catalytic domain thereby increasing Tec kinase activity. Autophosphorylation of a tyrosine residue in the SH3 domain further prevents the inhibitory intramolecular interaction resulting in a robust Tec kinase activation.

Among the substrates and downstream effectors of Tec kinases are phospholipase $Cy2$ and PKC βI resulting in a sustained calcium influx and eventual activation of MAPKs. The interaction with the GDP/GTP exchange factor Vav can potentially activate Rac/Cdc42/Rho pathways, which can modulate actin cytoskeleton dynamics and also lead to JNK and p38 MAPK activation eventually inducing apoptosis. Paradoxically, Tec kinases may also trigger antiapoptotic signals by stimulating PI3-kinase and \blacktriangleright Akt and promote proliferation by activating STATs.

Naturally occurring mutations of Btk were identified in human immunodeficiency diseases and X-linked agammaglobulinemia, where a lack of mature circulating B cells and immunoglobulins are observed, supporting a central role for Btk in B-cell maturation. In contrast, the knockout of Itk results in a lack of mature T cells and defects in T-cell receptor signaling. Furthermore, Btk and Etk/Bmx are able to complement a weakly oncogenic Src

in transformation of hepatocytes and fibroblasts suggesting their participation in anchorage-independent growth and development of cancer.

Syk

Syk and ZAP-70 are early intermediates in the transduction of signals from immune receptors, including the B- and T-cell receptors for antigen, activatory natural killer-cell receptors, the mast cell and basophil receptor for IgE, and the widely distributed receptors for the Fc portion of IgG. Immune receptors control checkpoints in lymphocyte development and serve to integrate the responses of innate and acquired immunity.

The current model proposes that upon engagement of immune receptors Src-family kinases are recruited that phosphorylate tyrosine residues in specific regions of the receptors, the immunoreceptor tyrosine-based activation motifs (ITAMs). These phosphotyrosines serve as docking sites for the SH2 domains of Syk and ZAP-70 that subsequently autophosphorylate and generate binding sites for SH2 domain containing proteins, like phospholipase $C\gamma$, Vav, and the adaptor protein Cbl. Furthermore, Syk and ZAP-70 phosphorylate a number of cytosolic and transmembrane linker proteins, such as SLP-76 (SH2-containing leukocyte protein of 76 kD), LAT (transmembrane linker for activation of T cells), TRIMM (T-cell receptor-interacting molecule), and SIT (SHP2-interacting transmembrane adaptor protein) that function as scaffolds to localize and assemble signaling complexes. In addition to being a major player in immune receptor signaling, Syk has a role in the “inside-out” integrin activation signal that is necessary for fibrinogen binding and subsequent aggregation of platelets during hemostasis.

Drugs

PTKs have been shown to play significant roles in the development of many disease states, including immunodeficiency, atherosclerosis, psoriasis, osteoporosis, diabetes, and cancer. Therefore, in the last years numerous PTK inhibitors have been developed that are currently undergoing clinical trials. The majority of them are directed against RTKs; however, most impressive clinical results have been obtained with Imatinib (STI-571, signal transduction inhibitor 571, CGP57148B, *Glivec*TM, *Gleevec*TM) that in addition to its action against PDGF and c-Kit receptors, potently inhibits the activity of the nonreceptor PTK c-Abl. Imatinib is a phenylamino-pyrimidine that, like almost all kinase inhibitors, competes for binding of ATP to the catalytic domain. However, the mechanism of action of Imatinib is unique: it binds to and stabilizes an inactive conformation of the kinase domain preventing activation of c-Abl. In CML as well as in a subset of ALL Bcr-Abl fusion proteins with elevated kinase activity are the

causative molecular abnormalities. In clinical trials with CML patients, impressive response rates of more than 90% without severe adverse effects have been observed with once-daily oral doses of Imatinib. However, more recently a cardiotoxic potential of Imatinib was described and the impact of this observation on the therapeutic use of Imatinib is not yet foreseeable. As with almost all chemotherapeutics, resistance to Imatinib as a single agent was observed in patients that were irresponsive or relapsed after initial successful treatment. Major mechanisms for this resistance are Bcr-Abl amplifications and mutations in the kinase domain that reduce affinity for the drug. Imatinib resistance is addressed by second-generation c-Abl inhibitors, such as INNO-406 (NS-187, CNS-9), Nilotinib (AMN-107, *Tasigna*TM) and Dasatinib (BMS-354825, *Sprycel*TM) that has been approved for CML in 2006. Meanwhile, Imatinib is also used for the treatment of gastrointestinal stroma tumors (GIST), dermatofibrosarcoma protuberans (DFSP), myelodysplastic/myeloproliferative diseases (MDS/MPD), aggressive systemic mastocytosis (ASM), and hypereosinophilic syndrome/chronic eosinophilic leukemia (HES/CEL). The clinical activity of Imatinib in GIST is based on its ability to inhibit c-Kit, which is frequently mutated in this disease. Other indications, such as DFSP, HES/CEL, and a certain proportion of CML involve aberrant PDGF receptor signaling that is blocked by Imatinib.

Several other inhibitors of nonreceptor PTKs are currently in development but only a few of them are studied in clinical trials. Noteworthy, Dasatinib does not only inhibit c-Abl, but also potently blocks Src activity, a property that may contribute to its beneficial clinical effects in CML. Other kinase inhibitors being developed that inhibit c-Abl and/or Src are AZD-0530, AP-23994, PD-0183805, SU-6656, and Bosutinib (SKI-606). Furthermore, peptidomimetic SH2 domain inhibitors for Src, such as AP-22408 have been designed that decrease bone resorption and may be promising drugs to treat osteoporosis and other bone diseases, such as Paget's disease and osteolytic bone metastasis.

Other experimental drugs against nonreceptor PTKs with therapeutic potential are Jak2 inhibitors, such as AG490, a benzenmalononitrile that was shown to suppress the growth of leukemic cells and ovarian as well as breast cancer cell lines, to reduce myocardial infarct size and cardiomyocyte apoptosis in ischemia/reperfusion injury and to prevent experimental allergic encephalomyelitis. Furthermore, Fak and several Src family kinases are considered as valid targets for an anticancer therapy.

Future basic research and clinical studies will show whether other inhibitors of nonreceptor PTKs may be as successful drugs as Imatinib for the treatment of fatal diseases such as cancer.

Tyrosine Phosphatases

In contrast to tyrosine kinases, Tyrosine phosphatases (PTPs) are enzymes which act on phosphorylated proteins and catalyze the transfer of a phosphate group from a tyrosine residue to a water molecule, generating orthophosphates in a process which is referred to as “dephosphorylation.” PTPs are involved in many cellular signal transduction pathways.

Ubiquitin-Dependent Protein Degradation

Ubiquitin tags proteins for protein degradation. The ubiquitination requires three different enzymatic activities, a ubiquitin-activating enzyme (E1), a ubiquitin-conjugating enzyme (E2 or Ubc) and a ubiquitin ligase (E3). The action of all three enzymes leads to the establishment of a poly-ubiquitin chain on target proteins which are then recognized and proteolyzed by the 26S proteasome.

Synonyms

Protein degradation; Posttranslational protein modification

Definition

Protein modification by the covalent attachment of ubiquitin chains serves as a signal to mark proteins for the degradation by a multicatalytic proteinase complex called the proteasome. Thus the ubiquitin proteasome system (UPS) controls the stability of proteins in a

regulated manner affecting multiple essential cellular processes. In addition, dependent on the mode of linkage, ubiquitin regulates protein-protein interaction, endocytosis, replication and the formation of signaling complexes in a proteasome-independent fashion. Beside phosphorylation ubiquitination represents the most important posttranslational regulatory mechanism in biology.

Basic Mechanisms Ubiquitin Conjugation

Ubiquitin is a highly conserved 8.5 kDa polypeptide, which was first described in 1974. The discovery that the Ubiquitin proteasome system serves as a general mechanism to target proteins for destruction by the proteasome was awarded with the Nobel Prize for Chemistry in 2004.

Upon cleavage from a precursor ubiquitin becomes covalently attached to the ϵ -amino group of lysine (K) residues in specific target proteins by the consecutive activity of a set of E1, E2 and E3 enzymes. First an ubiquitin-activating enzyme (E1) is charged with ubiquitin. This is accomplished by using ATP to form a high energy bond at the C-terminus of ubiquitin. Subsequently this linkage is attacked by the sulfhydryl group of the active site cysteine present in the catalytic domain of the E1 enzyme resulting in a thioester formed between the E1 and ubiquitin. Ubiquitin can now be transferred from the E1 to the catalytic core of a second class of enzymes termed ubiquitin-conjugating enzymes (E2). The E1 is released and can now charge additional ubiquitin residues. Ubiquitin bound to E2 can finally be transferred to target protein substrates, a step which is catalyzed by E3 ligases. As ubiquitin itself contains several lysine residues, which can serve as targets for the linkage of additional ubiquitin molecules, variable chains of ubiquitin can be attached. Like most posttranslational modification mechanisms ubiquitin conjugation is a reversible process. Analogous to the activity of phosphatases in protein phosphorylation, ►deubiquitinating enzymes (DUBs) counteract ubiquitin modification by cleaving the molecule from modified substrates.

The hierarchical order of E1, E2 and E3 activity correlates with an increase in enzymatic specificity which ensures selective ubiquitin modification of distinct

Ubiquitin/Proteasome. Figure 1 Ubiquitin conjugation cycle. Ubiquitin (Ub) is ligated to target substrates (S) by the consecutive activity of ubiquitin activating enzymes (E1), Ubiquitin conjugating enzymes (E2) and ubiquitin ligases (E3). Deubiquitinating enzymes (DUBs) mediate deconjugation of ubiquitin bound to substrates.

target proteins. While only two E1 enzymes and around 50 E2 enzymes have been described more than 700 E3s are encoded in the human genome. The large group of E3 enzymes is mainly responsible to exert specificity in terms of substrate recognition. The existence of more than 80 different DUBs in humans adds further complexity to the system (Fig. 1).

Ubiquitin Modification as a Signal for Proteasomal Degradation

Single ubiquitin residues can be connected to one (monoubiquitination) or multiple lysine residues (multi-monoubiquitination) of the target protein. As different lysines within ubiquitin can serve as sites for the addition of further ubiquitin molecules, variable chains of ubiquitin can be connected to the substrate (polyubiquitination). The best-characterized lysines used for ubiquitin chain prolongation are K48 and K63. As depicted in Fig. 2 the fate of ubiquitin labeled proteins depends on the mode of linkage that is formed [1].

K48-linked polyubiquitin serves as a signal for proteolytic degradation by the 26S proteasome, a multisubunit complex composed of a core protease termed 20S proteasome and a 19S regulatory particle (PA700), attached at either one or both ends. The 19S regulatory particle can further be dissected into two substructures, a lid and a base. The base harbors six homologous ATPases. The 20S proteasome consists of four heptameric rings ($\alpha 1$, $\beta 1$, $\beta 2$, $\alpha 2$) that form a cylindrical, barrel shaped structure harboring three distinct catalytic domains in the β -subunits orientated towards the internal side. These different catalytic subunits were

Ubiquitin/Proteasome. Figure 2 Functional consequences of ubiquitin linkage. Substrates (blue bars) are linked via lysine residues (K) to ubiquitin or ubiquitin chains. (a) Attachment of chains connected via Lysines in position 48 of ubiquitin (K48) targets substrates for proteasomal degradation. In contrast modification of one (b) or multiple (c) lysines by a single ubiquitin molecule mediates novel protein interactions or initiates endocytosis. Conjugation of K63-linked polyubiquitin (d) alters protein function and can also serve as a signal for endocytosis.

shown to encompass chymotrypsin-like, trypsin-like and peptidyl-hydrolase like activity.

Recognition of ubiquitin conjugated proteins, detachment of the ubiquitin chains, and unfolding is accomplished by the regulatory 19S subunit. From there the polypeptide is translocated in the lumen of the 20S core proteasome and degraded by the proteolytic activity of the β -subunits (Fig. 3). The pore can be occluded by peptides from the α -subunits and PA700 functions as a gatekeeper by removing these occlusions. The process of 26S proteasome-catalyzed proteolysis is energy dependant i.e. depends on ATP hydrolysis.

The modular structure allows adaptation to different physiological demands by the exchange of subunit components in either the regulatory or proteolytic part of the proteasome. IFN- γ for example can modify the composition of the proteasome by mediating the exchange of the regulatory complex and replacement of proteolytic subunits. Proteolytic activities in this so-called immunoproteasome are altered in a way that generation of antigenic peptides suitable to be loaded to **MHC class I proteins** is favored. Thus the ubiquitin proteasome system exerts an essential function in antigen presentation, necessary for appropriate immune defense against pathogens [2].

Ubiquitin/Proteasome. Figure 3 Structure of the proteasome. Proteasomes form a barrel like structure and are composed of a 20S core particle and the 19S regulatory subunit located at one or both ends. Two heptameric β -rings (green), which contain the proteolytic domains, are attached to two outer α -rings (orange). Substrates (blue) are recognized by the regulatory particle, unfolded and upon detachment of ubiquitin chains (red) degraded in the lumen of the 20S core proteasome.

The UPS also plays a major role in protein quality control. In a process known as endoplasmic associated degradation (ERAD), misfolded proteins, which are formed in the endoplasmic reticulum, are translocated back to the cytoplasm and degraded by the proteasome.

The ubiquitin mediated degradation of certain proteins is also one of the key mechanisms underlying cellular growth control. Thus the half life of critical regulatory proteins of the cell cycle like p53, cyclins and cyclin dependant kinases (CDKs) is directly controlled by the ubiquitin system. Furthermore cell cycle progression depends on a coordinated network of ubiquitin mediated proteolysis of these factors. Key regulators of cell cycle checkpoints and cyclin degradation are the ►anaphase promoting complex (APC) and the ►Skp1/Cul1/F-box protein complex (SCF) both acting as ubiquitin ligases.

APC is active from mid-M phase (anaphase) to the end of G1 phase and required for disconnecting sister chromatids and exit from M-Phase to G1. The complex mediates the ubiquitination of Securin and Cyclin B. Degradation of these proteins, which block mitotic progression, promotes anaphase onset and exit from mitosis.

The SCF ubiquitylates proteins from late G1 to early M phase. This complex consists of a core together with different so called F-box proteins, which are responsible for the substrate recognition. Typically

interaction of F-box proteins with their substrate involves sites of phosphorylation, so called phosphodegrons. Thus a highly coordinated and specific degradation of different cell cycle regulators in distinct activation stages can be achieved [3].

Proteasomal degradation also plays an essential role in the activation of cellular signaling pathways. A prototype for this is the control of NF- κ B signaling, which has a pivotal role in inflammatory responses. Upon stimulation the inhibitory I κ B α protein is phosphorylated and thereby becomes a target substrate for K48-polyubiquitination. Proteasomal degradation of I κ B α releases the transcription factor NF- κ B, which subsequently translocates to the nucleus and activates specific target genes.

Non-Proteolytic Functions of Ubiquitin Conjugation

In contrast to the proteasome mediated degradation of proteins linked to K48-polyubiquitin chains, monoubiquitin-, multi-monoubiquitin- or K63-linkage of ubiquitin chains is not a signal for proteasomal degradation, but controls molecular mechanisms like protein activity and interaction, DNA repair and inflammation. Mono-ubiquitination and multi-monoubiquitination are crucial events in signal termination. Upon ligand binding surface receptors like receptor tyrosine kinases or G-protein coupled receptors are hereby marked for endocytosis and degraded via the endosomal/lysosomal pathway. Another example for non-proteolytic functions is the modification of proliferative cell nuclear antigen (PCNA), a DNA processivity factor. While K63-linked polyubiquitin modification results in error-free DNA repair, mono-ubiquitination of PCNA recruits an error-prone ►translesion polymerase [4].

Ubiquitin modification of substrates can be sensed by proteins, which serve as “ubiquitin receptors.” These proteins harbor domains capable of ubiquitin binding and help to translate the signal into the proper physiological response by forming signaling complexes or activating downstream effectors. So far more than 15 different ubiquitin recognition motifs have been identified.

Ubiquitin Like Proteins

Proteins can also be modified by so-called ubiquitin-like modifiers (UBLs). These proteins have structural similarity to ubiquitin and are linked to substrates in a similar way. Like ubiquitin UBLs are conjugated by the consecutive action of E1, E2 and E3 ligases and sometimes use the same enzymes mediating ubiquitin linkage. Prominent examples for UBLs are ►SUMO, ►NEDD8, ►FAT10 or ►Interferon stimulated gene 15 (ISG15), which have been shown to affect multiple cellular functions like protein localization, cell cycle progression, DNA repair and immune function [5].

Disease Associated with Perturbations of the Ubiquitin System

In concordance with the central role of ubiquitin modification in multiple cellular functions perturbations of this system are associated with a variety of diseases. Defects in the control of cell cycle regulators by the ubiquitin proteasome system are connected to cancer progression and many E3 ligases were originally identified as oncogenes.

As the ubiquitin proteasome pathway is a main route for protein clearance it is not surprising that in proteinopathies (disease caused by aggregate prone proteins) like sporadic Parkinson- or Huntington disease proteasome activity is reduced. Autosomal recessive loss of function of the E3 ligase parkin is the molecular base for one of the most common forms of familial Parkinson disease.

In ►**Cystic fibrosis** a point mutation of the cystic fibrosis transmembrane regulator (CTFR) prevents transport of this molecule to the cell surface. Instead this otherwise functional molecule is degraded by the ERAD-ubiquitin proteasome pathway.

Pharmacological Intervention

Proteasomal inhibition represents a novel strategy in cancer treatment and the small molecule Bortezomid (PS-341, Velcade™) has been approved for the treatment of refractory and relapsed multiple myeloma, a proliferative disease of plasma cells. Bortezomid inhibits an active site in a proteasome subunit and remarkably shows selective cytotoxicity to cancer cells. Although the underlying mechanisms are not completely understood bortezomid apparently induces a cell stress response in these tumor cells followed by caspase-dependent apoptosis. Whether bortezomid is beneficial for the treatment of other proliferative disease is currently being tested in clinical trials.

An example for a specific pharmacological approach within the ubiquitin system is to prevent ubiquitin mediated degradation of the tumor suppressor p53, which is mediated by the E3 ligase HDM2. Inhibition of HDM2 ligase activity by a family of closely related 7-nitro-5 deazaflavin compounds (HLI98) was shown to stabilize p53. Protein interaction between HDM2 and p53 was effectively prevented by nutlins, a class of *cis*-imidazoline compounds, which exhibited strong anti tumor effects in mice [3, 5].

Ubl1

Synonym

Ubiquitin-like Protein 1

►SUMOylation

UDP-Glucuronyl Transferase

UDP-glucuronyl transferases (UGTs) are a group of enzymes which catalyze the transfer of UDP-glucuronyl moieties from UDP-glucuronic acid into a variety of small lipophilic agents, which can be xenobiotics (drugs, environmental toxicants, carcinogens), as well as endogenous substances (steroids, bile acids, bilirubin, hormones, dietary constituents). Genes encoding UGTs have been cloned, and there are at least 15 UGTs in the mammalian system. Genetic polymorphisms have been observed in a variety of UGTs, which are responsible for differences in drug metabolism as well as for diseases like Crigler-Najjar's and Gilbert's syndrome.

Ultrarapid Metabolizer

An ultrarapid metabolizer (UM) is a drug metabolism phenotype that describes the ability to metabolize a drug at much faster rates than expected. The term was originally created for individuals who carry an allele of CYP2D6 with two or more functional gene copies, which results in increased enzyme protein being expressed in the liver. This condition can lead to lack of response and therapeutic failure, e.g. during treatment with antidepressants that are CYP2D6 substrates. Reliable prediction of the UM phenotype is not possible based on the genotype alone but requires phenotype determination using a probe drug.

►P450 Mono-oxygenase System

Unstable Angina

Defined as worsening (in intensity or frequency) angina attacks, sudden-onset angina at rest, and angina lasting more than 15 min. As these may herald myocardial infarction, they require urgent medical attention.

► Atherosclerosis

Unwanted Effects

► Adverse/Unwanted Reaction

UPR

Unfolded protein response, when mis-folded proteins accumulate in the ER, signal transduction pathways are activated that increase the biosynthetic capacity and decrease the biosynthetic burden of the ER.

► Chaperones

Uptake Transporter

While ABC-transporters eliminate their substrates in an energy-dependent manner from the intracellular space, uptake transporters facilitate the uptake of several substances into the cell. Currently a lot of different uptake transporters have been identified; they are organized in the so called solute carrier superfamily (SLC), which consists of around 350 members. While most of these transporters are not involved in the transport of pharmacological agents, members of the SLC22A- and SLCO-family have been demonstrated to be important in this context. The SLC22A-family comprises transporters for organic cations (organic cation transporter, OCT) as well as anions (organic anion transporter, OAT), while the members of the SLCO-family are especially involved in the transport of

bulky organic anions. In contrast to ABC-transporters, which generate their driving force by hydrolysis of ATP, the SLC-transporters act as sym- or antiporters and facilitate the uptake into the cell by building up a pore.

► ABC Transporter

Urate

► Uric Acid

Urea Transporter

UT1, the urea transporter, is an integral membrane protein which is highly selective for urea and is expressed at the apical plasma membrane of principal cells of the collecting duct. The apical plasma membrane is the rate-limiting membrane for overall transcellular urea transport. The UT1 is activated by vasopressin through the V2 receptor, urea is then transported through the cell into the interstitium. In this way urea contributes to the corticocapillary osmolality gradient, which provides the driving force for water reabsorption in the inner medulla of the kidney.

► Vasopressin/Oxytocin
► Anti-gout Drugs

Uric Acid

Uric acid is the endproduct of purine metabolism in man. Uric acid has a lower solubility than its progenitor metabolites, hypoxanthine and xanthine. Impaired uric acid elimination and/or increased uric acid production result in hyperuricemia and increase the risk of gouty arthritis. At physiological pH, 99% of the uric acid molecules are actually in the form of the urate salt. A decrease in pH increases the fraction of uric acid molecules relative to urate molecules. Uric acid possesses lower solubility than urate.

► Anti-gout Drugs

Uricosstatic Drug

Uricosstatic drugs inhibit the production of uric acid through the inhibition of xanthine oxidase. Allopurinol is the only therapeutically used uricosstatic drug.

► Anti-gout Drugs

Uricosuric Drug

Uricosuric drugs increase the renal excretion of uric acid by inhibiting its renal reabsorption. Therapeutically used uricosuric drugs are benzbromarone, probenecid and sulfinpyrazone.

► Anti-gout Drugs

Urodilatin

Urodilatin is a peptide similar to atrial natriuretic peptide, which is produced in the distal tubule of the kidney and promotes sodium excretion and diuresis by acting on receptors localized on the luminal site of the collecting duct of the nephron.

► Guanylyl Cyclases

Urographic Contrast Agents

Urographic contrast agents are contrast agents which possess the characteristics of very little enteral absorption, almost no protein binding or uptake into cells, an extracellular (interstitial) distribution and glomerular filtration. These pharmacokinetics are due to very little interaction with the organism, resulting in very low toxicity, preferably nonionic (neutral) molecules.

► Radiocontrast Agents

Urokinase-Type Plasminogen Activator

Urokinase-type plasminogen activator (uPA, urokinase) is synthesized by endothelial and tumor cells as a single-chain glycoprotein (scuPA) without catalytic activity. When it is converted to a two-chain protein (tcuPA) by plasmin, an active serine protease center develops, which activates plasminogen. Thus, uPA (55 kDa) results in the amplification of fibrinolysis.

► Fibrinolytics

Urotensin

Urotensin is a cyclic peptide of 11 amino acids, cleaved from a larger prepro-urotensin II precursor peptide of about 130 amino acids. The cyclic region of the peptide, which confers biological activity, has been highly conserved in evolution from fish to mammals. In humans, prepro-urotensin II is expressed mainly in the brain and spinal cord; it is also detected in other tissues, such as kidney, spleen, small intestine, thymus, prostate, pituitary and adrenal gland. In contrast, the receptor for urotensin II is found predominately in the heart and arterial vessels. Urotensin II is the most potent mammalian vasoconstrictor yet identified, being of the order of 10-fold more potent than endothelin-1. The receptor of urotensin II has recently been identified (GPR14) and belongs to the group of G-protein-coupled receptors.

Urticaria

Urticaria is a usually transient skin reaction marked by edema and the formation of wheals, smooth, raised areas.

VACht

Vesicular acetylcholine transporters.

► Vesicular Transporters

Vacuolar-type Proton Translocating ATPase

Vacuolar-type proton translocating ATPase is a heteromeric protein complex, which appears to translocate two protons across the vesicle membrane for each ATP molecule that is hydrolyzed, generating chemical (ΔpH) and electrical ($\Delta\Psi$) gradients. Although the ATPases present on different classes of intracellular vesicle have

similar functional properties, there are some differences in subunit composition.

► Vesicular Transporters

Vanilloid Receptor

The vanilloid receptor is named for its ability to respond to molecules that contain a vanillyl moiety, such as capsaicin, the “hot” component of chili peppers or resiniferatoxin. The vanilloid receptor mediates the pain evoked by capsaicin. It has been shown to be an ion channel, which belongs to the group of “transient-receptor-potential” (TRP) cation channels. Together with at least four other TRP-channels, it forms the subgroup of TRPV channels. TRPV1 (the vanilloid receptor; VR1) is mainly expressed in the sensory nerves and is activated physiologically by heat ($> 43^\circ\text{C}$), anandamide, phosphatidylinositol 4,5-bisphosphate (PIP_2) and H^+ ions.

► TRP Channels

Varizella Zoster Virus

Varizella zoster virus (VZV) is a highly contagious herpesvirus causing chickenpox upon primary infection. After recovery, the virus stays dormant in nerve roots. Weakening of the immune system, e.g. in people over the age of 60 or under immunosuppressive therapy, can lead to reactivation of VZV. This recurrence causes shingles (herpes zoster), a painful rash that develops in a well-defined band corresponding to the area innervated by the affected nerve cells.

► Antiviral Drugs

Vascular Endothelial Growth Factor

NAPOLEONE FERRARA

Genentech, Inc., South San Francisco, CA, USA

Definition

► **Angiogenesis** is known to be fundamental to a variety of physiological processes including embryonic and postnatal development, reproductive functions and wound healing. Furthermore, neovascularization plays an important pathogenic role in tumorigenesis and in the vision loss associated with ischemic retinal disorders and the wet form of age-related macular degeneration (AMD). Research performed in recent decades has established that angiogenesis is a complex and coordinated process, which requires a series of signaling steps in endothelial and mural cells elicited by numerous families of ligands. Moreover, a variety of endogenous inhibitors of angiogenesis have been identified, including endostatin, tumstatin and vasostatin. However, despite such complexity and potential redundancy, ► **vascular endothelial growth factor (VEGF)-A** appears to be necessary for growth of blood vessels in a variety of normal and pathological circumstances. *VEGF-A* is the prototype member of a gene family that includes also placenta growth factor (PlGF), VEGF-B, VEGF-C, VEGF-D and the orf-virus encoded VEGF-E.

Basic Characteristics

VEGF-A stimulates the growth of vascular endothelial cells derived from arteries, veins and. VEGF-A induces angiogenesis in a variety of in vivo models. Inactivation of a single VEGF-A allele results in embryonic lethality, indicating that during early development there is a critical VEGF-A gene-dosage requirement. VEGF-A plays an important role also in early postnatal life. Administration of VEGF inhibitors results in growth arrest and lethality in mice when the treatment is initiated at day 1 or day 8 postnatally. VEGF is important for endochondral bone formation and growth plate angiogenesis and morphogenesis. VEGF-A blockade reversibly inhibits of skeletal growth. Another key function of VEGF-A is the regulation of the cyclical angiogenesis that occurs in the female reproductive tract.

Alternative exon splicing results in the generation of four main VEGF-A isoforms, which have respectively 121, 165, 189 and 206 amino acids after the signal sequence is cleaved (VEGF₁₂₁, VEGF₁₆₅, VEGF₁₈₉, VEGF₂₀₆). Less frequent splice variants have also been reported (reviewed in [1]).

Like VEGF₁₆₅, native VEGF is a heparin-binding homodimeric glycoprotein of 45 kDa. In contrast, VEGF₁₂₁ lacks heparin-binding properties. VEGF₁₈₉

and VEGF₂₀₆ bind to heparin with affinity comparable to that of bFGF. Whereas VEGF₁₂₁ is a freely diffusible protein, VEGF₁₈₉ and VEGF₂₀₆ are almost completely bound to heparin-like moieties in the cell surface or in the extracellular matrix. VEGF₁₆₅ has intermediate properties in terms of heparin-affinity and bioavailability. The long isoforms may be released in a diffusible form by proteolytic cleavage. Early studies showed that plasmin is able to cleave VEGF₁₆₅ at the COOH terminus, generating VEGF₁₁₀, a bioactive fragment consisting of the first 110 NH₂-terminal amino acids. Recent studies have shown that various matrix metalloproteinases (MMPs) -especially MMP-3- may also cleave VEGF₁₆₅ to generate diffusible, non-heparin binding fragments.

VEGF-A binds two highly related ► **receptor tyrosine kinases (RTK)**, VEGFR-1 and VEGFR-2. VEGFR-1 was the first RTK to be identified as a VEGF receptor more than a decade ago, but the precise function of this molecule is still debated in the field [1]. The functions and signaling properties of VEGFR-1 appear to vary with the developmental stage and the cell type, e.g. endothelial versus non-endothelial cells. VEGFR-1 binds not only VEGF-A but also PlGF and VEGF-B and fails to mediate a strong mitogenic signal in endothelial cells. Non-mitogenic functions mediated by VEGFR-1 in the vascular ► **endothelium** include the release of growth factors and the induction of MMP-9. Furthermore, VEGFR-1 mediates hematopoiesis and monocyte chemotaxis in response to VEGF-A or PlGF.

VEGFR-2 also binds VEGF-A with high VEGF-C and VEGF-D may also bind and activate VEGFR-2, following their proteolytic cleavage. The key role of VEGFR-2 in developmental angiogenesis and hematopoiesis is underscored by lack of vasculogenesis and failure to develop blood islands and organized blood vessels in Flk-1 null mice. There is now agreement that VEGFR-2 is the major mediator of the angiogenic and permeability-enhancing effects of VEGF-A.

Neuropilin-1 (NRP1), a molecule that had been previously shown to be implicated in axon guidance as a receptor for members of collapsin/semaphorin family, has been characterized as a which interacts with the heparin-binding VEGF isoforms.

Drugs

Many tumor cell lines secrete VEGF-A in vitro (reviewed in [1]) In situ hybridization studies have demonstrated that the VEGF mRNA is expressed in many human tumors A variety of transforming events also lead to induction of VEGF gene expression. Oncogenic mutations or amplification of ras lead to VEGF up-regulation. Renal cell carcinomas have a particularly high level of VEGF-A expression, consistent with the notion that inactivating mutation in the von Hippel-Lindau (VHL) tumor suppressor gene, resulting in high transcription of the hypoxia-inducible factor

(HIF)-target genes under normoxic conditions, occur in ~50% of such tumors.

Monoclonal antibodies targeting VEGF-A have been reported to inhibit the growth of several tumor cell lines in nude mice. Inhibition of tumor growth has been achieved also with other anti-VEGF-A treatments, including small molecule inhibitors of VEGFR-2 signaling (reviewed in [2]), anti-VEGFR-2 antibodies.

Although tumor cells frequently represent the major source of VEGF-A, tumor-associated stroma is also a site of VEGF production. Tumor-derived PDGF-A may be especially important for the recruitment of an angiogenic stroma that produces VEGF-A and potentially other angiogenic factors.

Combining anti-VEGF treatment with chemotherapy or radiation therapy results in a greater anti-tumor effect than either of these therapies alone.

Several VEGF inhibitors have been developed as anti-cancer agents. These include a humanized anti-VEGF-A monoclonal antibody (bevacizumab), an anti-VEGFR-2 antibody, various small molecules inhibiting VEGFR-2 signal transduction [2], and a VEGF receptor chimeric protein.

The clinical trial that resulted in FDA approval of bevacizumab (February 2004) was a randomized, double-blind, phase III study in which bevacizumab was administered in combination with bolus-IFL (irinotecan, 5FU, leucovorin) chemotherapy as first-line therapy for previously untreated metastatic colorectal cancer [3]. Median survival was increased from 15.6 months in the bolus-IFL + placebo arm to 20.3 months in the bolus-IFL + bevacizumab arm.

The clinical benefit of bevacizumab is being evaluated in a broad variety of tumor types and lines of therapy including combination studies with several biologicals. Bevacizumab, combined with weekly paclitaxel in women with previously untreated metastatic breast cancer provided a significant improvement in the primary endpoint of progression free survival relative to paclitaxel alone. Combining bevacizumab with paclitaxel and carboplatin in patients with previously untreated, nonsquamous, NSCLC provided a significant improvement in the primary endpoint of overall survival. Also, combining bevacizumab with 5-fluorouracil, leucovorin, and oxaliplatin (FOLFOX) in patients with previously treated metastatic colorectal cancers provided a significant improvement in the primary endpoint of survival.

Preliminary, encouraging data with bevacizumab have been reported in a number of other cancers including renal cell ovarian and prostate. Taken together, these findings suggest that targeting VEGF-A with a neutralizing antibody may be a broadly applicable approach to the treatment of human cancer.

Besides bevacizumab, several other types of VEGF inhibitors are being developed. Among these, a variety of small molecule RTK inhibitors targeting the VEGF

receptors are at different stages of clinical development. The most advanced are SU11248 (sunitinib) and Bay 43-9006 (nexavar). SU11248 inhibits tyrosine phosphorylation of VEGFRs, platelet-derived growth factor receptors (PDGFRs), c-kit and Flt-3 and has shown efficacy in imatinib-resistant gastrointestinal stromal tumor and renal cell carcinoma. SU11248 was FDA-approved for the treatment of imatinib-resistant gastrointestinal stromal tumor. Also, Bay 43-9006 results in a significant increase in progression-free survival in patients with advanced renal cell carcinoma and the drug has been approved by the FDA for this indication.

Age-related macular degeneration (AMD) is the most common cause of severe, irreversible vision loss in the elderly. AMD is classified as nonexudative (dry) or exudative (wet or neovascular) disease. Although the exudative form accounts for ~10–20% of cases, it is responsible for 80–90% of the visual loss associated with AMD. Three pharmacologic therapies for neovascular AMD have been approved by the FDA: verteporfin (Visudyne[®]) photodynamic therapy (PDT), pegaptanib and ranibizumab [4]. Pegaptanib sodium is a pegylated oligonucleotide aptamer that binds to and inactivates VEGF₁₆₅. Pegaptanib sodium prevented moderate vision loss in 70% of subjects compared with 55% for the control group at one year. However, on average, patients in the pegaptanib sodium group lost ~8 letters at one year, compared with a loss of ~15 letters in the sham injection group. Ranibizumab is a recombinant, humanized Fab that binds to and potently neutralizes the biological activities of all known human VEGF-A isoforms, as well as the proteolytic cleavage product VEGF₁₁₀. Pivotal trial evaluating the safety and efficacy of ranibizumab in randomized subjects with wet AMD to monthly sham injections or monthly intravitreal injections of one of two doses of ranibizumab have demonstrated a significant benefit, including increases in visual acuity, in approximately one third of the patients treated with ranibizumab.

Perspectives

Research conducted for almost two decades has established that VEGF-A is important for regulation of the normal angiogenesis processes. Moreover, VEGF inhibition has been shown to suppress pathological angiogenesis in a variety of cancer models, leading to the clinical development of a variety of VEGF inhibitors. Definitive clinical studies have proved that VEGF inhibition, by means of bevacizumab in combination with chemotherapy, provides a significant clinical benefit, including increased survival, in patients with previously untreated metastatic colorectal cancer [3]. Furthermore, SU11248 and Bay 43-9006 have been recently approved by the FDA for metastatic renal cell carcinoma and their mechanism of tumor suppression consists, at least partly, of inhibition of VEGF signaling.

A particularly active area of research concerns the elucidation of the mechanisms of refractoriness or resistance to anti-VEGF therapy. Tumor cell-intrinsic or treatment-induced expression of angiogenic factors may be implicated. Very recent studies have provided evidence that, at least in some murine models, refractoriness to anti-VEGF therapy is related to the ability of the tumor to recruit CD11b+Gr1+ myeloid cells, which promote angiogenesis [5]. It remains to be established whether these findings also apply to human tumors.

Reliable markers are needed to monitor the activity of antiangiogenic drugs. Circulating endothelial cells and their progenitor subset are a potential candidate, as is MRI dynamic measurement of vascular permeability/flow in response to angiogenesis inhibitors, but neither has been clinically validated.

VEGF inhibitors have demonstrated a marked clinical benefit also in wet AMD. Blockade of all VEGF-A isoforms and bioactive fragments with ranibizumab not only slowed down vision loss, but unexpectedly appears to have the potential to enable many AMD patients to obtain a meaningful and sustained gain of vision. Further research is needed to determine whether the vision gain conferred by ranibizumab extends beyond 24 months and whether additional intraocular neovascular syndromes may benefit from this treatment.

Vasoactive Intestinal Peptide

Vasoactive Intestinal Peptide (VIP) is a 28-amino acid peptide, which has a variety of actions as a neuroendocrine hormone and a putative neurotransmitter. It

stimulates prolactin secretion from the pituitary and catecholamine release from the adrenal medulla. It acts also on cells of the immune system, stimulates electrolyte secretion and relaxes smooth muscles. VIP is produced from a precursor polypeptide (prepro-VIP). Two G-protein coupled receptors have been described which mediate the actions of VIP, VPAC₁ (VIP₁, PACAP type II) and VPAC₂ (VIP₂, PACAP-3). Both receptors also respond to pituitary adenylate cyclase-activating polypeptide (PACAP) and are coupled via G_s in a stimulatory fashion to adenylyl cyclases. In the autonomic nervous system, VIP is part of the NANC transmitter system. It is typically coexpressed with acetylcholine in postganglionic parasympathetic neurons, and functions as a cotransmitter which is involved in the induction of vasodilatation or bronchodilatation.

- ▶ Synaptic Transmission
- ▶ Cotransmission

Vasoconstrictor

Vasoconstrictors are drugs which increase the tone of smooth muscle cells in the vasculature. They include sympathomimetic amines and certain eicosanoids and peptides (angiotensin, vasopressin, urotensin or endothelin).

- ▶ Smooth Muscle Tone Regulation

Vasodilator

Vasodilators are a group of drugs, which relax the smooth muscle cells of the blood vessels and lead to an increased local tissue blood flow, a reduced arterial pressure and a reduced central venous pressure. Vasodilators reduce the cardiac pre-load as well as after-load and thereby reduce cardiac work. They are used in a variety of conditions including hypertension, cardiac failure and treatment/prevention of angina pectoris. Major groups are Ca²⁺-channel blockers (e.g. dihydropyridines), NO-donors (e.g. organic nitrates), K⁺-channel openers (minoxidil), phosphodiesterase inhibitors (e.g. sildenafil), Rho-kinase inhibitors (e.g. Y27632) or substances with unknown mechanism of action (e.g. hydralazine). Inhibitors of the

renin-angiotensin-system (e.g. ACE inhibitors, angiotensin II receptor antagonists or renin inhibitors) also act as vasodilators.

► Smooth Muscle Tone Regulation

Vasopeptidase Inhibitors

Vasopeptidase inhibitors are a group of drugs (e.g., omapatrilat, sampatrilat) which have a dual mechanism of action in that they inhibit two metalloprotease enzymes, neutral endopeptidase (NEP) and angiotensin converting enzyme (ACE). This results in increased availability of natriuretic peptides that exhibit vasodilatory effects (NEP-inhibition) and in reduced formation of angiotensin II (ACE-inhibition). Since these peptidases are intimately concerned with regulating the structural and functional properties of the heart and circulation, they were named “vasopeptidases.” Vasopeptidase inhibitors have been developed for the treatment of hypertension or congestive heart failure.

Vasopressin/Oxytocin

RICARDO HERMOSILLA

Department of Molecular Pharmacology and Cell Biology, Charité Medical University Berlin, Berlin, Germany

Leibniz-Institute of Molecular Pharmacology (FMP), Berlin, Germany

Synonyms

Vasopressin: 8-arginine-vasopressin (AVP); Antidiuretic hormone (ADH); Lysipressin; Oxytocin (OT); 8-leucine-vasotocin

Definition

AVP plays a central role in water homeostasis of terrestrial mammals, leading to water conservation by the kidney. OT is primarily involved in milk ejection, parturition and in sexual and maternal behaviour. Both hormones are peptides secreted by the neurohypophysis, and both act also as neurotransmitters in the central nervous system (CNS). The major hormonal targets for AVP are the renal tubules and vascular myocytes. The hormonal targets for OT are the myoepithelial cells

that surround the alveolar channels in the mammary gland and the uterus. AVP plays a central role in pathological processes like ►diabetes insipidus (DI) and the syndrome of inappropriate antidiuretic hormone secretion (SIADH).

Basic Characteristics

AVP and OT are cyclic nonapeptides with a disulphide bridge between the cysteine residues 1 and 6, resulting in a six-amino acid ring and a COOH-terminal α -amidated three-residue tail. OT differs only in two amino acids from AVP: Ile in position 3, which is essential for OT receptor (OTR) stimulation and Leu in position 8. AVP has a Phe in position 3 and an Arg in position 8. Arg 8 is essential for acting upon vasopressin receptors (Fig. 1). Lysipressin, found in pigs and some marsupials, has a Lys in position 8 [1].

AVP and OT are synthesized initially as preprohormones consisting of a signal peptide, the hormone, the binding protein neurophysin and, only for vasopressin, the glycosylated peptide copeptin. The preprohormone is processed into its final products in neurons located with their cell bodies in the supraoptic (SON) and paraventricular nuclei (PVN) of the hypothalamus. The axons of these cells project to form the neurohypophysis, where AVP and OT are secreted after appropriate stimuli. Two populations of neurons exist in the PVN: magnocellular neurons (with large cell bodies), terminating in the neurohypophysis, and parvocellular neurons (with smaller cell bodies), terminating in the median eminence, brain stem, spinal cord, limbic and olfactory areas. Parvocellular neurons terminating in the median eminence are the major source of hypophysiotropic corticotrophin releasing factor (CRF), which is released together with AVP (and possibly also OT) into the hypophysial portal circulation. High concentrations of CRF and AVP are transported by this route to the anterior pituitary gland, where they regulate the secretion of adrenocorticotrophic hormone (ACTH). A group of oxytocinergic neurons from the PVN project to extrahypothalamic brain areas (see below) and to the spinal cord, which are involved in the control of yawning, erectile function and copulation. Magnocellular and parvocellular neurons produce either AVP or OT [2].

Vasopressin/Oxytocin. Figure 1 Amino acid sequence of AVP and OT. The disulphide bridge between Cys 1 and Cys 6 is shown.

Several other areas of the CNS have also been described to possess nonmagnocellular OT-secreting neurons, like the hypothalamic nucleus, thalamic nuclei, hippocampus, amygdala, olfactory bulbs and others, suggesting a role for OT as neurotransmitter in these areas. Within the CNS, AVP regulates neuronal communication, feeding, thermoregulation and behavioural functions such as memory, social and sexual processes, anxiety and depression. Both neuropeptides are also an integral part of the mammalian emotional circuitry and are associated with the emergence of social bonding, parental care, stress regulation, social communication and emotional reactivity.

In addition, several other organs, like the heart, ovary, amnion, chorion, decidua, testis, epididymis and prostate, have been reported to synthesize OT, suggesting a paracrine role for this hormone in these tissues. Ectopic AVP production by lung cancer cells or other neoplasms has been described in humans, leading to ►the syndrome of inappropriate antidiuretic hormone secretion.

The stimuli for AVP secretion are plasma hyperosmolality (high sodium), hypovolaemia and hypotension. In addition, potent stimuli are nausea and vomiting, a less potent stimulus is hypoglycaemia. Several drugs induce AVP secretion, either directly, indirectly or by unknown mechanisms, like vincristine, cyclophosphamide, tricyclic antidepressants, apomorphine, nicotine, high doses of morphine and lithium. Lithium however also inhibits the renal effects of AVP. The secretion of AVP is suppressed by ►atrial natriuretic peptide (ANP), ethanol, opioids (particularly dynorphin), low doses of morphine, phenytoin, dopaminergic antagonists (fluphenazine, haloperidol, promethazine) and carbamazepine, which also has a renal antidiuretic action.

OT secretion is triggered by the stimulation of the nipples, resulting in the milk ejection reflex, and by the distension of cervix and vagina during labour. OT release is also stimulated by plasma hyperosmolality (high sodium) and hypervolaemia, suggesting a regulatory role in natriuresis and blood volume for this hormone. Secretion also occurs during sexual arousal and ejaculation. Higher OT levels are associated with socially pleasant sensory experiences, such as touch and smell. OT secretion is suppressed by alcohol and opioids.

AVP and OT elicit their physiological and pharmacological roles through cell surface receptors. The canonical receptors for AVP and OT form a subfamily within the ►G protein-coupled receptor (GPCR) family. Three different subtypes of AVP receptors are known ($V_{1A}R$, $V_{1B}R$, V_2R). A fourth receptor that binds AVP is the vasopressin-activated calcium-mobilizing receptor (VCAM-1/cul-5) that belongs to the cullin gene family. So far, there is only one type of OTR known.

AVP Receptors

The $V_{1A}R$ and $V_{1B}R$ selectively couple to ►heterotrimeric GTP-binding proteins (G proteins) of the $G_{q/11}$ family, which mediate the activation of distinct isoforms of phospholipase C_β (PLC_β) and extracellular-regulated kinase (ERK1/2) (Fig. 2). Both receptors have been reported to activate also PLD and PLA_2 . Activated V_1Rs catalyse the dissociation of the heterotrimeric G proteins into the $G_{\alpha q/11}$ subunit and the $G_{\beta\gamma}$ heterodimer. The activated $G_{\alpha q/11}$ subunit stimulates PLC_β , which catalyses the hydrolysis of phosphatidylinositol 4,5-bisphosphate into inositol 1,4,5-triphosphate (IP_3) and 1,2-diacylglycerol (DAG). IP_3 diffuses through the cytosol and binds to the IP_3 receptor (IP_3R), an intracellular ion channel that mediates the release of calcium from the endoplasmic reticulum (ER). DAG activates protein-kinase C (PKC) and the ERK1/2 pathway, which leads to the activation of Elk and c-Myc inducing cell growth and differentiation. The V_2R activates the G protein G_s , leading to the activation of adenylyl cyclase (AC) and consequently to an increase of cytosolic cyclic adenosine-monophosphate (cAMP). Stimulation of V_2Rs also leads to β -arrestin recruitment to the plasma membrane and to the activation of ERK1/2; a G_s -dependent and -independent pathway has been proposed, involving PKA, Raf-1, c-Src, receptor tyrosine kinase transactivation (MMP, HB-EGF, EGRF), MEK1/2 (Fig. 2). The precise function of V_2R -regulated ERK1/2 activity in vivo is still unknown, but it might play a role in abnormal cell growth or differentiation (polycystic kidney disease, tumor growth).

The $V_{1A}R$ mediates the extrarenal actions of AVP such as vasoconstriction, platelet aggregation and hepatic glycogenolysis by increasing cytosolic calcium concentrations. The $V_{1A}R$ is expressed in the liver (hepatocytes surrounding central veins), vascular and gastrointestinal smooth muscle, bladder, myometrium, platelets, the renal medulla, iris and throughout the brain. It is believed that $V_{1A}R$ function is essential for an efficient response to hypovolemic stress conditions, e.g. hemorrhagic shock, where AVP is secreted copiously. The $V_{1A}R$ in the brain is proposed to mediate the effects of AVP on memory, learning, antipyresis, brain development, selective aggression, partner preferences in rodents, cerebrospinal fluid production and analgesia. The $V_{1B}R$ is mainly expressed in humans in the anterior pituitary, adrenal medulla and kidneys, and believed to be present in the CNS. The activation of $V_{1B}R$ potentiates the response to CRF in the anterior pituitary lobe that leads to ACTH secretion into the systemic circulation and is involved in the genesis of anxiety and depression.

The V_2R is expressed in collecting duct cells; in rodents it is also expressed in cells of the thick ascending limb of Henle's loop (TAL). V_2R -induced G_s -mediated activation of AC, the subsequent increase

Vasopressin/Oxytocin. Figure 2 Schematic representation of the major signal transduction pathways of AVP and OT receptors. The signal transduction pathway and effects of OTRs do vary depending on the receptor's plasma membrane localization, e.g. in caveolae. Pharmacological intervention is possible by the use of selective agonists (AVP or OT analogues) or receptor antagonists. EGFR, epidermal growth factor receptor; HB-EGF, heparin-binding EGF-like growth factor; MMP, matrix metalloproteinase.

in cytosolic cAMP and the stimulation of PKA lead to the final step of the antidiuretic actions of AVP: the exocytic fusion of intracellular vesicles bearing the selective water channel ►aquaporin-2 (AQP2) with the plasma membrane of principal collecting duct cells (short-term regulation). The water permeability of the cells increases dramatically (10–20 fold), allowing not only the entry of water via the apical membrane but also the exit across the basolateral membrane through constitutively expressed water channels (AQP3 and AQP4). Due to the osmotic gradient of the inner medulla, water accumulates in the interstitium and is taken up by the circulation. AVP withdrawal is associated with endocytic retrieval of ►AQP2 back into intracellular vesicles. Activation of V₂R also stimulates the synthesis of ►AQP2 (long-term regulation) in principal cells; it also regulates the expression of the ►urea transporter A1 (►UT-A1) and activates it via PKA, thereby increasing urea absorption. In addition, it regulates the long-term expression and activation of the Na⁺-K⁺-2Cl⁻ symporter in the TAL. It enhances Na⁺ transport in the collecting duct by an increased expression of subunits of the epithelial sodium channel (ENaC). These effects contribute to an increase in medullary osmolality and thereby to an enhancement of renal water conservation. There is strong evidence for extrarenal V₂R expression in lungs, heart and skeletal muscle, inner ear, small-cell lung cancer, colon epithelial and endothelial cells. The administration of a V₂R agonist (desmopressin) to patients suffering from X-linked congenital nephrogenic DI (*AVPR2* gene defect) does not result in the usual increase of factor VIII, von Willebrand factor and tissue plasminogen activator in the blood. The therapeutic use of desmopressin for the treatment of coagulation disorders, like haemophilia A and von Willebrand's disease (type I), relies on the existence of extrarenal V₂R.

The VACM-1 receptor is a membrane-associated protein with a single putative transmembrane domain that binds selectively AVP ($K_D = 2$ nM), but cannot discriminate between V₁R and V₂R analogues. It is expressed in endothelial and medullary collecting duct cells and upon stimulation by AVP. It induces a mobilization of cytosolic-free Ca²⁺, decreases cAMP production and inhibits cellular growth via MAPK phosphorylation and p53 expression. The mechanism of action and physiological functions of this new receptor are not well understood, but it seems to participate in the regulation of AVP induced signal transduction pathways or of a yet unidentified peptide.

Congenital Nephrogenic Diabetes Insipidus (X-linked, Autosomal)

Congenital nephrogenic diabetes insipidus (NDI) is a rare disease, characterized by an inability to concentrate urine despite normal or elevated AVP plasma

concentrations. The syndrome is characterized by polyuria and polydipsia. If not treated, episodes of dehydration can result in mental retardation in the newborn. Other symptoms include vomiting, anorexia, failure to thrive and constipation. The more common form is X-linked NDI, caused by different mutations in the *AVPR2* gene. The excessive water loss through the kidney is due to an improper V₂R function. Mutations of the V₂R can lead to: (i) an altered affinity for AVP (►K_D increased) or (ii) an altered coupling to the G_s protein (►EC₅₀ increased), (iii) an altered mRNA synthesis or stability and (iv) the most common form, an altered transport to the cell surface (intracellular retained receptors). The autosomal NDI form, caused by mutations in the *AQP2* gene, is extremely rare [3]. In contrast to patients suffering from the X-linked NDI form, patients with the autosomal form show the typical coagulation response to desmopressin.

OTR

There is only one OTR known so far. Nevertheless, ►posttranslational modifications, localization in special plasma membrane compartments (lipid rafts or caveolae) and interactions with downstream signal transduction components modify OTR signalling. OTRs activate PLC_β and increase cytosolic Ca²⁺ (Fig. 2). These effects are transduced by the activation of the G protein G_{q/11}. The increase in cytosolic calcium concentrations is the main trigger for smooth muscle contraction. OTR activation also leads to activation of ERK1/2 in myometrial and endothelial cells (proliferation), an effect that involves βγ release from G_{q/11} and transactivation of the EGFR. In decidua activation of OTR induces PGF_{2α} release, which enhances uterine contractions, cervical ripening and luteolysis. This effect is G_i- and G_{q/11}-dependent and involves a Ca²⁺-mediated translocation of PLA₂ from the cytoplasm to cell membranes, in addition to the activation of PLA₂ by MAPK. When only a minor fraction of OTRs is located in lipid rafts (caveolae), they inhibit cell proliferation (via G_i, PLC, c-Src, PI3K, EGFR transactivation and persistent ERK1/2 activation), but when targeted to lipid rafts they have a strong mitogenic effect (via G_{q/11}, βγ release, EGFR transactivation and transient ERK1/2 activation) (Fig. 2).

OTRs are mainly expressed in myoepithelial cells of the galactiferous channels and the myometrium. The OTRs in vascular endothelial cells, renal epithelial cells (macula densa, proximal tubule) and cardiomyocytes induce the production of NO (vasodilation), natriuresis and release of ANP, respectively. The endometrium, ovary, amnion, testis, epididymis, prostate and thymus also express the OTR supporting a paracrine role of this peptide. Osteoblasts, osteoclasts, pancreatic islets cells, adipocytes, and several types of cancer cells also express OTRs. More over, expression of the OTR

has also been described in the brain (hypothalamus, nucleus accumbens, neurons and astrocytes), with patterns differing in sex, age and species, which may be related to differences in partnership, sexual, maternal and social behaviour.

There are several hints indicating a strong interaction between OTR expression and sexual hormones. During pregnancy, high plasma progesterone levels promote uterine relaxation and inhibit the function of the OTR by both genomic and nongenomic mechanisms. The myometrial OTRs are abundantly expressed in the last days of pregnancy, after estrogen secretion. Possibly progesterone and estrogens act in opposing manner on the function, expression, and/or regulation of OTRs. However, despite the striking dependence of the OT system on gonadal hormones, the human *OTR* gene does not contain a classical steroid responsive element and nongenomic mechanisms are not well characterized. Mechanical stretch is an important local stimulus for myometrial OTR expression at term. Although OT plasma concentrations remain relatively constant until labour itself, uterine sensitivity to OT is markedly increased around onset of labour. This is associated with a strong increase in the density of myometrial OTRs, reaching a peak during early labour (200 times higher than in the nonpregnant state). Thus, at onset of labour, OT can stimulate uterine contractions at plasma concentrations that are ineffective in the nonpregnant state. After parturition, the concentrations of uterine OTR rapidly decline. Downregulation of OTR may be necessary to avoid unwanted contractile responses during lactation, when OT plasma levels are raised [1].

Although the OT system may be regarded as a key regulator of labour, in OT-deficient mice, parturition remains unaffected. Moreover, OTR knockout mice do deliver in a normal fashion, but the offspring die during the very first days of life, due to starving, as the milk ejection reflex is absent in these animals. These experiments show that the OT system is not essential for labour or reproductive behaviour (at least in mice), but for the milk ejection reflex, which is fundamental for litter survival.

OTR is also expressed in male reproductive tissues, like testis, epididymis and in the prostate. OT increases the resting tone of prostatic tissue from guinea pig, rat, dog and human. The activation of these receptors could lead to the contraction of the prostate and the resulting expulsion of prostatic secretions during ejaculation.

Drugs

AVP Receptors

Agonists

AVP is mainly used in the replacement therapy in ►congenital diabetes insipidus (CDI), but has only a short effect of 4–6 h. It is also used in the therapy of gastrointestinal haemorrhage, as a local vasoconstrictor,

as a vasopressor during cardiac arrest and in the treatment of adult shock-refractory ventricular fibrillation. The major disadvantages of AVP in ►CDI therapy are its nonselective effects ($V_{1A}/V_{1B}R$ stimulation), short duration and contraction of the uterus and gastrointestinal tract. Otherwise, AVP is used to treat postoperative ileus and abdominal distension and to eliminate gas before abdominal radiographs.

The synthetic AVP analogue 1-deamino,8-D-arginine vasopressin (dDAVP) or desmopressin, is a mixed $V_{1B}/V_{2}R$ agonist in human. Its antidiuretic effect is longer than AVP and it does not cause vasoconstriction and is better tolerated than AVP. Desmopressin is used in the treatment of ►CDI, by intranasal spray application. It is also used in the therapy of nocturnal enuresis in some countries. Another important clinical application of desmopressin is the treatment of haemophilia A (factor VIII) and von Willebrand's disease (type I). Lysipressin (8-lysine-vasopressin) is also available for intranasal application. Terlipressin (triglycyl-lysine-vasopressin) a synthetic analogue of lysipressin is released in a slow and sustained manner permitting intermittent administrations. Side effects of desmopressin include vasodilatation that causes facial flushing, headache, nausea and occasional tingling. The major complication of AVP, lysipressin, desmopressin and terlipressin is water intoxication with hyponatraemia (iatrogenic syndrome of inappropriate antidiuretic hormone secretion).

OPC-51803 is a highly selective $V_{2}R$ agonist and may prove useful for the treatment of ►CDI, urinary incontinence, enuresis and pollakiuria. It has a much higher bioavailability after oral application than desmopressin.

Antagonists

Several nonpeptidic, orally active vasopressin receptor antagonists have been developed. The dual $V_{1A}/V_{2}R$ antagonist conivaptan is used in the treatment of hyponatraemia and could also become useful for diseases such as congestive heart failure, in which increased peripheral resistance and dilutional hyponatraemia both are present [4]. Side effects of conivaptan include headache, injection site reactions, vomiting, diarrhoea, constipation and thirst.

Relcovaptan (SR-49059) is a selective, orally active $V_{1A}R$ antagonist that prevents pain of primary dysmenorrhea and inhibits preterm labour and could be useful in the treatment of Raynaud's phenomenon. The selective $V_{1B}R$ antagonist SSR149415 showed beneficial effects in the treatment of depression and anxiety in several animal models.

Several selective $V_{2}R$ antagonists have also been developed (tolvaptan, lixivaptan, OPC-31260, Satavaptan, RWJ-351647). These substances, together with conivaptan, are also known as "►aquaretic agents".

Their main applications are the treatment of water disorders caused by congestive heart failure, liver cirrhosis, nephrotic syndrome, ocular hypertension and syndrome of inappropriate antidiuretic hormone secretion. Tolvaptan (OPC-41061) was successfully applied for the treatment of euvolemic or hypervolaemic hyponatraemia in two phase 3 studies (SALT-1 & SALT-2). It could also be used for polycystic kidney disease, since it antagonizes effectively the proliferative responses to the ►cAMP - B-Raf – Ras - ERK1/2 pathway. Some antagonists (conivaptan, relcovaptan, Satavaptan) are also known to have specific “chaperonal” activity, helping intracellularly retained NDI-causing V₂R mutants to fold to a native conformation and rescue their functional activity (►pharmacological chaperone). This is a new promising therapeutic approach for the treatment of congenital NDI and several other hereditary diseases that result from protein misfolding and intracellular transport.

OTR Agonists

OT is mainly used intravenously for labour induction without major side effects. It is also used to reduce postpartum bleeding and to facilitate milk ejection in mastitic cows. Carbetocin, a long-acting OT analogue with modifications in the terminal cysteine residue and in the disulphide bridge, is used to control bleeding after delivery. Orally available nonpeptide compounds are being developed for the treatment of various conditions including male erectile dysfunction, labour promotion and control of postpartum bleeding and milk letdown.

Antagonists

Atosiban is a combined OTR and V_{1A}R antagonist peptide that is successfully used intravenously as a tocolytic in preterm labour. This antagonist was shown to inhibit uterine contractions in women with threatened and established preterm labour, with a favourable side effect profile, when compared to ritodrine (β₂-sympathomimetic). A potential use of atosiban is in benign prostate hyperplasia, as it is known that OTRs play an important role in prostate contraction. Interestingly, atosiban acts also as a biased or protean agonist. It acts as an antagonist over the G_{q/11}-mediated pathway (uterus contraction) and as an agonist over the G_i-mediated pathway (inhibition of cell growth) of the OTR. This particular phenomenon is termed “agonist directed trafficking of receptor stimulus”. Substance-P analogues (SP-G/-D) are an example of protean agonists over V_{1A}R.

Barusiban is a long-acting, selective antagonist of OTR that is in development for preterm labour. It has a 300-fold higher affinity for the OTR than for the V_{1A}R and hence more selective action than atosiban on myometrial tissues. The duration of action may be longer than that of atosiban, providing the convenience

of less frequent administration in the clinic. Other nonpeptide OTR antagonists are under development [5].

Venus Flytrap Module

Synonyms
VFT Module

Definition

The VFT module is a protein module first characterized in bacteria, where it is involved in the transport through the periplasm of small molecules like amino acids, ions, peptides and sugars. Since then, a similar protein module has been shown to regulate the activity of operons (like the amidase operon that controls the expression of the amidase enzyme) and to be in the guanylyl cyclase and metabotropic glutamate receptors, for which it constitutes the ligand binding domain. This module is composed of two lobes interconnected by two or three linkers. In most cases, the two lobes are separated by a wide cleft in which the ligand binds. Binding of the ligand stabilizes a closed form of the protein, so that the ligand is trapped like an insect trapped between the two lobes of the leaves of the carnivorous plant “Venus Flytrap”.

Definition

The exocytotic release of neurotransmitters from synaptic vesicles underlies most information processing by the brain. Since classical neurotransmitters including monoamines, acetylcholine, GABA, and glutamate are synthesized in the cytoplasm, a mechanism is required for their accumulation in synaptic vesicles. Vesicular transporters are multitransmembrane domain proteins that mediate this process by coupling the movement of neurotransmitters to the proton electrochemical gradient across the vesicle membrane.

Basic Characteristics

Synaptic vesicles isolated from brain exhibit four distinct vesicular neurotransmitter transport activities: one for monoamines, a second for acetylcholine, a third for the inhibitory neurotransmitters GABA and glycine, and a fourth for glutamate [1]. Unlike Na⁺-dependent plasma membrane transporters, the vesicular activities couple to a proton electrochemical gradient ($\Delta\mu_{H^+}$) across the vesicle membrane generated by the vacuolar H⁺-ATPase (▶ vacuolar type proton translocating ATPase). Although all of the vesicular transport systems rely on $\Delta\mu_{H^+}$, the relative dependence on the chemical and electrical components varies (Fig. 1). The

Vesicular Transporters. Figure 1 Stoichiometry and bioenergetic dependence of the vesicular neurotransmitter transporters. The proton electrochemical gradient ($\Delta\mu_{H^+}$) that drives neurotransmitter transport into secretory vesicles is generated by the vacuolar-type proton translocating ATPase and consists of a 1–2 unit pH gradient (ΔpH) and a transmembrane potential ($\Delta\Psi$) $\sim +70$ mV (inside positive). The different families of transport proteins exhibit different dependences on these two components of the gradient, with VMATs and VAcHT most dependent on ΔpH , VGLUTs on $\Delta\Psi$, and VGAT dependent on both. These differences in dependence on $\Delta\mu_{H^+}$ reflect differences in the stoichiometry of transport. Abbreviations: VMATs, vesicular monoamine transporters; VAcHT, vesicular acetylcholine transporter; VGAT, vesicular GABA transporter.

vesicular monoamine and acetylcholine transport systems depend primarily on the chemical component of this gradient (ΔpH), whereas transport of GABA relies on both ΔpH and the electrical component of the gradient ($\Delta\Psi$), and glutamate transport almost exclusively on $\Delta\Psi$. These bioenergetic differences appear to reflect differences in protein structure.

Vesicular Monoamine Transport

The vesicular monoamine transporters (VMATs) were identified in a screen for genes that confer resistance to the parkinsonian neurotoxin MPP⁺ [2]. The resistance apparently results from sequestration of the toxin inside vesicles, away from its primary site of action in mitochondria. In addition to recognizing MPP⁺, the transporters mediate the uptake of dopamine, serotonin, epinephrine, and norepinephrine by neurons and endocrine cells. Structurally, the VMATs show no relationship to plasma membrane monoamine transporters.

VMAT1 is expressed in the adrenal medulla, by small intensely fluorescent cells in sympathetic ganglia, and by other nonneural cells that release monoamines. In contrast, VMAT2 is expressed by neuronal populations in the nervous system. The substrate specificity for the two isoforms is similar, but VMAT2 has a somewhat higher apparent affinity for all monoamines than VMAT1. In addition, only VMAT2 appears able to transport histamine, consistent with its expression by mast cells.

Transport by the VMATs involves the exchange of two luminal protons for one cytoplasmic, apparently protonated molecule of transmitter, predicting accumulation of transmitter inside vesicles 10^4 – 10^5 the

concentrations in cytoplasm [3]. Using reserpine binding (see below), a number of residues appear to be required for substrate recognition; reserpine still binds to these mutants, but cannot be displaced by substrates. In addition, $\Delta\mu_{H^+}$ accelerates reserpine binding to wild-type VMAT2, suggesting that H⁺ efflux reorients the substrate recognition site to the cytoplasmic face of the membrane. The substrate recognition mutants do not affect this stimulation by $\Delta\mu_{H^+}$. However, substitution of an aspartate in predicted transmembrane domain (TMD) 10 of the VMATs by a neutral residue abolishes reserpine binding even in the presence of $\Delta\mu_{H^+}$, and replacement by glutamate shifts the pH sensitivity of transport, suggesting that this residue contributes to H⁺ translocation. In terms of structure, a lysine in TMD2 also appears to form a charge pair with an aspartate in TMD11.

Vesicular Acetylcholine Transport

Closely related to the VMATs, the vesamicol-sensitive vesicular acetylcholine transporter (VAcHT) was identified in a screen for mutants resistant to inhibition of acetylcholinesterase in *C. elegans* [1]. Like VMATs, VAcHT recognizes a cationic substrate and depends primarily on ΔpH [2]. In contrast to VMATs, with substrate affinities in the low or submicromolar, the mammalian VAcHT exhibits an apparent affinity around 1 mM. The higher affinity of VMATs may reflect the need to lower cytoplasmic levels of potentially toxic monoamine transmitters. However, VAcHT has been postulated to have a similar stoichiometry for 2 H⁺, but to exhibit as well an H⁺ leak not present with the VMATs. VAcHT is expressed

in cholinergic neurons in the central, peripheral, and autonomic nervous systems.

Vesicular GABA Transport

Genetic and behavioral studies in the nematode *C. elegans* led to identification of the vesicular GABA transporter VGAT/vesicular inhibitory amino acid transporter (VIAAT) [4]. As predicted from studies with purified synaptic vesicles, VGAT mediates uptake of GABA with an apparent affinity in the low millimolar range and can be driven by ΔpH or $\Delta\psi$. VGAT also recognizes glycine as a substrate, suggesting that these two inhibitory neurotransmitters can be stored in and released from the same vesicle. VGAT is expressed in GABAergic, glycinergic neurons as well as in the pancreas.

VGAT shows no sequence similarity to VMATs or VACHT. Rather, it belongs to a large family of transporters that includes H^+ -coupled amino acid permeases in *Arabidopsis thaliana* and several mammalian proteins. One of the related mammalian transport proteins corresponds to classical amino acid transport system N, and others correspond to classical system A, which is responsible for much of the active amino acid uptake by mammalian cells. These glutamine transporters appear to mediate aspects of the glutamine–glutamate cycle involved in nitrogen metabolism by the liver and in the regeneration of glutamate from glutamine required for excitatory neurotransmission. The system N transporters SN1/SNAT3 and SNAT5 mediate glutamine efflux readily under physiological conditions and are expressed by astrocytes. In contrast, system A transporters SA1/SNAT2 and SA2/SNAT1 primarily mediate glutamine uptake, and the expression of SA1 and SA2 by neurons positions these transporters for the uptake of glutamine released from astrocytes by SN1. The principal difference between system N and A transporters appears to be the translocation of H^+ ; the system N transporters mediate the exchange of H^+ for Na^+ and an amino acid whereas the system A transporters mediate only Na^+ cotransport.

Vesicular Glutamate Transport

Glutamate is the principal excitatory neurotransmitter in the mammalian central nervous system, yet the vesicular glutamate transporter eluded identification until recently [5]. Initially isolated in a screen for genes upregulated by subtoxic doses of the excitotoxin N-methyl-D-aspartate, the brain-specific Na^+ -dependent phosphate transporter (BNPI) resembled a class of ►inorganic phosphate transporters and conferred Na^+ -dependent phosphate transport in *Xenopus* oocytes. Although suggested to participate in the regeneration of ATP at nerve terminals, BNPI expression is restricted to excitatory neurons, suggesting a more specific role in glutamate release. Indeed, the enzyme glutaminase that

produces glutamate for release as an excitatory transmitter requires inorganic phosphate for activity. Further, studies in *C. elegans* indicated a specific role for the BNPI orthologue EAT-4 in glutamate release. Recent work has suggested that other type I phosphate transporters related to BNPI mediate the transport of organic anions with higher affinity than phosphate. Together with the determination that BNPI localizes to synaptic vesicles, this suggested an alternative role for the protein in vesicular glutamate transport.

Heterologous expression of BNPI in a variety of cell systems indeed confers vesicular glutamate uptake with all of the properties demonstrated using synaptic vesicles from brain. In particular, glutamate uptake by BNPI depends primarily on $\Delta\psi$ rather than ΔpH , does not recognize aspartate, has an apparent affinity in the low millimolar, and shows a biphasic dependence on chloride with an optimum at 2–10 mM. BNPI has thus been renamed VGLUT1. In addition, vesicular glutamate transport by VGLUT1 leads to vesicle acidification, as previously demonstrated using native synaptic vesicle preparations. Presumably, a reduction in electrical potential caused by influx of the anionic glutamate secondarily activates the H^+ -ATPase. However, VGLUT1 and other related proteins also appear to exhibit a substantial chloride conductance that is blocked by substrate.

Although the expression of VGLUT1 is limited to a subset of glutamatergic neurons in the brain, a highly homologous protein, also initially characterized as a phosphate transporter and named differentiation-associated Na^+ -dependent phosphate transporter (DNP1), has a complementary pattern of expression. DNP1 also localizes to synaptic vesicles, mediates the vesicular uptake of glutamate and has been renamed VGLUT2. Although VGLUT2 exhibits transport activity very similar to VGLUT1, VGLUT2 appears to be expressed by a subset of glutamate neurons with a higher probability of release, and differences in subcellular location suggest differences in trafficking. In particular, the presence of two polyproline domains in the C-terminal cytoplasmic tail of VGLUT1 mediate interactions with endophilin, an SH3 domain containing protein that has been shown to be involved in synaptic vesicle recycling. A third vesicular glutamate transporter, VGLUT3 has also been identified. VGLUT3 is expressed in neurons not classically considered glutamatergic. Immunohistochemical and in situ studies indicate VGLUT3 is expressed in GABAergic, serotonergic, dopaminergic, and cholinergic neurons as well as astrocytes.

Vesicular Storage of Zinc, ATP, and Neuropeptides

Synaptic vesicles mediate the release of small molecules other than classical neurotransmitters and neuropeptides. Of these, zinc and ATP are the best characterized. NMDA and GABA receptors contain binding sites for zinc, and zinc exerts a direct effect on

excitatory and inhibitory neurotransmission. ATP activates both ionotropic and G protein-coupled receptors. As with the classical neurotransmitters, the exocytotic release of these compounds requires transport into synaptic vesicles.

ZnT3 has been implicated in zinc uptake by synaptic vesicles. ZnT3 belongs to a family of zinc transporters and localizes to synaptic vesicles. Further, mice deficient in ZnT3 show a loss of zinc staining from hippocampal neurons and expression of ZnT3 in PC12 cells increases vesicular zinc staining when coexpressed with the vesicular glutamate transporter VGLUT1. ZnT3 targeting to synaptic vesicles has also been shown to depend on the adaptor protein AP3. In *mocha* mice deficient in AP3, synaptic vesicles accumulate normally, but no longer contain ZnT3 or zinc, further supporting a role for ZnT3 in synaptic vesicle zinc storage.

Chromaffin granules, platelet dense core vesicles, and synaptic vesicles accumulate ATP. ATP uptake has been demonstrated using chromaffin granules and synaptic vesicles and the process appears to depend on $\Delta\mu_{H^+}$. It has generally been assumed that ATP is costored only with monoamines and acetylcholine, as an anion to balance to cationic charge of those transmitters. However, the extent of ATP storage and release by different neuronal populations remains unknown, and the proteins responsible for ATP uptake by secretory vesicles have not been identified.

Unlike classical neurotransmitters, neuropeptides enter the lumen of the secretory pathway in the endoplasmic reticulum, through cotranslational translocation. They then sort to large dense core vesicles (LDCVs) in the trans-Golgi network (TGN) and undergo processing to form the biologically active species. LDCV exocytosis exhibits a different dependence from synaptic vesicles on stimulation and calcium concentration. After release, neuropeptides undergo degradation; they are generally not repackaged, although certain luminal contents of dense core vesicles can remain tethered to the plasma membrane.

Regulation of Vesicular Transporters

Regulation of transmitter release may involve changes in the probability of release, or in the amount of transmitter per synaptic vesicle. A variety of mechanisms are known to regulate the probability of vesicle release. Similarly, changes in the amount of transmitter per vesicle, or quantal size, occur in several systems, including the neuromuscular junction. The mechanisms by which quantal size changes, however, remain less well characterized. Nonetheless, modulation of vesicular transport can clearly influence quantal size. VMAT2 knockout mice die shortly after birth, but heterozygous animals also exhibit substantial reductions in monoamine

release, and alterations in behavior relative to wild-type litter mates [4]. Conversely, overexpression of either VMAT2 or VACHT can increase quantal size.

Regulation of transporter expression may occur at the transcriptional level. Both VGLUTs were identified as genes upregulated by specific stimuli; VGLUT1 in response to an excitotoxin and VGLUT2 to the growth factor activin. The organization of the VACHT gene within an exon of the biosynthetic enzyme choline acetyl transferase further indicates a remarkable level of transcriptional coordination. In addition to transcriptional regulation of the VGLUTs, VMATs appear to be regulated by G proteins. Activation of the G protein $G\alpha_{O_2}$ downregulates their activity independent of $\Delta\mu_{H^+}$, but the mechanism remains unclear.

The major mechanisms for regulation of vesicular neurotransmitter transport appear to involve changes in membrane trafficking. VMATs undergo phosphorylation by casein kinase and this posttranslational modification influences their retrieval from maturing LDCVs. In addition, phosphorylation of VACHT upstream from a dileucine-like motif influences sorting into LDCVs at the level of the TGN. Since sorting to LDCVs versus synaptic vesicles will determine the site and mode of transmitter release, the regulation of transporter trafficking has great potential to influence signaling. In particular, it is well known that midbrain neurons release dopamine from their cell bodies and dendrites as well as from their terminals, and the trafficking of VMAT2 presumably contributes to these two very different modes of release. Interactions between VGLUT1 and endophilin have also been implicated in the regulation of synaptic vesicle recycling.

Drugs

VMATs are irreversibly inhibited by the potent antihypertensive drug reserpine. The depressive effects of reserpine helped to formulate the original monoamine hypothesis of affective disorders. Reserpine also appears to interact with the transporters near the site of substrate recognition. Tetrabenazine, which is used in treatment of movement disorders, inhibits VMAT2 much more potently than VMAT1, consistent with the less hypotensive action of this agent.

VMATs are not inhibited by drugs such as cocaine, tricyclic antidepressants and selective serotonin reuptake inhibitors that affect plasma membrane monoamine transport. Amphetamines have relatively selective effects on monoaminergic cells due to selective uptake by plasma membrane monoamine transporters, but their effect appears to be mediated by their ability as weak bases to reduce ΔpH , the driving force for vesicular monoamine transport that leads to efflux of the vesicular contents into the cytoplasm.

The vesicular acetylcholine transport can be inhibited by vesamicol and several related compounds. Vesamicol competitively inhibits transport by binding to a cytoplasmic domain on VACHT with a K_d of ~ 5 nM. Vesamicol binding can be used to estimate transporter number, but neither vesamicol nor its analogues are currently used clinically.

Vesicular GABA transport can be competitively inhibited by amino acids including glycine and β -alanine. Transport can also be competitively inhibited by γ -vinyl GABA, a derivative of GABA. γ -Vinyl GABA has been used in the clinical treatment of epilepsy and is known to inhibit GABA transaminase, an enzyme that metabolizes GABA. The mode of action for γ -vinyl GABA as an antiepileptic drug is thought to be through its effects on GABA transaminase, but inhibition of vesicular GABA transport could have an effect by increasing the nonvesicular release of GABA.

Several compounds that inhibit vesicular glutamate transport have been identified: These include the dyes Evans Blue and Rose Bengal. In addition, the stilbene derivative 4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid (DIDS), a compound commonly used as a specific inhibitor of anion channels, inhibits vesicular glutamate transport. Most known inhibitors have limited use as they are membrane impermeant, with the exception of Rose Bengal.

In addition to direct inhibition of the vesicular transport protein, storage of neurotransmitters can be reduced by dissipation of the proton electrochemical gradient. Bafilomycin (a specific inhibitor of the vacuolar H^+ -ATPase), as well as the proton ionophores carbonyl cyanide *m*-chlorophenylhydrazone (CCCP) and carbonylcyanide *p*-(trifluoromethoxy) phenylhydrazone (FCCP) are used experimentally to reduce the vesicular storage of neurotransmitters. Weak bases including amphetamines and ammonium chloride are used to selectively reduce ΔpH .

Vinca Alkaloids

Vinca alkaloids are derived from the Madagascar periwinkle plant, *Catharanthus roseus*. The main alkaloids are vincristine, vinblastine and vindesine. Vinca alkaloids are cell-cycle-specific agents and block cells in mitosis. This cellular activity is due to their ability to bind specifically to tubulin and to block the ability of the protein to polymerize into microtubules. This prevents spindle formation in mitosing cells and causes arrest at metaphase. Vinca alkaloids also inhibit other cellular activities that involve microtubules, such as leukocyte phagocytosis and chemotaxis as well as axonal transport in neurons. Side effects of the vinca alkaloids such as their neurotoxicity may be due to disruption of these functions.

Viral Proteases

CHRISTIAN STEINKÜHLER
IRBM – Merck Research Laboratories, Pomezia, Italy

Synonyms

Viral proteinases

Definition

Viral proteases are enzymes (endopeptidases EC 3.4.2) encoded by the genetic material (DNA or RNA) of viral pathogens. The role of these enzymes is to catalyze the cleavage of specific peptide bonds in viral polyprotein precursors or in cellular proteins. In most cases these proteolytic events are essential for the completion of the viral infectious cycle. Viral proteases may use different catalytic mechanisms involving either serine, cysteine or aspartic acid residues to attack the scissile peptide bond. This bond is often located within conserved sequence motifs extending for up to ten residues. Selective recognition of these sequence patterns by a complementary substrate binding site of the enzyme ensures a high degree of specific recognition and cleavage (Fig. 1).

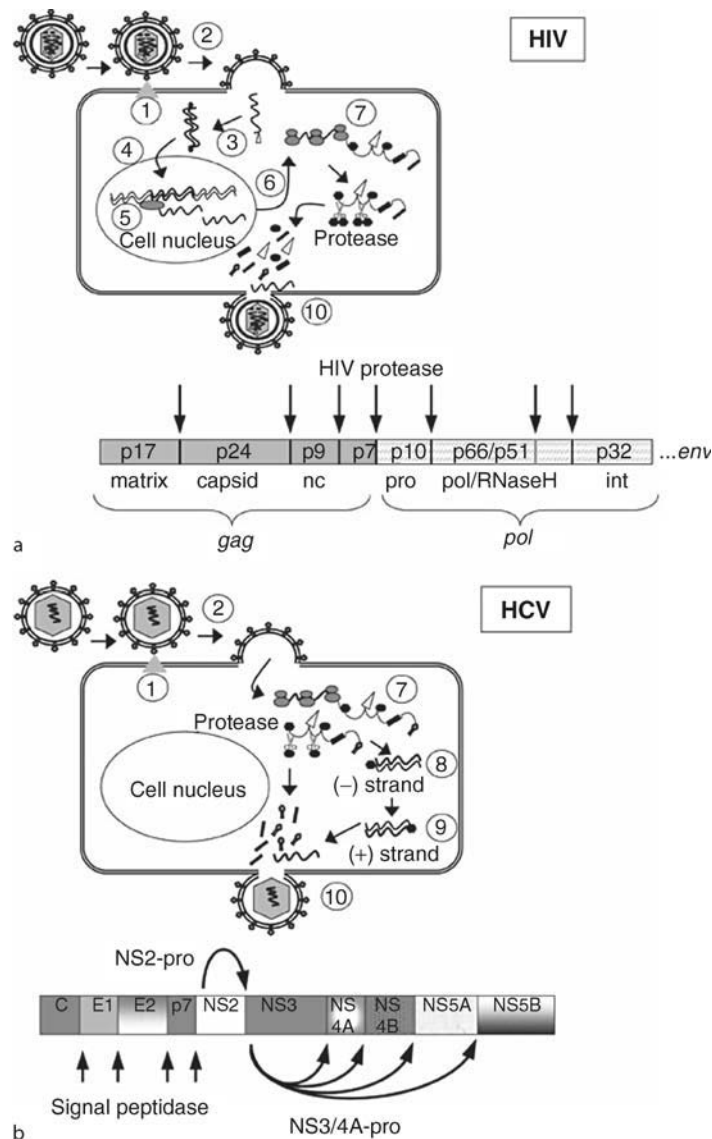

Basic Characteristics

The majority of approved antiviral pharmaceuticals belong to the category of nucleoside analogs that target viral polymerases. Adverse side effects, moderate clinical efficacy and especially the rapid emergence of drug-resistant mutant strains limits the efficacy of these inhibitors in monotherapy of chronic viral infections. Proteolytic maturation of large precursor proteins, catalyzed by virally encoded proteases, is a widespread strategy especially in viruses using RNA as genetic material. Since 1995, protease inhibitors have been successfully added to the therapeutic regimens of ► HIV infected individuals, and protease inhibitors are presently being developed to control other chronic viral infections such as ► hepatitis C (HCV). The infectious cycles of a retrovirus (such as the human immunodeficiency virus HIV), and of a (+)-strand-RNA virus (such as the

hepatitis C virus, HCV) are schematically shown below. Both viruses use RNA as genetic material but in contrast to (+)-strand RNA viruses, retroviral genomes are back-transcribed into a double stranded DNA molecule by a reverse transcriptase contained inside the viral particle and delivered to the cell during infection (► reverse transcription).

The HIV genome is organized into three major coding elements called *gag*, *pol* and *env* [1]. Upon integration of the provirus into the host cell genome, multiple copies of viral RNA are produced by hijacking the cellular transcription machinery. This RNA may have one of three different fates: A fraction of viral RNAs is reserved as genomes for new viral particles. Another fraction is spliced to yield subgenomic mRNA species that will be translated on membrane-bound polysomes to give rise to the *env* protein gp160, which is subsequently cleaved by cellular proteases into the envelope glycoproteins gp120 and gp41. Finally, a third fraction is used as mRNA for *gag* and *pol*. These gene products are produced as a nested set of precursor polyproteins such that the relative amount of *gag-pol* peptides (p160) is only 5% as abundant as *gag* peptides (p55). This relationship is maintained by partial bypassing of a translational stop signal at the end of *gag*. The *pol* gene encodes the viral enzymes protease, reverse transcriptase and ► integrase. Following a not well-understood autocatalytic event, the protease is released and performs nine different cleavages in the *gag* and *gag-pol* precursor proteins. Mutations in the protease lead to the generation of defective, noninfectious particles, demonstrating the essential role of this enzyme in the viral infectious cycle. The HIV protease belongs to the family of aspartic acid proteases (E.C.3.4.23) and is closely related to cellular enzymes such as renin, cathepsin D or pepsin. The structure of the HIV protease has been extensively studied by X-ray crystallography both, in its free form and complexed to inhibitors. It is a homodimer consisting of two identical polypeptide chains of 99 residues each. Each monomer contributes one catalytic aspartic acid residue in the active site, which is located at the dimer interface. Well-defined subsites and two flexible flap regions protruding over the active site contribute to specific recognition of substrates and inhibitors.

Reverse transcriptase and protease inhibitors interfere at different stages within the viral replication cycle. The former class of compounds (nucleoside analogs or nonnucleoside inhibitors) blocks infection at an early step prior to integration of the retro-transcribed viral genome into the genome of the host cell. Consistent with this mode of action, reverse transcriptase inhibitors are ineffective in arresting the spread of viruses from cells that are already infected. This is in contrast to protease inhibitors that act at a late stage of the infectious cycle. Many present therapeutic regimens simultaneously target both HIV enzymes by combining protease inhibitors with

Viral Proteases. Figure 1 Role of virally encoded proteases in the replication cycle of a retrovirus (HIV, part a) and of a (+)-strand RNA virus (HCV, part b). The numbers correspond to the following steps in the infectious cycle: (1) binding to cell surface receptor; (2) fusion; (3) reverse transcription; (4) integration; (5) transcription by host cell RNA polymerase; (6) RNA export and splicing; (7) translation; (8) (-)-strand synthesis; (9) (+)-strand synthesis; (10) assembly and budding of new viral particle. The proteolytic cleavage sites in the HIV gag-pol precursor and in the HCV polyprotein are schematically shown.

nucleoside analogs such as AZT, ddC, ddI, d4T or 3TC or nonnucleoside reverse-transcriptase inhibitors (nevirapine, efavirenz, delavirdine).

The infectious cycle of a (+)-strand RNA virus such as the hepatitis C virus differs by the fate of the viral RNA genome in the infected cell. Upon entry into the cell, the HCV genome is used as a messenger RNA to drive the synthesis of a large polyprotein precursor of about 3,000 residues [2]. The structural proteins are excised from the precursor by host cell signal peptidase.

The nonstructural region of the precursor, harboring the viral replication machinery, is cut into its mature components in a maturation reaction in which two viral proteases (NS2-pro and NS3/4A-pro) cooperate. Site-directed mutagenesis of an otherwise infectious cDNA has shown that both HCV-encoded proteases are necessary for viral infectivity, but most of the attention has so far been focused on one of them; a member of the serine protease family (EC 3.4.21) located in the N-terminal region of the viral NS3 protein.

The proteolytic activity of NS3 is turned on only upon binding to the cofactor NS4A, generating the active NS3/4A heterodimeric protease, and is used to perform a total of four different cleavages. The mature viral RNA-dependent RNA polymerase, the protein NS5B, also arises from one of these processing events. This enzyme subsequently replicates the viral genome in a two-step process involving a (–)-strand intermediate.

In contrast to retroviruses, proteolysis is an early event in the replication cycle of (+)-strand RNA viruses and both protease and polymerase inhibitors can be expected to halt the propagation of infectious viral particles from already infected cells.

The three-dimensional structure of the NS3 protease, either alone or in complex with its NS4A cofactor, was solved by both X-ray crystallography and by NMR spectroscopy. The enzyme adopts a chymotrypsin-like fold with two β -barrel domains contributing the residues that make up the catalytic triad; a histidine an aspartic acid and a serine residue. Comparison of structures obtained in the presence or in the absence of the cofactor lead to the conclusion that NS4A serves to stabilize the fold of the N-terminal beta-barrel of the protease thereby promoting the correct positioning of the catalytic machinery. In striking contrast to the HIV protease, there are no pronounced pockets or cavities in the proximity of the active site of NS3 that could serve to anchor inhibitors or substrates. Nevertheless, this protease is highly specific in binding to and processing of peptides with a consensus sequence spanning over ten residues. Specificity is conferred to this molecular recognition event by a series of weak interactions which are dispersed along a very extended interaction surface that involve hydrogen bonds, hydrophobic interactions and a crucial electrostatic complementarity between enzyme and active site ligand.

Drugs

HIV Protease Inhibitors

So far, five different protease inhibitors have been approved by the FDA for the treatment of HIV infection [3, 4]. Clinical trials in which protease inhibitors were evaluated in monotherapy demonstrated the potency of this class of inhibitors (decrease in HIV RNA levels, increase in CD4 cell counts). Treatment regimens were subsequently broadened to include reverse transcriptase inhibitors in combination with protease inhibitors. The result of these clinical trials has led to a list of guidelines with recommendations for the optimal treatment options. Prolonged control of the infection with combination therapy (highly active antiretroviral therapy, “HAART”) could be shown.

Saquinavir (SQV, Invirase)

Saquinavir was the first HIV protease inhibitor to obtain FDA approval in 1995 for the treatment of HIV infection

in combination with nucleoside analogs. Phase I clinical trials revealed low oral bioavailability due to limited gastro-intestinal absorption and extensive first-pass metabolism by human intestinal cytochrome P₄₅₀ 3A4 (CYP3A4) that may be limited by concomitant administration of CYP3A4 inhibitors (indinavir, ritonavir, ketoconazole, troleanomycin). Pharmacokinetics could also be improved by administration with a high-fat diet or in a novel soft gelatin capsule formulation (Fortovase). Saquinavir is generally well tolerated with mainly gastrointestinal side effects, including diarrhea, nausea and abdominal discomfort.

Ritonavir (RTV, Norvir)

Clinical evaluation of Ritonavir demonstrated good absorption from the gastrointestinal tract and high plasma drug levels. When given in combination with reverse transcriptase inhibitors, Ritonavir showed significant reduction of disease progression in clinical efficacy trials enrolling patients with advanced HIV disease, as compared to therapy with reverse transcriptase inhibitors alone. Ritonavir has a high affinity for several cytochrome P₄₅₀ isoenzymes and is a potent inhibitor of CYP3A4. This limits the concurrent use of ritonavir with agents that are metabolized by CYP3A4 such as various analgetics, antiarrhythmic agents, antibiotics, anticoagulants, anticonvulsants, antiemetics and antifungal agents. While such interactions may be clinically detrimental, simultaneous administration of low doses of Ritonavir was shown to boost plasma levels of other HIV protease inhibitors allowing for lower dosages or increasing dosing intervals. The most common adverse effects of Ritonavir are nausea, diarrhea, vomiting, muscular weakness, taste disturbance, anorexia, abnormal functioning of tissue and abdominal pain.

Indinavir (IDV, Crixivan)

Indinavir is a modified hydroxyethylamine peptidomimetic developed by rational drug design. In clinical trials, Indinavir was shown to significantly lower HIV RNA levels in plasma and to increase CD4 cell counts in both monotherapy and in combination drug regimens. Indinavir is generally well tolerated and in phase II clinical studies less than 6% of subjects taking Crixivan alone discontinued therapy due to drug-related adverse experiences. Nephrolithiasis was reported in 12.4% of adults and 29% of children, during clinical trials involving patients on Crixivan. As with other protease inhibitors, changes in body fat, increased bleeding in some patients with hemophilia, and increased blood sugar levels or diabetes have been reported. Additionally, severe muscle pain and weakness have occurred in patients also taking cholesterol-lowering medicines called “statins.”

Nelfinavir (NFV, Viracept)

Nelfinavir is a nonpeptidic, rationally designed HIV protease inhibitor. Nelfinavir has demonstrated efficacy in both monotherapy and in combination with the reverse transcriptase inhibitors stavudine (d4T) or zidovudine + 3TC. The major side effect is mild to moderate diarrhea.

Amprenavir (APV, Agenerase)

Amprenavir (APV, Agenerase) is the most recently approved HIV protease inhibitor. It is smaller and stereochemically less complex than the other drugs in this class. Adsorption of this compound was found to be impaired by high fat meals. Common side effects of Amprenavir are nausea, vomiting, diarrhea, rash and a tingling sensation around the mouth.

As with reverse transcriptase inhibitors, resistance to protease inhibitors may also occur. Mutations in the HIV protease gene were shown to confer resistance to each of the aforementioned molecules. In addition, passaging of virus in the presence of HIV protease inhibitors also gave rise to strains less susceptible to the original inhibitor or cross-reactive to other compounds in the same class.

New Drug Targets

Hepatitis C Virus Serine Protease [5]

Hepatitis C is a predominantly chronic infection affecting 1–3% of the world population. The infectious cycle of the hepatitis C virus has been outlined above. Inhibitors against the key viral protease, the NS3/4A serine protease are currently in clinical trials. This enzyme proved to be a particularly difficult target due to the peculiar architecture of its substrate recognition site (see above). An unusual feature of the NS3 protease is the property to undergo potent inhibition by its cleavage products. This property was exploited to generate a family of highly active peptide inhibitors that may serve as a basis for the development of peptidomimetics with improved pharmacokinetic properties. Also, mechanism-based inhibitors are being exploited.

Rhinovirus Protease [3]

Rhinoviruses, which represent the single major cause of common cold, belong to the family of picornaviruses that harbors many medically relevant pathogens. Inhibitors of the 3C protease, a cysteine protease, have shown good antiviral potential. Several classes of compounds were designed based on the known substrate specificity of the enzyme. Mechanism-based, irreversible Michael-acceptors were shown to be both potent inhibitors of the purified enzyme and to have antiviral activity in infected cells.

Virus-like Particle

A particle that spontaneously assembles from viral coat proteins in the absence of other viral components. Virus-like particles (VLPs) generated from recombinant coat proteins are used in vaccines against hepatitis B virus and papillomavirus.

► Biologicals

Vitamin A

Vitamin A describes a group of substances (retinol, retinyl esters, and retinal) with defined biological

activities. Certain metabolites of vitamin A, such as all-trans and cis-isomeric retinoic acids, can perform most of the biological functions of vitamin A; they are incapable of being metabolically reversibly converted into retinol, retinal, etc. The unit of measurement is the Vitamin A International Unit (IU) which measures growth in rat pups (1 mg retinol = 3333 IU Vitamin A).

► Retinoids

Vitamin B1

E. BACK¹, H. K. BIESALSKI²

¹Novartis Pharma GmbH, Nuremberg, Germany

²University of Hohenheim, Institute of Biological Chemistry and Nutrition, Stuttgart, Germany

Synonym

Thiamin (3-(4-amino-2-methyl-pyrimidin-5-ylmethyl)-5-(2-hydroxyethyl)-4-methylthiazolium)

Definition

Free thiamin is a base that is stable under acidic conditions up to pH 7, moderately light-sensitive and susceptible to oxidative degradation as well as inactivation by irradiation. For use in pharmaceutical and other preparations the vitamin is handled in the form of solid water-soluble thiazolium salts (thiamin chloride hydrochloride, thiamin mononitrate). There are also synthetic lipophilic derivatives of the vitamin, termed allithiamins. They can pass biological membranes more easily and in a nearly dose-linear fashion. Due to their improved bioavailability they can be used to build up high thiamin stores in certain target organs (drug targeting). In the human body, thiamin concentration is highest in the heart, followed by kidney, liver, and brain. Yeast, pulses, wholemeal cereals, nuts, and pork are good dietary sources for thiamin [1].

Thiamin

Thiaminpyrophosphate

Vitamin B1. Figure 1 Structure of thiamin and its coenzyme form thiaminpyrophosphate (TPP).

Some kinds of fish and crustacea contain thiaminases. These enzymes cleave thiamin and thus inactivate the vitamin. Some plant phenols, e.g., chlorogenic acid, may possess antithiaminic properties, too, though their mechanism of action is so far not well understood.

Figure 1 shows the chemical structure of vitamin B1 or thiamin (3-(4-amino-2-methyl-pyrimidin-5-ylmethyl)-5-(2-hydroxyethyl)-4-methylthiazolium) and its coenzyme form thiaminpyrophosphate (TPP).

Mechanism of Action

Several enzymes of the intermediary metabolism require thiaminpyrophosphate (TPP, Fig. 1) as coenzyme, e.g., enzymes of the pyruvate dehydrogenase complex, α -ketoglutarate dehydrogenase complex, or pentose phosphate pathway.

TPP-dependent enzymes are involved in oxidative decarboxylation of α -keto acids, making them available for energy metabolism. Transketolase is involved in the formation of NADPH and pentose in the pentose phosphate pathway. This reaction is important for several other synthetic pathways. It is furthermore assumed that the above-mentioned enzymes are involved in the function of neurotransmitters and nerve conduction, though the exact mechanisms remain unclear.

Clinical Use (Including Side Effects)

Thiamin has a very low toxicity (oral LD₅₀ of thiaminchloride hydrochloride in mice: 3–15 g/kg body weight). The vitamin is used therapeutically to cure polyneuropathy, ►beriberi (clinically manifest thiamin deficiency), and Wernicke–Korsakoff Syndrome (►Wernicke encephalopathy and ►Korsakoff psychosis). In mild polyneuropathy, 10–20 mg/d water-soluble or 5–10 mg/d lipid-soluble thiamin are given orally. In more severe cases, 20–50 mg/d water-soluble or 10–20 mg/d lipid-soluble thiamin are administered orally. Patients suffering from ►beriberi or from early stages of Wernicke–Korsakoff Syndrome receive 50–100 mg of thiamin two times a day for several days subcutaneously or intravenously until symptoms are alleviated. Afterwards, the vitamin is administered orally for several weeks.

Synonym

Riboflavin

Definition

Vitamin B2 or riboflavin is chemically defined as 7,8-dimethyl-10-(1Y-D-ribityl)isoalloxazine. **Figure 1** shows the oxidized and reduced form of the vitamin. The ending “flavin” (from the latin word flavus = yellow) refers to its yellowish color.

Riboflavin is heat-stable in the absence of light, but extremely photosensitive. It has a high degree of natural fluorescence when excited by UV light. This property can be used for detection and determination. Two coenzymes (**Fig. 2**), flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), are derived from riboflavin.

Milk, milk products, and foods of animal origin contain high amounts of (free) riboflavin with good bioavailability. In foods of plant origin, the majority of riboflavin is protein-bound and therefore less bioavailable. Cereal germs and bran are plant sources rich in riboflavin [1].

Vitamin B2. Figure 2 Structure of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD).

Mechanism of Action

The formation of FMN and FAD is ATP-dependent and takes place predominantly in liver, kidney, and heart. It is controlled by thyroid hormones [2].

So far, about 60 flavoenzymes have been identified, the majority containing FAD. Examples for flavoenzymes are the mitochondrial enzymes of the respiratory chain, succinate dehydrogenase, L-gulonolactone oxidase, monoamino oxidase, xanthinoxidase, thioreduxin reductase, and glutathione reductase. Flavin coenzymes are involved in both one- and two-electron transfer reactions and catalyze hydroxylations, oxidative decarboxylations, dioxygenations as well as reductions of oxygen to hydrogen peroxide. Through their functions as coenzymes, FMN and FAD are involved in the metabolism of glucose, fatty acids, amino acids, purines, drugs and steroids, folic acid, pyridoxin, vitamin K, niacin, and vitamin D.

The FAD-dependent enzyme glutathione reductase plays a role in the antioxidant system. Glutathione reductase restores reduced glutathione (GSH), the most important antioxidant in erythrocytes, from oxidized glutathione (GSSG) [1, 2].

Clinical Use (Including Side Effects)

Up to date, no case of riboflavin intoxication has been described in the literature and riboflavin intake is considered safe even at higher doses.

The vitamin is administered therapeutically to reverse riboflavin deficiency symptoms or to prevent deficiency in high risk groups. Among the high risk groups to develop riboflavin deficiency count persons who regularly take certain drugs (e.g., antidepressants, oral ▶**contraceptives**), malnourished patients, patients after trauma, patients suffering from malabsorption, and chronic alcoholics. The doses given are >10 mg/d. Two other groups who benefit from riboflavin supplementation are newborns with hyperbilirubinemia who are treated with phototherapy. The supply of 0.5 mg riboflavin/kg body weight and day can here accelerate the photodegradation of bilirubin. Furthermore, persons with congenital methemoglobinemia might profit from the intake of high doses of riboflavin (20–40 mg/d) [2].

²Institute of Biological Chemistry and Nutrition, University of Hohenheim, Stuttgart, Germany

Definition

Vitamin B6 (Fig. 1) is the collective name for all 3-hydroxy-2-methylpyridine-derivatives with vitamin

B6 function, including pyridoxin (= PN, alcohol), pyridoxal (= PL, aldehyde), pyridoxamine (= PM, amine), and their 5'-phosphorylated forms.

In general, pyridoxamine and pyridoxin are more stable than pyridoxal. All vitamers are relatively heat-stable in acid media, but heat labile in alkaline media. All forms of vitamin B6 are destroyed by UV light in both neutral and alkaline solution. The majority of vitamin B6 in the human body is stored in the form of pyridoxal phosphate in the muscle, bound to glycogen phosphorylase.

Plants contain to some extent less bioavailable forms of vitamin B6, e.g., glycosylates, or biologically inactive metabolites, e.g., ε-pyridoxin-lysine-complexes. In addition, the release of vitamin B6 from foods rich in fiber is assumed to be delayed. The bioavailability of vitamin B6 from animal-derived foods is therefore overall higher than from plant-derived foods. Good dietary sources of vitamin B6 include chicken, fish, pork, beans, and pulses [1].

Mechanism of Action

Pyridoxal phosphate mainly serves as coenzyme in the amino acid metabolism and is covalently bound to its enzyme via a Schiff base. In the enzymatic reaction, the amino group of the substrate and the aldehyde group of PLP form a Schiff base, too. The subsequent reactions can take place at the α-, β-, or γ-carbon of the respective substrate. Common types of reactions are decarboxylations (formation of biogenic amines), transaminations (transfer of the amino nitrogen of one amino acid to the keto analog of another amino acid), and eliminations.

Pyridoxamine phosphate serves as a coenzyme of transaminases, e.g., lysyl oxidase (collagen biosynthesis), serine hydroxymethyl transferase (C1-metabolism), δ-aminolevulinic synthase (porphyrin biosynthesis), glycogen phosphorylase (mobilization of glycogen), aspartate aminotransferase (transamination), alanine aminotransferase (transamination), kynureninase (biosynthesis of niacin), glutamate decarboxylase (biosynthesis of GABA), tyrosine decarboxylase (biosynthesis of tyramine), serine dehydratase (β-elimination), cystathionine β-synthase (metabolism of methionine), and cystathionine γ-lyase (γ-elimination).

Vitamin B6-coenzyme is involved in a variety of reactions, e.g., in the immune system, gluconeogenesis, erythrocyte function, niacin formation, nervous system, lipid metabolism, and in hormone modulation/gene expression [1, 2].

Vitamin B12

E. BACK¹, H. K. BIESALSKI²

¹Novartis Pharma GmbH, Nuremberg, Germany

²University of Hohenheim, Institute of Biological Chemistry and Nutrition, Stuttgart, Germany

Definition

Vitamin B12 (Fig. 1) is defined as a group of cobalt-containing corroids known as cobalamins. The common features of the vitamers are a corrin ring (four reduced pyrrole rings) with cobalt as the central atom, a nucleotide-like compound and a variable ligand. Vitamin B12 is exceptional in as far as it is the only vitamin containing a metal-ion. The vitamers present in biological systems are hydroxo-, aquo-, methyl-, and 5'-deoxyadenosylcobalamin.

Only microorganisms are able to synthesize vitamin B12. Microbiological vitamin B12 synthesis in humans takes place, however, in the lower intestine where the

body cannot sufficiently absorb the vitamin. Therefore, humans have to supply the vitamin via the diet. The vitamers differ in their photosensitivity, but they are all sooner or later inactivated when exposed to visible light. Good dietary sources of vitamin B12 comprise mostly animal-derived products, e.g., liver, meat, egg (yolk), milk and milk products, whereas vegan (▶vegetarian) diets are basically vitamin B12-free [1].

Vitamin B12 is special in as far as its absorption depends on the availability of several secretory proteins, the most important being the so-called intrinsic factor (IF). IF is produced by the parietal cells of the fundic mucosa in man and is secreted simultaneously with HCl. In the small intestine, vitamin B12 (extrinsic factor) binds to the alkali-stable gastric glycoprotein IF. The molecules form a complex that resists intestinal proteolysis. In the ileum, the IF-vitamin B12-complex attaches to specific mucosal receptors of the microvilli as soon as the chymus reaches a neutral pH. Then either cobalamin alone or the complex as a whole enters the mucosal cell.

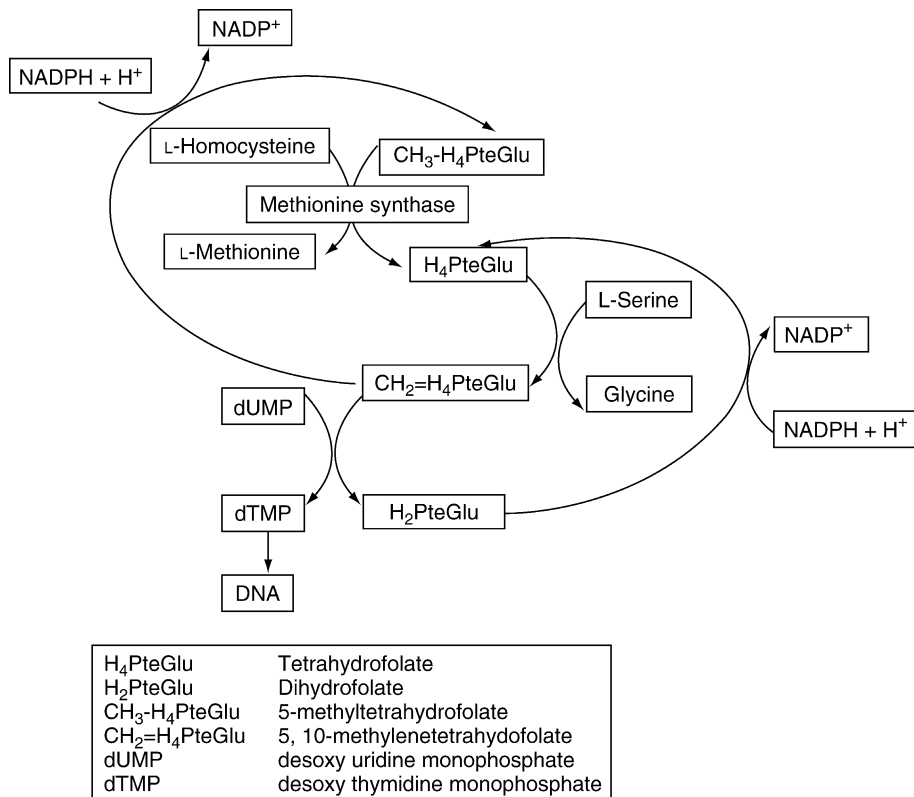

Mechanism of Action

Vitamin B12 appears in two coenzymatic forms, namely methylcobalamin (cytosol) and 5'-deoxyadenosylcobalamin (mitochondria). Vitamin B12-dependent enzymes are [1]

1. Methylmalonyl-CoA mutase: 5'-deoxyadenosylcobalamin is part of dimethylbenzimidazolecobamide coenzyme, a constituent of methylmalonyl-CoA mutase. This mutase catalyses the isomerization of methylmalonyl-CoA to succinyl-CoA (anaplerotic reaction of the citric acid cycle).
2. Leucine 2,3-amino-mutase.
3. N5-Methyltetrahydrofolate homocysteine methyltransferase (= methionine synthase). This reaction is essential to restore tetrahydrofolate from N5-methyltetrahydrofolate (Fig. 2).

Vitamin B12. Figure 1 Structure of the different vitamin B12 vitamers.

Vitamin B12. Figure 2 Selected reactions in which folic acid coenzymes are involved.

Clinical Use (Including Side Effects)

Vitamin B12 deficiency develops when the availability of intrinsic factor is reduced (atrophic gastritis, gastric mucosal defects, after gastrectomy), in persons with malabsorption syndromes, especially when the terminal ileum is involved, in breastfed infants whose mothers have lived on a vegan (refer to ►vegetarian) diet for years, in persons with congenital abnormalities in cobalamin metabolism, and in persons having intestinal parasites, especially fish tapeworms (*Diphyllobothrium latum*). The characteristic symptoms of vitamin B12 deficiency include macrocytic hyperchromic ►anemia (common symptom in both vitamin B12 and folic acid deficiency) and ►funicular myelitis (neurological disorder, characteristic of vitamin B12 deficiency) [1, 2].

Cyano- and hydroxocobalamin – both can be converted to the physiologically relevant coenzymes methyl- and 5'-deoxyadenosylcobalamin in the liver – are used for therapeutical applications. When pernicious anemia caused by chronic atrophic gastritis has been diagnosed, it is treated as follows: During the first 7 days of treatment, 1000 µg of hydroxocobalamin/d are administered parenterally, usually intramuscularly. Then, the same dose is given once weekly for 4–6 weeks. The aim is to alleviate the deficiency symptoms and at the same time to replenish the stores. Afterwards, 1000 µg hydroxocobalamin should be given parenterally every 2 months lifelong to avoid relapse [1, 2].

When ►funicular myelitis occurs in advanced stages of vitamin B12 deficiency, patients are given 250 µg vitamin B12/d during the first 2 weeks of treatment to alleviate the symptoms and to replenish the stores. If the deficiency has been caused by disturbed vitamin B12 absorption, lifelong monthly injections of 100 µg vitamin B12 are indicated [2].

Whether supplementation of vitamin B12 is useful in the therapy of a number of neurological disorders is still subject to discussion and further investigations.

Vitamin C

E. BACK¹, H. K. BIESALSKI²

¹Novartis Pharma GmbH, Nuremberg, Germany

²Institute of Biological Chemistry and Nutrition, University of Hohenheim, Stuttgart, Germany

Synonym

L-ascorbic acid

Definition

Vitamin C or L-ascorbic acid (Fig. 1) is chemically defined as 2-oxo-L-theo-hexono-4-lactone-2,3-enediol. Ascorbic acid can be reversibly be oxidized to semidehydro-L-ascorbic acid and further to dehydroascorbic acid.

Ascorbic acid is photosensitive and unstable in aqueous solution at room temperature. During storage of foods, vitamin C is inactivated by oxygen. This process is accelerated by heat and the presence of catalysts. Ascorbic acid concentration in human organs is highest in adrenal and pituitary glands, eye lens, liver, spleen, and brain. Potatoes, citrus fruits, black currants, sea buckthorns, acerola, rose hips, and red paprika peppers are among the most valuable vitamin C sources [1, 2].

Mechanism of Action

Ascorbic acid scavenges reactive oxygen and nitrogen species. The resulting ascorbate radical converts quickly to ascorbic acid and dehydroascorbic acid, but does usually react with other surrounding molecules. This is why ascorbic acid is such an important physiological antioxidant. Dehydroascorbic acid is enzymatically reduced to ascorbic acid in biological systems. This recycling helps to maintain the ascorbic acid stores in the tissue at a high level. In addition to its antioxidant function, ascorbic acid plays a role as a cofactor of mono- and dioxygenases in norepinephrine synthesis, hormone activation, collagen biosynthesis,

Vitamin C. Figure 1 Structure of ascorbic acid, semidehydroascorbic acid, and dehydroascorbic acid.

carnitine biosynthesis, and tyrosine metabolism (24). Furthermore, ascorbic acid improves intestinal absorption of inorganic iron by reducing Fe^{3+} to Fe^{2+} (only the latter has a high affinity to the mucosal iron receptor). In the stomach, ascorbic acid inhibits the formation of nitrosamines and thus might be important in protecting the stomach from ulcers and ►cancer. Finally, ascorbic acid competitively inhibits the glycosylation of proteins, a process that could be important for the long-term prognosis of diabetes (►diabetes mellitus) [2].

Vitamin C status is supposed to play a role in immune function and to influence the progression of some chronic degenerative diseases like ►atherosclerosis, ►cancer, cataracts, and osteoporosis. The role of vitamin C in immune function, especially during common cold and upper respiratory tract infection, is the subject of lively debate. The exact mechanisms of action have not yet been fully elucidated, but the results of several trials point to a reduced duration and intensity of infections in subjects consuming high amounts of vitamin C (200–1000 mg/d). However, the incidence of common cold was not influenced significantly (24).

Ascorbic acid is able to regenerate ►vitamin E from tocopheryl radicals. This reaction might be important in the context of ►atherosclerosis prevention. The role of vitamin C in cancer prevention is still unclear. Its importance in the etiology of various types of ►cancer has not yet been proven. The observed high vitamin C intake levels in groups with low cancer rates might simply have been a marker for high fruit and vegetable intake [2].

Clinical Use (Including Side Effects)

Presently, the full clinical picture of vitamin C-deficiency, called scurvy, is rarely seen. The typical symptoms include mucosal and subcutaneous bleedings, follicular hyperkeratosis, and gingivitis. Current issues regarding this vitamin include the question where the optimal dose lies to gain optimum health benefits. A daily intake of 75 mg for adults is considered sufficient to prevent vitamin C deficiency symptoms. The RDA for adults was recently increased by 25–50%, from 60 to 75 mg for females and 90 mg for males, acknowledging the fact that increased doses might help prevent chronic diseases. The results of numerous studies suggest that optimum health benefits are achieved (i.e., maintenance of maximum plasma and tissue stores) at even higher daily intakes of about 100–200 mg/d [2].

Vitamin C is not toxic and a hypervitaminosis has not yet been described in the literature. The statement that high vitamin C intake increases the risk of kidney stones could not be maintained.

Vitamin C requirements are increased during pregnancy and lactation, in patients undergoing hemodialysis and in smokers. Seniors often have suboptimal intakes.

On the basis of available results, persons suffering from common cold might benefit from taking 1–2 g/d of vitamin C. However, the usefulness of taking high amounts of vitamin C to prevent common cold has yet to be proven [2].

So far, it is not possible to give any recommendations concerning the vitamin C intake required for the prevention of osteoporosis, cataracts, ►cancer, or cardiovascular disease.

Vitamin D

Summary term for a number of steroid hormones and their precursors with differentiation-inducing activity in many tissues. As regards bone, three components are relevant: cholecalciferol (“vitamin D”); 25-hydroxyvitaminD3 (calcidiol) and 1,25-dihydroxyvitamin D3 (calcitriol). The latter is the biologically active form and increases both intestinal calcium absorption and bone resorption. Vitamin D preparations are widely used for the treatment of osteoporosis. Daily supplementation with vitamin D reduces bone loss in postmenopausal women and hip fractures in elderly subjects.

Vitamin E

JÜRGEN FRANK¹, HANS K. BIESALSKI²

¹zet - Centre for Alternative and Complementary Methods to Animal Testing, Linz, Austria

²Institut für Biolog. Chemie und Ernährungswissenschaft, Universität Hohenheim, Stuttgart, Germany

Synonyms

The term vitamin E describes a family of eight antioxidants, four tocopherols, alpha (α), beta (β), gamma (γ) and delta (δ), and four tocotrienols (also α , β , γ , and δ). α -Tocopherol is present in nature in only one form, RRR α -tocopherol. The chemical synthesis of α -tocopherol results in eight different forms (SRR, SSR, SRS, SSS, RSR, RRS, RSS, RRR), only one of which is RRR α -tocopherol. These forms differ in that they can be “right” (R) or “left” (S) at three different places in the α -tocopherol molecule. RRR α -tocopherol is the only form of vitamin E that is actively maintained in the human body and is therefore the form of vitamin E found in the largest quantities in the blood and tissue. A protein synthesized in the liver (α -TTP: alpha-tocopherol transfer protein) preferentially selects the natural form of vitamin E (RRR α -tocopherol) for distribution to the tissues. However, the mechanisms for the regulation of vitamin E in tissues are not known

Definition

In 1922, Evans and Bishop named the animal nutritional factor essential of reproduction “Vitamin E”. In the 1960s, vitamin E was associated with antioxidant function. Twenty-five years later, vitamin E has been found to possess functions that are independent of its antioxidant and free radical scavenging ability. α -Tocopherol specific molecular mechanisms were discovered which are still under investigation.

Mechanism of Action

The main function of α -tocopherol in humans appears to be that of a non-specific chain-breaking antioxidant that prevents the propagation of lipid peroxidation (Fig. 1). ►Reactive oxygen species (ROS) are formed primarily in the body during normal metabolism and also upon exposure to environmental factors such as pollutants or cigarette smoke. Fats (first of all several fold polyunsaturated fatty acids; PUFAS), which are an integral part of all cell membranes, are vulnerable to destruction through oxidation by ROS. The fat-soluble vitamin, α -tocopherol, is uniquely suited to intercepting free radicals and preventing a chain reaction of

lipid destruction (Fig. 1). Aside from maintaining the integrity of cell membranes throughout the body, α -tocopherol also protects the fats in low density lipoproteins (LDL) from oxidation. Oxidized LDL have been implicated in the development of cardiovascular diseases. When a molecule of α -tocopherol neutralizes a free radical, it is altered in such a way that its antioxidant capacity is lost. However, other antioxidants, such as vitamin C, are capable of regenerating the antioxidant capacity of α -tocopherol. If the rate of oxidation is greater than the rate of regeneration, α -tocopherol concentrations in the body will decrease. Low levels of α -tocopherol have been associated with increased incidence of cardiovascular diseases (heart disease and stroke), cancer, cataracts, and immune function. Several other functions of α -tocopherol have been identified which likely are not related to its antioxidant capacity.

Potential, Non-Antioxidant, α -Tocopherol Specific Effects [1]

A specific role for vitamin E in a required metabolic function has not been found. In addition to its direct antioxidant effects, α -tocopherol has been reported to have specific molecular functions.

The proposed molecular mechanisms of α -tocopherol are associated with transcriptional and post-transcriptional events. Activation of diacylglycerol kinase and protein phosphatase 2A (PP₂A) and the inhibition of protein kinase C (PKC), cyclooxygenase-1, 5-lipoxygenase, and cytokine release by α -tocopherol are all examples of post-transcriptional regulation. PKC inhibition by α -tocopherol was reported to be involved in cell proliferation and differentiation in smooth muscle cells, human platelets, and monocytes. The inhibitory effect of α -tocopherol on PKC can be correlated to a dephosphorylation of PKC α . Dephosphorylation of PKC occurs via the protein PP₂A, which has been found to be activated in vitro by treatment of α -tocopherol. Genes affected by tocopherols were divided in five groups. Group 1: genes that are involved in the uptake and degradation of tocopherols: α -TTP, cytochrome P450 (CYP3A), gamma-glutamyl-cysteine synthetase heavy subunit, and glutathione-S-transferase. Group 2: genes that are implicated with lipid uptake and atherosclerosis: CD36, SR-BI, and SR-AI/II. Group 3: genes that are involved in the modulation of extracellular proteins: tropomyosin, collagen-alpha-1, MMP-1, MMP-19, and connective tissue growth factor. Group 4: genes that are connected to adhesion and inflammation: E-selectin, ICAM-1 integrins, glycoprotein IIb, IL-2, IL-4, IL-1b, and transforming growth factor-beta (TGF-beta). Group 5: genes implicated in cell signaling and cell cycle regulation: PPAR-gamma, cyclin D1, cyclin E, Bcl2-L1, p27, CD95 (APO-1/Fas ligand), and 5 α -steroid reductase

Vitamin E. Figure 1 The role of vitamin E in the mechanism of lipid peroxidation: (1) *Initiation*: a radical (R^\bullet) must be present; (2) Hydrogen abstraction from a weakened C - H bond on carbon atoms adjacent to double bonds in a PUFA, forming a carbon centred radical; (3) *Propagation*: rearrangement to a conjugated diene followed by reaction with molecular oxygen (O_2) produces a highly reactive peroxy radical which simultaneously propagates the reaction by hydrogen abstraction from another PUFA (\rightarrow chain reaction); (4) *Termination*: hydrogen abstraction from α -tocopherol form a lipid hydroperoxide and a tocopheroxyl radical. The chain reaction is broken since α -tocopheroxyl radical will not react with an adjacent PUFA; (5) The α -tocopheroxyl radical can be recycled by vitamin C.

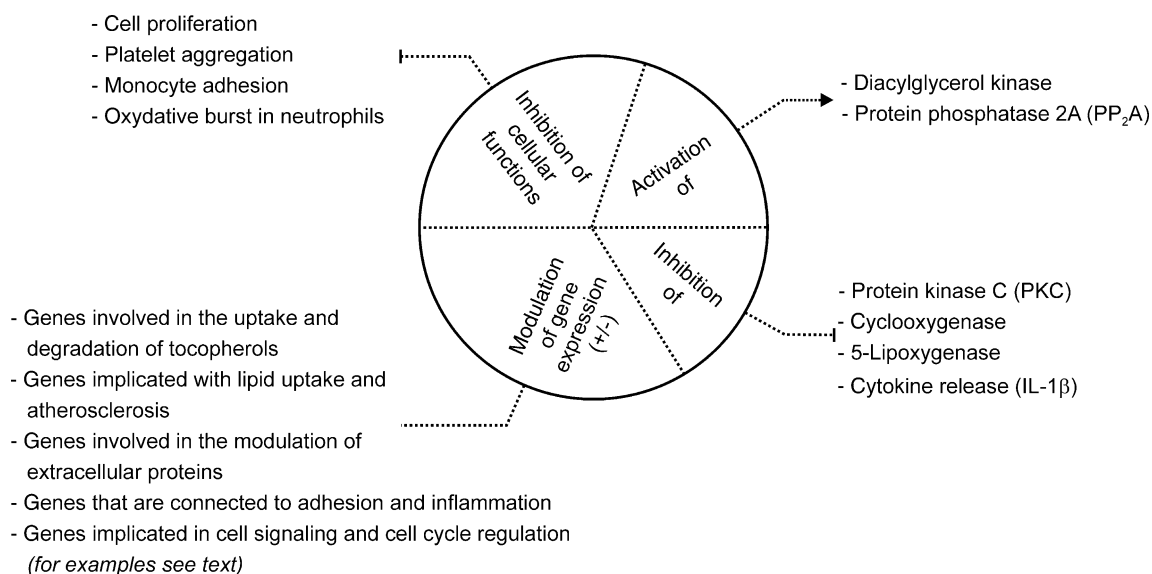

type 1. The transcription of p27, Bcl2, α -TTP, cytochrome P450 (CYP3A), gamma-glutamyl-cysteine synthetase heavy subunit, tropomyosin, IL-2, and CTGF appears to be upregulated by one or more tocopherols. All the other listed genes are downregulated

Gene regulation by tocopherols has mainly been associated with PKC because of its deactivation by α -tocopherol and its contribution in the regulation of a number of transcription factors (NF-kappaB, AP1). A direct participation of the pregnane X receptor (PXR)/retinoid X receptor (RXR) has been also shown. The antioxidant-responsive element (ARE) and the TGF-beta-responsive element appear in some cases to be implicated as well. The observed immunomodulatory function of α -tocopherol may also be attributed to the fact that the release of the proinflammatory cytokine interleukin-1 β can be inhibited by α -tocopherol via

inhibition of the 5-lipoxygenase pathway. In addition, the inhibition of PKC activity from monocytes by α -tocopherol is followed by inhibition of phosphorylation and translocation of the cytosolic factor p47 (phox) and impaired assembly of the NADPH-oxidize and of superoxide production. An overview of the non-antioxidant effects of α -tocopherol is summarized in Fig. 2.

Clinical Use (Disease Treatment) Role in Cardiovascular Diseases

Low levels of vitamin E have been associated with increased incidence of coronary artery disease. Observational studies have therefore suggested that supplemental α -tocopherol might have value in the treatment of cardiovascular disease. Clinical studies demonstrated contradicting results regarding the benefits of vitamin E in the prevention of cardiovascular disease. Four

Vitamin E. Figure 2 Non-antioxidant properties of α -tocopherol.

large-scale, randomized, double-blind clinical intervention studies have tested the ability of vitamin E to prevent myocardial infarction. One was strongly positive, the other three were neutral. Therefore, the role of α -tocopherol supplementation in the treatment of cardiovascular disease is unclear and the results of further large intervention trails must be bided to clarify the role of vitamin E in the pathogenesis of cardiovascular diseases. In a recently published meta-analysis, the authors concluded that available data (peer-reviewed articles in MEDLINE from 1966 up to July 2005) do not support the supplementation of vitamin E in cardiovascular disease [2]. The authors of the extended HOPE (Heart Outcomes Prevention Evaluation) study even came to the conclusion that long-term vitamin E supplementation does not prevent major cardiovascular events and may increase the risk for heart failure.

Role in Diabetes Mellitus

It has been proposed that the development of the complications of **diabetes mellitus** may be linked to oxidative stress and therefore might be attenuated by antioxidants such as vitamin E. Furthermore, it is discussed that glucose-induced vascular dysfunction in diabetes can be reduced by vitamin E treatment due to the inactivation of PKC. Cardiovascular complications are among the leading causes of death in diabetics. In addition, a postulated protective effect of vitamin E (antioxidants) on fasting plasma glucose in type 2 diabetic patients is also mentioned but could not be confirmed in a recently published triple-blind, placebo-controlled clinical trial [3]. To our knowledge, up to now no clinical intervention trials have tested directly whether vitamin E can ameliorate the complication of diabetes.

Role in Alzheimer's Disease

Alzheimer's disease is a degenerative disease of the brain, in which oxidative stress appears to play a role. Vitamin E is thought to prevent brain cell damage by destroying toxic free radicals. In a 2-year, double-blind, placebo-controlled, randomized, multicentre trail, supplementation of 341 patients who had moderate neurological impairment with 2,000 IU synthetic α -tocopherol daily resulted in a significant slowing of the progression of Alzheimer's disease [4]. Although these results are promising, it is too early to draw any conclusions about the usefulness of vitamin E in Alzheimer's disease or other neurological diseases. In general, clinical studies demonstrated contradicting results regarding the benefits of vitamin E in these diseases with the exception of Alzheimer's disease, which seemed to show benefit when vitamin E was used. Therefore, further studies are required to determine the role of vitamin E supplementation in central nervous system disorders.

A recent review [5] concluded that there is little convincing evidence that vitamin E increases antioxidant defences in the body. This would also question a benefit of vitamin E in the prevention and management of the diseases mentioned above.

Friedreich Ataxia

Friedreich's ataxia (FRDA) is the most common inherited ataxia. FRDA is an autosomal recessive degenerative disorder caused by a GAA triplet expansion or point mutations in the *FRDA* gene on chromosome 9q13. Decreased mitochondrial respiratory chain function and increased oxidative stress have been implicated in the pathogenesis of FRDA, raising the possibility that energy enhancement and antioxidant therapies may be an

effective treatment. Pilot studies have shown the potential effect of antioxidant therapy in this condition and provide a strong rationale for designing larger clinical randomized trials. In the cases of Ataxia with vitamin E deficiency, high levels of vitamin E (800 IU) increased the blood concentration and stabilized the neurological signs especially in early stages of the disease. These patients lack a key protein in the liver (α -TTP) that is responsible for putting the vitamin E in the blood lipoproteins for transport to the tissues. For this reason, these patients develop serious deficiency which cause major neurological and muscle damage.

Side Effects

Due to bleeding risk, individuals on anticoagulant therapy or individuals who are vitamin K-deficient should not take vitamin E supplementation without close medical supervision. Absent of that, vitamin E is a well-tolerated relatively non-toxic nutrient. A tolerable upper intake level of 1,000 mg daily of α -tocopherol of any form (equivalent to 1,500 IU of RRR α -tocopherol or 1,100 IU of all-rac- α -tocopherol) would be, according to the Food and Nutrition Board of the Institute of Medicine, the highest dose unlikely to result in haemorrhage in almost all adults.

Vitamin K

DONATUS NOHR, HANS K. BIESALSKI
Institute of Biological Chemistry and Nutrition (-140-),
University of Hohenheim, Stuttgart, Germany

Synonyms

Phylloquinones (vitamin K1, produced by plants) and menaquinones-n (MK-n, vitamin K2)

Definition

Vitamin K represents two groups of substances named “phyloquinones” (vitamin K1; produced by plants) and menaquinones-n (MK-n; vitamin K2). Menaquinones are synthesized by bacteria, using repeated 5-carbon units in the molecules side chain. n stands for the number of 5-carbon units. Interestingly, MK-4 is synthesized only in small amounts by bacteria but can be produced by animals (including humans) from phyloquinones and is found in a number of organs. For an overview see [1, 2].

Vitamin K belongs to the group of fat-soluble vitamins. The term “K” refers to its main actions in blood-clotting, coagulation, in German named “Koagulation”. In the coagulation cascade seven coagulation factors depend on Vitamin K which acts as coenzyme for a vitamin K-dependent carboxylase that catalyzes the carboxylation of glutamic acid. This specific carboxylation occurs only in a small number of proteins but is essential for their ability to bind calcium [5]. Vitamin K is light-sensitive but almost resistant to heat.

Vitamin K carboxylase is a transmembraneous protein in the lipid bilayer of the endoplasmatic reticulum (ER). It is highly glycosylated and its C-terminal is on the luminal side of the membrane. Besides its function as carboxylase it takes part as an epoxidase in the vitamin K cycle (Fig. 1). For the binding of the γ -carboxylase the vitamin K-dependent proteins have highly conserved special recognition sites. Most vitamin K-dependent proteins are carboxylated in the liver and in osteoblasts, but also other tissues might be involved, e.g., muscles.

Mechanism of Action

General Aspects

Although vitamin K is a fat soluble vitamin, only little stores are found in the body which have to be refilled permanently via dietary input. The role of vitamin K derived from bacteria in the colon is controversially discussed, as the concentration of biliary acids for the resorption the fat-soluble vitamin K is very low in the colon. In addition, only diseases of the small intestine lead to a deficit in vitamin K concentration which cannot be restored by K2 production of colonic bacteria. However, water-soluble vitamin Ks can be resorbed by the colonic mucosa. Maybe because of the little stores for vitamin K, the process of vitamin K-dependent carboxylation of proteins is part of a cycle with several steps during which vitamin K normally is regenerated (see Fig. 1) and thus can be used several times.

Coagulation

Binding calcium ions (Ca^{2+}) is a prerequisite for the activation of seven clotting factors in the coagulation cascade that are dependent on vitamin K. The term cascade indicates, that the factors involved depend from

Vitamin K. Figure 1 The vitamin K cycle. w indicates where warfarin or other vitamin K antagonist inhibit the cycle.

each other to become activated and to fulfil their special part to stop bleeding. Prothrombin (factor II), factors VII, IX, and X play central roles in the coagulation cascade, protein Z seems to enhance the thrombin action via promoting its association with phospholipids in cell membranes. The proteins C and S (as a cofactor for C) act as anticoagulant proteins (they inhibit clotting factors Va and VIIIa) such providing an also vitamin K-dependent control and balance of the whole cascade. With both, coagulant and anticoagulant factors present in the cascade in the liver, uncontrolled bleeding and/or clotting can be well prevented. On the other hand, liver damage or diseases can disturb this well controlled cascade, e.g., via reduced clotting factors in the circulating blood resulting in uncontrolled bleeding (hemorrhage) [4] which in turn seem to be treatable by the application of recombinant factor seven (rFVIIa) [3].

Bone Mineralization

In bone, three proteins have been described which are vitamin K-dependent, osteocalcin (bone Gla protein), matrix Gla protein (MGP), and protein S. Osteocalcin is synthesized by osteoclasts, regulated by the active form of vitamin D, calcitriol. Its capacity to bind calcium needs a vitamin K-dependent γ -carboxylation of three glutamic acid residues. The calcium binding capacity of osteocalcin indicates a possible role in bone mineralization, but its exact function is still unclear. However, it is widely used as a serum marker for bone mineralization. Protein S, mainly a coagulant, is also vitamin-K dependent and synthesized in the liver. Children with

reduced protein S levels express enhanced blood clotting and a reduced bone density. MGP has been found in several supportive tissues (bone, cartilage) and in soft tissues including blood vessels. At least animal studies gave hints that MGP prevents soft tissues as well as cartilage from calcification while on the other hand it facilitates bone development and growth. Even the phenotype of mice lacking MGP supports this description, but the molecular mechanisms are still unknown. Rat studies with warfarin (vitamin K antagonist, see Fig. 1) led to prominent deformations of the skeleton of fetuses as well as newborns including excessive mineralization of growth plates and nasal cartilage, and stunted growth. Comparable effects were seen in humans after a therapy with vitamin K antagonists during pregnancy. The so called warfarin-embryopathy includes hypercalcification of the growth plates (Chondroplasia punctata), a nasal hypoplasia and disturbances in the growth of facial and hollow bones. For a more detailed overview see.

Cell Growth

Growth arrest-specific gene 6 (Gas6) is a γ -carboxylated protein found throughout the nervous system, in the heart, lung, stomach, kidneys, and cartilage. It is regarded as a ligand for several families of receptor tyrosine kinases (RTKs) which, when overexpressed, have effects on malignant cell survival. The exact mechanisms of Gas6 function have not yet been clarified but it is discussed as a cellular growth regulation factor with cell signaling activities as well as a supporter of

hematopoietic cells in the bone marrow. In addition, a role in the developing and the aging nervous system is under discussion and protective effects for cortical neurons have been shown. Other groups described an enhanced proportion of neurite-bearing PCD12 cells and acetylcholinesterase activity when cells were treated with nerve growth factor (NGF) and vitamin K in comparison to NGF treatment only which could be blocked by protein kinase A or MAP kinase inhibitors.

Clinical Use (Including Side Effects)

Vitamin K Deficiency

There are clearcut differences in deficiencies concerning infants, especially newborns, and adults. Deficiencies of vitamin K are really seldom in healthy adults, because the supply through daily food is (more than) enough, vitamin K is repeatedly recycled and therefore only a small loss appears, and – although not really accepted and because of the K₂ production by intestinal bacteria (see above). On the other hand, those people with severe liver diseases or taking vitamin K antagonist anticoagulants have a risk of vitamin K deficiency. Symptoms are impaired blood clotting as revealed by routine tests measuring clotting time, unusual bleeding after smaller wounding, nose bleeding, heavy menstrual bleeding or a great susceptibility to hematoma.

The picture is different concerning infants during the first days of life, especially for those being breast fed. Coagulation-related (vitamin K-dependent) plasma proteins develop slowly during pregnancy resulting in markedly reduced levels after birth. In addition, human milk is a low-vitamin K nutrient, the newborns intestine almost totally lacks menaquinone-synthetizing bacteria, and the vitamin K cycle might not yet be established. These deficiencies can lead in healthy newborns to uncontrolled, in worst cases lethal intracranial bleedings. Due to that risk, in most countries newborns are supplied with phylloquinones, normally by injections, or by bottle feeding. Although there have been some hints in retrospective studies in the early 1990s on a correlation of vitamin K supplementation of newborns with the development of leucaemia, other retrospective studies found no correlations [2]. Therefore, a routine vitamin K prophylaxis of newborns is still recommended because the risk of early postnatal bleedings is much greater than the (unproven) risk of cancer.

Osteoporosis

This illness is mainly characterized by an age-related bone loss. The detection of osteocalcin in bone was the starting point for a series of studies on the role of vitamin K-dependent proteins in bone development and maintenance and on possible supplementantion therapies. Epidemiologic studies found differences in the risk of hip fractures depending on the dietary vitamin K

intake (35% risk at 250 µg/day of those with 50 µg/day), although no association between dietary intake and bone density could be found. Osteocalcin has been found to be a reliable marker of bone formation and vitamin K is necessary for the carboxylation of this protein. Therefore, the degree of carboxylation of osteocalcin is a reliable marker for the respective vitamin status. Blood levels of undercarboxylated osteocalcin were found to be higher in postmenopausal women and markedly higher in women over 70. Studies with elderly women resulted in a positive correlation of the blood level of undercarboxylated osteocalcin and the risk of bone fractures. Interestingly, also a correlation of undercarboxylated osteocalcin with the vitamin D nutritional status were described.

Application of vitamin K-antagonistic anticoagulants like warfarin gave no clearcut results concerning bone density or a changed risk for bone fractures.

Supplementation with high doses of vitamin K₁ (1 mg/day for 14 days) or MK-4 (45 mg/day) resulted in decreased levels of undercarboxylated osteocalcin and increase of bone formation markers and in a significant reduction in bone loss, respectively. Using such high doses, any kind of effects besides vitamin K can not yet be ruled out and have to be further elucidated by long term studies. An overview can be found in a review by Palacios [4].

Atherosclerosis

In contrast to the formation and calcification of bones, vitamin K seems to lower the risk of aortic calcification. The mechanisms for these “antagonistic” effects is not known but a participation of osteocalcin (expressed in atherosclerotic plaques) as well as of matrix Gla protein (MGP) are discussed. In addition, the vitamin K epoxide reductase complex seems to be involved [5].

Safety and Toxicity

As the above mentioned studies with high supplementation dosages exemplarily show, there is no known toxicity for phylloquinone (vitamin K₁), although allergic reactions are possible. This is NOT true for menadione (vitamin K₃) that can interfere with glutathione, a natural antioxidant, resulting in oxidative stress and cell membrane damage. Injections of menadione in infants led to jaundice and hemolytic anemia and therefore should not be used for the treatment of vitamin K deficiency.

People using warfarin or other anticoagulants should try to consume the recommended daily intake very regularly to avoid interferences with their anticoagulant dosage adjusted by the physician. Interestingly, high doses of vitamins A and E seem to antagonize vitamin K, vitamin A interfering with vitamin K absorption and vitamin E (tocopherol quinone) inhibiting vitamin K-dependent carboxylase enzymes.

Vitamin K. Table 1 Vitamin K content of selected nutrients in alphabetic order

Nutrient	Vitamin K content (µg/100g)
Bovine meat	210
Broccoli	130
Brussels sprouts	570
Butter	60
Cauliflower	300
Chicken	300
Chicken egg	45
Mayonnaise	81
Milk (3.5% fat)	3.7
Oil (sunflower)	500
Porcine meat	18
Rice, white	1
Sauerkraut	1540
Soyabeans (semen)	190
Spinach	810
Tea, black leaves	262
Tea, green leaves	1428
Tomatoes	8
Wheat (germs)	350
Wheat (grains)	17

The adequate intake level (AI) for the US given by the FNB of the Institute of Medicine is 120 µg/day and 90 µg/day for men and women older than 19 years, respectively. In Germany, 60–80 µg/day for adults, 4 µg/day for sucklings <4 months, and 50 µg/day for children <15 years are proposed by the German Nutrition Society (DGE).

Food Sources

Phylloquinone (vitamin K1) is the form of vitamin K synthesized by mainly green leafy vegetables and such also appears in plant oils (soybean, cottonseed, canola, olive). Both are good sources for a daily supply, although the need of such a supply is still under discussion. [Table 1](#) shows some good sources and their content of vitamin K1.

Voltage-dependent Ca²⁺ Channels

FRANZ HOFMANN

Institut für Pharmakologie und Toxikologie,
Technische Universität München, München, Germany

Synonyms

High voltage-activated (HVA) calcium channels; Low voltage-activated (LVA) calcium channels

Definition

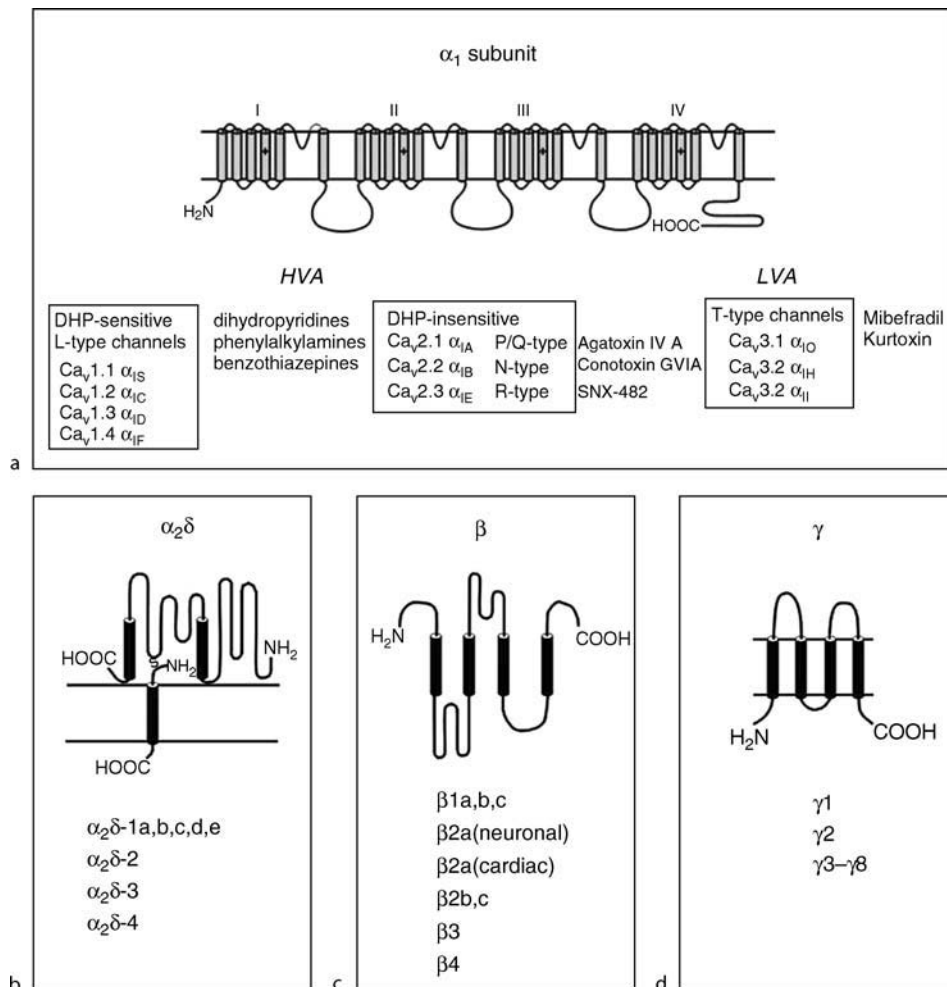

► **Voltage-dependent Ca²⁺ channels** are a family of multi-subunit complexes of five proteins responding to membrane depolarisation with channel opening allowing the influx of calcium into a cell. Voltage-dependent calcium channels are subdivided into three subfamilies: the HVA DHP-sensitive L-type calcium channels, the HVA DHP-insensitive calcium channels and the LVA T-type calcium channels [2].

Basic Characteristics

Voltage-activated calcium channels regulate the intracellular calcium concentration and contribute thereby to calcium signalling in numerous cell types. These channels are widely distributed in the animal kingdom and are an essential part of many excitable and non-excitable mammalian cell signalling pathways. Electrophysiological studies characterised different calcium currents identified as L-, N-, P-, Q-, R- and T-type current [1, 2]. The opening of these channels is primarily triggered by depolarisation of the membrane potential, but is also modulated by a wide variety of hormones, protein kinases, protein phosphatases, toxins and drugs. Site-directed mutagenesis has identified sites on these channels, which interact specifically with other proteins, inhibitors and ions.

HVA calcium channels are biochemically heterooligomeric complexes of five proteins encoded by four gene families (Fig. 1): The α_1 subunits of ~190–250 kDa contain the voltage-sensor, the selectivity filter, the ion-conducting pore, the binding sites for most calcium

channel blockers, and the interaction sites for ▶heterotrimeric GTP-binding protein subunits and other proteins. Seven α_1 genes have been identified (Fig. 1). Four genes ($\text{Ca}_v1.x$) encode L-type, dihydropyridine-sensitive channels. Three genes ($\text{Ca}_v2.x$) encode the none dihydropyridine-sensitive neuronal N-, P-, Q-, R-current. These α_1 subunits are associated with four auxiliary proteins (Fig. 2). The $\alpha_2\delta$ subunits, disulfide-linked dimers, are transcribed from four different genes and are clipped posttranslationally into the extracellular located α_2 - and the transmembrane δ -protein. The intracellular located β subunit and the transmembrane γ subunit are encoded by four and up to eight distinct genes, respectively. With the exception of the skeletal muscle calcium channel, a heterooligomer containing the $\text{Ca}_v1.1$ (α_{1S}), $\beta 1$, $\alpha_2\delta$ -1 and $\gamma 1$ subunit, the exact composition of individual channels is not known. The identity of these complexes is further complicated by the existence of several splice variants for most genes that confer significant effects on the electrophysiological and/or pharmacological properties of the channels.

Voltage-dependent Ca²⁺ Channels. Figure 1 Structure, identity and blockers of calcium channel subunits.

Voltage-dependent Ca^{2+} Channels. Figure 2 Subunit composition of a HVA calcium channel. The selectivity filter of the channel is created by four glutamates (E).

The exact subunit composition of the **Low Voltage-activated (LVA) Ca^{2+} channels** is unknown [3, 6]. Three α_1 subunits, $\text{Ca}_v3.x$, have been identified which induce large T-type current after expression in *Xenopus* oocytes and in HEK cells in the absence of additional subunits. The T-type current can be affected by the $\alpha_2\delta$ and the γ_6 subunit suggesting a maximal subunit composition of $\alpha_1/\alpha_2\delta/\gamma$.

Properties of the α_1 Subunits: Each α_1 subunit contains four repeats that are composed of six transmembrane helices and a pore region between helix S5 and S6. The selectivity filter of the channels is located in the pore region and calcium selectivity of the HVA channels is created by four glutamates (E) in each pore, whereas the LVA channels have glutamates in the pore of repeat I and II and aspartates (D) in that of repeat III and IV. Conformational changes of the protein allow the channel to occupy one of three states: the closed, open or inactivated state. The change in membrane potential is sensed by the S4 helices of each repeat which contain a number of positive charged amino acids. Movement of these helices induces opening of the channel pore. HVA channels are activated approximately at a membrane potential of -30 mV with a maximal activation around 0 mV, whereas the LVA channels activate at potentials around -60 mV and have a maximal inward current around -10 mV. The LVA channels active and inactivate faster than the HVA channels. Inactivation of all channels is voltage-dependent and accelerated if the membrane is depolarised for prolonged time. Voltage-dependent inactivation may be mediated by sequences present in repeat I and II. Some of the HVA channels, especially the $\text{Ca}_v1.2$ channel, show calcium-dependent inactivation. Calcium flowing through the channel binds on the internal side to

calmodulin, a calcium binding protein tethered to the carboxy terminal tail of the α_1 protein by an isoleucine/glutamine (IQ)-motive. The calcium-calmodulin complex induces a conformational change in the α_1 protein that leads to inactivation of the channel. The $\text{Ca}_v1.4$ and the LVA channels do not have this type of inactivation.

The intracellular loop between repeat II and III couples and signals to intracellular effectors. The II–III loop of the $\text{Ca}_v1.1$ protein couples directly with the ryanodine receptor 1 located at the sarcoplasmic reticulum in the skeletal muscle triad. In contrast, the cardiac $\text{Ca}_v1.2$ channel is in close proximity but not in direct contact with the cardiac ryanodine receptor 2. This cardiac ryanodine receptor channel is activated by the calcium flowing through the open $\text{Ca}_v1.2$ channel. The II–III loops of the neuronal presynaptic localised $\text{Ca}_v2.1$ and $\text{Ca}_v2.2$ channels interact directly with the SNARE complex of the neurotransmitter containing vesicles and facilitates together with the inflowing calcium fusion of the vesicle and plasma membrane resulting in opening of the vesicle. Similar interactions occur probably between the $\text{Ca}_v1.2$ II–III loop and insulin containing vesicles of the pancreatic islets.

Neurotransmitter receptors inhibit the neuronal $\text{Ca}_v2.x$ channels by activation of G-proteins. The β/γ subunit of the **heterotrimeric GTP-binding proteins** binds to a QxxER sequence that is located at the I–II loop. Binding of the β/γ subunits confers the “reluctant phenotype” to these channels. This phenotype includes a reduced channel activation and current at normal depolarised membrane potentials. The I–II loop interacts also with the calcium channel β subunit with high affinity allowing transport of the α_1 protein from the Golgi to the membrane surface and a shift in the voltage-dependence of channel opening and closing.

► **Channel blockers:** Distinct blockers have been identified for the various HVA calcium channels which are listed in Fig. 1. ► **Dihydropyridines,** ► **phenylalkylamines** and ► **benzothiazepines** block all Ca_v1.x L-type calcium channels. These compounds are used mainly to lower the blood pressure in hypertensive patients. In therapeutic concentrations, they block mainly the smooth muscle Ca_v1.2 channel. The dihydropyridines bind with high affinity to the inactivated state of the L-type channels. Binding requires amino acids on the IIS5, IIS6 and IVS6 helices. Mutation of Thr1061 in IIS5 to tyrosine abolished completely the high affinity interaction of dihydropyridines with the Ca_v1.2 channel protein. The difference in the sensitivity between the cardiac and the smooth muscle L-type calcium channel is in part caused by the use of alternative exons (No. 8) coding for the IS6 helix [7]. The phenylalkylamine and benzothiazepine binding sites contain amino acids present in the IIS6 and IVS6 helices and the glutamates in the pore region of repeat III and IV. The latter two groups include compounds that block neuronal Ca_v2.x channels at similar concentrations as the Ca_v1.x channels.

The LVA α_1 subunits are blocked by moderate to low (10 μ M) concentrations of nickel and bind the channel blocker mibefradil and kurotoxin. Both compounds are not specific LVA channel blockers because they block also Ca_v1.x and Ca_v2.x channels at about tenfold higher concentration. Interestingly, the endogenous cannabinoid ► **anandamide** binds to LVA channels and stabilises the inactivated state. This effect decreases T-type calcium current and neuronal firing activities.

The $\alpha_2\delta$ subunit 1 and 2 bind gabapentin with high affinity. This interaction may be causally related to its antiepileptic and neuropathic pain alleviating property.

Localisation of channels: The Ca_v1.1 channel is present in skeletal muscle at the triad. The Ca_v1.2 channel is widely distributed and represents the major L-type calcium channel in most tissues. In contrast, the Ca_v1.4 channel has been detected only in the retina, so far. The Ca_v1.3 (α_{1D}) channel is mainly found in neuroendocrine cells and the inner ear. The Ca_v2.1, Ca_v2.2 and Ca_v2.3 are mainly localised presynaptic. The Ca_v2.1 and Ca_v2.2 channels interact with the vesicular release machinery and regulate the release of neurotransmitters.

The LVA channels are expressed in a wide variety of tissues. In the cardiac sinus node and the thalamus, activation of LVA channels seems to be necessary to generate action potentials upon depolarising the membrane.

Mutation and Deletion

Deletion of the Ca_v1.1 and Ca_v1.2 gene is not compatible with viable mouse pups [4, 5]. The Ca_v1.2 channel is absolutely required for the contraction of the developing mouse heart after embryonal day 14.

Mutation of the human Ca_v1.1 gene is associated with hypokalemic periodic paralysis. Deletion of the Ca_v1.3 gene leads to viable pups that are deaf and have cardiac arrhythmia at rest. Mutation of the human Ca_v1.4 gene is associated with X-linked congenital stationary night blindness.

Mutation in the neuronal Ca_v2.1 channel is associated with familial hemiplegic migraine and episodic ataxia in humans. Deletion of the Ca_v2.1, Ca_v2.2 and Ca_v2.3 gene is compatible with life accompanied by a variety of central and peripheral defects.

Deletion of the Ca_v3.1 channel in thalamocortical relay neurons prevents ► **absence epilepsy**. Block of the neuronal LVA channels alleviates certain forms of epilepsy. Deletion of Ca_v3.2 leads to coronary artery constriction and focal myocardial fibrosis.

Deletion of the $\beta 1$ subunit is lethal, whereas deletion or mutation of the $\alpha_2\delta$ -2, $\beta 3$, $\beta 4$, $\gamma 1$ and $\gamma 2$ genes is associated either with no or various neuronal phenotypes.

More recent analysis of tissue specific gene deletions showed that the Ca_v1.2 channel is involved in a wide variety of function including hippocampal learning, insulin secretion, intestine and bladder motility. Further analysis will be required to unravel the functional significance of voltage-dependent calcium channels for specific cellular functions.

Drugs

Numerous dihydropyridine calcium channel blockers have been introduced to treat hypertension and stable angina pectoris. Nifedipine, nitrendipine, nisoldipine, nilvadipine, nicardipine, amlodipine, felodipine, isradipine block preferentially the vascular, smooth muscle Ca_v1.2 calcium channel at therapeutic doses. Nimodipine that has a short half life has been used to alleviate cerebral vasospasms after subarachnoidal bleeding. The phenylalkylamines verapamil and gallopamil and the benzothiazepine diltiazem have been used as antihypertensive drugs and to treat supraventricular tachyarrhythmia. Mibefradil – a compound thought to inhibit preferentially T-type channels – that blocks at low concentrations vascular Ca_v1.2 L-type channels in the mouse, has been used for a short period as an antihypertensive drug. It has been removed from the market due to intolerable interactions with other drugs.

Gabapentin and pregabalin are prescribed in certain epileptic diseases such as absence epilepsy and in neuropathic pain. Their therapeutic target for pain suppression is the $\alpha_2\delta$ -1 subunit.

Voltage-dependent Inactivation

Voltage-dependent inactivation is channel inactivation at depolarised membrane potentials.

► Voltage-dependent Ca²⁺ Channels

Voltage-dependent Na⁺ Channels

KEIJI IMOTO

National Institute for Physiological Sciences, and School of Life Science, The Graduate University for Advanced Studies, Okazaki, Japan

Synonyms

Voltage-gated sodium channel; Na⁺ channel

Definition

Voltage-dependent sodium channels are a family of membrane proteins that mediate rapid Na⁺ influx, in response to membrane depolarization to generate action potentials in excitable cells.

Basic Characteristics

Electrophysiological studies (mainly using voltage-clamp and patch clamp) revealed the essential properties of the sodium channels; kinetics of channel ► gating and selective ion permeation. Sodium channels are

closed at negative resting membrane potentials. Membrane depolarization evokes very rapid activation of the channel, followed by inactivation typically within several milliseconds. The sodium channels recover quickly from fast inactivation when the membrane is repolarized. When the membrane is depolarized for a longer period (from hundreds of milliseconds to seconds), the sodium channels undergo slow inactivation. There are probably multiple types of slow inactivation. Recovery from slow inactivation requires a longer time of repolarization.

The sodium channels are very selective for Na⁺ over K⁺, allowing Na⁺ influx down the electrochemical gradient to generate positive membrane potentials. The sodium channels are also permeable to Li⁺ and NH₄⁺. The narrowest portion of the channel pore is estimated to be rectangular (3.1 × 5.2 Å).

In addition to the ionic current, membrane depolarization evokes the gating current even in the absence of permeant ions. This tiny current represents the movements of charged parts of the sodium channel proteins. Comparison of the voltage-dependence of ionic currents and gating currents, together with other lines of evidence, suggests that the sodium channels undergo multiple conformational transitions between the resting and open states. These transitions are successfully simulated using a framework of Markov process. Conformational changes are essential for state-dependent effects of various drugs acting on the sodium channels.

The primary role of the sodium channels is to generate action potentials in excitable cells. In case of neurons, the sodium channel density is high at axon hillocks or axon initial segment where action potentials start to propagate. The sodium channels are also present in dendrites. The sodium channels contribute to amplifying synaptic inputs (particularly those distally located) and are actively involved in ► back propagation of action potentials into dendrites. Subtle differences in properties of sodium channels influence the dendritic processes of synaptic integration in and complex ways.

Molecular Structure

The three-dimensional structure of the sodium channel (from electric eel) was determined at 19-Å resolution using cryo-electron microscopy and single-particle image analysis. The sodium channel has a bell-shaped outer surface of 135 Å in height, 100 Å in side length at the square bottom, and 65 Å in diameter of the spherical top. An interesting finding is that there are several inner cavities connected to outer orifices.

Molecularly, mammalian voltage-dependent sodium channels are composed of the main pore forming α subunit and smaller auxiliary β subunits. The rat brain sodium channel contains the 260-kD α subunit, the 36-kD β 1 subunit and the 33-kD β 2 subunit. The subunit stoichiometry is α : β 1: β 2 = 1: 1: 1.

The α subunit is the main component of the sodium channels, consisting of $\sim 2,000$ amino acid residues. Amino acid sequence analysis reveals four repeated units of homology (repeat I–repeat IV), each containing six hydrophobic, putative transmembrane segments. The N- and C-termini and the linking regions between repeats are assumed to reside in the cytoplasmic side. The fourth hydrophobic segment, S4, of each repeat has a well-conserved motif of positively charged residues appearing every third residues. This motif is found in other voltage-dependent channels, and contributes to sensing voltage changes. S4 moves outward in response to depolarization and becomes accessible from the extracellular side. Among sodium channel subtypes, the linker regions between repeats are less homologous than the transmembrane regions, except for the linker connecting repeats III and IV.

The conserved linker between repeats III and IV is critical for fast inactivation. Cleavage of the III–IV linkage causes a strong reduction in the rate of inactivation. A cluster of three hydrophobic residues (IFM) in the linker is an essential component, probably serving as a hydrophobic latch to stabilize the inactivated state. Other parts of the α subunit are also involved in fast inactivation. Conformational changes in the P region contribute to the slow inactivation process.

The region between S5 and S6 of each repeat is commonly called “P region” (P for “pore”), and is important for forming the narrow part of the ion conducting pathway and the selectivity filter. Mutagenesis studies identified the most critical amino acid residues, D, E, K, and A for repeats I–IV, respectively. Interestingly, alteration of K to E in repeat III and A to E in repeat IV dramatically change the ion-selectivity properties, to resemble those of calcium channels, suggesting that these amino acid residues participate in forming the selectivity filter. This observation also suggests a close evolutionary relationship between the voltage-dependent sodium and calcium channels, although a prokaryotic voltage-gated sodium channel is encoded by a single domain. The “P region” also forms the binding site for tetrodotoxin

▶(TTX) and ▶saxitoxin, which block the channel pore from the outer side. The difference in ▶TTX sensitivity among the sodium channels is caused by a single amino acid difference in the “P region” of repeat I (phenylalanine or tyrosine in TTX-sensitive channels; cysteine or serine in TTX-resistant channels). The S6 segments contribute to forming the inner pore of the channel and binding sites for local anesthetics.

Molecular cloning has detected multiple α subunit genes, more than expected from electrophysiological and pharmacological measurements (Table 1). The primary transcript from a sodium channel gene undergoes a developmentally regulated complex pattern of alternative splicing, generating further heterogeneity. The sodium channels are practically classified into two major classes based on the sensitivity to ▶TTX. The sodium channels are relatively similar in properties, showing rapid activation and inactivation.

Note that the numbering of the new system is not the same as for the gene symbols. A closely related sodium channel-like proteins have been identified and named Na_x. Functional properties of these proteins are not known, except for the NaG protein, which functions as a sodium sensor of body fluid.

The β subunits ($\beta 1$ – $\beta 4$) are membrane proteins with a single transmembrane domain and an extracellular immunoglobulin-like motif, and perform the regulatory roles of the sodium channel. The $\beta 1$ subunit accelerates the activation and inactivation kinetics. The $\beta 2$ subunit is covalently linked to the α subunit, and is necessary for the efficient assembly of the channel. The more recently identified $\beta 3$ subunit is homologous to $\beta 1$, but differs in its distribution within the brain and in a weaker accelerating property. The $\beta 4$ subunit is similar to $\beta 2$ and is covalently linked to the α subunit.

Functions of and Associated Disorders of Sodium Channel Subtypes

CNS neurons express at least four types of sodium channels, Na_v1.1, Na_v1.2, Na_v1.3, and Na_v1.6. Na_v1.1 is found in the somatodendritic membrane,

Voltage-dependent Na⁺ Channels. Table 1 Mammalian sodium channel α subunits

Type	Conventional names	Gene symbol (human)	TTX sensitivity	Primary tissues
Na _v 1.1	Brain type I	SCN1A	S	CNS, PNS
Na _v 1.2	Brain type II, type IIA	SCN2A	S	CNS
Na _v 1.3	Brain type III	SCN3A	S	CNS, PNS
Na _v 1.4	$\mu 1$, SkM1, SCN4A	SCN4A	S	skeletal muscle
Na _v 1.5	Heart 1, SkM2, hH1, SCN5A	SCN5A	R	heart
Na _v 1.6	NaCh6, Scna8, PN4, CerIII	SCN8A	S	CNS, PNS
Na _v 1.7	hNE-Na, Na _s , PN1, Scn9a	SCN9A	S	PNS
Na _v 1.8	SNS, PN3, NaNG, Scn10a	SCN10A	R	PNS
Na _v 1.9	NaN, SNS2	SCN11A	R	PNS
Na _x	Na _v 2.1, Na _v 2.3, NaG, SCL-11	SCN7A		CNS, PNS, heart, uterus

whereas Na_v1.2 is predominantly found on axons and at or near axon terminals. A sequence of nine amino acid residues has been identified in the cytoplasmic C-terminus of Na_v1.2, which mediates axonal compartmentalization. Na_v1.2 is likely to be involved in action potential initiation at the initial segment. Knock-out of Na_v1.2 is lethal. Na_v1.3 is expressed predominantly in embryonic and early postnatal stages. Na_v1.6 is localized at Nodes of Ranvier and dendrites (Fig. 1).

In cerebellar Purkinje cells, a TTX-sensitive inward current is elicited, when the membrane was partially repolarized after strong depolarization. This “resurgent current” contributes to high-frequency repetitive firing of Purkinje neurons. The resurgent current results from open channel block by the cytoplasmic tail of the β4 subunit. The *med* Na_v1.6 mutant mice show defective synaptic transmission in the neuromuscular junction and degeneration of cerebellar Purkinje cells.

Generalized epilepsy with febrile seizures plus (GEFS+) is an autosomal dominantly inherited syndrome, which is distinct from febrile seizures, displaying seizures persisting beyond 6 years of age and generalized epilepsies. GEFS + is associated with mutations in the genes encoding the sodium channel β1 subunit (GEFS + type 1), the Na_v1.1 α subunit (GEFS + type 2), and the Na_v1.2 α subunit. GEFS + also results from GABA_A receptor dysfunction. Severe myoclonic epilepsy of infancy is associated with Na_v1.1 mutations.

In peripheral nervous system, Na_v1.7, Na_v1.8, and Na_v1.9 are expressed in addition to the CNS sodium channel subtypes. Whereas large-diameter neurons in dorsal root ganglia (DRG) generate TTX-sensitive currents (presumably mediated by Na_v1.6 and Na_v1.7), small cells also generate TTX-resistant currents (presumably mediated by Na_v1.8, possibly by Na_v1.9).

The Na_v1.7 has slow closed-state inactivation and carries a significant current in response to ramp depolarization. The results suggest that Na_v1.7 amplifies the “generator potentials” in nociceptor nerve endings. Recently, clinical studies revealed a critical role of Na_v1.7 for nociception. Missense mutations were identified in patients with inherited primary erythromelalgia, a disorder characterized by intermittent pain, redness, heat, and swelling in the extremities. Furthermore, genetic analysis of patients with “congenital indifference to pain” showed that three nonsense mutations abolished the Na_v1.7 channel function. When peripheral nerves are damaged, expression of Na_v1.8 and Na_v1.9 are downregulated, whereas Na_v1.3 is upregulated. The β3 subunit is also upregulated in injured nerves. This deranged sodium channel expression may cause aberrant ectopic activity in sensory neurons, generating ►neuropathic pains.

Mutations of the NaV1.4 channel gene cause various types of muscle diseases, including hyperkalemic periodic paralysis, paramyotonia congenita, ►myotonia fluctuans, acetazolamide-sensitive myotonia. Mutations disrupt inactivation and cause both myotonia (enhanced excitability) and attacks of paralysis (inexcitability resulting from depolarization).

In the ►Long QT Syndrome (LQTS), the repolarization phase of the cardiac muscle is delayed, rendering the heart vulnerable to an “arrhythmia” known as torsade de pointes. LQTS is associated with five genes encoding ion channels. LQTS type 3 (LQT3) results from mutations of Na_v1.5, which cause persistent sodium current. In contrast, sodium channel mutations associated with Brugada syndrome reduce the expression level of cardiac sodium channels.

Voltage-dependent Na⁺ Channels. Figure 1 Na⁺ Channel subtypes in PNS.

Channel Modulation

Protein kinase A attenuates sodium current amplitude by phosphorylating serines located in the I–II linker. There is a consensus protein kinase C phosphorylation site in the III–IV linker. Activation of protein kinase C decreases peak sodium current and slows its inactivation. Sodium channels interact with G proteins. Coexpression of G protein $\beta\gamma$ subunits greatly enhances sodium currents, slows inactivation, and shifts the steady state inactivation curve to the depolarizing direction. The C-terminal region of the sodium channel contains the G $\beta\gamma$ -binding motif Q-X-X-E-R, suggesting that the sodium channel is directly modulated by G $\beta\gamma$ subunits. The sodium channel has the IQ-motif sequence of non-Ca²⁺-dependent calmodulin binding in the C-terminal region. This motif is conserved in various types of sodium channel, but its physiological function remains elucidated. The sodium channel interacts with a variety of proteins, which include AKAP15 (15 kDa A-kinase anchoring protein), ankyrin-G, 14-3-3, dystrophin, and syntrophin.

Drugs

The sodium channels are targets of various chemicals and drugs. TTX and saxitoxin block the channel pore from the outside. Lidocaine and other local anesthetics act on the S6 transmembrane segment of repeat IV (IVS6), and delay the recovery from the inactivated state. Batrachotoxin, aconitine, and grayanotoxin interact with IS6, to shift the voltage-dependent activation and to slow inactivation. Scorpion toxins slow inactivation (α -toxins) and shift the voltage dependence of activation to more negative potentials (β -toxins). The peptide toxin μ -conotoxin GIIIB is a specific blocker for Na_v1.4, but no other pharmacological tools are available to specifically discriminate the sodium channel subtypes.

Kv-channels

Definition

Voltage-gated potassium (Kv) channels are membrane-inserted protein complexes, which form potassium-selective pores that are gated by changes in the potential across the membrane. The potassium current flow through the open channel follows by the electrochemical gradient as defined by the Nernst equation. In general, Kv channels are localized in the plasma membrane.

Basic Characteristics

Functional Characteristics

Kv channels may be important determinants of cellular activities correlated with changes in membrane potential. Examples range from neural signal transduction, action potential wave forms, action potential propagation, action potential frequency, pacemaking and secretion to the regulation of cell volume and cell proliferation. In addition to changes in voltage, Kv-channel activities may be regulated by various physical and/or chemical stimuli. They include Na⁺, Ca²⁺, Mg²⁺, ATP, O₂, pH, pressure, redox potential, phosphorylation/dephosphorylation, G protein binding, interaction with cytoskeletal proteins, and more [1]. Once Kv channels have been activated, they catalyze a rapid passage of K⁺ through the open pore along the electrochemical gradient as defined by the Nernst equation. Activated Kv-channels often tend to inactivate [2, 3]. The kinetics of inactivation may occur in time ranges of ms to tens of seconds. The inactivation mechanism of ►Shaker-channels, which inactivate rapidly, has been thoroughly investigated. One mechanism utilizes an amino-terminal inactivating domain. This domain is able to bind to the open pore of Shaker-channels. Thereby, the pore becomes both occluded and locked in an open state. Upon repolarization, inactivated Kv-channels recover from inactivation. Inactivated Kv-channels are refractory to activation. In most circumstances, intracellular K⁺ concentrations are higher than the extracellular ones, and the membrane potential is positive to the Nernst potential. Therefore, the direction of K⁺ current flow through Kv-channels is

mostly outward. But there are important exceptions, where either the membrane potential at which the Kv-channel opens is negative to the Nernst potential or the extracellular K⁺ concentration is not very different from the intracellular one. For example, inactivated Kv-channels like ►HERG-channels (see above) may recover from inactivation at very negative membrane potentials. During recovery they pass through an open state permitting an inward flow of K⁺ current. Depending on the particular conditions, hyperpolarizing Kv-channel activity may attenuate cellular excitability (e.g., the firing of action potentials) or they may balance depolarizing activities (e.g., clamp the membrane potential to a certain value to allow a steady inward flow of calcium ions). Frequently, repolarizing Kv-channel activity shifts the membrane potential into a hyperpolarizing direction.

Kv-channels are closed in the resting state. Upon depolarization of the cellular membrane potential, closed Kv-channels undergo a series of voltage-dependent activating steps until they reach an activated state from which they can open and close in a voltage-independent manner.

A particularly interesting example of Kv-channel inactivation is represented by HERG-channels. HERG-channels have faster inactivation than activation kinetics, and they very rapidly recover from inactivation at negative membrane potentials. This behavior may result in a situation where most of the current carried by HERG-channels occurs during their recovery from inactivation at negative potentials, that is, it represents an inward rather than outward current.

Structural Characteristics of Kv-Channels

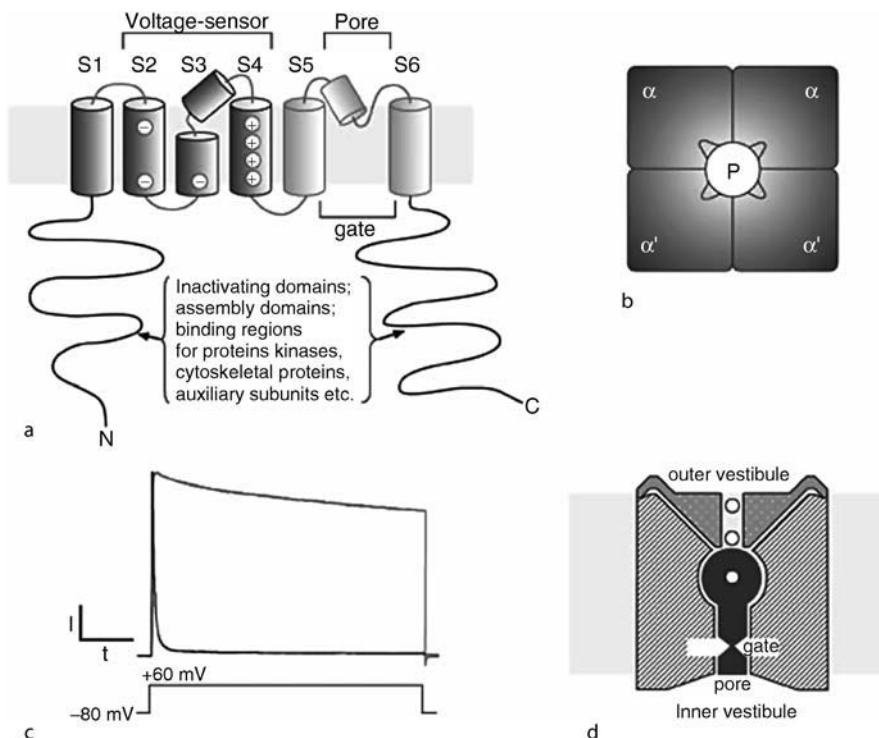

Kv-channels are frequently heteromultimeric protein assemblies of pore-forming membrane-integrated α -subunits and of auxiliary subunits [2, 3]. The first Kv-channel subunits were cloned from *Drosophila*. This work initiated the subsequent identification and cloning of many more Kv-channel genes constituting a superfamily of related proteins. The design of the proteins is structurally and functionally highly conserved. Kv-channel α -subunits have cytoplasmic amino- and carboxy-termini, which frame a membrane-spanning core domain. The core domain consists of six hydrophobic membrane-spanning segments S1 to S6. Segments S5 and S6 are linked by the so-called P-loop. This P-loop enters and exits the plasma membrane from the extracellular face. Figure 1a shows a cartoon of the most likely membrane topology of Kv-channel α -subunits. Four subunits are necessary to form a functional channel. Homo- as well as heterotetrameric assembly of Kv-channels is possible (Fig. 1b). Kv-channels can be expressed in vitro in heterologous expression systems (Fig. 1c). The relative ease to

in vitro mutagenise Kv-channel cDNAs and to express Kv-channel cDNAs heterologously in the *Xenopus* oocyte or tissue culture expression systems has produced a detailed understanding of many basic features concerning Kv-channel activity. The results showed that the voltage-sensing apparatus of Kv-channels is mainly formed by amino acids residing in segments S2 to S4. Most notably is the occurrence of a repeat sequence (R/KXX)_{n=3-5} in segment S4, lining up several positive charges in the membrane electric field. The charges apparently move in the electric field when the Kv-channels become activated, giving rise to a gating current across the membrane. Gating currents are observed during the voltage-dependent activation of Kv-channels.

Amino acid residues residing in the S5–P–S6 region are engaged in forming the pore, most notably a highly conserved P-loop sequence TVGY/FGD/N, which has been dubbed the K-channel signature sequence. This sequence forms part of the selectivity filter of the Kv-channel pore. It has been possible to crystallize a bacterial K-channel (KcsA). The crystals provide a high-resolution picture of the pore of a K-channel with its surrounding transmembrane helices [4]. The preservation of K-channel pore structures during evolution suggests that Kv-channels have a pore structure similar to the one of the KcsA-channel.

According to the KcsA crystal structure data, hallmarks of the pore structure are an outer vestibule with a relatively flat surface. Beneath, in the upper-third of the membrane, lies a narrow selectivity filter. This is followed by a central aqueous cavity narrowing into the internal mouth of the pore (Fig. 1d). Kv-channels, during voltage-dependent activation and opening, undergo marked conformational changes. In the resting state, it is assumed that the pore is closed by a “gate” and that upon activation the gate opens. Amino acid residues in the carboxy-terminal half of the S6 region seem to play a pivotal role for the structure and function of the Kv-channel gate. Other Kv channel domains e.g. the S4-S5 linker region, may also contribute to channel gating, likely by indirect and/or allosteric mechanisms.

In addition to the membrane-inserted core domain of Kv channels, their cytoplasmic domains have important roles for Kv-channel function [5]. Many of these functions are related to subunits assembly, channel trafficking to and from the plasma membrane, and interactions with cytoskeletal components (Fig. 1a). A tetramerization (T) domain for subunit assembly has been well defined in Shaker-channels, where it is localized in the amino-terminus. Other Kv-channels (e.g., eag, HERG, ►KvLQT1) may have comparable domains within the cytoplasmic carboxy-terminus. ER retention and retrieval signals have been found

Voltage-gated K⁺ Channels. Figure 1 Basic features of voltage-gated potassium channels. (a) Schematic drawing of the membrane topology of Kv α -subunits. Transmembrane segments are numbered S1–S6. The linker regions between segments S3/S4 and S5/S6 contain small α -helical regions marked as cylinders. Negative charges (–) in segments S2 and S3 and positive charges (+) in segment S4 contribute to the voltage-sensor of Kv-channels. Pore-forming residues are located within the S5/S6 linker region and segment S6. The gate which opens and closes Kv-channels is not exactly known. Amino acid residues of the S4/S5 linker region, segment S5, and segment S6 are directly and/or indirectly involved in the gating machinery. Brackets give examples for additional functions and properties associated with sequences and domains of the cytoplasmic amino- and/or carboxy-termini. (b) Assembly of four Kv α -subunits is needed to form functional Kv-channels with a central pore P. α and α' indicate that assembly of homo- and heteromultimers is possible. (c) Typical examples of potassium outward currents (I) mediated by Kv-channels upon jumping from a holding potential of –80 mV to a test potential of +60 mV. Black trace: rapidly inactivating outward current; gray trace: noninactivating delayed-rectifier type current. Time-scale (t) is in ms. Upon repolarization from a depolarizing test potential to a hyperpolarizing holding potential an inward current or tail current can be observed that reflects the closure of open channels. (d) Schematic diagram of pore structure. A hypothetical sagittal section through the pore is shown. The pore has an outer vestibule, a selectivity filter (dotted gray) in the upper third of the membrane, an aqueous cavity, a gate (black), and an inner water-filled vestibule. Potassium ions are drawn approximately to scale as white circles.

in the cytoplasmic amino- or carboxy-termini. Also, cytoplasmic Kv-channel domains may contain recognition sequences for a variety of serin/threonine and/or tyrosine kinases. Finally, motifs have been characterized that interact with a variety of cytoskeletal components. For example, the conserved carboxy-terminal amino-acid motif TDV is recognized by MAGUK(PSD)-proteins of the post- and presynaptic densities.

Auxiliary Subunits

Kv α -subunits may coassemble with auxiliary subunits (see Table 1). Auxiliary subunits (e.g., Kv β -subunits)

may bind to cytoplasmic regions of the Kv α -subunits extending the reach of the membrane-integrated core channel into the cytoplasm (Fig. 2a). A particularly interesting group is the KChIP-family. KChIP stands for K-channel interacting protein. The proteins are small Ca²⁺-binding proteins being related to the superfamily of neuronal calcium sensors. They are tightly associated with somato-dendritic rapidly inactivating Kv-channels (Kv4.1, Kv4.2, Kv4.3). Alternatively, the auxiliary subunits may be membrane integrated proteins like Kv α -subunits (Fig. 2b). Examples are members of the KCNE-family of auxiliary subunits that may assemble with a great variety of Kv-channels including

Membrane is shaded gray.

► **KCNQ-channels**, HERG-channels, and Shaker-related Kv-channels.

Functional activities of auxiliary subunits may include chaperone activities during assembly, for example, Kv β -subunits have been shown to exert a chaperone function for the assembly of Shaker α -subunits or the recognition of ER-retention signals as discussed for KChIPs. Notably, auxiliary subunits may modulate the biophysical and pharmacological properties of Kv-channels. Certain Kv β (Kv β 1.1 and Kv β 3.1) confer a rapid-inactivation behaviour to otherwise noninactivating Kv-channels. Association of KCNE1 with KvLQT1 leads to a significant slowing of Kv-channel activation, a depolarizing shift in the voltage dependence of activation and a change in drug sensitivity (e.g., for mefenamide). On the other hand, association of KCNE3 with KvLQT1 leads to channels that are no longer activated by voltage, but behave like potassium-selective pores in the membrane.

Drugs

In the animal kingdom, a great number of toxins from snakes to scorpions, insects, spiders, and sea anemones that block various Kv-channels with nano- to picomolar affinities have been identified. Two kinds of block may be discerned in general. The toxin may bind to the outer vestibule of the Kv-channel pore and thereby occlude the pore (Fig. 3a). In this case, the binding of one toxin per channel may suffice to block channel activity. Alternatively, the toxin may interfere with the voltage-sensing machinery and modify Kv-channel gating. The voltage-sensing machinery is located in the periphery of the pore. As each subunit appears to have its own

Voltage-gated K⁺ Channels. Figure 3 Schematic drawing of Kv-channel binding sites for toxins and drugs. (a) Side view of a cut-open Kv-channel. Intracellular open-channel blockers may bind to the inner vestibule of Kv-channels (hatched) formed by segment S6. (b) View of a Kv-channel from the top. Pore-blocking toxins bind to receptor sites formed by the Kv-channel pore and the outer vestibule. Gating modifiers have binding sites outside of the pore (striped) and interfere with the voltage-sensing machinery.

EA, episodic ataxia; LQT, long QT syndrome; JLN, Jervell–Lange Nielsen syndrome; BFNC, benign familial epilepsy; DFNB2, deafness syndrome

voltage-sensing apparatus, gating-modifying toxins may have four binding sites per Kv-channel (Fig. 3b). Characteristically, gating-modifying toxins induce a positive shift in the current–voltage relationship of Kv-channels and accelerate channel deactivation (closing of the open channel).

Many nonpeptidergic compounds are known to block Kv-channels. Where the mechanism of block is known, it is related to pore occlusion. Most frequently, nonpeptidergic drugs block the pore by interacting with amino acid residues located in the carboxy-terminal part of segment S6 (Fig. 3a). This part is particularly hydrophobic in the pore of HERG-channels. Apparently, it distinguishes HERG-channels from other Kv-channels and renders HERG-channels exceptionally sensitive to block by many pharmaceuticals. Since HERG-channels make an important contribution to cardiac action potential repolarization, HERG-channel block may be frequently responsible for cardiac side effects of drugs. Tetraethylammonium, 4-aminopyridine, and quinidine are unspecific drugs blocking Kv-channels by binding to the inner entrance of the pore. TEA may also bind to the outer entrance of Kv-channel pores.

Mutations in Human Kv-Genes Associated with Hereditary Channelopathies

Mutations in human Kv-channel genes have been detected that are associated with hereditary diseases ranging from heart arrhythmia (long QT-syndrome) and deafness to epilepsy and ataxia (see Table 2). Typically, many Kv-channel related channelopathies are correlated with a mutant phenotype that is episodic in nature and appears as a dominant hereditary trait.

Outlook

Several additional crystal structures of K⁺ channels have been solved since this article was written. Importantly,

crystal structure for the voltage-gated Kv1.2 channel in complexes with Kvβ2 has been solved (Long SB, Campbell EB, MacKinnon R (2005) *Science* 309, 897–903; see also: Long SB, Tao X, Campbell EB, MacKinnon R (2007) *Nature* 450, 376–382)

Voltage-gated Na⁺ Channel

- ▶ Voltage-dependent Na⁺ Channels

Voltage Sensor

The voltage sensor is the part of a channel protein responsible for detection of the membrane potential. A voltage sensor of the voltage-dependent Na⁺ channel was predicted by Hodgkin and Huxley in 1952. Positively charged amino acid residues in S4 of each repeat play an essential role as the voltage sensor.

► Voltage-dependent Na⁺ Channels

von Willebrand Factor

The von Willebrand factor (vWf) is a heterogeneous multimeric plasma glycoprotein produced by megakaryocytes and endothelial cells which is found in platelets, plasma and the subendothelium. Subendothelial vWf facilitates platelet adhesion, especially under high shear stress, by binding to glycoprotein GPIb-V-IX, a complex of four leucine-rich repeat proteins on platelets.

Vomiting, Act of

The act of vomiting is a complex process accompanied by several events apart from activation of the motor nerves and various voluntary muscles involved in the increase of intragastric pressure and evacuation of the stomach contents. Vomiting is preceded by a deep inspiration, closure of the glottis and raising of the soft palate to prevent vomitus entering the trachea and nasopharynx, respectively. There is also increased heart rate, pallor, salivation, sweating and lacrimation.

Watson-Crick Base Pairing

The rules of base pairing (or nucleotide pairing) are:

A with T: the purine adenine (A) always pairs with the pyrimidine thymine (T)

C with G: the pyrimidine cytosine (C) always pairs with the purine guanine (G).

This is consistent with there not being enough space (20 °) for two purines to fit within the helix and too much space for two pyrimidines to get close enough to each other to form hydrogen bonds between them. These relationships are often called the rules of Watson-Crick base pairing.

Wernicke's Syndrome/ Encephalopathy

Wernicke's syndrome is a serious consequence of alcoholism and thiamine (vitamin B₁) deficiency. Certain characteristic signs of this disease, notably ophthalmoplegia, nystagmus, and ataxia, respond rapidly to the administration of thiamine but to no other vitamin. Wernicke's syndrome may be accompanied by an acute global confusional state that may also respond to thiamine. Left untreated, Wernicke's syndrome frequently leads to a chronic disorder in which learning and memory are strongly impaired. This so-called Korsakoff's psychosis is characterized by confabulation, and is less likely to be reversible once established.

- ▶ Drug Addiction/Dependence

Wheal

The classical skin response to local release of histamine that results from contact with an allergen, irritant or following an insect bite. A central wheal develops as a direct result of local inflammation and the the oedema that follows the increased capillary permeability caused by histamine acting on H₁-receptors on vascular endothelial cells.

Wnt Signaling

NATHAN D. OKERLUND, BENJAMIN N. R. CHEYETTE
University of California, San Francisco,
CA, USA

Synonyms

Int-1; Wingless, wg

Definition

Wnts are secreted proteins with important signaling roles in the development of all multicellular animals. Wnt signaling can be divided into two major types: ▶ “canonical” β -catenin-dependent signaling, and ▶ “non-canonical” non- β -catenin signaling, which itself is further divisible into multiple subtypes. Wnt signaling helps regulate cell fate specification, cell morphology, cell proliferation, cell migration, cell polarity, and tissue patterning in both ▶ vertebrates and ▶ invertebrates; misregulation of Wnt signaling is linked to some developmental disorders and too many forms of cancer.

Basic Mechanisms

Wnt takes its name from the *wingless* (*wg*) gene of the fruitfly *Drosophila melanogaster* (one hypomorphic mutation of the gene produces an adult fly without wings) and the *int-1* proto-oncogene, a target of MMTV, the mouse mammary tumor virus (which causes abnormal gene activation when it integrates into the host genome). The discovery that *Drosophila wg* and mouse *int-1* are orthologs and are part of a large conserved family of genes led to the contracted name “*Wnt*.”

Wnt Structure and Biochemistry

There are 7 related *Wnt* genes in *Drosophila* and 19 in humans that generally have close orthologs in mice (Fig. 1). Orthologous *Wnt* gene-products are often very highly conserved between species.

The length of vertebrate Wnt protein precursors varies from about 100 amino acids to over 400 amino acids. All Wnt proteins contain a cleavable amino-terminal signal peptide that targets them for secretion, a conserved cysteine-rich composition, and multiple N-linked glycosylation sites. Wnt proteins synthesized in vivo are glycosylated and palmitoylated, rendering them very hydrophobic. Once outside the cell, mature Wnt glycoproteins associate with extracellular matrix and bind to ▶ heparin sulfate proteoglycans which help to stabilize and regulate their distribution. The secreted Wnt activates a ▶ Wnt receptor complex on target cells, leading to downstream signaling effects. In *Drosophila* non-wg producing cells endocytose wg that has been secreted by neighboring cells. Genetic studies have demonstrated that this endocytic activity is important both for facilitating wg signaling and for regulating its distribution.

Autocrine signaling by Wnt proteins may be important, both as a feedback mechanism during normal biological processes and in pathogenesis. Tumors induced by MMTV are clonal, suggesting that once the virus activates the *Wnt1* gene in a single mouse mammary gland cell, Wnt secretion stimulates uncontrolled proliferation in that cell and possibly other oncogenic changes as well. Similarly, some tissue culture cell lines transfected either with a *Wnt* gene or with DNA from MMTV-induced tumors become transformed and clonally tumorigenic. In *Drosophila*, there is evidence that autocrine signaling through wg activates a signaling cascade that is genetically partly distinct from paracrine wg signaling.

It has been proposed that the vertebrate *Wnt* genes can be classified based on whether they activate β -catenin-dependent or non- β -catenin signaling pathways (see below). However, the response to a Wnt of one proposed class can be switched to that of the other class by coexpressing a specific Wnt receptor.

Wnt Signaling. Figure 1 A sequence relatedness tree among the 19 human *Wnt* gene-products. *Drosophila wg* is included for comparison. The percent of amino acid residues in each protein that are identical to Wnt1 (boxed) is indicated. Wnt1/int-1 was chosen as the index sequence for purely historical reasons (it is not evolutionarily ancestral to the other Wnts). This tree is based on overall identity among predicted *Wnt* gene-products and is **not** meant to convey absolute evolutionary relationships. Horizontal distance from a node correlates with degree of sequence divergence; vertical distance is arbitrary. Sequences were obtained from the protein database of the National Center for Biotechnology Information and compared using the default matrix settings of MacVector 6.5.3 (Oxford Molecular Group). A non-Wnt sequence (FGF9) was used to root the tree (not shown).

Similarly, in developing *Drosophila* the response to wg is influenced by the relative abundance and ligand affinity of receptors expressed in the target tissue. A synthesis of the available data from all species suggests that the response to a specific Wnt signal in vivo is influenced both by the particular Wnt protein secreted and by the receptors and other downstream molecules present in the target tissue.

Wnt/ β -catenin-Dependent (“Canonical”) Signaling

The Wnt/ β -catenin-dependent pathway is typified in vertebrates by responses to a subclass of the vertebrate Wnt proteins and \blacktriangleright Frizzled (Fz) receptors, plus \blacktriangleright LRP5 or 6; in *Drosophila* it is typified by wg, *Drosophila* Frizzled 2 (DFz2), and the *Drosophila* LRP homolog (“arrow”). The central feature of this pathway is a multi-protein degradation complex that controls cytoplasmic concentrations of the multi-functional protein β -catenin. β -catenin plays a structural role at the inner cell membrane of adherens junctions, but also acts as a transcriptional coactivator in the nucleus. The concentration of soluble β -catenin in the cytoplasm and nucleus is determined by its rate of degradation through ubiquitination-dependent targeting to the proteosomal pathway. \blacktriangleright Glycogen synthase kinase-3 (GSK3; particularly isoform GSK3 β) regulates this process by phosphorylating β -catenin, targeting it for degradation. Besides GSK3 itself, other components of the degradation complex include \blacktriangleright Dishevelled (Dvl), Axin, and

Adenomatous Polyposis Coli (APC). Whereas Dvl is a Wnt pathway activator, GSK3, Axin and APC are all inhibitors. Axin and APC help to stabilize the activity of GSK3, keeping β -catenin levels low and Wnt target gene transcription off in the absence of a Wnt signal (Fig. 2a).

During Wnt/ β -catenin-dependent signaling several molecular events occur: (i) Dvl becomes phosphorylated (several different kinases, including Casein Kinase I (CK1), Casein Kinase 2 (CK2), and the Par1 kinase from *Drosophila* have been implicated in this). (ii) Axin dissociates from the degradation complex, translocates to the inner plasma membrane, and becomes less stable. (iii) Another protein called GSK3 Binding Protein (GBP or FRAT) binds both GSK3 β and Dvl. (iv) GSK3 β is phosphorylated, inhibiting its kinase activity. The net effect of these events is to destabilize the degradation complex, leading to phosphorylation/inactivation of GSK3 β . This prevents ongoing GSK3-mediated phosphorylation of β -catenin. Unphosphorylated β -catenin, which is not ubiquitinated nor targeted to the proteasome, then accumulates. In the nucleus, this free β -catenin acts with members of the LEF/TCF family of transcription factors to regulate expression of Wnt target genes (Fig. 2b).

Besides the well-established Wnt/ β -catenin-dependent pathway components mentioned above, several additional cytoplasmic inhibitors of Wnt/ β -catenin-dependent signaling have been identified that share

Wnt Signaling. Figure 2 Wnt/β-catenin-dependent signaling. (a) Inactive (no Wnt). (b) Active (+Wnt). Activation of a Fz/LRP6 receptor complex by a Wnt causes phosphorylation of Dvl and Gsk3, translocation of Axin to the membrane, and association of GSK3 with GBP. This downregulates GSK3-mediated phosphorylation of β-catenin, which normally leads to degradation of free β-catenin. Unphosphorylated free β-catenin accumulates in the cytoplasm and nucleus where it acts as a transcription coactivator with members of the LEF/TCF gene family.

the ability to bind Dvl. These include the *Drosophila* gene *naked cuticle* (*nkd*) and the vertebrate proteins Idax and Dact (Dpr/Frodo). In the case of Dact there is conflicting evidence that it may act positively in Wnt/β-catenin-dependent signal transduction. In general, proteins that interact directly with Dvl, such as Nkd and Dact, also play roles in Wnt/non-β-catenin signaling (see below). There are also several secreted extracellular inhibitors of Wnt/β-catenin-dependent signaling that are biologically important for development and disease. These include cerberus (*cer*) and secreted Frizzled Related Proteins (sFRPs), which bind Wnt and therefore act as general Wnt inhibitors, Dickkopf (*dkk*), which binds to LRP6 and is therefore specific for Wnt/β-catenin-dependent signaling, and Wnt Inhibitory Factor-1 (WIF-1), which resembles the LRP extracellular domain.

Wnt/non-β-catenin (“Non-canonical”) Signaling

Wnt/non-β-catenin signaling is not as well characterized biochemically as the Wnt/β-catenin-dependent pathway; this may reflect that it is molecularly more diverse, at least in vertebrates. In *Drosophila* the best characterized Wnt/non-β-catenin pathway is ►planar cell polarity (PCP) signaling. Ironically, although it certainly depends on a Fz receptor, it remains

controversial whether PCP signaling actually involves a Wnt ligand. Despite the fact that *wg* has been shown to bind Fz, there is no conclusive evidence that the endogenous ligand for Fz during PCP signaling is *wg*. The PCP pathway downstream of Fz has been defined on the basis of a combination of genetic and molecular data. As with Wnt/β-catenin-dependent signaling, the *Drosophila* Dvl homolog (*dsh*) is involved, although the requirement for conserved subdomains of the *dsh* protein and its subcellular localization differ in the two pathways (see glossary and Fig. 3a). Also, as with Wnt/β-catenin-dependent signaling, several *dsh*-interacting proteins have been identified that participate in PCP signaling, including the putative calcium-sensitive protein *nkd* and the Formin homology protein *Daam1*, which also binds the small GTPase RhoA. RhoA activates the *Drosophila* Rho-associated kinase (ROCK), which causes cytoskeletal changes by phosphorylating the nonmuscle myosin regulatory light chain and possibly other proteins (Fig. 3a).

PCP signaling has also been associated with activation of Jun-N-terminal Kinase (JNK), which can alter gene expression through the AP-1 transcription factor. However, the physiologic significance of this for endogenous PCP signaling remains unclear because JNK activation is a fairly nonspecific phenomenon in signaling biology.

Wnt Signaling. Figure 3 Wnt/non- β -catenin signaling. (a) PCP/Convergent-Extension signaling. Signaling through Fz causes Dvl to translocate to the inner plasma membrane. Dvl, with the RhoA-binding protein Daam1, activates the small GTPase RhoA. RhoA has multiple signaling outputs, including Rho-Associated Kinase (ROCK), which can directly regulate cytoskeletal dynamics. The JNK pathway may also be a downstream PCP effector. Multiple molecules not shown here are also implicated (see text). (b) Wnt/Calcium Signaling. Vertebrate Wnt5a and Wnt11 cause a transient increase in intracellular calcium, probably through inositol triphosphate (IP_3) and diacylglycerol (DAG) released by Phospholipase C (PLC). Calcium and DAG activate Protein Kinase C (PKC), Calcium/Calmodulin-regulated Kinase II (CamKII), and the NFAT1 transcription factor. The role of heterotrimeric G-proteins associated with the Fz receptor complex in Wnt pathways is still unclear, but most seven-pass transmembrane receptors are coupled to downstream signaling pathways in this way. The pathways presented in 3a and 3b may be alternate facets of a single conserved Wnt/non- β -catenin pathway, but there may also be a variety of Wnt/non- β -catenin signaling pathways, especially in vertebrates (see text).

Aside from the PCP pathway proteins described above, several other genetically identified components play roles that are not yet understood at a biochemical level. Although arrow/LRP6 is not required for PCP signaling, at least three other transmembrane proteins have been implicated that may act independently of, or even antagonistically to, Fz receptors: flingo (*fmi*), strabismus (*stbm* or *vang*), and fuzzy (*fy*). Also implicated is the membrane-associated daschous (*ds*) protein, a member of the cadherin superfamily. Cytoplasmic proteins that play a role include the gene-products of *prickle* (*pk*), *inturned* (*in*), and *multiple wing-hair* (*mwh*). How these proteins connect to other components of the PCP pathway is not yet known, but the Wnt/non- β -catenin signaling function of at least some of them is conserved in vertebrates. Homologs of these proteins have been implicated in “convergent-extension” movements during vertebrate development. This suggests that the same Wnt/non- β -catenin signaling pathway controls

aspects of cell polarity in *Drosophila* and cell shape and movement in vertebrate embryos.

Another non- β -catenin pathway antagonizes β -catenin-dependent Wnt signaling and is typified by responses to Wnt5a and Wnt11 in vertebrate cells. The main characteristic of this pathway is IP_3 -mediated rapid increase of intracellular calcium followed by activation of Protein Kinase C (PKC), Calcium/Calmodulin-regulated Kinase II (CamKII), and the NFAT1 transcription factor (Fig. 3b). There is considerable evidence that initial signaling downstream of the Fz receptor complex in this **Wnt/Calcium signaling pathway** occurs through **heterotrimeric G-proteins**. Studies in mammalian cultured cells and in *Xenopus* embryos have demonstrated that Wnt5a activates the JNK cascade, providing a possible link between the vertebrate Wnt/Calcium signaling pathway and the *Drosophila* PCP pathway. Furthermore, activators of the Wnt/calcium pathway (e.g., Wnt5a) and of PCP signaling (e.g., *Stbm* and *Nkd*) similarly

affect convergent-extension movements during vertebrate gastrulation. One attractive hypothesis is that the Wnt/Calcium and PCP signaling pathways are two aspects of the same conserved molecular cascade. This remains speculative in part because the Wnt/Calcium signaling pathway has been characterized primarily through cell biological approaches in vertebrates, whereas the PCP pathway has been characterized primarily through genetic approaches in *Drosophila*.

Finally, among the most unexpected recent Wnt signaling findings is that in response to wg stimulation at the *Drosophila* neuromuscular junction, the intracellular domain of the DFz2 receptor is cleaved and translocates to the nucleus. It is unclear what function this DFz2 fragment serves, or how widespread this potential mechanism of Wnt signal transduction might be.

LRP5 and 6 are not required for Wnt/non- β -catenin signaling; instead a protein called **Ryk** (derailed in *Drosophila*) is the best characterized coreceptor for the Fz proteins in non- β -catenin signaling. Ryk/derailed was first implicated in axon guidance, but could conceivably play a more general role in all forms of Wnt/non- β -catenin signaling controlling cell shape, movement, and polarity.

Wnts and Cancer

Alteration in the Wnt/ β -catenin-dependent signaling pathway is now a well-established etiologic agent in oncogenesis. The evidence is most striking for two downstream intracellular signaling components: the gene-product of the *APC* locus, and the β -catenin protein. APC is a negative regulator of Wnt/ β -catenin-dependent signaling that is mutated in the majority (>80%) of sporadically occurring colorectal adenomas and carcinomas. In addition, *APC* mutations cause the genetic disease Familial Adenomatous Polyposis, characterized by proliferation of initially benign colonic polyps that greatly predispose afflicted individuals to intestinal cancer. Similarly, mutations in β -catenin have been described in many different cancer types. Mutations in other Wnt pathway components have likewise been associated with cell transformation in vitro and with pathogenesis of an array of cancer types in vivo (Table 1). A general model is that inappropriate activation of Wnt/ β -catenin-dependent signaling alters gene expression, leading to abnormalities in cell fate and proliferation.

Interestingly, the role of Wnt/non- β -catenin signaling in controlling cell morphology and movement may contribute to another important aspect of neoplasticity:

Wnt Signaling. Table 1 Some of the major Wnt signaling components^a in human cancer

^aSee text for full molecule names and roles in Wnt signal transduction.

metastasis. There is growing evidence that genes involved in Wnt/non- β -catenin signaling are specifically misregulated in tumors as they increase in stage and become more invasive and aggressive.

Wnts and Other Diseases

Given the prevalence and biological significance of Wnt signaling, it should not be surprising that it has also been linked to many other diseases. A rare childhood disorder of bone formation, Osteoporosis-Pseudoglioma Syndrome, is caused by a genetic disruption in Wnt/ β -catenin-dependent signaling. Disruptions in Wnt signaling underlie an assortment of other diseases as well (Table 2). There is emerging evidence that Wnt signaling contributes to pathogenic processes ranging from scar formation to heart failure to neuropsychiatric disorders, and it is also an important signaling pathway in stem cell biology. Research into Wnt signal transduction therefore can lead to therapies that may 1 day help alleviate a corresponding variety of medical problems.

Pharmacological Intervention

Direct pharmacological manipulation of Wnt signaling (i.e., by activating Fz and/or LRP receptors or by inhibiting the Wnt/Fz interaction) by small-molecule drugs is not yet possible; large peptide ligands such as Wnts are difficult to mimic with the small, relatively nonpolar molecules that make good drugs. However,

native protein inhibitors of Wnt signaling, such as sFRP and Dkk proteins, may eventually be used to inhibit Wnt signaling in vivo. Similarly, expression of other negative regulators of Wnt signaling such as APC, Axin, and related proteins may prove useful in cancer treatment. Antisense oligonucleotides and RNA interference strategies targeting Wnt signaling components are under investigation both in pharmaceutical companies and in academic laboratories.

Other molecules that participate in Wnt-activated signaling pathways are pharmacologically accessible by more traditional treatments. The antitumor agent Gleevec/STI-571 has been shown to downregulate Wnt/ β -catenin-dependent signaling, as have retinoids, implying a link between Wnt and retinoic acid signaling. Fumagillin, an antitumor drug that acts as an angiogenesis inhibitor, has been shown to block Wnt/non- β -catenin signaling. Nonsteroidal antiinflammatory drugs (NSAIDs) that inhibit the cyclooxygenases COX 1 and 2 may also prove useful; these proteins are implicated in many human cancers and contribute to aberrant Wnt signaling in ways that await full elucidation.

In noncancer-related pharmacology, GSK3 is inhibited by lithium at therapeutic concentrations, implying that the long-established effectiveness of lithium in the treatment of psychiatric mood disorders (and more recently as a neuroprotective agent) may be linked to GSK3 inhibition. Antipsychotics such as haloperidol

Wnt Signaling. Table 2 Some of the major Wnt signaling components^a implicated in human disease

Wnt Signaling (general)	Wnt4	Sfrp	Fz	LRP5	Dvl	GSK3	β -catenin
Polycystic kidney disease (Polycystin-1 activates canonical Wnt signaling pathway)	Injury-induced renal fibrosis	Heart failure	Ulcerative colitis	Osteoporosis-Pseudoglioma Syndrome (genetic syndrome of defective bone formation)	Ulcerative colitis	Familial Alzheimer's disease (through interaction with Presenilin-1)	Familial Alzheimer's disease (through interaction with Presenilin-1)

				Other bone-growth syndromes		Schizophrenia (reduced levels in prefrontal cortex)	
						Bipolar Disorder (enzymatic activity reduced by therapeutic agents)	

^aSee text for full molecule names and roles in Wnt signal transduction.

have also been shown to change Wnt signaling in the brain, suggesting a link between neurotransmitter receptors (such as their target dopamine receptors) and downstream Wnt signaling components. Since many neurotransmitter receptors are members of the seven-pass transmembrane receptor superfamily that includes the Fz proteins, this raises the interesting possibility that a common mechanism might mediate interactions between cell surface receptors and Fz-interacting proteins such as Dvl in neurons.

The indisputable role of Wnt signaling in cancer pathogenesis ensures that molecules capable of altering Wnt signal transduction will continue to be a subject of intense pharmaceutical interest. Technological advances in the pharmacologic manipulation of these signaling pathways are sure to lead to important discoveries about Wnt signaling in a wide array of basic biological and clinically relevant processes.

Wnts and Vertebrate Development

The first clue to a role for Wnt/ β -catenin-dependent signaling in vertebrate development came from over-expression studies in the classical embryonic system, the frog *Xenopus laevis*. When Wnt1 is ectopically expressed in cells that would normally contribute to the ventral embryo (i.e. the future belly), they instead adopt

a dorsal and anterior fate (i.e. they become future head). This induction of a “secondary dorsal axis” produces a striking phenotype: two-headed tadpoles. The ability of ectopic Wnt1 to induce a secondary dorsal axis derives from the participation of Wnt/ β -catenin-dependent signaling in dorsal cell fate specification early in vertebrate embryogenesis. However it remains unclear whether an endogenous intercellular Wnt signal, or only the downstream intracellular signaling cascade, is normally responsible for early dorsal fate determination. Nonetheless, experimental analyses across vertebrate model organisms have established the importance of Wnt signaling in a broad spectrum of developmental events.

► Wnt Signaling

Wortmannin

Wortmannin, a metabolite of the fungus *Penicillium funiculosum*, is a specific inhibitor of phosphoinositide 3-kinases (PI3Ks) with an inhibitory concentration (IC₅₀) determined in vitro of around 5 nM, making it a more potent inhibitor than LY294002, another commonly used PI3K inhibitor. It displays a similar potency in vitro for the class I, II and III PI3K members although it can also inhibit other kinases.

► Phospholipids

WW Domain

Protein-protein interaction domain which, like SH3 domains, bind to polyproline sequences.

► Adaptor Proteins

Xanthine Oxidase

Xanthine oxidase (XOD) is the key enzyme in purine catabolism. XOD catalyses the conversion of hypoxanthine to xanthine and of xanthine to uric acid, respectively. The uricostatic drug allopurinol and its major metabolite alloxanthine (oxypurinol) inhibit xanthine oxidase.

X-linked Nephrogenic Diabetes Insipidus

X-linked nephrogenic diabetes insipidus (NDI) is caused by mutations in the gene for the vasopressin V2 receptor leading to an insensitivity of the kidney for the antidiuretic hormone arginine vasopressin (AVP). The main symptom of the disease is diuresis, i.e., the production of a large amount of diluted urine. Due to the massive loss of water, the patients suffer from thirst and are in danger of dehydration. The disease usually becomes evident shortly after birth.

Radiocontrast agents; X-ray contrast agents; Contrast media; Contrast materials

Definition

Molecular imaging modalities are being developed with the desire for earlier detection of abnormalities before they develop into diseases, earlier detection of responses to therapy and more precise and specific information on the quality and site of disease processes. According to a consensus of a group of experts molecular imaging refers to techniques that serve to “directly or indirectly monitor and record the spatio-temporal distribution of molecular or cellular processes” [1]. Although MR spectroscopy detects and quantifies endogenous biomolecules and thereby allows evaluation of molecular and cellular processes, the basic idea is to achieve the goal by administration of visible pharmaceuticals that distribute in the living organism and either accumulate in specific areas and/or generate or change a signal which can be detected by imaging equipment.

The purpose of this article is to discuss whether and how X-ray contrast media may contribute to molecular imaging.

Mechanism of Action

Basic Properties of X-ray Contrast Agents

X-ray contrast agents absorb X-rays either more or less strongly than the usual body constituents, primarily water. Gas has a low density and therefore does not absorb X-rays to an extent that would be relevant to medical imaging. Nevertheless, gas is still used to outline body cavities but in most cases is replaced by dense compounds containing heavy elements. The most commonly used X-ray contrast agents are water-soluble triiodinated derivatives of benzoic acid (Fig. 1). This class of compounds was developed during a selection process which began with the discovery of X-rays. Over the last 60 years all new X-ray contrast molecules belonged to this class of compounds. Only after the introduction of metal chelates (Fig. 2 and 3) as contrast agents for MRI, elements other than iodine were reconsidered for use as X-ray contrast media. Up to now, however, none of the chelates has been approved for X-ray imaging.

Whereas imaging agents that can serve to detect molecular and cellular processes must in some way directly or indirectly participate in these processes or interact with components participating in the processes, the development of X-ray contrast agents led in the opposite direction: Molecules displaying the least possible interaction with body constituents and processes were preferred because of advantages in tolerability [2].

X-ray contrast media are usually highly concentrated aqueous solutions. A typical product contains 300–370 mg iodine/ml, which corresponds to about 600–800 mg of the iodinated organic molecule per ml. The high concentration of the contrast substance leaves limited room for water (about 0.7 ml per ml of contrast agent) and restricts the design of the molecules because

X-ray Contrast Agents and Molecular Imaging.

X-ray Contrast Agents and Molecular Imaging.

Figure 2 Gadobutrol, a metal chelate used in magnetic resonance imaging. Metal content: 26% of weight.

limitations regarding osmolality and viscosity of the final preparation must be observed in addition to solubility, chemical stability, and cost. One important restriction is that an extremely high content of iodine or other heavy element is required in the molecules. The iodine content of molecules in currently available X-ray contrast media is in the range of 44–49%. It is a drawback of metal chelates that their metal content reaches only half this value. The larger the proportion of the organic constituents contributing very little to X-ray absorption, the less room remains for water, which further increases viscosity and osmolality. Due to their very high iodine content, X-ray contrast agents have a specific weight of up to 1.4 g/ml which is much higher than that of any biological tissue.

X-ray Contrast Agents and Molecular Imaging. Figure 3 Examples of X-ray contrast agents that enhance contrast due to intracellular uptake. (a) Liver enhancement following intravenous administration of a lanthanide chelate. (b) Visualization of e.g., lymph nodes following intravenous injection of colloidal thorium oxide. The agent is severely toxic but the example indicates that specific uptake of radiopaque compounds can be sufficient to opacify small structures in conventional radiographs (Börner et al (1960) Zur Problematik der Thorotrastschäden. Klinische und radiologische Untersuchungen zum Verhalten von Thorium und seiner Zerfallsprodukte im Organismus. Fortschr Röntgenstr 93:287–297).

Sensitivity

X-ray imaging can be used throughout the body. X-rays penetrate all body constituents with modest scattering, which allows precise localization of objects deep in the tissue.

X-ray absorption is a well understood process. It provides precise quantification of e.g., contrast agent concentration in the tissue or body cavities and excellent spatial and temporal resolution. Diagnostic applications do not require advancing the X-ray source

or detector into body cavities by endoscopic methods as with optical imaging or when special coils are used to improve image quality in MRI.

Most disease-specific molecular and cellular processes involve low concentrations and have low capacities. Therefore, molecular imaging requires highly sensitive imaging modalities to detect and quantify the imaging probes as it is done with short-lived radioisotopes. Optical imaging and ultrasound are next in sensitivity. MRI would require too high contrast agent concentrations

to allow detection of biomolecules, e.g., by labeled antibodies, or to trace intracellular metabolism.

The most relevant drawback of X-rays is their low contrast sensitivity. Even in CT a minimum concentration of 0.5 mg iodine/ml is required to achieve a detectable change of about 10–15 HU and ten times this concentration would be desirable. 0.5 mg iodine/ml corresponds to a 1–4 mM concentration of a molecule labeled with 1–3 iodine atoms.

Examples of X-ray contrast agents which reach sufficient concentrations by active transport mechanisms are compiled in Table 1. The smallest dose is about 3 g iodine in case of ►cholegraphic agents and about 3 g gadolinium when Gd EOB DTPA is used for enhancement of liver parenchyma. Targeting smaller volumes of tissue than liver parenchyma may require less contrast material. Small lesions will, however, receive only a small proportion of cardiac output. If perfusion is in the same range as in best perfused normal tissue, i.e., 1 ml/g/min, it will take almost 10 h until the blood volume of 5 L passes a 10-ml lesion. Meanwhile competing processes will have diminished blood concentration. If extraction is 100% during one passage of the blood and contrast enhancement of 50 HU in the 10-ml tissue is desired this would mean a dose of 100 mg iodine or 500 mg contrast agent under optimistic assumptions, as described in following list.

Estimation of minimum dose necessary to achieve 50 HU contrast enhancement by a specifically binding or transported iodinated contrast agent

- 50 HU corresponds to 2 mg iodine/ml tissue.
- 10 g of tissue requires 20 mg iodine.
- 20 mg iodine is contained in 5 L of blood if a dose of 100 mg iodine is injected and the mean blood level for the next 10 h is 20% of the theoretical initial concentration (80% loss due to biodegradation, diffusion into tissues, excretion; most likely losses will be higher).
- 100% extraction of the contrast agent during first pass, 10 h of perfusion.
- If the specific contrast agent molecule contains 20% (weight) iodine the total dose required is 500 mg.

Improvements in contrast sensitivity require higher radiation doses or the application of lower energy X-rays, both are not acceptable for most patients and indications. Monoenergetic X-rays or X-rays with narrow energy distribution make better use of the sudden rise in absorption occurring at the k-edge of iodine and other heavy elements but none of these measures would result in dramatic improvements regarding sensitivity. Consequently, molecular imaging

using X-ray imaging can be used only for the detection of high capacity molecular or cellular processes, the detection of molecules which occur in high concentrations, or processes which result in physicochemical states that lead to accumulation of contrast agent molecules independently of an active transport or specific binding.

Specificity of Extracellular X-ray Contrast Agents

Although frequently called “nonspecific” the currently dominating extracellular X-ray and MR contrast agents display very useful specificities for a large variety of diseases. The contrast media are distributed throughout the body by the blood flow and diffusion according to the permeability of capillaries and the size of the interstitial space [3]. Perfusion, capillary permeability, and the proportion of extracellular space differ in ischemic states, inflammation, and tumors [4]. The faster the imaging becomes and the larger the volumes simultaneously scanned, the better the early distribution phase of rapidly injected contrast media is displayed. This early distribution allows best to differentiate perfusion- and diffusion-dependent differences in contrast. As scanners were much slower in the past, the potential benefits of the extracellular contrast media were not fully recognized.

Limitations are obvious if the diseased tissue does not differ from normal tissue or successfully treated tissue in respect of the above-mentioned criteria. Under these conditions, even a contrast agent with high absorption of X-rays is of no help. Another drawback is the short-lasting contrast which requires repeated injections if the diagnosis is missed during the first scan or if persistent visualization of a lesion is required during an interventional procedure.

Monitoring of Molecular and Cellular Processes by X-ray Contrast Agents

Molecular and cellular processes were visualized by X-ray contrast agents long before the term “molecular imaging” became popular and even before the advent of early CT (Table 1). Because of the above-mentioned limitations in the sensitivity of contrast detection by X-ray radiography, the latter can only visualize high capacity transport mechanisms and the nonspecific uptake of particles by specialized cells.

None of the products or experimental preparations is currently in clinical use or under development. Thorium oxide was not excreted at all; furthermore it proved to be toxic because of long-lived α -radiation [4]. Other agents were not pursued because they displayed various types of toxicity or were less well tolerated than the extracellular contrast agents. Except thorium dioxide, none of them resulted in reliable and satisfactory contrast or provided important diagnostic information which could not have been obtained with a similar quality by more recently established imaging methods. In spite of an everlasting

interest in specific contrast agents one after the other of these specific contrast agents disappeared from the market.

Admittedly, none of the X-ray contrast agents that used to be labeled as specific were developed to solve important diagnostic problems that are of interest today such as early tumor detection or diagnosis of non-obstructive inflammatory arterial or degenerative cerebral disease.

Directions of Future Research

It is not very likely that X-ray contrast agents will be used for molecular imaging. The minimal concentration required is probably far too high to be reached by specific binding even if small molecules are used to direct iodine or other radiopaque elements to diseased tissue. Nevertheless, some metabolic or transport processes operate with high capacity. In these cases, the required concentration may be reached if the metabolized or transferred contrast agents accumulate in the cells, tissues, or cavities where the process takes place. Such accumulation may occur if the contrast agent is caught in the cells or cavity because of unidirectional transport or is biotransformed to charged or more hydrophilic, nondiffusible metabolites or there is precipitation because the concentration exceeds solubility.

Other mechanisms that indicate abnormalities but are less directly dependent on molecular or cellular processes may be used to achieve sufficient accumulation of X-ray contrast agents: There are several disease processes that result in changes of e.g., extracellular pH or accumulation of calcium or extracellular matrix materials [4,6]. It is conceivable that specifically designed contrast agent molecules accumulate by precipitation at acidic pH or formation of large aggregates or binding to calcium deposits. The process may be enhanced if the contrast agent molecules tend to bind to each other either already in aqueous solution or after they change their shape or ionicity following any kind of reaction or binding at the target location.

Although a variety of concepts seem to offer opportunities for the development of X-ray contrast media with specificities different from those of the currently used inert small molecules with extracellular distribution one has to consider the following obstacles:

- In the past 100 years many approaches tested intentionally or unintentionally have failed. Nevertheless, the underlying concepts may be tested again today with promise, applying current knowledge in biology and chemistry.

- The mechanisms that are most likely to result in sufficient specificity and contrast medium concentration involve complicated multiple step reactions.
- Toxicity of accumulating X-ray contrast agents requires specific attention.
- Cost caused by expensive development and production must be balanced against the medical benefit.

Increasing spatial and to some extent also contrast resolution of X-ray equipment and advances in the understanding of disease processes are in favor of improved X-ray contrast agents which provide important additional information.

Conclusions

The combination of molecular imaging and X-ray contrast agents sounds like an unresolvable contradiction. Extracellular, well-tolerated and cheap **▶ nonionic contrast media** that allow us to assess perfusion, permeability, and the proportion of interstitial space do indeed set a standard that is difficult to reach or even surpass. Yet, X-ray contrast media meeting a broad definition of molecular imaging were used in the past. They failed because the processes displayed were of too little medical significance and/or tolerance was not satisfactory. An X-ray contrast agent indicating a universal process such as pH-lowering or extracellular matrix accumulation may find a place within the broad range of diagnostic imaging methods.

Zellweger Syndrome

Fatal hereditary disorder that typically presents in the neonatal period. Clinical features include an array of hepatic, renal and neurological dysfunctions. Patients with Zellweger syndrome rarely survive the first year of life. The disease is caused by mutations in the Pex proteins leading to an defective import of peroxisomal matrix proteins and consequently to a loss of most peroxisomal metabolic pathways.

► Protein Trafficking and Quality Control

Zero-Order Kinetic

Zero-order kinetics describe the time course of disappearance of drugs from the plasma, which do not follow an exponential pattern, but are initially linear (i.e. the drug is removed at a constant rate that is independent of its concentration in the plasma). This rare time course of elimination is most often caused by saturation of the elimination processes (e.g. a metabolizing enzyme), which occurs even at low drug concentrations. Ethanol or phenytoin are examples of drugs, which are eliminated in a time-dependent manner which follows a zero-order kinetic.

► Pharmacokinetics

ZES

► Zollinger-Ellison Syndrome

Zinc Finger

Zinc fingers are structural motifs which were first recognized in DNA-binding domains of various proteins but which are now known to occur also in proteins that do not bind to DNA. In the classical C_2H_2 zinc finger domain, three secondary structures, an α -helix and two β -strands with an antiparallel orientation, form a finger-like bundle, which is held together by a zinc ion. Zinc ions are bound by 2 cysteine and 2 histidine residues, which are localized in the β -strands and the α -helix. The C_2H_2 zinc finger domain, which can insert its α -helix into the major groove of DNA, is one of the most common DNA-binding motifs in eukaryotic transcription factors. A second type of zinc finger structure, designated the C_4 zinc finger, is found in nuclear receptors. While C_2H_2 zinc finger proteins generally contains 3 or more repeating zinc finger motifs and bind as monomers to DNA, nuclear receptors contain only 2 C_4 zinc finger units and bind to DNA as homodimers or heterodimers. The C_4 zinc finger motif is structurally quite as distinct from the C_2H_2 zinc finger domain.

Zollinger-Ellison Syndrome

Zollinger-Ellison syndrome (ZES) is characterized by the development of a tumor (gastrinoma) or tumors that secrete excessive levels of gastrin, a hormone that stimulates production of acid by the stomach. In most cases, the tumor or tumors arise within the pancreas and/or the upper region of the small intestine (duodenum).

► Proton Pump Inhibitors

► Proton Pump Inhibitors and Acid Pump Antagonists

Zona Glomerulosa

The adrenal cortex is functionally divided into three zones, the zona glomerulosa, fasciculata, and reticularis. Only the outermost zone, the zona glomerulosa, synthesizes aldosterone. The other zones are responsible for the generation of glucocorticoids and androgens.

- ▶ Epithelial Na⁺ Channel (ENaC)
- ▶ Gluco-/Mineralcorticoid Receptors

Zymogen

Zymogen is a precursor protein that is converted to an active protease when one or more of its peptide bonds are cleaved. Zymogens involved in coagulation include factors II (prothrombin), VII, IX, X, and XI.

- ▶ Anticoagulants
- ▶ Coagulation/Thrombosis
