Biomarkers of exposure have had the most success in environmental and occupational epidemiology, but there is also considerable interest in other types of biomarkers. Reduced acetylcholinesterase activity is a classic biomarker of effect resulting from exposure to organophosphate pesticides. While DNA adducts are often considered markers of biologically effective dose, mutations in particular genes, a possible result of DNA adducts, can provide markers of early effects in the process leading to cancer. For example, a specific mutation in *p53*, an important tumor suppressor gene, has been found in liver cancer patients from areas with high aflatoxin exposure.¹ Sperm counts have been extensively used as markers in studies of male reproductive toxicants. Measurement of anogenital distance is a recent innovation in this field.¹² Imaging technology, particularly functional MRI scans of the brain, hold promise for neurotoxicology.¹³

► BIOMARKERS OF SUSCEPTIBILITY

People may be more susceptible to a given exposure for a number of reasons, such as genetics, age, or preexisting health conditions. Biomarkers of susceptibility primarily focus on genetics: variations in specific genes can modify an exposure-disease relationship, for example, shifting the dose-response curve, leading to the concept of *gene-environment interaction*. Two types of genes have received the most attention, genes coding for enzymes involved in DNA repair and biotransformation (metabolism) of xenobiotics.¹⁴ A classic example of the latter are “slow acetylators,” individuals who possess a variant of the *N*-acetyltransferase gene (*NAT2*) have increased risk of bladder cancer following exposure to aromatic amines or smoking. Similarly, *XRCC1* is an example of a DNA repair enzyme with known polymorphisms that alter the risk of lung cancer.¹⁵ In addition to genetic factors, preexisting health conditions can also increase susceptibility by altering certain exposure-disease relationships. For instance, the risk of liver cancer due to aflatoxin exposure is significantly increased among individuals who test positive for hepatitis B surface antigen.¹

► SUMMARY

A primary goal of biomarker research is to characterize the relationship between a biological measurement and the actual biological phenomenon of interest. However, this process is complicated by several factors such as inter- and intra-individual variability and inter- and intra-laboratory variability. It is difficult to characterize a normal range of values in the general population when there are so many factors that can potentially affect biological measurements. Most biomarkers are experimental and measured via analytical techniques that are specialized and expensive, further complicating the process of replicating results in multiple studies that evaluate different populations over time. Furthermore, biomarker research poses a number of important ethical issues. How should results be communicated to participants, particularly when the interpretation and implications for health are unclear? Could insurance agencies or employers potentially use genetic data to discriminate against susceptible individuals? Despite these challenges, biomarkers have already proven their value in environmental and occupational epidemiology. Valid and reliable biomarkers can become effective screening tools that facilitate the process of monitoring for exposure and disease.

Asbestos and Other Fibers

Kaye H. Kilburn

► ASBESTOS

Asbestos-Associated Diseases

Prevention of asbestosis and reduction in lung cancer mortality in asbestos-exposed subjects has occurred in the last generation in the United States. Massive medical evidence compelled the primary industry to quit using asbestos by making use excessively expensive as risks became uninsurable. This led to successive waves of court awards for liability and punitive damages and settlements negotiated to user workers, co-contaminated workers, and bystanders. Jury awards for mesotheliomas were frequently \$1 million, and for asbestosis ranged from thousands to hundreds of thousands of dollars: an effective way to stem an epidemic. Unfortunately widespread substitution of human-made fibers in construction may predestine a repeat performance.

Clinical Recognition of Asbestosis

Asbestosis is a fibrotic disease of the lung from asbestos after a suitable latent period. Cellular infiltrates and fibrosis surround small bronchioles and limit forced expiratory flow to impair pulmonary function. Asbestosis is diagnosed from chest radiographs by diffuse, irregular opacities in the lung fields or by circumscribed or diffuse pleural thickening, which are defined by international criteria.¹

Asbestos exposure produces *no acute symptoms*. Pathological fibrosis of lung or pleura is well advanced when expiratory airway obstruction permits “early diagnosis,” radiographic abnormality follows and only then do workers have *breathlessness on exertion*, or *cough productive of phlegm*. Usually asbestosis has incubated for two decades or more from the first exposure; this is called the “latent” period. Asbestos and cigarette smoking *synergize* to impair function and produce fibrosis and carcinoma.

History

Although the first use of asbestos by humans is lost in antiquity, it is mentioned by Plinius, who referred to asbestos as *immun vivum*, “durable linen,” and Roman slaves who worked in these mines grew breathless and died prematurely. Asbestos has properties of incombustibility, durability, and resistance to friction, which have made it useful for insulation and heat protection in modern industry. H. Montague Murray,² a London physician, recognized a new disease in the badly scarred lungs of an asbestos worker, presumably from a textile factory, who died after a brief illness characterized by extreme breathlessness. Murray connected the workplace exposure to the scarring in testifying before an inquiry at the British Government Commission on Occupational Disability in 1907 and stated hopefully that with the recognition of the cause, he would predict few future cases. His singular finding was ignored until 1924, when Cooke³ described pulmonary fibrosis in a woman who had worked for 20 years in an asbestos textile factory. The illness was widely

regarded as a manifestation of tuberculosis, the plague of those times, and thus was largely ignored. Cooke⁴ also introduced the name “pulmonary asbestosis” as a pneumoconiosis, one of the dust diseases (as named by Zenker 60 years earlier). He suggested optimistically that recognition would lead to prevention.

After further scattered reports of asbestosis in individual workers, an epidemiologic investigation was conducted by Merewether and Price⁵ of the workers in British asbestos textile factories in 1930. They systematically associated factory dust containing asbestos with radiographic findings of asbestosis in card room workers as reported by Pancoast et al.⁶ in 1918. Gloyne’s autopsy studies of the workers’ lungs⁷ showed lesions of membranous and respiratory bronchioles. Later the 1930’ supporting studies, the Metropolitan Life Insurance Company study by Lanza et al.,⁸ reported that two-thirds of the x-ray films of 126 “randomly selected” persons (from those) with three or more years of employment had asbestosis. In 1938, Dreessen et al.⁹ studied 511 employees of asbestos textile factories in North Carolina and found a low prevalence of abnormalities in the x-ray films in largely newly hired hands with short exposures. However, when several dozen workers who had been discharged from these factories were traced, many of their x-ray films showed characteristic asbestosis.¹⁰⁻¹² Dreessen’s study and the associated reports made it clear that asbestosis produced abnormalities in the chest x-ray and shortness of breath.

In the 1930s, additional reports of insulators, boilermakers, and men in other trades who manufactured or used asbestos showed that they had abnormal x-ray films, shortness of breath, and in some cases, rales in the chest, clubbing of the digits, and cyanosis. However, World War II intervened before the prevalence was measured or exposure controlled. Thus, knowledge of the pervasiveness of asbestosis waited until the 1960s and 1970s, when studies in the shipbuilding and construction trades showed chest x-rays were abnormal in many exposed workers. Large studies of asbestos miners and millers¹³ showed that airway obstruction and reduction in vital capacity and diffusing capacity occurred before the chest x-ray abnormalities.

Lung Cancer

Lung cancer in individuals exposed to asbestos was reported in the 1930s, but the causal connection developed slowly. Merewether¹⁴ reported in 1947 that 13.5% of the asbestos textile workers studied in 1931 had died of lung cancer within 16 years. Heuper¹⁵ by 1942 concluded in his textbook that asbestos was a more important cause of lung cancer than arsenic or radium. Richard Doll,¹⁶ in a well-designed study of a textile factory cohort (a defined population), noted long latency of lung cancer and its importance as a cause of death, in 1955 found occupational exposure to asbestos increased lung cancer deaths 10-fold above the expected rate. Mancuso and Coulter,¹⁷ who confirmed Doll’s findings in the United States, and Selikoff¹⁸ first reported a large excess of lung cancer among major users of

asbestos—insulators. Findings indicating that users were in danger vastly increased the numbers of persons at risk for lung cancer and made control urgent. In their 20-year prospective study of mortality rates among almost 18,000 insulators begun in 1967, Selikoff and Seidman,¹⁹ by 1979, found excessive death rates not only for lung cancer, mesothelioma, and asbestosis but also for cancers of the gastrointestinal tract, larynx, oropharynx, and kidney (Tables 23-1 and 23-2), and synergistic interactions between cigarette smoking and asbestos in these cancers. Age-standardized rates per 100,000 person-years are as follows: individuals who neither worked with asbestos nor smoked cigarettes had a calculated death rate of 11.3; asbestos workers who did not smoke had a rate of 58.4. Smokers in general (not asbestos workers) showed a rate of 122.6, whereas those who had both types of exposure, cigarettes and asbestos, had a rate of 601.6.

Mesothelioma, a Twentieth-Century Tumor

Klemperer and Rabin²⁰ in 1931 described this rare tumor, characteristically spread on the pleural surface, and reasoned that the responsible carcinogen must penetrate to these inaccessible pleura and peritoneum surfaces. Reports of mesotheliomas in subjects exposed to asbestos were rare in the 1940s and 1950s until Wagner et al.,²¹ in 1960, reported 47 mesotheliomas in people who had worked in or lived near the crocidolite works in South Africa 15 years earlier. Such a clear association between a rare tumor and a causal agent was unprecedented, but it was quickly corroborated by other studies. Although Wagner's study lacked control subjects, his germinal observations were confirmed by population-based data. Consequently, the diagnosis of a mesothelioma stimulates a search for asbestos exposure that is seldom unfulfilled. Latent intervals of 30–40 years are characteristic, so many recent and current patients were exposed in U.S. shipyards that built and repaired a two-ocean navy and shipping fleet during World War II.

Asbestos Minerals

Fibers and Fibrils

"Asbestos" is a general name for naturally occurring fibrous minerals that include serpentine and amphibole fibers, but excludes fibrous forms of other minerals such as wollastonite, brucite, gypsum, and calcite. Chrysotile, the only serpentine asbestos, occurs in "cobs" about the size of a palm of a hand in pockets, often within platelike and nonfibrous silica deposits. The fibers can be seen with an optical microscope; the fibrils that compose them are of micrometer size, and, therefore, single fibrils isolated or in tissue are ordinarily visible only with an electron microscope. Fortunately, there are crude associations among "dustiness" (the gravimetric measurement of the total airborne concentration), the visible fibers recognized with the optical microscope (particularly with the help of phase contrast or polarized light), and the concentrations of fibrils measured with the electron microscope. For industrial hygiene, the rough relationships between total dust measured gravimetrically from air samples and fibers visible with the light microscope have produced reasonable dose-response relationships in miners and millers of asbestos, asbestos textile workers, and workers producing asbestos (calcite) pipe. Estimates of maximal human exposure to fine fibers range widely from several hundred fibrils per cubic meter of air to several hundred millions of fibrils.

Sources

The commercially important asbestos fibers are chrysotile, amosite, and crocidolite. Chrysotile, or white asbestos, is mined mainly in Canada's Quebec province and in the Ural Mountains of the former Soviet Union. U.S. mines in Arizona and California produced small quantities. The three amphiboles are crocidolite, or blue asbestos, which is highly associated with mesothelioma; amosite (named for the Asbestos Mining Organization of South Africa), called brown

TABLE 23-1. LESS COMMON MALIGNANT NEOPLASMS: DEATHS AMONG 17,800 ASBESTOS INSULATION WORKERS IN THE UNITED STATES AND CANADA, JANUARY 1, 1967–DECEMBER 31, 1986

Site of Cancer Causing Death	Expected Deaths ^a	Observed		Ratio o/e

Nonsmokers	40	7/97	7.2	
Ex-smokers	44	29/131	22.1	3.1
Current smokers	48.2	37/191	19.4	2.7

asbestos because of its iron content; and anthophyllite, which is found in Finland. Actinolite, or fibrous tremolite, contaminates minerals. Examples include crocidolite and talc from many sources, particularly the Gouverneur district of New York State.

Mining and milling exposes far fewer human subjects to asbestos than to do thermal insulation and construction materials: surfacing materials, preformed thermal insulating products, textiles, cementitious (concrete-like) products, paper products, roofing felts, asbestos-containing compounds, flooring tile and sheet goods, wall coverings, and paints and coatings. Dispersal of the fibrils into the air of “massive containers”—ships and industrial facilities such as aluminum refineries, copper smelters, glass and fiberglass factories, paper mills, and powerhouses—exposes all workers, well beyond those who handle asbestos products.

Use of Asbestos in Industry and Construction

Asbestos serves in heat insulation, friction-resistant products, and construction.²² As heat insulation, asbestos cloth is used in blankets, gloves, suits, and boiler packing and is combined with magnesia in pipe insulation. Asbestos combined with portland cement, or blue mud, was widely used to free-form insulation around pipes and boilers. Friction products included brake shoes and pads, clutch facings, and other woven products that must resist both friction and the heat it generates. The major tragedy of asbestos exposure since World War II was in workers in the construction trades, where, for reasons never stated but including availability, cheapness, and binding properties, asbestos has been used in drywall, in spray ceilings, paint, floor tile, ceiling tile, and as filler in many other products. Analogous to fine sand, as the inert material in paint, asbestos was added to products whether or not it conferred useful properties.

Peak Use of Asbestos

Asbestos use peaked in the United States in the early 1970s. Although the yearly consumption rose steadily from 1890 to 1950, was virtually level at more than 7000 metric tons per year from 1950 through 1969, and fell precipitously in the 1980s. The profile is similar for other developed nations, where asbestos was widely used in construction.

Patterns of Use

Asbestos litigation and regulation since the mid-1970s have excluded asbestos from many consumer products, from building materials, and lastly from brakes and friction goods. Pioneering synthetic brake materials, Volvo Corporation in Sweden produced pads and shoes that, although twice as expensive, lasted three or four times as long as asbestos. Progress has been uneven. Asbestos insulating products continued to be installed in New Jersey schools (without the addition of warning labels) well into the early 1980s, and in 1986 an inventory of a U.S. Navy warehouse for ship fittings disclosed 130 products containing asbestos. Many of these were gaskets and other relatively low-exposure items, but others included thermal insulation and blankets. Because asbestos use accompanied the intense industrialization

of the twentieth century, a key concern is that developing countries will probably continue letting economic determinants take precedence over health. Even in Israel, asbestos pipe containing crocidolite was manufactured through the 1970s, and asbestos remains in place in sugar mills and oil refineries in Mexico, Brazil, and China. In February 2005, WR Grace & Co. and seven executives were indicted on federal charges that they knowingly put workers and the public in danger through exposure to vermiculite ore contaminated with tremolite in Libby, Montana.²⁴ Earlier the U.S. Justice Department alleged Grace fraudulently transferred money before filing a Chapter 11 bankruptcy.²⁵ Asbestos firms have paid injured workers \$20 billion and have repeatedly sought “relief from asbestos claims” by appeals to the Supreme Court to halt trials²⁶ and via new legislation.²⁷ Costs of present and future claims are estimated at \$200 billion and 10 major asbestos product manufacturers filed Chapter 11 bankruptcies in 2000–2001.²⁶

Removal of Asbestos

Fragmentation and degeneration due to heat and vibration increase the liberation of fibrils from asbestos during renovation, removal, or repair.²⁸ The highest doses for workers may be generated during the removal of asbestos without proper procedures, including wetting material down and restricting the area to properly suited, well-trained personnel using air-supply respirators.²² If the asbestos is placed in plastic bags and buried, the hazard is minimized. These safeguards have been neglected in many asbestos-removal efforts, where levels of more than 100 fibers per millimeter have been measured.

Biological Effects of Asbestos

Molecular Effects

Asbestos fibrils in vitro hemolyze red blood cells and generate reactive oxygen- and nitrogen-derived species to damage DNA.²⁹ Chrysotile also mediates the uptake of exogenous DNA into monkey cells in such a way that the genes on the DNA are expressed.²⁴ In several cultured human cell lines chrysotile and amosite induce changes including DNA breakage.^{29–33} Asbestos, and synthetic fibers, induced rat alveolar macrophages to form and release tissue necrosis factor- α .³⁴ Amphiboles induce cytotoxic effects in cultured macrophages, which caused hyperplasia and squamous cell metaplasia.³⁰ Chrysotile was more toxic than amosite in normal and transformed epithelial cell lines and in plasminogen activation.³³ Crocidolite fibers induced loss of wild-type alleles, decreased apoptosis, accelerated tumor growth, invasion, and lymphoid dissemination.³⁴ Amosite fibers disrupt mitochondria and induce apoptosis.³⁵

Cellular Effects

Heppleston^{36,37} and Allison³⁸ two decades ago showed that macrophages that had phagocytosed asbestos fibrils generated inflammatory signals. Macrophages caused fibrosis in animal models^{39,40} and in the human lung, where asbestos caused recruitment and proliferation.⁴¹ In contrast, quartz was disturbingly lethal for cells. Observations of cells in vitro and in permeable chambers implanted in the peritoneum of rats showed that asbestos causes macrophages to produce peptides that stimulate fibroblasts (fibronectin and others) to replicate and produce collagen.^{42–44}

Target Organ

Processing asbestos in the lung^{45–46} evidently begins in airways, particularly the small airways where fibrils impinge. Short-term clearance depends on fiber size and type; chrysotile, for example, clears from guinea pig lungs faster than amosite.⁴⁷ The probable scenario in airways is that fibrils pass between the epithelial cells, cross the basement membrane, and lodge in the connective tissue, attracting macrophages. Macrophages on the airway surfaces may phagocytose some fibrils, but fibrils are simply carried away on the mucociliary escalator. Others, apparently a small minority, are coated with iron-rich protein and become asbestos (ferruginous) bodies (Fig. 23-1).

Figure 23-1. Asbestos (ferruginous) bodies in lung tissue consist of an asbestos core with an iron protein coat that make them appear tan or brown ($\times 600$).

Airway walls thicken beneath the epithelium, and cells are attracted to the alveolar side of membranous small airways. Next is bridging, via the lymphatic vessels, between the peribronchiolar scars, linking them like a lattice. Previous assumption that this linked-up network “shrank” the lung to reduce volume is no longer tenable. Volumes lost to shrunken zones are compensated for by areas of emphysema.⁴⁸ Interstitial fibrosis is seen only with advanced asbestosis, particularly in subjects who have smoked cigarettes.

Transport of Fibrils

Fibrils are transported to other sites, via regional lymphatic vessels, and into the pleural space. Hillerdal⁴⁹ suggested that the fibrils, absorbed in small airways and alveoli, move via the lymphatic vessels or within cells to the pleural surface, cross the pleural “space,” and impinge on the parietal pleura, where the macrophages are retained. Here they send signals to fibroblasts and to mesothelial cells to proliferate and produce collagen.⁵⁰ This produces characteristic hyaline plaques of the parietal pleura. When pleural effusion intercedes, the pleura may fuse producing dense adhesions. In some instances, fibrosis invades the lung from pleural surfaces via the perivenous lymphatics. Retrograde flow may occur because symphysis obliterates the pleural space so that it is no longer accessible as a sump for the fibrils, which move into the peripheral lung. Fibrils remain in the perivenous lymphatics. Whatever the mechanism, such fibrous strands, as seen on cut surfaces of the lung or on high-resolution computer-augmented tomograms, are most dense at the pleura and attenuate progressively toward the hilum.

Immune Responses

Association of rheumatoid factor with asbestosis^{51–52} has posed unresolved questions: first, whether subjects who develop rheumatoid factor are more susceptible to the clinical disease after asbestos exposure; second, whether immunoglobulin synthesis is stimulated by asbestos; and third, whether such elevations enhance the development of asbestosis. Alterations in populations of lymphatic T cells have also been associated with asbestos exposure and with asbestosis^{53–54} that poses questions similar to those for the role of immune globulins. Antinuclear antibodies were more frequent and higher titers in tremolite exposed residents of Libby, Montana than in controls.⁵⁵

Summary

Macrophages export peptides that stimulate fibroblasts to proliferate and produce collagen in cell systems and diffusion chambers of plants

and animals.^{37,38} Fibronectin and at least one other fibroblast-stimulating factor can be stimulated by asbestos in cells.^{54–56,57} Implantation of asbestos and human-made fibers in the pleural space of experimental animals, and refinements of this technique with milling and sizing of the fibrils, led Stanton and Wrench⁵⁸ to propose that the physical properties—the diameters and lengths of the fibers or fibrils—were responsible for mesothelioma. Intracellular asbestos fibrils interfere with chromosome aggregation in mitosis, although whether this interference is linked to neoplasia is unclear.²⁴ It appears that physical, surface, and chemical properties of the fibrils may be important in cell proliferation and in forming tumors.

Human Exposure

Workers

Contained air space into which asbestos has been dispersed, such as in a textile factory, ship, power station, factory, smelter, or refinery where there is heat conservation concentrates the dose. Open air spraying of asbestos insulation on the structural steel of high-rise buildings in New York City, exposed sprayers heavily and asbestos was detected in ambient air as far away as Cape May, New Jersey. Sprayers themselves, within the skeleton of the building were at greatest risk. During mining and milling, moisture and nonasbestos rock bind fibers and impair the discharge of fibrils into the air. In comparison, textile operations, in which the fibers are carded and spun, generate dry fibrils into the workplace air, and to the spraying of asbestos insulation is similar. Obviously, partially bound asbestos-containing materials are less hazardous than those that readily release fibers or generate fibrils into the air. Cleaning brake drums with compressed air disturbs many fine fibrils (Fig. 23-2), as does the removal of insulation that has been cooked on boilers or steam lines. If prevalence of asbestosis reflects cumulative exposures, insulators, sheet metal workers, boilermakers, and pipefitters are at high risk whereas electricians, carpenters, laborers, workers, and mechanics have had less exposure and less disease after 15–25 years. Ships with perforated plates for decks maintain fibrils in the air space, similar to asbestos textile factories.⁵⁹ Thus in taking a patient’s history, determining patient involvement in asbestos heat-conservation or heat-protection is essential. For example, asbestosis has been diagnosed in cafeteria and office workers employed in asbestos pipe plants where they had shared a building with production workers for 15–20 years.

Secondary Human Exposure

Family Members

Families of amosite factory workers⁶⁰ in Paterson, New Jersey showed effects from exposure to asbestos brought home by workers on their person and clothes. About 48% of wives, 21% of daughters, and 42% of sons showed parenchymal or pleural evidence of asbestosis. Shifting to a less intense work exposure, that of shipyards, another family study showed that 11.3% of wives, 2.1% of daughters, and 7.6% of sons had signs of asbestosis.⁶¹ In the past, consumer electrical goods contained asbestos but to date there has been no evidence of disease from exposure at the levels of fibrils released from electric irons, electric hair dryers, or even asbestos-containing artificial logs used in fireplaces. Nevertheless, discontinuance of such exposure is the responsibility of the Consumer Products Safety Administration.

Schools and Other Buildings

Passive bystander asbestos exposure—as occurs to people in buildings with asbestos as heat insulation on steam pipes, boilers, and ducts leading to the rooms and sprayed on ceilings and walls or as construction materials—has been the subject of contentious discussion, rule making, and litigation for the past two decades.^{62,63} Surveys by the U.S. Environmental Protection Agency (EPA) in 1985 estimated that 31,000 schools and 733,000 public and commercial

Figure 23-2. A workman removing insulation containing asbestos shows cavalier lack of caution. He should be protected with an air supply respirator venting into his impervious clothing and gloves. He must gather all material into double thickness strong plastic bags for safe disposal.

buildings contained friable, easily crumbled asbestos-containing material.²² After mesotheliomas were diagnosed in 3 Los Angeles school custodians, 205 school maintenance workers, and custodians with 10 years on the job showed 16% had pleural and 13% had parenchymal signs of asbestosis.⁶⁴ New Jersey custodians (S Levine, personal communication) had similar prevalences. In neither of these studies were custodians with prior exposure to asbestos excluded nor was it possible to ascertain which ones were working on the maintenance of boilers and heat- and power-generating facilities. In Boston schools,⁶⁵ 52 custodians showed signs of asbestosis related to workplace exposure. Teachers and students sharing these air spaces may show signs as well, but neither has been studied. Many school boards have had asbestos removed from the schools; some have issued bonds for this purpose, and some have sued the suppliers of asbestos-containing products to recover the costs. In response to pressure from consumer groups and legislatures, the EPA has recommended removal of such products when air levels of asbestos are 0.1 to 0.01 fiber/mL.²² Our society needs to make changes based on the known harmfulness of asbestos, without assessing morbidity and mortality rates from a particular exposure.^{61,62}

Asbestosis

Diagnosis

The diagnosis of asbestosis requires, first, a history of exposure, usually occupational or as a bystander in a trade in which asbestos has been used. Second, a suitable latent period elapsed since the start of exposure. The third criterion is typical pulmonary or pleural abnormalities on the chest x-ray. The minimal latent period in developed countries exposures in the past 30 years, is 10 years, prevalences of asbestosis climb at 20, 30, and 40 years. In shipbuilding and construction trades, workers who were virtually continuously exposed for 25–35 years, the prevalence of asbestosis, including pleural disease, is 25–35%. Full-size posteroanterior (PA) chest radiographs show irregular opacities in the lower half of the lung fields near the lateral pleural surfaces. Pleural signs are circumscribed or diffuse areas of pleural thickening, so-called hyaline plaques of the parietal pleura, which are seen easily when located laterally or on the diaphragm but may also be located posteriorly or anteriorly and seen face on (en face) or in profile. Descriptions of the patterns of changes in chest radiographs as a result of asbestosis have been progressively enhanced and detailed by the International Labor Organization (ILO) working committees since 1919. The 1980 revision¹ included a set of standard radiographs with the major ILO categories portrayed (Fig. 23-3, A to E). Pleural changes are described by their location, thickness, and extent (Fig. 23-3F). Use of the ILO classification scheme has improved communication between investigators in various countries and become the medical-legal criteria for recognizing asbestos. Recent studies of several thousand exposed workers showed that the functional implications of pleural and pulmonary signs are similar: both impair expiratory flow and produce air trapping.^{66–68} Furthermore, despite radiographic distinctions between circumscribed plaquelike and diffuse pleural thickening, the only physiological difference was greater when diffuse thickening surrounded the base of the lung. Spiral CT scans have enhanced recognition and help map pulmonary pleural asbestos but it is not clear that they are more sensitive than the full size PA x-ray.

Pathology

British pathologist Roodhouse Gloyne⁷ described the classic cellular aggregates and cell proliferation around the small airways, the terminal and respiratory bronchioles, a diagnostic gold standard. The primacy of this lesion was obscured in later descriptions of fibrosis throughout the lung, with dense aggregates of macrophages and asbestos bodies in the surviving alveoli that led to characterization of asbestosis as interstitial fibrosis. However, new human pathological descriptions and animal experiments confirm the membranous and respiratory bronchioles as the focus of fibrosis (Fig. 23-4). Subsequent bridging extends between the bronchioles, creating a lattice-work; additional interstitial fibrosis may develop as the process advances.⁴⁸ Another distinctive lesion involves perivenous lymphatics visualized on extended scale computer-assisted tomograms of subjects showing increased markings in the lung bases.^{69,70} Fibrosis is well visualized peripherally and attenuates toward the hilum, opposite to ordinary vascular and bronchial markings, which attenuate toward the pleural surfaces. Accentuated secondary lobular septa occur at about 1-cm intervals along the lateral margins of the lung, where they are recognized as “laddering” on the chest radiograph.

A small percentage of asbestos-exposed subjects have pleural effusions, healing of these effusions may obliterate the costophrenic angles and produce diffuse pleural scarring.^{71,72}

Undoubtedly, fibrils migrate to the pleura from their locus of deposition in small airways or alveoli.⁴⁹ Whether they are translocated as free fibrils or within macrophages after phagocytosis is unknown. In either case, they exit the lung to the pleural space and move with the lymph flow to the parietal pleural lymphatic vessels.⁴⁹ Here they apparently stimulate macrophages or stimulate the retention of the macrophages in the outer layers of the pleura and stimulate fibroblastic proliferation. Thus, circumscribed thickening (plaques) is found in the lower two-thirds of the lateral dorsal and ventral parietal pleura and

Figure 23-3. The International Labor Organization (ILO) classification for pneumoconiosis has provided criteria for asbestosis on chest x-ray films since 1959, using a scheme from 1916. Classification is based on a standard 14×17 inch posteroanterior radiograph of a technical quality that distinguishes details in the lungs. In 1980, copies of radiographs were supplied for normal, **A** 0/0, and for the three major categories of profusion of opacities for each size: s, t, and u. **B** 1/1 slight opacities, notable in outer lung regions; **C** 2/2 = moderate opacities, partly obscuring pulmonary vessels; and **D** 3/3 = opacities so profuse as to obscure the pulmonary vessels. **E** shows the standard films for opacities 3–10 mm in diameter (u/u). **F** shows circumscribed plaque (UL), diffuse pleural plaques (UR), calcified diaphragmatic plaque (LR), and calcified wall (LL).

Technical quality. With modern x-ray equipment, dedicated technicians can take nearly ideal maximally inflated chest radiographs in all instances except morbid obesity, severe infirmity, or distortion of the chest cage or internal organs. The common correctable error is underinflation, which is recognized when the right side of the diaphragm is above the ninth intercostal space. Such films must be repeated after the subject is instructed in holding a deep breath. Films of high quality can be ensured if the qualified reader has suboptimal films repeated before the subject leaves the x-ray unit.

The 12-point scale. The profusion of opacities was classified into one of four major categories by comparison with standard radiographs and a number, 0 to 3, written to the left of the slash. If during this rating, the major category above or below was seriously considered as an alternative, this was recorded on the right side of the slash, thus, "2/1" represents a profusion of major category 2 but with category 1 having been seriously considered. Profusion without serious doubt, in the middle of the major category, was recorded as 2/2. If the category above was seriously considered, profusion was recorded as 2/3.

Figure 23-3. Table Information

ILO CLASSIFICATION OF CHEST RADIOGRAPHS FOR ASBESTOSIS

Small Opacities Irregular	Short (1971) Classification	1980 Extended Classification
Profusion	1, 2, 3	0/0, 0/1, 1/0, 1/1, 1/2, 2/1, 2/2, 2/3, 3/2, 3/3, 3/4 1 = Slight, 2 = Moderate, 3 = Advanced
Type	s, t, u	s, t, u s = Width to about 1.5 mm t = Width exceeding 1.5 mm and up to 3 mm u = Width exceeding 3 mm and up to 10 mm
Extent	—	6 zones: Right and left—upper, middle, and lower
Large opacities: Pleural thickening: Chest wall	>10 mm	
	<ul style="list-style-type: none"> ■ Circumscribed (plaques) Face-on (enface) Width (a, b, c) Extent (1, 2, 3) 	Right, left
	<ul style="list-style-type: none"> ■ Diffuse Face-on Width (a, b, c) Extent (1, 2, 3) Diaphragm Costophrenic angle obliteration a = Maximum width up to ≈ 5 mm b = Maximum width > ≈ 5 mm and up to ≈ 10 mm c = Maximum width > ≈ 10 mm 1 = Total length up to one-fourth (of the projection of the lateral chest wall) 2 = Total length exceeding one-fourth but not half of the projection of the lateral chest wall 3 = Total length exceeding half of the projection of the lateral chest wall 	Right, left Right, left
Additional symbols: classification of other abnormalities on the x-ray films.		
ax = Coalescence of small pneumoconiotic opacities		fr = Fracture rib
bu = Bullae		hi = Enlargement of hilar or mediastinal lymph nodes
ca = Cancer of lung or pleura		ho = Honeycomb lung
cn = Calcification of small pneumoconiotic opacities		id = Ill-defined diaphragm
co = Abnormality of cardiac shape or size		ih = Ill-defined heart outline
cp = Cor pulmonale		kl = Septal (Kerley's) lines
cv = Cavity		od = Other significant abnormalities
di = Marked distortion of intrathoracic organs		pi = Pleural thickening
ef = Effusion		px = Pneumothorax
em = Definite emphysema		rp = Rheumatoid pneumoconiosis
es = Eggshell calcification of hilar or mediastinal lymph nodes		tb = Tuberculosis

on the dome of the diaphragm. Plaques are disks of dense hyalinized collagenous connective tissue up to several millimeters thick.

Clinical Features

The principal symptom is insidious shortness of breath on exertion and the symptom gradually worsens before radiograph abnormalities are seen. Cough with phlegm production is common and, when present for three months in two succeeding years diagnoses chronic bronchitis. Bronchitis increases in prevalence as the duration of asbestos exposure exceeds 20 years, even in workers who have never smoked.

Physical examination of the chest reveals decreased breath sounds. Wheezing on forced expiration increases in frequency as the lesions on x-ray films become more profuse. Fine crepitant rales may be heard after the radiographic changes are moderately advanced (ILO category 2/2 and greater) but are rare earlier. Peripheral cyanosis and finger clubbing, typical in advanced asbestosis, are uncommon and should arouse suspicion of other causes. Asbestos skin "warts," are rare but were common in insulators who handled asbestos daily.

Physiological Impairment

The key pathological lesions of asbestos in the lungs are narrow and constricted membranous and respiratory bronchioles. These lesions, in turn, reduce mid and terminal flow rates,^{73,74} that is,

obstruct expiratory air flow, causing the earliest physiological finding in asbestosis.^{13,66} Over 1,700 workers who had never smoked cigarettes were studied to define the effects of asbestos alone.^{13,66} Their small airways were obstructed before the irregular opacities of asbestosis appeared on the posteroanterior chest radiograph (Fig. 23-5). Such airflow limitation produced air trapping noted by an increased ratio of residual volume (RV) to total lung capacity (TLC) ratio (RV/TLC), and the increased residual volume reduced vital capacity. This reduced vital capacity led to the concept that asbestosis is a restrictive lung disease similar to idiopathic pulmonary fibrosis. However, reduced vital capacity is not a reliable measure of restrictive disease, which is defined solely by loss of total lung volume, in the *absence of obstruction*.⁷⁵ These effects are exaggerated by cigarette smoking (Fig. 23-6). Gas dilution using helium or nitrogen ignores the volume of air that is not connected, that is, air trapped so does not measure all of the total lung capacity, just as happens in patients with emphysema. Thus radiographic⁷⁵ or body plethysmographic methods must be used for accurate measurement of total lung capacity.⁷⁶ Radiographs must be obtained when the lungs are fully inflated, while in the latter one, expiratory reserve volume must be measured carefully with plethysmograph measurements. Total lung capacity is slightly increased due to effects of cigarette smoking; 85% of workers exposed to asbestos also smoked cigarettes for many years.

Figure 23-4. **A.** This terminal bronchiole that is 16 or more bifurcations from the trachea shows a division to the left. It has a greatly thickened fibrotic wall that causes small airway obstruction. **B.** In this more advanced stage, such bronchioles have been eliminated and alveoli are fibrotic, producing the irregular opacities seen on chest x-rays (original magnification 100x.).

Progressive impairment of airflow and air trapping occur with an increasing profusion of opacities on radiographs^{59,66,68} (Figs. 23-5, A and B, and 23-6, A and B). Further limitation of expiratory flow from 25 to 75% of vital capacity (FEF₂₅₋₇₅) indicates increased airway obstruction, which has increased air trapping, within a normal total lung capacity. As flow (FEF₂₅₋₇₅) decreased, both forced expiratory volume, in 1 second, and vital capacity decreased; lung volume was maintained. Further proof of this relationship came from the 46 men with severe asbestosis, as shown by ILO profusions of 2/3 and greater from 8000 asbestos-exposed workers, none of whom had reduced thoracic gas volume or TLC. Four additional subjects who appeared to have restrictive disease had had a lobe or more of lung removed for cancer. In summary, “a small, tight lung” does not characterize asbestosis. Rather it is an airway obstructive disease in which total lung volume, the measure of restrictive lung disease, has increased by 10% due to cigarette smoking.⁶⁸ Gas transfer capacity—that is, the diffusing capacity for carbon monoxide, measured during a single breath-hold of 10 seconds—does not decrease until air trapping has reduced vital capacity. Thus decreased diffusing capacity is not an early sign of asbestosis.

Cigarette Smoking Interaction

Men with asbestosis who smoked cigarettes had an increasing profusion of irregular opacities (Table 23-2).⁷⁷ Cigarette smoking produced obstructive lesions of the small airways and caused emphysema by departing the distal portion of the lung. Because of these well-known effects of cigarette smoke on the airways, obstruction in asbestos workers was attributed to cigarette smoke. However, studies of large numbers of workers who never smoked showed that airway obstruction was characteristic of asbestosis alone.^{13,66-68}

Not only is there a strong correlation between the profusion of irregular opacities and physiological impairment, but airways obstruction can be measured in workers after 15 years of exposure in the absence of radiographic lesions. Airway obstruction also characterizes the physiological pattern in those workers who show only pleural signs of asbestosis, either circumscribed or diffuse,⁷⁸ on chest x-rays as was hypothesized by Fridriksson et al.⁷⁹ and confirmed by many physiological studies. Subjects with both pleural and parenchymal asbestosis on chest x-rays are more impaired than those with either pleural or pulmonary changes alone.

Pleural Effusions and Their Sequelae

The recognition that pleural effusions occur with asbestosis without other proximate causes, waited on tuberculosis becoming rare in American workers. During the past two decades, there have been reports⁷¹⁻⁷² of pleural effusions that last weeks to months; are without bacterial flora, stigmata of tuberculosis, or malignant cells; and have a benign course. Such effusions may precede diffuse pleural thickening with adhesions between the visceral and parietal pleura

(A)

(B)

Figure 23-5. **A.** Mid-flows (FEF₂₅₋₇₅) in 1777 men who were never smokers as a percentage of predicted (adjusted for height and age) are shown as box plots against ILO categories 0/0 to 3/3 with median line, 25–75% limits as the box bottoms and tops and whiskers equal to three halves of the interquartile range rolled back to where there are data. Regression equation for FEF₂₅₋₇₅ percent predicted = 99.01 – 4.92 ILO category ($p < 0.0001$, $R^2 = 2.4\%$). **B.** Residual volume/total lung capacity (RV/TLC) is plotted against ILO categories as in top. RV/TLC = 36.6 + 2.54 ILO category ($p < 0.0001$, $R^2 = 6.7\%$).

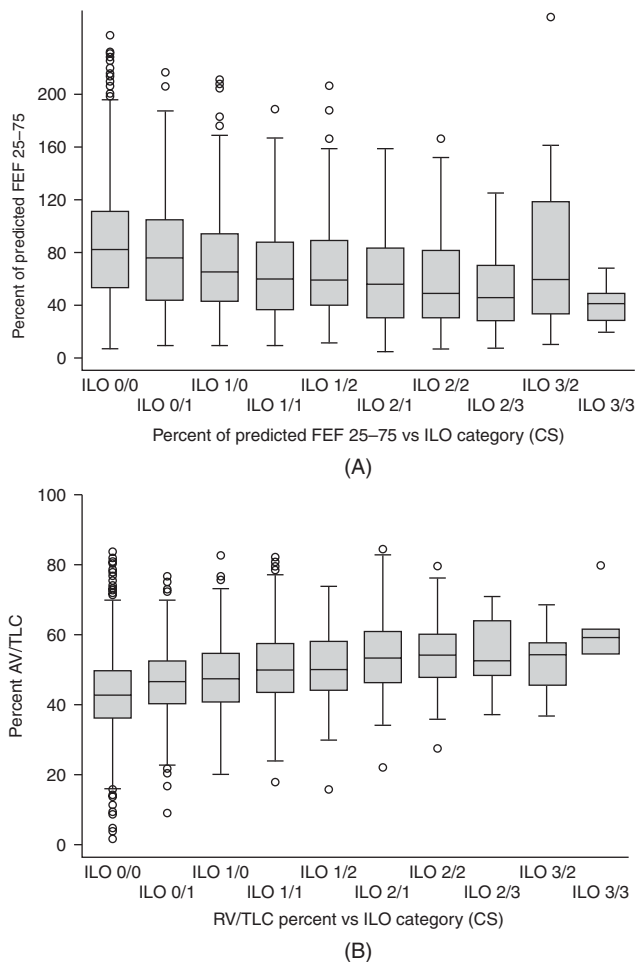

Figure 23-6. **A.** Mid-flows (FEF₂₅₋₇₅) in 4550 men who were current smokers as percentage of predicted (adjusted for height, age, and duration of cigarette smoking) are plotted against ILO categories as in Figure 23-5. FEF₂₅₋₇₅ percent predicted = 89.4–4.93 ILO category ($p < 0.0001$, $R^2 = 3.5\%$). **B.** Residual volume/total lung capacity (RV/TLC) is plotted against ILO categories for current smokers. RV/TLC = 41.2 + 2.04 ILO category ($p < 0.0001$, $R^2 = 7.9\%$).

and obliteration of costophrenic angles, as many workers with these signs have histories of pleural effusion. Follow-up of some reported subjects has been likewise confirmatory.⁷¹ It is inferred that fibrosis, more dense in the periphery of the lung and attenuating toward the hilum, which is recognized with extended-scale, computer-augmented tomography^{69,70} (Fig. 23-7), may be due to asbestosis pleural effusions. These workers are more functionally impaired than are others with pleural asbestosis disease.⁷⁸ Inferring that they develop thick pleural encasement of the lungs that may require surgical removal (decortication) to relieve lung trapping, but this is not confirmed.

Mesothelioma

The pleura and peritoneum are lined with mesothelial cells derived from mesoderm that may develop into connective tissue cells or ends of endothelial cells. Asbestos is translocated to mesothelial cells and initiates tumors that grow rapidly, have an excellent blood supply, and thus rarely show necrosis. Mesothelioma invades nerves to cause pain and kill by interfering with breathing. Microscopic metastases are frequent but rarely clinically important. These tumors arise in response to asbestos fibers or fibrils that have either penetrated the lung to reach the pleural space or penetrated the bowel wall to reach the peritoneum.

Figure 23-7. The lacelike white shadows are calcified pleural plaques seen en face in both posterior lung fields and in profile as plateaus on the diaphragms.

Mesotheliomas spread rapidly over the surfaces, displacing or engulfing vital organs rather than invading them (Fig. 23-8). In the peritoneum or pleura, the bumpy growths are white or light yellow and vascular without necrosis. Histological sections show either a dense fibroblastic connective tissue, with stroma cells forming tubular structures resembling capillaries, or small vessels or glands, or a combination.⁸⁰ They are sometimes difficult to distinguish from metastatic adenocarcinoma from lung, pancreas, colon, or stomach tissue but ultrastructural and histochemical studies are helpful.⁸¹

These otherwise rare tumors serve as sentinel or signal neoplasms, strongly suggesting asbestos exposures. Similarly, nasal sinus carcinomas are sentinels for exposure to nickel carbonyl or wood dust from certain tropical hardwood trees. Angiosarcoma of

Figure 23-8. Pleural mesothelioma in a 35-year-old housewife. Her father, a shipyard employee, had brought dusty work clothes home from the shipyard to be cleaned. He died of lung cancer. Her mother died of pleural mesothelioma.

the liver in the United States suggests exposure to vinyl chloride monomer, but similar tumors of the liver in Africa associate with aflatoxin exposure. Historically, the scrotal cancers in the chimney sweeps causally related to coal tar by Percival Pott were sentinels for coal tar exposure.

In the general population, the incidence of mesothelioma varies from 1:1000 to 1:10,000 deaths, but in heavily exposed insulators, it caused 8–10% of deaths. Add to these the mesothelioma deaths, others from contamination of the home by asbestos brought in by shipyard or asbestos factory workers, and deaths of subjects who had brief exposures. Although the latency period for mesothelioma averages 35–40 years, it may be as brief as 5 years. There is no relation to cigarette smoking, nor is there convincing evidence for a dose-response or an enhanced risk from intensive or prolonged exposure to asbestos. Amphiboles may be more potent than is chrysotile. Thus in the shipbuilding trades, the incidence of mesothelioma is related to the number of workers at risk in all of the trades, whereas the prevalence of asbestosis is higher in heavily exposed workers such as pipe coverers, pipe-fitters, and boilermakers.

Experiments of implanting of fibers of various types and sizes into the pleural space of rats and guinea pigs showed Stanton and Wrench that fibrous glass, rock wool, palygorskite, and brucite caused mesothelioma.⁵⁸ In Turkey, erionite, a fibrous zeolite, has been associated with an extraordinary prevalence of mesotheliomas around Cappadocia.^{82,83} Before zeolite can be accepted as a cause, however, it must be noted that fibrous tremolite has also been found in this area and is a contaminant of natural products used for building material. Thus fibrous tremolite, an amphibole, may be responsible for these mesotheliomas as in vermiculate-exposed Libby, Montana. The animal experiments caution against widespread adoption of human-made substitutes for asbestos. Carbon fibers, because of their size and shape, may share the potential for inducing mesothelioma, and they and vitreous fibers may also produce pulmonary fibrosis, although they have not been tested.

Management of mesothelioma is discouraging to the patient and frustrating to the physician. Survival after diagnosis is usually one year. Patients rarely live five years. Used alone, radiotherapy, chemotherapy, and surgery offer no advantage to the natural course. Debulking of the tumor surgically, and multi-drug chemotherapy, with doxorubicin (adriamycin), cyclophosphamide, and cisplatin, increase the life span after diagnosis about one year. Because mesotheliomas invade nerves, pain relief is a major concern in palliation.

Lung Cancer

The major public health concern and principal cause of death from asbestos in developed countries is lung cancer. Some groups of asbestos-exposed workers have a lung cancer mortality rate as high as one in five. Causality with cigarette smoking unquestionably makes the relative risk 50–100 times higher in the asbestos-exposed smoker as in the non-asbestos-exposed subject who has never smoked.^{19,84} Because 65–85% of workers exposed to asbestos have smoked and about 50%, in 1990, continued to do so,⁸⁵ their excessive risk of lung cancer calls for intervention to quit smoking. Although the smoking rate for males in the general population is now less than 30%, despite clear evidence that stopping smoking reduces the risk of cancer,⁸⁶ more than 50% of asbestos workers surveyed from 1987 to 1994^{77,78,85} in the construction, shipbuilding, and metal trades continued to smoke. Workers with an extreme risk of cancer have only one hope, one practical approach: to quit smoking. Treatment of lung cancer has advanced so little in the past 40 years that only 5–8% of patients survive five years after discovery. Although investigations with genetic markers and surface antigens suggest that we may be on the verge of earlier clinical recognition, the logistics of extending expensive and time-consuming methods to several million asbestos-exposed workers active and retired are practically impossible.

The latency for lung cancer in asbestos-exposed workers appears to be similar to that in non-asbestos-exposed workers, with incidence peaking around age 60.^{19,84,87} Because of a rapidly decreasing risk with the cessation of smoking, efforts to induce asbestos-exposed persons to stop smoking are a public health priority. Similar risk reduction must apply to bystanders and household-exposed groups, as well as persons lesser exposed in buildings containing asbestos. Although proof that the tumors are due to asbestos considered to be difficult in the absence of radiographically demonstrated asbestosis, a recent study showed that almost all the lungs removed for cancer from asbestos-exposed individuals show microscopic fibrosis.⁸⁸ One lesson from history is clear: when asbestos exposure was sufficiently great that asbestosis was a principal cause of death, opportunities to survive long enough to develop lung cancer are diminished. For example a German asbestos industry study in Dresden showed that one-fourth of the deaths after World War II in asbestos workers were due to asbestosis; less than 2% had lung cancer.⁸⁹ After the war, extensive industrial hygiene controls reduced the risk of fatal asbestosis in asbestos workers, they lived longer and died of lung cancer.

The dismal prospect for treatment of lung cancer and the large number of people exposed to asbestos who still smoke make the public health priority cessation of smoking among blue collar workers who have breathed asbestos. Workers can be motivated by a physician who directs personal attention to effects of cigarette smoke such as signs of chronic bronchitis and emphysema and emphasizing the higher cancer risks when combined with asbestos exposure.⁸⁷ This strategy should be extended in the United States and most of the developed world, as during the past 20 years asbestos exposure has been progressively reduced. Stopping smoking can substantially reduce the risk of millions of people for lung cancer from exposures in the previous era, to improve public health and decreasing medical and societal costs (lost wages and dependent families).

Other Asbestos-Related Neoplasms

Many other neoplasms have been attributed to asbestos by careful long-term studies of large numbers of insulators and asbestos workers so that contributions from other factors and a long time are required because many individuals in the study populations also smoking cigarettes, using alcohol, and other occupational carcinogens can be ascertained. Asbestos exposure is associated with neoplasms of the pancreas and kidney, certain types of lymphoma, and neoplasms of the esophagus, mouth, and colon. The most extensive study, which served to anchor the experience, is that of the heat and frost insulators, a cohort of 17,800 workers who have been studied by Selikoff and Seidman¹⁹ since January 1967. In this group, the ratio of observed to expected cancers of the esophagus, larynx, kidney, pharynx, and buccal mucosa was greater than 2; whereas the ratio for cancers of the stomach, colon, and rectum was greater than 1.5. Thus, it appears that these common epithelial cancers are caused by asbestos exposure, despite causal interactions with cigarette smoke and alcohol (Table 23-2).

The mortality from asbestos disease was elevated 2.6 times the expected rate, and that due to lung cancer was 9.1 times the expected rate in British workers certified by medical panels as having asbestosis in 1980.⁸⁴ Criteria were sufficient exposure and the presence of two of four conditions (pulmonary [radiological] abnormality, pulmonary functional impairment, basal rales, and finger clubbing); 39% died of lung cancer; 9% of mesothelioma; and 20% of asbestosis. Selikoff and Seidman¹⁹ studied all deaths in United States and Canadian insulators, found in the 1967 to 1987 interval excess of deaths 1.4 times the expected number, and with deaths from cancer 3.0 times the expected number. Lung cancer accounted for 23.6% of deaths; mesothelioma, 9.3%; and asbestosis, 8.6%.

Societal Impact

Beginning in the 1970s, workers' compensation and tort litigation were undertaken for workers with mesothelioma, lung cancer, and asbestosis threatened by death or showing impairment of function.

Fifty different laws in the states and no record linkage contribute to the absence of accurate figures on the numbers of plaintiffs who have successfully threaded through the legal maze of workers' compensation. This system was a social construct to avoid litigation and provide compensation without adversarial confrontation. It was focused on workplace injuries. The trade-off for the worker (plaintiff) was to give up all legal redress for injury or illness. In practice, obtaining workers' compensation may be more difficult than pursuing third-party litigation. Costs have been shifted to society from industry after the workers' resources have been exhausted, employing public assistance, Social Security disability, Medicare, and Medicaid.

In the mid-1970s, civil actions (torts) were filed against major asbestos suppliers and manufacturers on behalf of patients with asbestos disease. More than a decade of such litigation has made the use of asbestos expensive because insurance is difficult or impossible to buy. Juries awarded large sums to a small fraction of plaintiffs with mesothelioma and lung cancer and some with pulmonary asbestosis. Smaller awards or settlements were made for pulmonary impairment associated with asbestosis in the lungs. The associated (nonpulmonary) neoplasms and pleural asbestosis have fared less well, with smaller jury awards and less frequent settlements. The co-responsibility of cigarette smoking has not been accepted by the tobacco companies, nor has litigation succeeded against them for their contribution to the lung cancer death toll. In 1978, the U.S. Congress asked for an appraisal of workers' compensation programs for occupationally related lung disease, which included asbestosis, byssinosis, and black lung, as the prelude to an omnibus bill. However, by 2005 no omnibus bill had passed. Although on paper the situation is worse than in 1978, verdicts in the courts have collectively pushed bankruptcy proceedings led by Johns Mansville to more than a dozen major asbestos firms because they lost insurance and bore large costs in fighting and settling asbestos cases. Meanwhile, installation and use of new asbestos products have virtually ceased in the United States. More members of the exposed workforce know the hazards and hygiene of asbestos removal. Exposure has certainly decreased in developed countries. Currently, the burden of asbestosis is on the individual who tries to obtain Social Security, county welfare, public assistance, disability compensation, or Medicare payments. The likelihood of obtaining such help apparently depends on luck.

Regulations to control exposure in the workplace were enacted in 1977; a temporary standard allowed workers to be employed in environments that contained up to 2 fibers/ml of air, or 2 million fibers/m³.^{90,91} The National Institute for Occupational Safety and Health (NIOSH) has recommended to the Occupational Safety and Health Administration (OSHA) a 0.1 fiber/ml industrial exposure in the United States, which was adopted in 1990 as a time-weighted average value. In view of the temporizing slowness of this approach, it is reassuring that the use of asbestos in the United States has steadily fallen since 1978, that it has been proscribed in consumer products, that in California a home cannot be sold without an asbestos inspection and amelioration of any problems found, and that it is a public sense to avoid asbestos. Asbestos products are not being installed in new construction because of EPA rules. The EPA expanded its asbestos ban to most uses in July 1989.⁹² But brake blocks, pipe, and shingles were banned in 1996 after a three phase-out stages. After 1990, only 10% of products had been phased out but most exceeding the EPA standards ceased production by November 1993, including brake linings, friction materials, flooring felt, and tile. Disappearance of asbestosis will be slow because of its long latency and some exposure from asbestos that was in place. Although in many jurisdictions removal is done legally by specially trained workers in disposable suits and using air supply respirators, some fly-by-night removal companies use laborers uninformed of the dangers of asbestos and lacking instructions for safe handling. Such avoidance of responsibility also characterized our earlier eras. Such unconscionable disregard of human suffering underscores the need for tighter controls and genuine accountability. Criminal penalties may be needed as were threatened in Libby, Montana in 2005. Brakes and clutch facings needed for safety can be free of asbestos

materials, and although they cost more than the products replaced, they needed to be replaced less often and avoid asbestos diseases for workers.⁹³ Asbestos use in the United States fell from 240,000 metric tons in 1984 to 85,000 metric tons in 1987.^{84,85,92}

► NATURAL NONASBESTOS AND MANUFACTURED FIBERS

Natural Nonasbestos Fibers

According to the Mine Safety and Health Administration, about 150 minerals are fibrous or contain fibers. A fiber is an elongated polycrystalline unit resembling cotton or animal hair. Mineralogists define fibers as particles with an aspect ratio (length to diameter) equal to or greater than 10 to 1. "Asbestiform" denotes a type of silicate fiber that has a high tensile strength, extreme aspect ratio (i.e., high length/diameter ratio), flexibility, heat resistance, and aggregation of fibrils into bundles. Chrysotile is a good example. The Occupational Safety and Health Administration has defined the asbestos fiber as being greater than 5 μm in length with an aspect ratio of 3 to 1 or greater.

The pulmonary toxicity of natural and human-made fibers is determined by the dose, the dimensions, and durability of the fiber. Fibers with long residence time because of high durability are more toxic than those with shorter residence time. Mesotheliomas are produced in animal models by pleural or peritoneal injection of fibers such as amosite, crocidolite, chrysotile, anthophyllite, tremolite, attapulgite, erionite (zeolite), borosilicate glass, aluminum silicate glass, mineral wool, aluminum oxide, potassium titanate, silicon carbide, sodium aluminum carbonate, and wollastonite.⁵⁸ Amphiboles are more durable than chrysotile in solution and in animal tissues, including lung.

Whether talc, a sheetlike silicate, is toxic to the lung is unclear because in most North America deposits it is significantly contaminated by fibers of tremolite, anthophyllite, and crystalline quartz.⁹⁴ Pure cosmetic talc, that is, talc with minimal fiber content, produces few, if any, toxic reactions. Thus toxicity of talc appears due to fiber contamination, and perhaps free silica content.

Vermiculite, a family of hydrated magnesium-aluminum-iron silicates, is sheetlike. The mineral is expanded by heat after removal from the mines and used for insulation and for fillers in paint, plasters, rubber, and other materials. The health hazard from vermiculite is attributable to its contamination with fibrous tremolite.⁹⁵ Vermiculite workers and residents of Libby, Montana had numerous mesotheliomas, lung cancers, and asbestosis from tremolite.

Zeolites, a group of crystalline and hydrated aluminum silicate minerals, consist of extremely fine tubes of mordenite or erionite. The tubes are 10–20 μm in length and less than 1–3 μm in diameter. Naturally occurring deposits of zeolites are distributed worldwide, but adverse health effects have been investigated near Karain, Turkey, in the central Anatolia.^{82,83} Although mesotheliomas, pleural thickening, and plaques were attributed to exposure to erionite, it appears that it was contaminated with chrysotile and tremolite.⁸² Airborne fibers in Karain, which average less than 0.01 fiber/m³ and a peak level of 1.38 fibers/m³, are significantly below the current standard for asbestos fibers. Either this is an unrecognized hazard from low-level airborne erionite exposure, or to tremolite.^{94,95} Wollastonite deposits are scattered around the world. A study in Finland showed that workers from a limestone-wollastonite quarry had a high frequency of pleural thickening and pulmonary fibrosis. Fibrosis was observed in only 3% of a worker cohort in the United States, but these subjects' reductions in expiratory airflow were related to dust levels.⁹⁶ Further studies of effects of erionite and wollastonite on human populations are needed, but the data suggests caution in handling these materials.

Human-Made Fibers

The physical characteristic of fibers made by humans, from slag, rock, glass, ceramics, and carbon vary greatly with their manufacture.⁹⁷ Carbon fibers are used in making sailboat masts and aircraft

components (as in the Stealth bomber). The same considerations of dose, dimensions, and durability that apply to natural fibers extend to human-made filaments⁹⁸ with a range of diameters. It is clear that little human respiratory hazard should be predicted for fibers with diameters greater than 10 μm because these fibers do not split into fragments that are respirable. Current commercial fibrous glasses are highly heterogeneous, with some fiber diameters of 1 μm or less. Both rotary spinning and flame attenuation produce fibers less than 1 μm (Fig. 23-9, A and B). Currently the National Institute for Occupational Safety and Health⁹⁴ recommends that fibrous glass exposure be limited to 3 fibers/ m^3 . These fibers are defined as less than 3.5 μm in diameter and equal to or greater than 10 μm in length. Rotary spinning, the process analogous to that for making cotton candy, requires less energy and is replacing flame attenuation for producing fine fibers. The thermal coefficient, a measure of insulating capacity, is increased as fiber diameters are reduced (Fig. 23-9C). Where high thermal coefficients are needed with low weight, such as aerospace applications, uniformly fine fiberglass is preferred. Fine fiberglass is also used in refrigerator doors and in insulating industrial construction and homes because it is mixed (heterogeneously) with larger fibers. This usage exposes production and construction workers to some respirable fibers.

Effects of Nonrespirable Fibers

Nonrespirable fibers irritate the skin,⁹⁹ causing itching, burning, and irritation of the conjunctivae and the nasal and pharyngeal passages.¹⁰⁰ Removal from exposure stops it as it does for natural irritants such as peach fuzz or stinging nettle. Striking dermatographism, histamine wheal and flare, precludes further exposure in some people.

Effects of Respirable Fibers

Longer fibers resist phagocytosis and produce ferruginous bodies after variable periods of residence. Shorter fibers are phagocytized and release peptides that stimulate recruitment of cells for production of collagen and other fibers.¹⁰¹ Intrapleural injection of fibers produces mesothelioma in animals.⁵⁸ Inhalation, even for a long period in rodents¹⁰²⁻¹⁰⁴ and in monkeys,¹⁰³ produces macrophage accumulations and granulomas containing fibrous glass but little fibrosis, but in rats, plaques develop on the visceral pleura.¹⁰³

Insulators who use materials with a high thermocoefficient and low weight—as in the construction of cabins of aircraft or space vehicles—should be studied to learn whether these fine fibers imitate asbestos. In the past, many of these workers were exposed to asbestos used in these applications or in similar work. Furthermore, the manufacturing sites for fiberglass have been rich in asbestos insulation. Finally, the duration of human exposure in many of these facilities has been less than the 20 or 25 years,¹⁰⁵ which is the usual “latent period” for effects of asbestos exposure. Therefore, it is logical that the hazard from fine fiberglass is analogous to that from asbestos, as has been demonstrated recently.¹⁰⁶

Workers were studied in a midwestern appliance plant where refrigerator doors, and previously, entire cabinets, were insulated with fiberglass sheeting and loose rotary-spun fiberglass.¹⁰⁶ Spirometry and lung volumes were measured, respiratory and occupational questionnaires were administered, and chest x-ray films were read for pneumoconiosis using International Labor Office 1980 criteria in 284 men and women with exposures of 20 years or more to heterogeneous fine fiberglass. Electron microscope measurements of fiber size in several samples showed that 49–83% had diameters under 5 μm . Air samples were examined only by light microscopy so that low levels of 0.1–0.4 fibers/ml were are meaningless.

Expiratory flows were reduced including FEV₁ (mean 90.3% of predicted [pr]), FEF₂₅₋₇₅ [85.5% pr], and FEF₇₅₋₈₅ (76.2% pr). Forced vital capacity was significantly reduced (92.8% pr) and total lung capacity was significantly increased (109.2% pr). In white male smokers, a group large enough for comparisons, pulmonary function reductions paralleled the appearance of irregular opacities. Forty-three

Figure 23-9. A. Rotary process of producing fine fiberglass used both centrifugal force and air jets to attenuate the glass. Heterogeneous fiber diameters result. B. Flame attenuation provides heat and drive force to pull the fibers into smaller diameters. C. Insulating capacity, the reciprocal of thermal conductivity, is increased as fiber diameter is reduced.

workers (15.1%) had evidence of pneumoconiosis on chest radiographs: 26 of these (9.1%) had no known exposure to asbestos and 17 (6.0%) had some exposure. Our best judgment was that in 36 (13.0%) pulmonary opacities or pleural abnormalities were due to fiberglass.

Commercial rotary-spun fiberglass used for insulating appliances produced human disease similar to asbestosis.

Radiographic studies of workers at seven fibrous glass and mineral wool facilities, 40 years ago, demonstrated 10% had small irregular opacities of low profusion, 0/1 to 1/1.¹⁷ Physiological testing was not done.^{17,104,105}

Mortality rates for fibrous glass workers have been studied without regard to the respirability (size) of the fibers; generally there have been no excess deaths from malignant or nonmalignant respiratory disease.¹⁰⁷ A 17-plant study in the United States under the auspices of the Thermal Insulation Manufacturers Association and a 72-plant seven-country European study by the European Insulation Manufacturers Association found risks for lung cancer above those of control populations, a 12% increase in glass wool workers and a 36% increase in mineral wool workers.¹⁰⁷ Serious questions were raised about the suitability of national versus regional versus area controls for tracking cancer mortality rates so the mortality rate remains unsettled.^{108–110} Because society's members are contaminated by many chemicals, suitable comparison groups are difficult to locate. Human mesotheliomas from fiberglass have not been identified although construction workers installing loose fiberglass had exposures of 7 fibers/ml.¹⁰⁹

Public Health Considerations

Research

Because of the analogous dimensions and respirability of fine fibrous glass and other man-made fibers and variable durability, additional studies are needed of health effects and mortality in populations that have been exposed for at least 20-year latent periods and without exposure to asbestos.¹¹¹ If these studies confirm those above, they will help choose the safe alternatives to asbestos. Meanwhile, the association of mesothelioma with siliceous filaments in sugarcane factory workers in India¹¹² raises the possibility of a "natural fiber" of plant origin mimicking asbestos exposure or perhaps asbestos exposure has not been adequately ruled out. A better history of exposure, examination of lung tissues, fiber content with scanning electron microscopy, and energy-dispersive analysis propose many questions of competing etiology as asbestos is replaced.

Control Measures

It seems ironic that we are witnessing widespread adoption of fibrous glass without key information needed to determine the human health risks.^{98,100,108–111,113} Clearly, determination of the health hazards of fine human-made fibers is a high priority before their production and application in industries produces a problem for this new century that mimics that from asbestos. Meanwhile, it is prudent to regard respirable fibers as needed with the same precautions as asbestos.¹¹⁰

Coal Workers' Lung Diseases

Gregory R. Wagner • Michael D. Attfield

Historical Perspective

Lung disease among underground coal miners has been a recognized occupational hazard since at least the mid-seventeenth century. Miners' black lung, now called coal workers' pneumoconiosis (CWP) was first documented among Scottish coal miners in 1837.¹ Although the disease was thought to be disappearing in Britain at the turn of this century, wider use of chest radiographs following World War I showed pneumoconiosis, similar to silicosis, among coal miners in South Wales. By 1934, British physicians were beginning to accept coal dust as an occupational exposure that could result in disability and death. In 1942, the Committee on Industrial Pulmonary Diseases of the Medical Research Council introduced the term "coal workers' pneumoconiosis."^{2,3}

In marked contrast, appreciation of CWP as an occupational disease and public health problem occurred much later in the United States, as did legislation to prevent or compensate CWP and associated respiratory disease. One reason for the relatively late recognition of CWP as a distinct disease entity in the United States was the early emphasis placed on the etiological role of silica in pneumoconiosis. The Hawk's Nest tragedy (1932–1934), in which more than 400 workers died of acute silicosis and tuberculosis after working on the tunnel at Gauley Bridge, West Virginia, reinforced the prevalent theory that silica content was the critical etiological agent in pneumoconiosis. The first systematic study of U.S. coal miners was conducted by the Public Health Service between 1928 and 1931 in the anthracite coal fields in eastern Pennsylvania.⁴ Because of the relatively high silica content and similarity to silicosis, the term "anthracosilicosis" was used to describe the pneumoconiosis found among those miners. Of 2711 men studied, 23% were found to be affected. The prevalence of pneumoconiosis was related to the number of years underground, particles per cubic meter, and free silica content of the dust. "Pulmonary infection" was more frequent among miners with higher dust exposure and greater than 15 years underground. Among miners over age 55, pulmonary tuberculosis was as much as 10 times more common than in the general population.⁵ Little additional progress was made in the United States until 1954, when the Public Health Service published a bibliography of American and British reports on respiratory disease among coal miners.⁶ Following this, various clinical and epidemiologic studies^{7–9} further documented the importance of CWP. At the direction of Congress, the Public Health Service began a comprehensive survey of the Appalachian coal fields in 1963. Of 2549 working miners and 1191 nonworking miners, 9% of the working and 18% of the nonworking miners were found to have radiographic evidence of pneumoconiosis.¹⁰ This study, published in 1968, together with the disastrous November 20, 1968, Farmington, West Virginia, mine explosion that killed 78 miners, triggered increased pressure from miners, their union (the United Mine Workers of America), and public health advocates, and led to passage of the Federal Coal Mine Health and Safety Act of 1969 (Public Law 1973).¹¹ This was the first

American mining law to recognize the importance of both health and safety hazards and provide a mandate for strong preventive measures.

Since that time, awareness has grown indicating that CWP is not the only occupational pulmonary disease affecting coal miners. The results of the study by Rogan and colleagues¹² were the first to show a clear link between chronic airflow obstruction and dust exposure, independent of CWP status, while Rae et al.¹³ demonstrated that respiratory symptom prevalence was related to level of dust exposure. Emphysema is increased in coal miners,¹⁴ and is related to both retained dust in the lung, and to cumulative dust exposure.^{15,16}

Legislation

Although the Federal Coal Mine Health and Safety Act of 1969 was a landmark piece of legislation, it was by no means the first or last legislation to deal with occupational risks of mining (Table 24-1). The 1969 Act addressed several issues specifically and has served as a model for subsequent occupational safety and health legislation. The provisions included the following:¹⁷

- Mandatory health standards to be prescribed by the Secretary of Health and Human Services (HHS)
- Right of entry for inspection (Department of Interior) and investigation (HHS)
- Power to close mining operations, issue abatement orders, and penalize operators for noncompliance
- A respirable dust standard of 3 mg/m³ to be reduced to 2 mg/m³ 3 years after passage of the Act
- Medical surveillance of underground coal miners through entry and periodic chest x-ray examinations
- Rights of miners (transfer rights) with evidence of pneumoconiosis to work in a low dust area (now < 1 mg/m³) with increased dust monitoring. If job transfer is necessary, there is no loss of pay (rate retention)
- Autopsies on deceased miners, administered by the National Institute for Occupational Safety and Health (NIOSH) through the National Coal Workers' Autopsy Study
- Compensation for miners with total disability and for dependents of those miners who die of lung disease from coal mine employment
- Research and training

The medical surveillance provisions of the Act were implemented through specifications developed by the NIOSH Appalachian Laboratory for Occupational Safety and Health in August 1970. Since that date, more than 350,000 examinations have been performed. Subsequently, Title IV of the 1969 Act has been amended twice by Congress, each time modifying requirements that qualify miners for benefits and making coal operators responsible for providing trust funds to pay these benefits. In 1977, the 1969 Act was revised and

TABLE 24-1. COAL MINING HEALTH AND SAFETY LEGISLATION IN THE UNITED STATES

1865:	Bill is introduced to create Federal Mining Bureau. It is not passed.
1910:	Bureau of Mines is established but specifically denied right of inspection.
1941:	Bureau of Mines is granted authority to inspect, but it is not given authority to establish or enforce safety codes (Title I, Federal Coal Mine Safety Act).
1946:	Federal Mine Safety Code for Bituminous Coal and Lignite Mines is issued by the Director, Bureau of Mines (agreement between Secretary of the Interior and the United Mine Workers of America) and included in the 1946 (Krug-Lewis) UMWA Wage Agreement
1947:	Congress requests coal mine operators and state agencies to report compliance with the Federal Mine Safety Code; 33% compliance is reported.
1952:	Title II of the Federal Coal Mine Safety Act is passed. All mines employing 15 or more persons underground must comply with the act. Enforcement is limited to issuing orders of withdrawal for imminent danger or for failure to abate violations within a reasonable time.
1966:	Amendments to 1952 law are passed. Mines employing under 15 employees are included under 1952 Act; stronger regulatory powers are given to Bureau of Mines, such as the provision permitting the closing of a mine or section of a mine because of an unwarrantable failure to correct a dangerous condition.
1969:	Federal Coal Mine Health and Safety Act is passed. The hazards of pneumoconiosis are, for the first time, given prominence, in addition to those of accidents.
1972:	Black Lung Benefits Act of 1972 is passed. Several sections of the Title IV are amended, liberalizing the awarding of compensation benefits.
1977:	Federal Mine Safety and Health Act of 1977 is passed. It amends Coal Mine Health and Safety Act of 1969 largely by adding health and safety standard setting, inspections, and research provisions for metal and nonmetal miners, while leaving the 1969 act largely intact. This act also consolidates health and safety compliance activities for general industry (OSHA) and mining (MSHA) in the Department of Labor.
1977:	Black Lung Benefits Revenue Act of 1977 is passed. This provides for an excise tax on the sale of coal by the producer to establish trust funds to pay black lung benefits.
1977:	Black Lung Benefits Reform Act of 1977 is passed, to improve and further define provisions for awarding black lung benefits. Additionally, it establishes (a mandate) that a detailed study of occupational lung disease would be undertaken by the Department of Labor and NIOSH.

largely incorporated into a new, comprehensive mining law—the Federal Mine Safety and Health Act of 1977. Pub L No 91-173, amended by Pub L No 95-164, 101¹⁸—which extended many of the provisions of the 1969 Act to metal and nonmetal miners. Significant new responsibilities were given to the Department of Labor (Mine Safety and Health Administration) for establishing health standards and mine inspections and to HHS (NIOSH) for research and surveillance in noncoal mines.

Definition of CWP

CWP is a specific occupational lung disease arising from the prolonged inhalation of coal mine dust. Black lung is a generic term that has been used legislatively and popularly to mean any lung disease that may arise from coal mine employment. This includes both pathologically defined CWP and also obstructive airway disease among coal miners. CWP occurs in two forms: (1) simple (chronic) CWP and (2) complicated CWP, or progressive massive fibrosis (PMF). The characteristic lesion of simple CWP is the coal macule, which is a focal collection of dust-laden macrophages at the division of the respiratory bronchioles together with associated focal emphysema.¹⁹ Micro- and macronodules of simple CWP usually are smaller than 1 cm in diameter. Complicated CWP, or PMF, consists of solid, heavily pigmented masses generally greater than 2 cm in diameter, commonly located in the apical region of the lung and occurring on a background of simple CWP.

Environmental Exposures

Significant exposure to coal mine dust may occur not only underground but also in surface strip and auger mines, in coal preparation plants, and in coal-handling operations. U.S. coal reserves are extensive, covering some 400,000 square miles across the country (Fig. 24-1). Coal in the United States may be classified by four ranks: lignite, subbituminous, bituminous, and anthracite, reflecting the degree of metamorphosis of the coal. Anthracite deposits, which are mined on a limited basis only in northeastern Pennsylvania, are associated with the highest rates of pneumoconiosis. Bituminous coals, which are mined from central Pennsylvania westward to Utah are less fibrogenic than

anthracite, there being a gradient in toxicity from low-volatile bituminous (more fibrogenic) to subbituminous coal (less fibrogenic). Lignite, which also is mined on a limited basis, has not been adequately studied epidemiologically. Workers engaged in face work and coal preparation often have the highest exposures to respirable coal dust and thus the highest rates of CWP. Drillers and other workers involved in tasks which generate free silica dust are also at risk of contracting silicosis.

Prior to 1970, dust concentrations in face jobs in underground mine were ranging from 6 to 10 mg/m³. Subsequent to the 1969 Act,¹¹ dust levels were limited first to 3 mg/m³ and then to 2 mg/m³. Overall, the regulations brought about a marked reduction in dust exposures in coal mines,²⁰ although not without problems being reported periodically.²¹ Recent evidence suggests that miners are not being uniformly protected from developing disease.²² New technological developments, such as the machine-mounted continuous respirable dust monitor²³ may help to identify and control future overexposures.

Surface coal mining accounts for an increasing fraction of coal mined in the United States, while the underground mining workforce has been decreasing. Surface mining is prevalent in the western states, and some parts of Appalachia as “mountaintop removal.” Surface miners generally experience lower levels of dust exposure than their counterparts underground.²⁴ Some surface mine jobs, however, can involve very high exposures to silica, especially if dust control measures are missing or ineffective. Drillers, in particular, are at risk of both acute and chronic silicosis, and severe cases have been reported.²⁵

Pathophysiology

Pathologically-defined simple CWP consists, at a minimum, of the characteristic coal macule lesion(s).^{17,19} These may occur as microscopic manifestations of CWP associated with little or no functional impairment. With greater dust deposition in the lung, micronodules (less than 7 mm in diameter) and nodules (larger than 8 mm but less than about 1 cm) are found, predominantly in the upper lung zones (Fig. 24-2). These nodules consist of collagen in addition to a preponderance of reticulin. With increased profusion of nodular lesions in the lung come greater functional abnormalities, but until marked, CWP often is not associated with significant respiratory symptoms or limiting impairment.

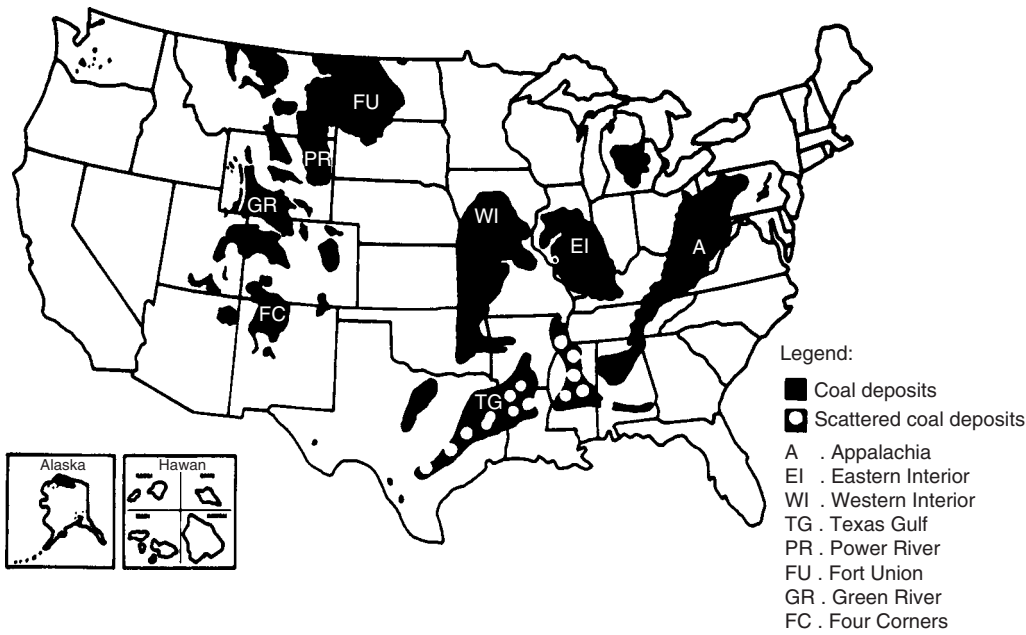

Figure 24-1. Coal deposits in the United States.

The presence of simple CWP is a significant risk factor for development of PMF; and its probability increases with the severity of simple CWP (Fig. 24-3).^{26,27} PMF lesions usually occur in the posterior portion of the upper lobes and in the superior segment of the lower lobes. Unlike silicotic lesions, they cut easily and may

have cavities containing inky fluid. The margins may be rounded or irregular, with fibrous strands extending into adjacent lung tissue.

Caplan's syndrome, consisting of pulmonary nodules associated with rheumatoid arthritis, occurs rarely in coal miners. The nodules, Caplan's lesions, are similar to large (up to 5 cm) silicotic nodules on

Figure 24-2. Whole lung section showing simple CWP with associated focal emphysema but otherwise preserved lung architecture.

Figure 24-3. Whole lung section showing progressive massive fibrosis with cavitation involving the superior segments of the lung on a background of simple CWP and extensive emphysema.

gross examination, usually have smooth borders and concentric internal laminations, and in contrast to PMF lesions, often have little dust contained within the lesion.¹⁹

Although other forms of emphysema occur in coal miners as they do in the general population, focal emphysema is integral to the coal macule (Fig. 24-2). Focal emphysema is associated with local loss of elastic fibers and alterations in capillary density. The panlobular, irregular, centrilobular, and bullous emphysema associated with these massive lesions is often extensive and destructive; it frequently results in marked pulmonary impairment.¹⁹ Increasing pathological and physiological evidence has strengthened the view that coal mine dust exposure causes centrilobular emphysema.²⁸⁻³⁰ Chronic bronchitis, characterized pathologically by hypertrophy and hyperplasia of the bronchial mucous glands with an associated increase in the goblet cells of the small airways, occurs as a result of dust exposure.³¹ Clinically defined as the chronic production of phlegm, chronic bronchitis is a frequent clinical finding among coal miners,³² and its prevalence and incidence are related to dust exposure.^{13,33}

Physiologically, miners with simple CWP have been found to have increased residual volumes, decreased maximal expiratory flow rates, reduction in PaO₂, increased alveolar arterial oxygen differences, and slight hyperventilation, especially with exercise.^{34,35} These findings may be nonexistent or slight in those in the earliest stages of CWP, but become progressively more significant with advancing disease.

In PMF (again varying with the extent of the lesions), moderate-to-severe airway obstruction is manifested by markedly reduced flow rates, decreased diffusing capacity, perfusion defects, and reduced PaO₂, together with obstructive and restrictive mechanical changes in the lung.³⁴ These findings often are marked. Pulmonary hypertension with cor pulmonale is a frequent consequence of advanced PMF.

Clinical Features

There are no pathognomonic signs or symptoms of CWP. In the early stages of CWP, workers may be asymptomatic and without functional impairment. Chronic cough and phlegm are, however, associated with prolonged inhalation of coal dust. These symptoms may or may not be associated with functional impairment. As CWP progresses, shortness of breath and functional impairment become more common, yet some miners with advanced simple CWP remain symptom free. Those with PMF, especially those with large lesions, typically present with cough, phlegm, and shortness of breath. The chest radiograph is the standard method for detection of CWP. Although the radiographic examination is somewhat limited in sensitivity, the correlation between the profusion of CWP pathologically and radiographically is reasonably good.³⁶ An internationally developed and accepted method of radiograph classification distributed by the International Labor Office can be used to describe the extent, size, shape, and distribution of radiographic opacities and also to describe pulmonary, cardiac, pleural, and other thoracic abnormalities that may appear on a chest radiograph.³⁷ This classification divides simple pneumoconiosis into four major subcategories (0, 1, 2, and 3), each of which is subdivided into three categories (i.e., 1/0, 1/1, and 1/2), resulting in an approximation to a continuous scale. PMF is divided into three categories (A, B, and C), depending on lesion size. Although designed as a tool for public health surveillance and epidemiological investigation, this classification also has been adopted internationally to describe CWP clinically and is used for compensation purposes in some jurisdictions. Computerized tomography (CT or HRCT) is used routinely where available to clarify ambiguous findings on the standard chest radiograph and to investigate the possibility of cancer in miners with large opacities. Use of CT for routine screening is not recommended currently, although it is employed in some countries for medical monitoring of dust-exposed workers. There is no internationally-accepted standardized method for classification of CT studies in dust-exposed workers; however, some have been proposed but not yet validated.³⁸

Epidemiology

Mortality patterns among coal miners have been studied extensively and have generally shown increased standard mortality ratios (SMRs) for accidents, nonmalignant respiratory disease, pulmonary tuberculosis, and stomach cancer.³⁹⁻⁴³ Mortality rates by major radiographic category have shown significant excesses for those with complicated CWP over those with category 0,⁴⁴ particularly for miners who developed PMF early in their working life.⁴⁵ Little evidence has been found for a gradient of increasing mortality with increasing category of simple CWP, although Miller and Jacobsen showed reduced survival among those with simple CWP compared to those with category 0.⁴⁵

Mortality from all nonviolent causes was found to be related to cumulative dust exposure.⁴⁵ Importantly, mortality from bronchitis and emphysema was also related to dust exposure, an observation confirmed by Kuempel et al., using both underlying and contributing causes of death.⁴⁶ The latter study also showed a relationship between mortality from pneumoconiosis and cumulative dust exposure.

In the main, mortality from lung cancer in coal miners is not increased, but there is widely varying evidence regarding a link between CWP and lung cancer. In studies where excesses were found, lack of control for confounding factors may have been responsible.⁴⁷ Using detailed case-control methods, Ames and colleagues were unable to detect a CWP-lung cancer relationship. By contrast, stomach cancer mortality has been almost uniformly increased in coal mining cohorts in both Britain and the United States,^{39,40,43} and a relationship with dust exposure has been detected.⁴⁵ Ong and coworkers⁴⁸ have hypothesized, supported by laboratory mutagenesis data, that compounds in coal may undergo intragastric nitrosation or interaction with exogenous chemicals or both to form carcinogenic compounds that may with time cause stomach cancer. The Meyer hypothesis,⁴⁹ which posits that miners with good lung clearance are at increased risk of stomach cancer because of ingestion of cleared dust while those with impaired clearance get nonmalignant lung disease, has been invoked as one explanation of the increased mortality from stomach cancer in coal miners. This hypothesis was confirmed in one analysis using CWP as an indicator of impaired clearance,⁵⁰ but not in another using airway obstruction as the indicator.⁵¹

Morbidity studies of coal miners have dealt with various outcomes relating to nonmalignant pulmonary disease. Preeminent among these has been the association between radiographic evidence of CWP and dust exposure. In 1959, the Pneumoconiosis Field Research (PFR), a scientific study initiated by the National Coal Board of Great Britain, began a massive, long-term cohort study of 26 collieries. After 10 years of study, analysis of the respirable dust and radiographic findings provided clear dose-response relationships, which resulted in new dust standards in the United States and in Great Britain.⁵² These findings were confirmed in a subsequent study of 10 of the original collieries (Fig. 24-4).⁵³ Free silica content in respirable samples was found not to influence pneumoconiosis risk, once cumulative exposure to mixed mine dust was taken into account. Despite this, it was found that a small number of miners with rapid progression had higher exposure to free silica, suggesting the development of silicosis rather than CWP.⁵⁴ Further examination of these data has led to a warning that even brief overexposures to silica in the coal mine can be hazardous.⁵⁵ Coal rank, in addition to mixed mine dust exposure, has consistently found to be an important predictor of CWP prevalence and incidence.⁵⁶⁻⁵⁸ A substantial degree of variation exists between mines which cannot be accounted for by dust exposure and other environmental factors.⁵⁹ Findings from similar studies in the United States conducted by NIOSH are consistent with the British pneumoconiosis field research data (Fig. 24-5).^{57,60}

Because of the strong association between PMF and respiratory impairment and increased mortality, the attack rate of PMF has been of particular interest. The risk of developing PMF increases with

Figure 24-4. Lines (a) and (b) are estimates of probabilities of developing category 2 or 3 of simple pneumoconiosis over an approximately 35-year working life at the coalface, in relation to the mean dust concentration experienced during that period. (a) is based on 10 years of data, Interim Standards Study, Pneumoconiosis Field Research. (b) is an update of (a) based on 20 years of data, Pneumoconiosis Field Research. (Source: Data from Hurley JF, et al. Simple Pneumoconiosis and Exposure to Respirable Dust: Relationships from Twenty-Five Years' Research at Ten British Coal Mines. *Institute of Occupational Medicine, Report No. TM/79/13.*)

increasing radiographic category of CWP,⁶¹ and with progression of CWP.²⁷ These studies are important because they provide the basis for recommending removal of a miner with radiographic evidence of CWP from areas of high dust exposure, as is implemented in the federal regulations associated with the 1969 Act.¹¹ It is important to note, however, that there is the potential for PMF to develop directly from a background of category 0 in response to dust exposure.⁶² This indicates that the incidence of PMF cannot be controlled merely by the prevention of simple CWP. The attack rate of PMF does not appear to depend on presence of pulmonary tuberculosis, as once suspected.^{17,19,63}

Smoking has not been found to affect CWP development,⁶⁴ nor did bronchitis appear to play a role.⁶⁵ The exposure-response relationship for CWP and dust exposure is similar for current coal

Figure 24-5. Ten-year predicted incidence and progression of CWP for various starting categories. (Source: *The Division of Respiratory Disease Studies/NIOSH.*)

miners and ex-miners, although ex-miners had more disease owing to higher exposures.⁶⁶ Although rounded-type small radiographic opacities have been traditionally studied in connection with CWP, there is evidence that small irregular opacities also increase in prevalence with degree of dust exposure.^{67,68} Small irregular opacities may be linked with lung function deficits.⁶⁹

While radiographic evidence of CWP has been the major focus of epidemiological research on CWP, much attention has also been paid to coal dust exposure and other nonmalignant lung diseases (including bronchitis, obstructive airway disease, and emphysema). Unlike CWP, these diseases are known to be of multifactorial etiology, including a major influence of cigarette smoking among smokers. Hence their interpretation and significance in terms of occupational exposure has been associated with some controversy.

There is now overwhelming evidence of an exposure-response relationship for cumulative dust exposure and diminished ventilatory function. This has been found in cross-sectional studies,^{12,70-72} and in longitudinal studies.^{73,74} Smoking was not found to potentiate the effect of dust exposure, nor was presence of CWP a prerequisite for ventilatory function loss. Although the average effect of dust exposure obtained from the exposure-response analyses may appear small, this appearance is misleading, and there is evidence that some miners suffer important deficits in ventilatory function from their work.^{26,75} Severe declines in underground coal miners are associated with increased mortality,⁷⁶ and may not only be due to dust exposure but also arise from other airborne factors, such as water used for dust suppression.⁷⁷ There is no epidemiologic evidence that the effect of smoking and dust exposure differ in nature.⁷⁸ More recent evidence suggests that new recruits to mining suffer large initial declines in ventilatory function, followed by lesser long-term declines.^{33,79,80}

Respiratory symptoms associated with chronic bronchitis have been shown to be related to cumulative dust exposure and its surrogates, in both smokers and never smokers.^{13,32,81} The presence of emphysema, as detected on the chest radiograph, is linked with extent of cumulative dust exposure.⁸² This finding is consistent with the results of from several pathologic studies, which indicate that emphysema is associated with both retained dust and cumulative exposure (or its surrogates) during life.^{15,16,83}

Prevention

The key to preventing CWP is prevention of prolonged inhalation of significant concentrations of coal mine dust. This can be accomplished by the control of respirable coal mine dust through proper ventilation, use of water spray dust suppression, and enclosure of mining operations.⁸⁴ Secondary prevention strategies, for example, removal of miners with early evidence of CWP to low-dust jobs can assist in reducing the incidence of severe disease. Both strategies were mandated by Congress in the Federal Coal Mine Health and Safety Act of 1969 and have been implemented with substantial but incomplete success in underground operations of the U.S. coal industry. Since passage of the 1969 Act, respirable dust levels have been reduced for most high-risk jobs to meet the 2.0 mg/ml standard. Recent evidence suggests that control of dust for prevention of CWP will have similar rates of success with other coal-mining-related lung diseases.⁸⁵

NIOSH CWP surveillance of U.S. miners has documented decreases in radiographic prevalence of CWP (category 1 or greater) over the period 1987-2001 from 20% to about 5% to in miners with 25 or more years in mining. In contrast, prevalence rates for miners with less than 20 years tenure in mining have remained relatively stable, ranging from about 1-4% in 2001 for those with 0-9 to 15-19 years of tenure (Fig. 24-6).

Despite these gains in prevention, concern has been expressed about the adequacy of control measures,⁸⁶ and there remains evidence of excessive risk for underground coal miners in certain localities, as manifested by cases of rapid progression of CWP.²² In addition, although dust concentrations in surface mines have averaged less than half those of underground mining, high exposures to coal dust and free silica may occur for those who drill, crush, and prepare coal for transport. NIOSH has described several cases of acute or accelerated

Figure 24-6. Trends in coal workers' pneumoconiosis prevalence by tenure among examinees employed at underground coal mines, U.S. National Coal Workers' X-Ray Surveillance Program, 1987–2002.

silicosis in young (<35 years old) drillers, and has recommended the use of wet drilling and exhaust ventilation as effective prevention measures.²⁵

In response to evidence of limitations in the effectiveness of current U.S. effort to fully control lung disease in coal miners, NIOSH produced comprehensive recommendations for addressing this problem.⁸⁷ This criteria document makes the following recommendations:

- Control of respirable coal mine dust to 1 mg/m³
- Improved engineering control and work practices
- Improved hazard surveillance
- Extension of health screening and surveillance to include tests of pulmonary function for all coal miners—both underground and surface

In response to the NIOSH recommendations, the U.S. Secretary of Labor empaneled an Advisory Committee on the Elimination of Pneumoconiosis Among Coal Mine Workers.⁸⁸ This committee reviewed the scientific data on the causes of disease persistence and issued 20 recommendations. Those include recommendations for improved dust control, and inspection and enforcement of exposures to coal mine dust including silica dust. A strengthened program of medical screening and health surveillance was also endorsed.

Ultimately, improved prevention depends on adoption and application of these recommendations.

Silicosis

Stephen Levin • Ruth Lillis

Silicosis is a fibrotic lung disease produced by the inhalation of dust-containing free crystalline silicon dioxide (SiO_2). Free silica and silicates represent a large part of the earth's crust. Silicon and oxygen are the two most important elements in the crust; about 27.7% of its composition is silicon, and 46.6% is oxygen. Free silica, the most widespread naturally occurring substance known to have a fibrogenic effect on the lungs, occurs in crystalline and amorphous forms. The crystalline forms that are fibrogenic are quartz, tridymite, and cristobalite; cryptocrystalline forms (consisting of minute crystals) are flint, chert, opal, and chalcedony. There are numerous forms of amorphous silica.

At high temperatures (800–1000°C), quartz, the most common crystalline form of free silica, is converted into tridymite, and at even higher temperatures (1100–1400°C) it is transformed into cristobalite. Flint, chert, opal, chalcedony, and amorphous forms of free silica, including kaolin and diatomaceous earth, are also transformed into tridymite and cristobalite at these temperatures. This effect of high temperatures is of importance, since both tridymite and cristobalite are more potent than quartz in producing pulmonary fibrosis.

History

Silicosis undoubtedly originated in antiquity with the mining and processing of metals and building stone. Agricola, in his book *De Re Metallica* (1556), was probably the first to recognize the adverse effects of inhaled dust. The first monograph on miners' diseases, *Von der Bergsucht* by Paracelsus in 1567, included a classic description of "miners' phthisis." Van Diembroeck described how the lungs of stonecutters dying of "asthma" cut like masses of sand (*Anatomi Corporis Humani*, 1672). Bernardino Ramazzini included a description of diseases of stonemasons and miners in *De Morbis Artificum Diatriba* (1700). In England, the disease (phthisis) was described in flint knappers, needle pointers, knife grinders, fork sharpeners, and cutters of sandstone. John Scott Haldane (1923) described the cellular storage and retention of dust, including the long-term retention of silica, and recommended better ventilation of mines and factories. The distinction between tuberculosis and silicosis followed Koch's discovery of the tubercle bacillus in 1882. The earliest description of silicosis in the United States, in the nineteenth century, was of employees of a cutlery plant; the disease was then detected among miners. Tunnel work generated numerous cases of silicosis. The tunnel at Gauley Bridge in West Virginia, where many workers contracted both acute and chronic silicosis in the 1930s, attracted much public attention. This resulted in the initiation of dust suppression and respiratory protection methods, improved industrial hygiene, and the introduction of laws for compensation of silicosis victims.

Although the magnitude of the silicosis risk was gradually reduced in tunnel drilling and mining operations, significant silica exposure continued to occur in other industrial operations, such as foundries, the manufacture and use of silica flour, the production of detergent soaps with a high content of free silica, and sandblasting.

Work Exposures

Mines. The quartz content of the ores mined and the intensity of exposure to dusts determine the relative risks of working in the following situations: metal ore mines, especially gold, copper, tin, silver, nickel, tungsten, uranium, and platinum; coal mines (drilling through rock or work in areas with narrow seams); mines or quarries for silicates (talc, kaolin, bentonite, mica, clays, etc.), slate, graphite, and fluorspar and their processing; drilling for exploration; and crushing operations. A recent study among South African gold miners with an average length of service of 21 years reported a prevalence of silicosis among 19%.¹

Quarries. Quarries of materials with high free crystalline silica content (quartz, sandstone, granite, slate, porphyry, etc.) and the processing of such materials place workers at risk for silicosis. Sandstone is almost pure silica; granite may have a variable silica content, 20–70%; and slate usually is approximately 40% silica. The cottage industry producing slate pencils in India has produced numerous cases of severe silicosis.²

Tunnels. Tunnel drilling and other excavations in rocks with high SiO_2 content may represent a severe hazard, especially since ventilation usually is poor. Among the earliest studies of silicosis in the United States were those of disease in subway and tunnel builders in New York City in the mid-1920s. Cases of silicosis also have been traced to the excavation of deep foundations in sandstone in Australia. In northeastern Brazil, a high incidence of silicosis in pit diggers has been reported.³

Highway Repair. A recent study examined highway construction trends, silicosis surveillance case data, and environmental exposure data and found that a large population of highway workers is at risk of developing silicosis from exposure to crystalline silica.⁴ High levels of silica exposure have been identified in this setting: the potential for respirable quartz concentrations involving disturbance of concrete were reported to range up to 280 times the National Institute for Occupational Safety and Health (NIOSH) Recommended Exposure Limit of 0.05 mg/m³, assuming exposure for an 8- to 10-hour workday.⁵

Stone Masonry. Stonemasons may be subjected to significant and seldom well-controlled silica exposure. Sandstone and granite are the most important materials.

Foundry Work. A significant risk of silica exposure is associated with the mixture of sand and clays used for molds; the temperature of the molten metal poured into the molds fuses some sand to the surface of the castings and converts some quartz into tridymite or even cristobalite. Sometimes the molds are dusted with powders of high

free-silica content, which adds a significant risk. The separation of castings from molds and cores, by shaking or knocking or automatically on vibrating tables, generates dangerous concentrations of dust. Fettling, the process by which the remnants of molds are removed from the castings by various abrading and polishing techniques carries a substantial risk.

Grinding. Grinding and polishing with sandstone or other abrasive materials of high silica content have largely been replaced by less hazardous procedures, since these methods have resulted in numerous severe cases of silicosis. Nevertheless, grinding with such synthetic materials as Carborundum does not totally eliminate the risk, since remnants of the silica-containing mold are a source of airborne silica dust. Crushed sand, sandstone, and quartzite have been used for metal polishes and sandpaper.

Sandblasting. Sandblasting, used in foundries; in construction work, especially for the polishing of metal surfaces before painting and for cleaning building stone; and in the etching of glass and plastics, is an extremely hazardous occupation with high levels of exposure to very fine particles. Steel shot, iron garnet, and Carborundum are sometimes used instead of sand, but these replacement materials have not undergone adequate study in animal models, especially under conditions comparable to long-term occupational exposure.⁶ Sandblasting of relatively small objects can be done in enclosed chambers operated from the outside. A hazardous exposure persists, however, for workers entering the sandblasting booths to remove the objects or clean the floors. Sandblasting in construction work or shipbuilding is much more difficult to enclose; hence adequate respiratory protection of all persons in the work area is essential. Sandblasting was banned in the United Kingdom in 1951 and in the European Economic Community in 1966 but is still widely used in the United States, where cases of rapidly progressing silicosis attributed to this type of exposure have been reported.^{7,8} The NIOSH recommends that silica sand be prohibited as abrasive blasting material and that less hazardous materials be used in blasting operations.⁴

Refractory Brick Manufacture. Manufacture of refractory brick and other refractory products (especially the acid refractories) carries a high risk of silicosis. Quartzite, sandstone, sands, or grits with a high quartz content are crushed, milled, shaped, dried, and fired at high temperatures, and a proportion of quartz is converted to tridymite and cristobalite.

Bricklaying. Bricklaying and dismantling or repair of refractory bricks in ovens, furnaces, kilns, and boilers carry a high risk of silicosis, especially because of the presence of cristobalite along with the quartz.

Pottery. The pottery industry may generate significant risks when the raw materials (mostly clays) contain free silica, even though use of powdered flint, which was a major source of silica in the pottery industry in Great Britain, has been discontinued. Glazes with variable contents of quartz also are used; firing at high temperatures (up to 1400°C) may create another source of significant silica exposure. In the United States, wollastonite, a calcium metasilicate, is used instead of flint, quartz, sand, and china clay, and, therefore, the health hazard in this industry is less than that reported in Great Britain in the past.

Glass. Glass industry workers, especially those grinding and polishing with fine quartz, and sandblasters of glass have considerable silica exposure.

Manufacture of Abrasive Soaps. The manufacture of soaps containing fine sand (silica flour) has in the past been a cause of rapidly progressing silicosis, "abrasive soap pneumoconiosis."

Fillers. Fillers used in the paint, rubber, plastic, and paper manufacturing industries may include silica flour, a finely ground, highly toxic quartz. It is sometimes incorrectly labeled as amorphous silica.⁹

Rapidly progressing silicosis has resulted from the production of silica flour in Australia¹⁰ and the United States.¹¹

Enamel. Vitreous enameling, using mixtures of pulverized materials containing quartz at high temperatures, may present a significant risk; enamel spraying is particularly hazardous.

Diatomaceous Earth. Calcined diatomaceous earth carries a significant risk, since part of the amorphous silica is transformed through calcination into cristobalite and tridymite. It is used in filters, absorbents, and abrasives and may generate significant exposure and risk of silicosis.

Ceramic Fiber Insulation. Ceramic fiber insulation is being used increasingly as a refractory lining for heat-treating and preheating furnaces in the iron and steel industry. Studies have shown that the fibers undergo partial conversion to cristobalite when exposed to high temperatures.

Other Exposures

In rural African women, cases of pneumoconiosis ("Transkei Silicosis") were identified and attributed to silica inhalation during hand grinding of maize between rocks (sandstone). The criteria for diagnosis included rural domicile, radiographic and lung biopsy evidence of pneumoconiosis, no exposure to mining or industry, and no evidence of active tuberculosis.¹²

Five cases of silicosis, four of them with progressive massive fibrosis, have been reported in workers from two dental supply factories.¹³ Forty-two Brazilian stone carvers were examined with chest x-rays and high resolution CT studies; the prevalence of silicosis was 54%.¹⁴

Occurrence

Accurate data on the occurrence of silicosis in various industries and in different parts of the world are difficult to obtain and hard to compare, in part because of different notification systems. Cross-sectional surveys of exposed populations, such as miners, indicate the prevalence of the disease. The attack rate or incidence of the disease is less well known. The incidence of silicosis undoubtedly increased in the majority of the industrialized countries until the 1950s. Methods of dust suppression and control that had been developed and applied mainly in large industrial facilities then led to a decrease in silicosis incidence. Dust control became more rigorous as the hazards were recognized, but smaller industries and new industrial processes continued to expose workers to dangerous levels of silica.

In industrialized countries with intensive mining, such as West Germany, silicosis is still one of the most important problems of occupational medicine; as many as 3500 new cases and approximately 1500 deaths due to silicosis occurred annually in the 1960s, five times more than the total number of fatal work accidents. France reported a similar incidence and mortality from silicosis.

In India, silicosis was diagnosed as soon as systematic examinations of miners were initiated in the 1950s and 1960s. In the Bihar mining area, 34% of those examined were found to have advanced silicosis. Similarly, in Japan a high prevalence of silicosis (63%) was found in some metal ore miners.

Much of the available information is based on compensation cases. Because the criteria for compensation differ from country to country, only general trends can be detected. In the United Kingdom, for example, 721 persons were awarded industrial injury compensation for silicosis in 1957; in 1969, only 162 new awards for silicosis were made. Mining, quarrying, and slate industries had not shown a significant downward trend in silicosis rates, however.

In the United States, the incidence of silicosis has decreased in the Vermont granite quarries,¹⁵ but metal mining is still an important cause of silicosis. A survey of more than 76% of the workforce in 50 metal mines, conducted by the Public Health Service and the Bureau of Mines between 1958 and 1961, revealed a silicosis prevalence of 3.4%. In one-third of cases, complicated silicosis was present. Prevalence was related to silica content of the rock, occupation, and length of exposure. Trasko in 1956 estimated the total number of silicosis

cases in 20 states to be about 6000.¹⁶ Miners and foundry workers were each represented by more than 1600 cases, but the number of cases was probably underestimated. In a British study of foundry workers,¹⁷ the prevalence of simple pneumoconiosis was 34% among fitters and 14% in foundry floor workers. Similar data for the United States are not available.

In 1971, milling of bentonite (sodium montmorillonite) was found to have produced severe silicosis in Wyoming¹⁸; a silicosis risk in this industry had not been suspected in the past.

In 1983, the National Institute of Occupational Safety and Health estimated that approximately 3.2 million workers in 23,800 plants in the United States were potentially exposed to crystalline silica.

Watts et al. (1984)¹⁹ analyzed respirable silica exposures in metal and nonmetal mines in the United States (41,502 samples taken from 1974 to 1981). Workers in sandstone, clay, shale, and various nonmetallic mineral mills had the highest exposures to silica dust. Crushing, grinding, sizing, and bagging operations and general labor tasks were associated with the highest exposures.

In 1984, the U.S. Mine Safety and Health Administration identified approximately 2400 work sites in coal mines where the level of 5% silica in respirable dust had been exceeded, representing the work environment of 15,000–20,000 coal miners (about 10% of U.S. coal miners). Floor and roof samples were found to contain 18–82% quartz; coal itself contained only 1–4%.²⁰ Continuous mining machines; cutting of roof, floor, and inclusion rock bands; and roof-bolting operations were the major sources of silica exposure.²¹

The median silica content of respirable dust in 1743 personal air samples collected by the U.S. Occupational Safety and Health Administration in U.S. foundries from 1974 to 1981 ranged from 7.3% to 12.0%. Of 10,850 samples collected in iron and steel foundries, 23% had concentrations in excess of 0.20 mg/m³ respirable silica.

Reports on a high (37%) prevalence of silicosis in workers in silica flour mills, with a significant proportion of cases developing massive fibrosis,⁷ and reports of acute silicosis in sandblasters in the Louisiana Gulf area²² point to the fact that silicosis continues to be an important occupational health risk, although the number of individuals affected probably has been reduced substantially. A recent report from the Center for Disease Control and Prevention presented evidence for a decline in silicosis mortality and incidence in the United States during the period from 1968 to 2002,²³ although evidence for considerable underreporting and underrecognition of silicosis and silicosis mortality has been reported as well.^{24,25} The International Agency for Research on Cancer (IARC) has reported an estimated risk of death up to age 65 from silicosis after 45 years of exposure at 0.1 mg/m³ silica (the current standard in many countries) was 13 per 1000, while the estimated risk at an exposure of 0.05 mg/m³ was 6 per 1000. Both of these risks are above the risk of 1 per 1000 typically deemed acceptable by Occupational Safety and Health Administration (OSHA).²⁶

Effects on Health

Classic silicosis is a chronic and slowly progressive disease. Acute silicosis and silicoproteinosis (alveolar lipoproteinosis-like silicosis) occur in epidemic outbreaks under circumstances of heavy silica exposure. Sandblasting, abrasive soap manufacture, tunnel drilling, and refractory brick manufacture have been the major sources of such outbreaks.

Dust concentration, particle size (in the 0.1–2 µm range, which reach respiratory bronchioles and alveoli), and duration of dust exposure define the hazard. Thus high concentrations of fine dust overburden the limited direct clearance capacity of the distal zones of the lung, and longer exposures increase the risk of developing silicosis.

The interactions of concentration, particle size, and duration of exposure are the main determinants of the attack rate, latency period, incidence, rate of progression, and outcome of the disease.

In industrial processes in which silica-containing materials are heated at temperatures exceeding 800°C so that transformation into tridymite and cristobalite occurs, the higher fibrogenic potency of these forms of SiO₂ results in a higher attack rate and more severe silicosis. In the superficial layers of refractory brick that have been repeatedly subject to contact with molten metal, cristobalite may reach a concentration of 94%. Fuscification of

diatomaceous earth also results in high cristobalite concentrations (up to 35%).

In experimental studies and in an investigation of human subjects with silicosis, silica particles have been shown to initially produce an alveolitis, characterized by sustained increases in the total number of alveolar cells, including macrophages, lymphocytes, and neutrophils. Advances in genomics and proteomics have provided tools for developing a better understanding of the molecular mechanisms involved in the pathogenesis of silicosis.

In vitro and in vivo animal studies, as well as investigations in humans strongly support the role of macrophage products in the development and progression of silicosis. Such products include enzymes and reactive oxygen species, including superoxide, hydrogen peroxide, and nitric oxide, which may cause lung damage; cytokines which recruit and/or activate polymorphonuclear leukocytes and thus result in further oxidant damage to the lung; and fibrogenic factors which induce fibroblast proliferation and collagen synthesis.²⁷ Evidence has accumulated that implicates reactive oxygen species in the initial activation of alveolar macrophages (AMs),^{28,29} and that grinding or fracturing quartz particles breaks Si-O bonds and generates ·Si and Si·O radicals on the surface of the cleavage planes. Upon contact with water, these silica-based radicals can generate hydroxyl radicals (·OH) directly, causing lipid peroxidation, membrane damage, and cell death.³⁰ Silica has been shown to induce apoptosis, marked by DNA fragmentation and increased levels of cytosolic histone-bound DNA fragments in human alveolar macrophages, mediated by activation of the interleukin-converting enzyme family of proteases.³¹

In rats, chronically exposed by inhalation to nonoverload levels of crystalline silica dust, activation of nuclear factor-kappaB (NF-κB)/DNA binding in bronchoalveolar lavage cells was evident after five days of silica inhalation, which increased linearly with continued exposure. Parameters of pulmonary damage, inflammation and alveolar type II epithelial cell activity rapidly increased to a significantly elevated but stable new level through the first 41 days of exposure and increased at a steep rate thereafter. Pulmonary fibrosis was measurable only after this explosive rise in lung damage and inflammation, as was the steep increase in tumor necrosis factor-alpha (TNF-α) and interleukin-1 production from bronchoalveolar lavage cells and the dramatic rise in lavageable alveolar macrophages. Indicators of oxidant stress and pulmonary production of nitric oxide exhibited a time course which was similar to that for lung damage and inflammation with the steep rise correlating with initiation of pulmonary fibrosis. Staining for inducible nitric oxide synthetase and nitrotyrosine was localized in granulomatous regions of the lung and bronchial associated lymphoid tissue.³² NF-κB is induced in alveolar macrophages by silica exposure in a dose-dependent way, with a consequent increase in the expression of the TNF-α gene.³³ Inducible nitric oxide synthase-derived nitric oxide has been shown in other studies to contribute to the pathogenesis of silica-induced lung disease.³⁴ Crystalline and amorphous silica can directly upregulate the early inflammatory mediator COX-2, prostaglandin E (PGE) synthase, and the downstream anti-fibrotic prostaglandin E-2 in primary human lung fibroblasts.³⁵

The alveolar macrophage plays a prominent role in lung inflammation via the production of oxygen radicals, enzymes, arachidonic acid metabolites, and cytokines. Studies in miners with and without significant silicosis report that gene-environment interactions involving cytokine polymorphisms play a significant role in silicosis by modifying the extent of and susceptibility to disease.³⁶ Silica exposure in mice has been found to induce a significant increase in interstitial macrophages with an antigen presenting cell phenotype, as well as an increase in the antigen presenting cell activity of alveolar macrophages.³⁷ Bronchoalveolar lavage in silicosis and coal workers' pneumoconiosis showed a large influx of mononuclear phagocytes, increased production of oxidants, fibronectin, neutrophil chemotactic factor, interleukin-6, and TNF-α.³⁸ Macrophage-derived growth promoting activity factors were shown to have characteristics consistent with platelet-derived growth factor, insulin-like growth factor-1, and fibroblast growth factor-like molecules.³⁹

An effect of age on macrophage function has been reported. In young rats, silica induced a significant increase in bronchoalveolar

lavage, TNF- α , and lactate dehydrogenase, as well as in cell numbers, which correlated with increased collagen deposition and silicotic nodule formation. In old rats, however, no changes in bronchoalveolar lavage or lung parameters were observed following silica instillation. These *in vivo* results were also confirmed *in vitro*, where silica failed to induce TNF release in alveolar macrophages obtained from old animals.⁴⁰

Transforming growth factor-alpha (TGF- α), a cytokine with potent mitogenic activity for epithelial and mesenchymal cells, may play a role in the lung remodeling of silicosis. TGF- α may be critical in directing the proliferation of pneumocytes type II that characterize silicosis.⁴¹ Transforming growth factor-beta 1 (TGF- β 1) was demonstrated in fibroblasts and macrophages located at the periphery of silicotic granulomas and in fibroblasts adjacent to hyperplastic type II pneumocytes.⁴² Silica causes release of TNF from mononuclear phagocytes. Experimental studies indicate that silica can upregulate the TNF gene and thus increase TNF gene transcription in exposed cells.⁴³

Inhalation of crystalline silica particles produces a rapid increase in the rate of synthesis and deposition of lung collagen. Lungs of silica-exposed rats showed increased alveolar wall collagen and fibrotic nodules at 79 and 116 days of exposure with increased collagenase and gelatinase activity. Matrix metalloproteinases were significantly elevated in alveolar macrophages after 40-day exposure. Stromelysin expression was demonstrated in alveolar macrophages and cells within fibrotic nodules.⁴⁴ Silica-induced fibrosis is unique among all the animal models and most human fibrotic lung disease thus far examined in that the excess collagen deposited in the lung contains normal ratios of the two major collagen types of the lung, types I and II; nevertheless it is biochemically different from normal lung collagen. The difference seems to be due to altered intermolecular cross-links; there is an increased hydroxylysine content of collagen. Dysfunctional cross-links are more likely to be derived from hydroxylysine. Hydroxylysine replaces lysine in the primary structure of a specific collagen α -chain to form the altered cross-links.

In the alveolar spaces of rats exposed to very high concentrations of quartz or cristobalite, a material similar to that found in human alveolar lipoproteinosis together with a significant increase in the number of type II alveolar cells have been detected. This alveolar material is acellular and has a high phospholipid content with osmophilic bodies similar to those present as inclusions in type II alveolar cells. Phosphatidylcholine and phosphatidylglycerol are components of the increased amounts of surfactant found in the alveolar spaces under such circumstances.

Significant increases in surfactant production associated with type II epithelial cell hypertrophy and hyperplasia were shown to be associated with a proportional enhancement of surfactant proteins (SP-A and SP-B) and phospholipids.⁴⁵

Thus it seems that two different types of reactions can occur as a result of the penetration of silica particles into alveolar spaces: triggering of a fibrogenic reaction by altered macrophages or production of excess phospholipids by type II alveolar cells. The rate at which silica particles accumulate in the alveoli is of great importance; exposure to high concentrations results in lipoproteinosis; exposure to relatively lower concentrations of silica, over longer periods of time, leads to the development of typical nodular fibrosis. Most silicosis cases are of the classic nodular type, characterized by the presence of collagenous and hyaline nodules.

Pathology

Silicotic nodules are readily felt in the lung and seen on the cut surface. Their size usually varies between 2 and 6 mm; they are hard, grayish, and more frequent in the apical and posterior parts of the lung. Sectioned nodules show a characteristic whorled pattern. The hilar lymph nodes most often are enlarged and also contain silicotic nodules.

Large fibrotic masses tend to be located mostly in the upper and posterior parts of the lungs; they are the result of coalescence of individual nodules when their profusion is high. Cavitation in large fibrotic masses can occur and most often is due to complicating tuberculous infection; cavitation due to ischemic necrosis is relatively rare

in silicosis. Emphysema frequently is present when large fibrotic masses have developed. Enlargement of the right chambers of the heart and the pulmonary artery can be found in advanced silicosis.

In a classic example of nodular disease in gold miners, the quartz content of the lungs is 2.5–3 g of the total 7–10 g dust content; in foundry workers it is between 1 and 2 g with approximately 10 g total dust content. In contrast, in stellate or diffuse fibrosis in hematite miners, the total dust content may be 60 g with 3.5 g quartz, and in coal miners, 40–55 g with 1–1.5 g quartz.⁴⁶

Silicotic nodules initially appear in the area of the respiratory bronchiole and around arterioles. The nodules consist of concentric layers of collagen; hyalinization of the collagen occurs with time and progresses from the center to the periphery of the nodule; reticulin fibers usually are present in the periphery. A cellular peripheral layer is characteristic of relatively early lesions; it consists mostly of fibroblasts and macrophages. Particles of silica can be found in the center of the nodules; polarized light is particularly useful to visualize the birefringent SiO₂ particles.

The alveoli around the silicotic nodule most often are normal, although scar emphysema occasionally can be observed; centrilobular emphysema is not a feature of silicosis.^{47,48} Small pulmonary arterioles and venules are involved in the fibrotic process and are often obliterated. With continuous exposure, the silicotic nodules grow and new nodules appear. Progression may continue even after exposure has been discontinued, especially when the dust is characterized by high silica concentration and small particle size.

Coalescence of nodules occurs when the profusion of silicotic nodules has increased beyond a critical level. Dense hyalinized collagen masses develop in which individual nodules can still be identified, especially at the periphery. These lesions destroy the normal architecture of the lung; necrosis in the avascular center can occur even in the absence of tuberculous infection, although the latter is a frequent complication.

In *rapidly developing silicosis*, because of exposure to high concentrations of fine silica particles, the characteristic pathological features consist of the rapid development of numerous small nodules, together with areas of diffuse fibrosis and the rapid coalescence of nodules into large fibrotic masses.

Acute or hyperacute silicosis resembles idiopathic alveolar lipoproteinosis and has been associated with extremely high exposures to pure or almost pure free silica and very small particle sizes. The term *silicolipoproteinosis* has been proposed for this condition.⁴⁹ Exposures in the manufacture of abrasive soap, quartz milling, the grinding of quartzite and sandstone to produce silica flour, and sandblasting with quartzite have been associated with silicolipoproteinosis.

In this form of silicosis, the lungs are firm and edematous. A few silicotic nodules can be present; alveolar walls are infiltrated by mononuclear and plasma cells or thickened by fibrosis, and alveoli are filled with an eosinophilic PAS-positive lipid and proteinaceous fluid with numerous fine granules and desquamated cells. The latter are mostly type II alveolar cells, containing osmiophilic lamellar bodies. Diffuse interstitial pulmonary fibrosis is present, but silicotic nodules are rare or absent. These lesions have been reproduced in experimental animals exposed to inhalation of high concentrations of fine quartz particles.^{50,51}

Proteinuria and renal failure have been associated with silica exposure from sandblasting or refractory bricks.^{52,53} This appears to represent the effect of high levels of renal silicon dioxide crystals transferred to the kidney after pulmonary deposition.

Clinical Features

Classic nodular silicosis sometimes can be completely asymptomatic, although relatively numerous silicotic nodules can be present on the chest x-ray film. In most such cases, no abnormalities can be detected on physical examination. As the disease progresses, cough, sputum production, and dyspnea on exertion gradually develop in most cases. In some there is only a dry cough; in others small amounts of mucoid sputum are produced. An increased susceptibility to repeated respiratory

infections develops in many patients and can result in larger amounts of mucopurulent sputum.

In the advanced stages of silicosis, distortion of the normal architecture of the bronchi develops, especially when coalescence into massive fibrosis has taken place. Rhonchi and wheezes can be detected in such cases and paroxysms of coughing can occur. Shortness of breath develops gradually as the disease progresses; initially it is limited to heavy exercise, but later it manifests itself with moderate or even minor efforts. Physical signs are practically absent in the initial stages of silicosis. With the development of massive fibrosis or of a major infectious complication such as tuberculosis, abnormalities on percussion and auscultation (rales, rhonchi, areas of reduced or increased resonance) and cyanosis can develop.

Cor pulmonale is the most frequent complication of silicosis in industrialized countries. Pulmonary hypertension with a loud second pulmonic sound and corresponding electrocardiographic signs can be detected; overt congestive heart failure with hepatomegaly and peripheral edema is less frequent and is thought to occur mainly in cases with significant associated emphysema or marked chronic bronchitis.

In patients with "acute" silicosis similar to idiopathic alveolar lipoproteinosis, symptoms develop rapidly over a period of several weeks or months; time from onset of exposure to first symptoms can vary from less than 1 year to a few years. Fatigue, cough, sputum production (mostly mucoid), chest pain of pleuritic type, rapidly progressive shortness of breath, weight loss, and rapid deterioration are characteristic for such cases. Shortness of breath at rest, cyanosis, and abnormalities on percussion and auscultation with presence of crepitations are noted frequently. The rapid and fatal course of the disease leads to death in hypoxic respiratory failure.⁵⁴

Radiographic Findings

The radiographic changes in silicosis are essential for the diagnosis and classification of the disease, for the evaluation of its progression, and for the detection of important complications, such as tuberculosis, emphysema, and cor pulmonale. Nevertheless, it should be emphasized that pathological changes precede, often by several years, the appearance of the earliest radiographic changes, since to be

detected on the standard posteroanterior chest film, the pathological changes (silicotic nodules) have to reach a certain size, profusion, and radiological density. Because of this radiological latency period of silicosis, a normal chest x-ray film does not exclude the existence of the pathological process of silicosis in a person with significant exposure. Nevertheless, the disease seldom is symptomatic in this stage of radiological latency, with the notable exceptions of "acute silicosis," alveolar lipoproteinosis, and chronic bronchitis due to silica.

The earliest radiographic changes consist of fine linear-reticular opacities, often described as "lace-like," in the upper and middle lung fields and extending to the periphery. These linear reticular opacities increase in thickness with time.

The most characteristic radiographic abnormalities are silicotic nodules (Fig. 25-1), which usually appear initially in the middle and upper right lung fields. The earliest discrete round opacities are small, with a diameter of 1–3 mm and of low radiopacity. The diameter of silicotic nodules increases with time, as does their profusion and radiopacity, and they become more visible in most of the lung fields, with the exception of the lower lateral areas. The International Labor Office's Classification of Radiographs of Pneumocostoses (1980) grades simple silicosis according to the profusion of the opacities, from 1/0 to 3/+, and to the size of most of the nodules, "p" for less than 1.5 mm, "q" for between 1.5 and 3 mm, and "r" for opacities with a diameter of more than 3 mm but less than 10 mm. The nodules often are seen against a background of a linear-reticular pattern.

As the number of rounded opacities increases, the profusion progresses, and eventually coalescence of nodules, initially in small limited areas in the upper lateral parts of the lung fields, becomes apparent. At this stage, when coalescence into large opacities is suspected (and their size is relatively small, less than 5 cm in diameter), they are classified as Ax. This marks the point at which simple silicosis progresses to complicated silicosis.

As the large opacity becomes definite, it is classified according to size into category "A" (less than 5 cm), "B" (one or more opacities with a diameter of more than 5 cm but with a combined area of less than the equivalent of the right upper zone), and "C" (one or more opacities whose combined area exceeds the equivalent of the right upper zone). The large opacities in silicosis usually are bilateral and

Figure 25-1. Simple silicosis. Small rounded opacities (q-diameter, approximately 3 mm) in upper lung fields, bilaterally.

Figure 25-2. Small, rounded opacities (r-diameter, approximately 3–10 mm) predominantly in upper and middle lung fields; large opacity due to coalescence of nodules in left upper lung field (size B, according to International Classification of Radiographs of Pneumoconioses).

most often located in the upper, but also in the middle, lung fields (Figs. 25-2 and 25-3). When the opacities are observed over time, contraction may be noted, and migration to the enlarged hilar opacities is not unusual. Distortion of the pulmonary and mediastinal structures is frequent in this stage, as are emphysematous changes, including bullae, in the rest of the lung. Hilar lymph node enlargement is observed quite consistently in silicosis; calcification of the periphery of the lymph nodes, “eggshell calcification,” may be present occasionally. Pleural adhesions also may be found; quite characteristic are the longitudinal pleural plicatures extending from the diaphragmatic pleura along the interlobar fissures.

In rapidly progressive silicosis, the radiological latency period—a few months to 2 years—is much shorter than in classic silicosis. The radiological abnormalities are different from those of classic (nodular) silicosis, a fact that may have contributed to the underestimation of the incidence of this form of silicosis. Early changes consist of a diffuse haziness of reticular, irregular opacities in the middle and lower lung fields. Rounded and linear opacities develop rapidly over the entire lung fields. Occasionally, very small opacities are the main feature. The hilar shadows are only moderately enlarged. Rapid coalescence and large opacities, sometimes involving an entire lobe, can be observed in some cases; in others the numerous small, rounded opacities do not coalesce, and death ensues rapidly.

Alveolar lipoproteinosis is characterized by diffuse, hazy infiltrates found most often in the lower lung fields, particularly above the diaphragm. Changes similar to those characteristic for pulmonary edema are present sometimes; in other cases, small rounded opacities indicating alveolar filling can be observed.

Pulmonary Function

With classic silicosis, the typical change in pulmonary function is a gradual reduction in lung volume, beginning with reduction in vital capacity. The functional changes are less than would be predicted from the radiographic evidence. Airway obstruction, however, often is present because chronic bronchitis frequently coexists, especially

in foundry workers, brickworkers, hematite miners, and workers in user industries. The diffusing capacity is normal until relatively late in the course of the disease. Thus, in classic silicosis there is a decrease in total lung capacity, vital capacity, and residual volume, with arterial blood oxygen tension normal or slightly decreased. A mixed pattern of restrictive and obstructive ventilatory dysfunction is found most often in advanced, complicated silicosis. Evidence has accumulated that suggests that chronic levels of silica dust that do not cause disabling silicosis may cause the development of chronic bronchitis, emphysema, and/or small airways disease that can lead to airflow obstruction, even in the absence of radiological silicosis.⁵⁵

Imbalance of ventilation-perfusion occurs in the more advanced stages of the disease. Impairment of gas exchange and signs of cor pulmonale can develop. The coexistence of chronic bronchitis with airway obstruction results in reduced forced expiratory volume in one second (FEV₁), reduced flow at 25–75% of vital capacity (FEF_{25–75}), and in increased airway resistance. With severe obstruction, arterial blood oxygen tension is reduced and carbon dioxide tension increased. Acute silicolipoproteinosis almost always causes marked restrictive dysfunction with reduced diffusing capacity and arterial desaturation.

Complications

The complications of silicosis include tuberculosis, cor pulmonale, and Caplan’s syndrome. Tuberculosis has been the most persistent problem over the past 150 years. There is no doubt that involvement of the lungs by silicosis increases the susceptibility for tuberculosis infection. In contrast, there is no added risk of tuberculosis after exposure to asbestos or other nonsilica dusts. Thus, patients with silicosis in whom tuberculosis is suspected on the basis of a positive tuberculin test and a suggestive x-ray film should be treated with antituberculous chemotherapy, because demonstration of mycobacteria by smear or culture is difficult in silicotuberculosis, and the disease sometimes advances rapidly.

The high risk of tuberculosis in subjects with silicosis has been quantified in a cohort study of 1153 gold miners with and without silicosis, followed for seven years. The annual incidence of tuberculosis was 981/100,000 in the 335 men without silicosis and 2707/100,000 in the 818 men with silicosis.⁵⁶ Tuberculosis mortality in the United States is still seen in excess among workers exposed to silica dust.⁵⁷

Chronic bronchitis is not infrequent in some occupational groups exposed to silica dust, such as foundrymen.¹¹ Bronchitis due to acute or subacute infections of the distorted bronchi associated with advanced silicosis has been well characterized.

Emphysema is considered a side effect in the silicotic process. Small areas of scar emphysema can be found around nodules; coalescence of nodules into fibrotic masses often produces larger areas of emphysema, often bullous, mostly in the lower lung fields. In a group of 1553 South African gold miners who had undergone autopsy examination between 1974 and 1987, it was found that a miner with 20 years in high-dust occupations had 3.5 times higher odds of significant emphysema at autopsy than a miner not in a dusty occupation.⁵⁸ In a study of 207 workers evaluated for possible pneumoconiosis using high-resolution CT scans for detection, typing, and grading of emphysema, a significant excess of emphysema was found in those with pneumoconiosis and in smokers with silica exposure (as compared to those with asbestos exposure). Thus silica exposure was shown to be a significant contributing factor to the development of emphysema.⁵⁹

Cor pulmonale is a well-recognized complication of silicosis; the massive involvement of the pulmonary vasculature in the fibrotic process with obliteration of numerous arterioles eventually results in a marked increase in resistance and consequently in pulmonary artery pressure. Right ventricular heart failure with overt clinical signs is seen less frequently, although it is not unusual. In such cases, death due to congestive heart failure can occur. In cases with coexistent emphysema and chronic bronchitis with marked airflow obstruction or complicating tuberculosis, right ventricular heart failure is encountered more frequently.

Figure 25-3. Rounded opacities (r/q) in upper and middle lung fields; bilateral multiple large opacities due to coalescence of nodules.

The presence of cor pulmonale at death was analyzed in a study of 732 South African gold miners. Marked emphysema was the highest risk factor, with an odds ratio of 21.32 (95% confidence interval (C.I.) 5.02–90.7), followed by extensive silicosis (odds ratio 4.95, 95% C.I. 2.92–8.38).⁶⁰

Epidemiological studies have shown strong associations between silica exposure and several autoimmune diseases, including rheumatoid arthritis,⁶¹ scleroderma, and systemic lupus erythematosus. Mice exposed develop silicosis and exacerbated autoimmunity following crystalline silica exposure, including increased levels of autoantibodies, proteinuria, circulating immune complexes, pulmonary fibrosis, and glomerulonephritis, possibly resulting from silica-induced alterations in immunoglobulin levels, increased TNF- α , increased B1a B cells, and CD4⁺ T cells, with decreased regulatory T cells.⁶² In rats, silicosis was associated with elevated IgG and IgM levels in blood and bronchoalveolar lavage fluid, relative to nonexposed controls. Draining lung-associated lymph nodes were the most important sites for increased IgG and IgM production, with lungs contributing to a lesser degree.⁶³

Caplan's syndrome, the association between rheumatoid arthritis and silicosis, is rare. It is characterized by the appearance of large nodules (more than 1 cm in diameter) on a background of preexisting silicotic nodules. The larger nodules of Caplan's syndrome occasionally cavitate.

Renal lesions have been described in cases in which heavy occupational exposure to free silica has led to silicolipoproteinosis. Glomerular and tubular lesions have been described. Proteinuria and hypertension were associated with these renal lesions. The silica content of the kidney was found to be high in such cases. End-stage renal disease has been found at higher rates among silicotic and non-silicotic ceramic workers exposed to silica,⁶⁴ and epidemiological studies in silicotics have demonstrated an increased risk of end-stage renal disease.⁶⁵

Silica and Cancer

The question of a possible carcinogenic effect of silica has received increasing attention. Experimental studies on the possible carcinogenic effect of crystalline silica have been conducted on rats, mice, and hamsters, using various routes of administration: inhalation, intratracheal instillation, intrapleural and intraperitoneal injection. Findings from these studies were negative in mice and hamsters. In rats, the incidence of adenocarcinoma of the lung and squamous cell carcinoma was significantly increased, and intraperitoneal injections caused malignant lymphomas, cirrhosis, liver cell adenomas, and carcinomas.⁶⁶

Epidemiological studies have in the past been conducted on numerous silica-exposed groups, such as metal ore miners, coal miners, and workers in the granite and stone industry, the ceramics, glass, and related industries, foundries, and in persons diagnosed as having silicosis. There were methodological difficulties with many of these early studies; confounding by cigarette smoking and insufficient information on exposure to other carcinogens, such as radon (mostly in mining and quarrying operations), polycyclic aromatic hydrocarbons (mostly in foundries), and arsenic (in metal ore mining and possibly in the ceramics and glass industries), were the most important issues of concern.

Metal ore mining has not been associated with an increased incidence of respiratory cancer in some studies^{67,68}; in other cohorts of metal ore miners, mortality rates for respiratory cancer were found to be 20–50% above levels in the general population.^{69,70} In most studies of coal miners, no increased incidence of lung cancer was detected.

Earlier studies of granite workers generally yielded negative findings.^{71,72} A more recent mortality study of Vermont granite workers analyzed industrial hygiene data collected from 1924 to 1977 in conjunction with mortality data to examine quantitative exposure-response for silica, lung cancer, and other lung diseases.

A clear relationship of mortality from lung cancer, tuberculosis, pneumoconiosis, nonmalignant lung disease, and kidney cancer was found with cumulative exposure. An exposure to 0.05 mg/m³ from ages 20 to 64 was associated with a lifetime excess risk of lung cancer for white males of 27/1,000.⁷³

A cohort study among workers compensated for silicosis between 1988 and 2000 from the stone and quarry industry in Germany, found an increased risk of developing lung cancer based on the mortality rates of the general population of Germany.⁷⁴ A similar study of the mortality of Australian workers compensated for silicosis found, after adjusting for smoking, a standardized mortality ratio for lung cancer of 1.9 (95% C.I. 1.5–2.3).⁷⁵ In a case-control study utilizing industry/occupation information on death certificates, those deceased who were postulated to have had detectable crystalline silica exposure had a significantly increased risk for silicosis, COPD, pulmonary tuberculosis, and rheumatoid arthritis. In addition, a significant trend of increasing risk with increasing silica exposure was observed for these same conditions and for lung cancer. Those postulated to have had the greatest crystalline silica exposure had a significantly increased risk for silicosis, lung cancer, COPD, and pulmonary tuberculosis only.⁷⁶

In the ceramics and pottery industry, a moderately increased mortality from respiratory cancer has been detected in some studies.^{77,78} A number of reports on foundry workers have pointed to slightly to moderately increased respiratory cancer mortality.^{79–81} In a nested case-control analysis within a cohort mortality study of North American industrial sand workers, a causal relationship was found between lung cancer and quartz exposure after allowance for cigarette smoking.⁸² An increased lung cancer risk was found among Japanese tunnel workers after control for smoking.⁸³ A dose-related increase in lung cancer risk was reported among diatomaceous earth workers, independent of radiographically evident silicosis.⁸⁴

A mortality study of 716 cases of silicosis, diagnosed from 1940 through 1983, was undertaken as part of the North Carolina pneumoconiosis surveillance program for workers in dusty trades. Five hundred forty-six death certificates were obtained among 550 deceased. Mortality for lung cancer was increased among whites (SMR 2.6); the SMR was 2.3 in those without other exposure to known carcinogens. Age- and smoking-adjusted rates in silicotics were 3.9 times higher than in nonsilicotic metal miners.⁸⁵

The association between silicosis and lung cancer mortality was studied in 9912 (369 silicotics and 9543 nonsilicotics) white metal miners examined by the U.S. Public Health Service from 1959–1961 and followed through 1975. The SMR for lung cancer was 1.73 (95% C.I. 0.94–2.90) in silicotics and 1.18 (C.I. 0.98–1.42) in nonsilicotics. Confounding from exposure to radon or other carcinogens, such as arsenic, could not be ruled out.⁸⁶ A mortality study of 3328 gold miners in South Dakota found an SMR for lung cancer of 1.13 (C.I. 0.94–1.36). No positive exposure-response trend was evident with cumulative exposure. Silicosis and tuberculosis were significantly increased (SMRs of 3.44 and 2.61, respectively).⁸⁷

A statistically significant relationship between silica exposure and esophageal cancer has been reported among workers employed in underground caissons; the study controlled for smoking and alcohol use.⁸⁸

DNA binding to crystalline silica surfaces may be important in silica carcinogenesis by anchoring DNA and its target nucleotides to within a few Angstroms of sites of oxygen radical production on the silica surface.⁸⁹ Silica exposure induced significant suppression of lung p53mRNA in mice.⁹⁰ In a study of the p53 and K-ras gene mutations in the lung cancers of workers with silicosis, distinctive mutation distributions were evident in the exons, differing from those of lung cancers not associated with silicosis.⁹¹

As summarized by the American Thoracic Society, “The balance of evidence indicates that silicotic patients have increased risk for lung cancer. It is less clear whether silica exposure in the absence of silicosis carries increased risk for lung cancer.”⁹² In 1997, the IARC classified inhaled crystalline silica as a human carcinogen (group 1). The IARC found sufficient evidence in humans for the

carcinogenicity of inhaled crystalline silica in the form of quartz or cristobalite from occupational sources (Group 1). It found inadequate evidence in humans for the carcinogenicity of amorphous silica (Group 3). There was sufficient evidence in experimental animals for the carcinogenicity of quartz and cristobalite. There was inadequate evidence in experimental animals for the carcinogenicity of uncalcined diatomaceous earth and synthetic amorphous silica.⁹³

Diagnosis

A history of exposure to free silica is important for the diagnosis of silicosis. A detailed work history is necessary, with appropriate attention to occupations held in the past, since the latency period for the appearance of characteristic chest x-ray abnormalities is often decades, especially with relatively low silica concentrations in the airborne dust.

The other essential element for a correct diagnosis of silicosis is a good quality chest x-ray film. Nodular silicosis is not difficult to recognize, although nodular opacities can be found in many other diseases. Enlarged hilar opacities are quite characteristic for silicosis.

The sensitivity of the chest radiograph was evaluated in 557 gold miners in South Africa by comparing profusion of rounded opacities with pathological findings (average 2.7 years between chest x-ray and pathological examination). The sensitivity of the chest x-ray (using ILO category 1/1 or greater as a positive diagnosis of silicosis) was found to be 0.393, 0.371, and 0.236 (for three independent readers). A large proportion of those with moderate silicosis were not diagnosed radiologically. The authors concluded that the sensitivity of the chest radiograph could be improved by using 1/0 as a cutoff point for a positive diagnosis of silicosis (for exposure to relatively low-dust concentrations) and 0/1 for workers exposed to high average concentrations of silica dust.⁹⁴

Computed tomography scanning in the early detection of silicosis was shown to be significantly more informative than the chest radiograph. Thirteen of 32 subjects classified as normal on standard chest x-rays were found to be abnormal on CT scanning using conventional and high-resolution techniques, as were four of six subjects classified as “indeterminate” on the standard chest radiograph. In addition, the CT scans added six cases of confluence of small opacities to the three cases detected with standard chest x-rays.⁹⁵ The profusion of opacities on high-resolution CT scans has been demonstrated to correlate with functional impairment. The presence of branching centrilobular structures and nodules may be helpful in early recognition of silicosis.⁹⁶

Pulmonary function tests are not particularly helpful in the diagnosis of silicosis since they can be entirely normal in the presence of well-developed nodular opacities. When abnormalities are present, they are most often of a mixed, obstructive-restrictive type, although cases with only restrictive or obstructive dysfunction also can be found.

The differential diagnosis has to exclude conditions such as sarcoidosis, miliary tuberculosis, carcinomatous lymphangitis, pulmonary hemosiderosis, rheumatoid lung, fibrosing alveolitis, alveolar microlithiasis, and histoplasmosis. Massive fibrosis seldom presents difficulties in diagnosis, although early in its development, when a single large opacity is detected, differential diagnosis with lung cancer can be a problem. The presence of nodular opacities around the large opacity most often facilitates the correct diagnosis of silicosis with coalescent, massive fibrosis. The diagnosis of tuberculosis in the presence of silicosis is difficult; this complication should always be considered and frequent sputum cultures should be obtained.

The diagnosis of acute silicosis is more difficult than that of classic nodular silicosis because the radiographic changes are less characteristic and the clinical course more rapid. Idiopathic alveolar proteinosis, acute allergic alveolitis, and tuberculosis have to be considered in the differential diagnosis. A careful occupational history with evidence of exposure to high silica dust levels is extremely important for the diagnosis of this form of silicosis.

Treatment

Although poly-2-vinyl-pyridine-1-oxide and polybetaine prevent silicosis in experimental animals, possibly by altering the surface charge on silica particles, the results of clinical trials have been unrewarding. Treatment of patients with silicosis by the inhalation of powdered aluminum was undertaken in the 1950s, but aluminum itself carries the risk of diffuse interstitial fibrosis. Thus neither of these forms of prophylactic treatment can be recommended. Potential future therapeutic strategies that have been proposed include inhibition of cytokines such as interleukin-1, TNF- α , and the use of antioxidants.⁹⁷ There is no specific treatment for established silicosis; therapy of complications, such as bronchitis and pneumonitis, is important to prevent rapid deterioration of functional status.

Prompt treatment of silicotuberculosis with regimens in which isoniazid, rifampin, and ethambutol are given together is most satisfactory. The treatment should be vigorous, carefully monitored, and longer than that for uncomplicated tuberculosis. Appropriate treatment for congestive heart failure always has to include the management of coexisting chronic obstructive bronchitis. No specific treatment is useful for rapidly progressive silicosis. In contrast, lipoproteinosis due to silica can be treated by bronchopulmonary lavage, which may be helpful in clearing the alveoli of the deposited particles,⁹⁸ and by steroid therapy to suppress the inflammatory reaction.

Prognosis

The prognosis for nodular silicosis is relatively good, particularly if the progression of the disease is slow. For rapidly progressing silicosis, early death is almost the rule. Lipoproteinosis may resolve spontaneously without treatment or may improve rapidly after removal of free silica from the lung by bronchopulmonary lavage. There is some evidence that lipoproteinosis proceeds to diffuse fibrosis if left untreated.⁹⁹

Control and Prevention

The recognition of the silicosis hazard and stringent dust control engineering measures are essential. Frequent monitoring of airborne dust levels is needed to ensure a safe working environment. The effectiveness of dust control measures in preventing silicosis has been emphasized dramatically by the reduction in silicosis in Great Britain and the European Economic Community since sandblasting was outlawed. A special effort is necessary to avoid exposure to cristobalite and tridymite, which are produced in the calcining of silica within diatomaceous earth, fuller's earth, and particularly in the regrinding of broken or salvaged refractory brick, in the scaling of boilers, and in steel foundries. Reduction of exposure to quartz above the threshold limit value of

$$\frac{10 \text{ mg/m}^3}{\% \text{SiO}_2 + 2}$$

would reduce the silicosis attack rate considerably. The NIOSH has proposed a further reduction of the time-weighted average silica exposure to 50 $\mu\text{g}/\text{m}^3$. The effects of dust levels on other workers in the area must be considered because even if sandblasters or brick grinders are protected by appropriate respirators, workers in other trades within the same area may be affected. Failure to apply occupational standards to workplaces employing five or fewer workers also has resulted in cases of silicosis. In addition, it appears essential to regard silica in quantities of 5% or less within other rock, such as limestone, kaolin, gypsum, graphite, or portland cement, as important and capable of producing disease if total dust concentrations are as high as they often are in mining or other operations. The problem of silica exposure in foundries is well known and may require changes in technology to bring it under control. Personal respiratory protection is valuable when it is otherwise impossible to control environmental dust levels.

Health Significance of Metal Exposures

Philippe Grandjean

The term metal has important meanings in physics and chemistry. In environmental medicine, arsenic and selenium are often considered part of the metals group. Nutritionists often refer to trace metals as those constituting less than 1 g of the human body, an arbitrary limit which would exclude iron. Although “toxic metals” is a common term, all metals may actually exert toxic effects, and the dose and time of exposure determines whether or not toxicity ensues. Frequently, heavy metals (with a gravity of 4 g/cm³ and above) are considered most important with regard to adverse health effects. This belief stems from the observation that the toxicity of the metals tends to increase toward the right and bottom of the periodic table, where the molecular weight of elements increases. However, increased atomic number and increased gravity are of little medical significance and would not account for the toxic potential of beryllium. Instead, the relative toxicity on a molar basis would seem to be related to the affinity to various ligands and the resulting biochemical activity. On the basis of such considerations, metals may be separated into hard metals (class A), with a lower affinity toward sulfur and nitrogen than toward oxygen, and the soft metals (class B), where the opposite is the case.¹ Among the metals considered in this chapter, aluminum and beryllium belong to the generally less toxic class A, while the other metals are either borderline or class B metals.

In contrast to organic compounds, which may be broken down by detoxification processes, metals will remain metals. However, some changes may occur due to oxidation/reduction, as with mercury vapor and chromate, and most metals will be bound to organic compounds, notably proteins such as metallothionein. Some metals form rather stable organometal compounds with a covalent bond between carbon and the metal. Some organic compounds, such as tetraethyl lead and tributyltin, are dealkylated in the body. On the other hand, methylation in the liver is an important part of arsenic and selenium kinetics. These metabolic processes affect the toxicity and may vary between individuals.

When present as airborne particles, retention in the airways is governed by physical principles related to the aerodynamic diameter of the particles. Some metal compounds are corrosive and exert their effect on the mucous membranes. Such is the case with osmium tetroxide and zinc chloride. In other situations, systemic effects, whether mediated by oral or respiratory intake, are most important and will then depend on the amount absorbed. Solubility of metal compounds is of major significance and, in the gut, some interaction between metals may occur. Thus, zinc and copper tend to mutually inhibit the absorption of the other metal. The same appears to be true for iron and cobalt, but the absorption of several divalent metals is increased in iron deficiency. In addition, phosphate and other components may decrease the absorption, due to formation of insoluble

compounds. The variability is illustrated by the fact that gastrointestinal absorption of lead sulfide is barely detectable, while a soluble compound ingested during a fasting period may result in a 50% absorption rate.

Exposure potentials have increased considerably due to the development of metallurgy and associated processes and due to the contamination from energy production. Chemical elements that are rare in the earth's crust may now result in heavy exposures of workers, neighbors, and consumers. In comparison with atmospheric emissions from natural sources, air pollution with lead from human activities is more than 10-fold greater, and the amounts of cadmium, zinc, and several other metals in anthropogenic air pollution are also comparatively large. Table 26-1 shows a provisional grouping of some metals, according to their abundance and annual production rate. Although only major tendencies would appear from such crude grouping, the rarer metals seem to cause much less prevalent exposures than do the metals that are common in the earth's crust. However, production figures tend to increase, in particular for aluminum, molybdenum, nickel, and rare earths.

When the intake of iron, zinc, or other essential metals is insufficient, signs of deficiency may develop. Many of these cases have occurred as part of multiple nutrient deficiencies or as a result of long-term parenteral nutrition. Refined food in general tends to be an insufficient source of essential minerals.

When toxicity is compared, the rarer metals appear to be more toxic than elements that are more common components of the earth's crust and the “natural” environment. In Table 26-1, the molar limits for occupational exposure have been used for classifying metals into three groups with different toxicities. A similar grading of the toxicity could be based on LD₅₀ values from animal experiments.

In preventive medicine, the target organ, sometimes referred to as the critical organ, is of special importance, as the earliest effects of metal toxicity are said to originate from this location. As a consequence, if effects in the target organ can be prevented, no other toxicity should be expected. However, prevention becomes somewhat more difficult when considering that the critical effect of respiratory exposure to some chromate or nickel compounds is respiratory cancer; such stochastic effects may be fully prevented only if exposures are effectively eliminated. Other complex problems relate to the prevention of contact dermatitis in individuals who have developed metal allergies; even oral intake of the offending metal can induce or worsen the hand eczema in these patients. Individual susceptibility must therefore be taken into account. In this regard, interactions between metals are also of importance. Thus, at least in experimental studies, zinc supplements may prevent cadmium toxicity, and selenium may potentially protect against mercury toxicity.

TABLE 26-1. NATURAL OCCURRENCE, PRODUCTION, AND HEALTH SIGNIFICANCE OF METALS, AS INDICATED BY APPROXIMATE GROUPING OF RELEVANT PARAMETERS

<i>Abundance in Earth's Crust</i>	<i>Annual Production</i>	<i>Occupational Exposure Limit</i>	<i>Significance of Daily Oral Intake</i>
I. Common ($>10^{-2}$ mol/kg) Al, Fe, Mg, Mn, Ti	I. Large ($>10^{11}$ mol/yr) Al, Cu, Fe, Mg, Mn, Zn	I. High ($>10^{-4}$ mol/m ³) Al, Fe, Mg, Ti, Zn	I. Deficiency recorded Cr, Cu, Fe, Mg, Se, Zn
II. Medium (10^{-4} – 10^{-2} mol/kg) Ba, Be, Co, Cr, Cu, Ni, V, Zn, Zr	II. Medium (10^9 – 10^{11} mol/yr) Ba, Cr, Mo, Ni, Pb, Sb, Sn, Ti, Zr	II. Medium (10^{-6} – 10^{-4} mol/m ³) As, Ba, Be, Cd, Co, Cr, Cu, Mn, Mo, Ni, Sb, Se, Sn, Ta, V, W, Zr, rare earths	II. Unknown or no significance Ag, Al, Be, Mn, Mo, Ni, Os, Pt, Sb, Sn, Ta, Te, Ti, Tl, V, W, Zr, rare earths
III. Rare ($<10^{-4}$ mol/kg) Ag, As, Cd, Hg, Mo, Os, Pb, Pt, Sb, Se, Sn, Ta, Te, Tl, U, W, rare earths	III. Low ($<10^9$ mol/yr) Ag, As, Be, Cd, Co, Hg, Os, Pt, Se, Ta, Te, Tl, U, V, W, rare earths	III. Low ($<10^{-6}$ mol/m ³) Ag, Hg, Os, Pb, Pt, Te, Tl, U	III. Environmental toxicity recorded As, Ba, Cd, Co, Hg, Pb, U

As preventive efforts become more efficient, the patterns of adverse effects change and, in fact, become more difficult to recognize. Most metals accumulate in the body, and storage depots or "slow compartments" may slowly release metals to the blood or may actually be the site of delayed toxicity. The resulting insidious, delayed effects are often hard to detect, also for the patient. In the absence of pathognomonic symptoms and a history of a recent hazardous exposure, an etiologic diagnosis may be almost impossible to verify.

The diagnosis of metal poisoning has been frequently supported by the detection of increased or toxic levels of the metal in blood or urine. Methods have now been further refined and become routine parameters for biological monitoring of metal exposures.² Special care is needed when collecting blood and urine samples to avoid external contamination.³ Recent developments have included more sensitive analyses and methods for *in vivo* detection of cadmium and mercury in kidney and liver, for measurement of lead levels in calcified tissues, and for assessment of various biochemical abnormalities, which indicate early biological effects of metal exposures. Biological monitoring will become an essential part of future preventive activities with regard to environmental and occupational metal exposures. However, because metals are ubiquitous and often disseminated through a multitude of pathways, the sources of human exposures must be known before a preventive strategy can be planned. Attention must also be paid to intakes from mineral supplements and from the use of metals in pharmaceuticals and traditional medicines.

In the following pages, the metals of greatest public health significance are dealt with in alphabetical order. The general outline includes: environmental occurrence, uses, exposure sources; absorption and fate in the human organism; essential functions and toxic effects in humans; preventive measures; and limits applicable. Relevant publications from the International Programme on Chemical Safety and from the International Agency for Research on Cancer are mentioned, but otherwise references have been limited to a few recent key studies or reports. For more detailed information and reference to additional literature sources, some most recent edition of the standard handbook should be consulted.⁴

▶ ALUMINUM

Exposures

Aluminum is a silvery-white, light, ductile metal with a high resistance against corrosion and used in light metal alloys, in particular with magnesium. Kitchenware, aluminum foil, and automobile bodies are important uses, and the aircraft industry is one of the major consumers. The most intense occupational exposures occur in the aluminum refineries, where the metal is produced by electrolysis of aluminum oxide dissolved in molten cryolite. Refinery and foundry workers, welders, and grinders working with aluminum or its alloys may be exposed to high levels of aluminum fumes or particles. Aluminum

chloride is used in petroleum processing and in the rubber industry, and alkyl compounds are used as catalysts in the production of polyethylene. Other aluminum compounds are also widely used, notably for flocculation of drinking water.⁵

Aluminum compounds in soil are soluble at low pH values (below six) (e.g., caused by acidification). Soft drinking water may also dissolve traces of aluminum flocculants used in municipal water treatment. In such cases, the aluminum concentration may occasionally exceed 1 mg/L, but otherwise the concentrations in water are usually well below 100 µg/L, and drinking water is then an insignificant source of exposure. Among food items, meat products and vegetables may exhibit relatively high levels; the total daily intake through food and beverages is generally about 10 mg. Sources of excess exposures include aluminum silicate used as an anticaking agent and aluminum powder used for decorating pastry. Small amounts may be released from aluminum pots and pans at low pH levels, especially when acid foods are stored. Ulcer patients may ingest several grams of aluminum hydroxide every day in their antacid medicine.

Aluminum is barely absorbed from the gastrointestinal tract, probably because sparingly soluble aluminum phosphate is formed. Patients who ingest aluminum-containing antacids appear to absorb about 0.1% of the amount ingested. Concurrent intake of fruit juices may substantially increase the absorption. Inhalation of fine aluminum dust can lead to retention in the alveoli, and the concentration of this metal in the lungs increases with advancing age. When released to the blood, aluminum appears to be effectively excreted, almost entirely in the urine.

Effects

Salts of aluminum are irritants because acid is liberated on hydrolysis. Thus, conjunctivitis, eczema, and upper airway irritation may result, and even local necrosis of the cornea has been recorded. A form of pneumoconiosis, sometimes called aluminum lung or aluminosis, is associated with severe exposures to aluminum oxide; the most frequent symptoms are dyspnea and dry cough. Unilateral pneumothorax has been seen more often than expected in workers exposed to aluminum dust.

Aluminum exposure may cause neurotoxicity, particularly in patients undergoing dialysis.⁵ Due to the deficient excretion of aluminum in the urine of these patients, accumulation in the body occurs from small amounts from the dialysis water and if aluminum hydroxide gels are used to decrease phosphate absorption in the gut. In particular, aluminum accumulates under those circumstances in the brain and seems to be at least a partial cause of dialysis dementia. The early symptoms are speech impairment and dysphasia, followed by myoclonic movements, seizures, and progressive global dementia with prominent symptoms from the parietal lobe. This disease appears to be irreversible, and survival beyond a few years is uncommon. The introduction of calcium-based phosphate binders and reverse osmosis for water purification has effectively eliminated this problem.

In addition, aluminum seems to accumulate, although to a much lesser extent, in the brain of patients with Alzheimer's disease. This accumulation may be a phenomenon secondary to the disease development, and the possible causative role of aluminum has not yet been determined. A different type of encephalopathy may develop as an apparent result of heavy occupational aluminum exposure. Thus, aluminum is undoubtedly neurotoxic, but the extent to which this occurs in individuals with normal kidney function still has to be clarified.

Dialysis osteomalacia is a complication that has occurred rarely in patients undergoing long-term dialysis treatment; it causes development of sclerosis and osteoporosis, leading to skeletal pains and multiple fractures. The occurrence of this disease was closely associated with long-term aluminum accumulation. Bone toxicity has also been described in patients receiving chronic parenteral nutrition containing aluminum-contaminated case in hydrolysate and in patients who had ingested large doses of aluminum-containing antacids for extended periods.

Prevention

Aluminum measurements of serum are extensively used in the monitoring of patients undergoing dialysis treatment. Although high levels of aluminum may be accurately estimated by most laboratories, reference levels have decreased significantly indicating an improved contamination control in the laboratories. Serum levels below 10 $\mu\text{g/L}$ (0.37 $\mu\text{mol/L}$) are usually considered normal. In the past, serum concentrations in dialysis patients could exceed 50 $\mu\text{g/L}$ (1.85 $\mu\text{mol/L}$), and the risk of adverse effects of aluminum was much increased if the serum level exceeded 100 $\mu\text{g/L}$ (3.7 $\mu\text{mol/L}$). Aluminum has a short biological half-life in the blood of individuals with normal kidney function, thus rendering aluminum measurements of serum samples of limited value in occupational health practice. However, urinary excretion of aluminum reflects short-term exposures, while a better indication of the chronic accumulation is the excretion after an exposure-free interval of several days. A measure of the body burden is the concentration in a bone biopsy from the iliac crest.

Aluminum toxicity in dialysis patients can be prevented by using dialysis water with an aluminum concentration below 10 $\mu\text{g/L}$ (0.37 $\mu\text{mol/L}$) after reverse osmosis or other effective treatment. Also, substitution of oral aluminum-containing phosphate binders by calcium-based compounds has been widely instituted. Solutions used for parenteral nutrition should be examined for aluminum contents, and low-level products should be preferred. Desferrioxamine has only limited therapeutic use as an aluminum chelator.

In the United States, aluminum is regulated as an inert dust, with an exposure limit of 15 mg/m^3 for dust and 5 mg/m^3 for respirable particles. This limit may not entirely protect against adverse effects. The limits recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) are: 10 mg/m^3 for aluminum metal and oxide, 5 mg/m^3 for aluminum pyro-powders and welding fumes, and 2 mg/m^3 for soluble aluminum salts and (unstable) aluminum alkyls.

► ANTIMONY

Antimony is used for various alloys with lead and other metals, for semiconductors, and for thermoelectric devices, and antimony compounds are widely employed, especially as pigments and (antimony trioxide) as a flame retardant in textiles. Occupational antimony exposures mainly occur in the nonferrous mining and refining of the metal and in the production of pewter, solder, storage battery plates, and babbitt metal. Coal combustion and waste incineration are additional major sources of anthropogenic emission. Exposure to antimony compounds has been reported in the glass industry and from the production of abrasives, textile dyeing, and handling of pigments and catalysts. Antimony-containing pharmaceuticals (e.g., against leishmaniasis and schistosomiasis) are still in wide use in certain parts of the world.

Adverse health effects seen in relation to occupational antimony exposures are difficult to evaluate, because concomitant exposures to arsenic often occurs. While cardiotoxicity has been documented as a side effect in antimony pharmaceuticals, electrocardiogram changes related to occupational exposures have only occasionally been reported. An increased mortality from ischemic heart disease in antimony smelter workers was suggested by one study, where the difficulty in obtaining a proper control population was emphasized. More commonly, antimony compounds have given rise to irritation of the mucous membranes, irritant eczema, and even chemical burns and perforation of the nasal septum. In particular, antimony trioxide frequently causes the so-called antimony spots (i.e., small, erythematous papules that develop under intense itching on exposed, moist skin areas in hot environments) that are fortunately short lasting. A benign pneumoconiosis is related to antimony exposures. The lung cancer risk may be increased by exposures to this metal, and a relation to increased frequency of abortions has been reported in one study.

In the presence of strong acid, stibine (SbH_3) may be formed. Storage battery workers and metal etchers may be exposed to this hazard. This gas is very toxic and causes severe hemolysis, shock, central nervous system (CNS) symptoms, and even death due to anuria.

Most antimony absorbed is rather rapidly excreted, Sb(V) mostly in the urine, Sb(III) mostly via the gastrointestinal tract. A slow compartment seems to exist, probably reflecting accumulation in liver and kidneys. Severe toxicity has not been documented at urine levels below 1 mg/L (8.2 $\mu\text{mol/L}$), but biological monitoring of antimony levels in blood and urine has so far been used only rarely. The limit for occupational antimony exposures is 0.5 mg/m^3 ; for stibine this level corresponds to 0.1 ppm.

Antimony exposure can, also, be medically assessed via measurement of antimony levels in hair, which have been found to increase with treatment of antimony compounds. However, monitoring of hair is not recommended, as there is always a risk of external contamination from the metal, which would not be distinguishable from absorbed antimony.

► ARSENIC

Exposures

Arsenic occurs widely in the environment, and dissolved arsenic compounds in groundwater can cause severe exposures from deep wells, especially in certain parts of South America, West Bengal, and Taiwan. Some crustaceans may contain as much as 100 mg/kg , but most arsenic in seafood occurs as less harmful organic complexes. Other food items usually contain little arsenic. Major sources of environmental pollution are primary metal smelters and coal burning.⁶

Occupational exposure to arsenic occurs in the following branches of industry: metal smelting, where arsenic occurs as a contaminant or by-product; production and use of various alloys, especially with lead and copper; semiconductor industry; production and use of wood treatment (chromated copper arsenate) and agricultural pesticides (e.g., calcium and lead arsenate); production of opal glass; certain kinds of enameling; production of pharmaceuticals; production of paints and coatings; leather tanning and the taxidermist industry; and the production, handling, analysis, etc., of arsenic and arsenic compounds. When arsenic-containing ores are heated, arsenic trioxide (As_2O_3 , white arsenic) is formed, and this compound constitutes the main product for the arsenic-consuming industry. Experimental studies suggest that this As(III) is more toxic than the As(V) , which occurs in arsenate compounds, for example, wood treatment products. Arsine (AsH_3) is particularly toxic. However, little is known about the speciation of arsenic in occupational exposures.

Easily soluble arsenic compounds may be absorbed rather efficiently through the respiratory and gastrointestinal tracts; absorption through the skin has also been documented. As(V) seems to be partially converted to As(III) . Methylation occurs in the liver, and the methylated arsenic species usually constitute the main part of the urinary arsenic excretion after exposure to inorganic arsenic compounds.

The methylation process varies between species and between human populations.⁷ Such variations may suggest genetic differences in the enzymes responsible for the methylation of arsenic, but the methylation rate may also be influenced by such factors as the arsenic species absorbed, dose level, age, nutrition, and disease. The extent to which variation in arsenic methylation affects its toxicity, including carcinogenicity, is not known. Arsenobetaine and arsenocholine from fish and crustaceans are relatively rapidly excreted unchanged in the urine. The biological half-life for inorganic arsenic in the body averages about four days; after an acute exposure to inorganic arsenic, the arsenic excretion in urine is therefore increased for a week or more. An additional, somewhat slower excretion occurs through hairs, nails, and skin cells. Both skin and lungs may constitute a “slow” arsenic compartment with a long biological half-time.

Effects

Acute intoxication due to ingestion of arsenic trioxide or lead arsenate first causes vomiting, colics, and diarrhea, then follows fever, cardiotoxicity, peripheral edema, and shock, which can lead to death within 12–48 hours. Patients who survive an acute intoxication usually exhibit anemia and leukopenia and may experience peripheral nervous damage 1–2 weeks later. Late effects include loss of hair and nail deformities. Recovery from peripheral neurotoxicity is slow and may take several months. Neonatal exposure to arsenic from contaminated milk supplements has caused severe developmental neurotoxicity that resulted in permanent cognitive deficits. Anecdotal evidence suggests that long-term intake of small amounts of arsenic can lead to a decrease in acute toxicity, but the mechanism of this apparent tolerance is not known, as is the possible implication for chronic toxicity.

Another kind of acute poisoning may occur following inhalation of the extremely toxic arsine (AsH_3), which smells like garlic. This compound is formed when arsenic (frequently as an impurity) comes into contact with strong acid, and prolonged inhalation of 10 ppm or more of arsine is lethal. The patient first suffers dizziness, headache, pains in the stomach, arms, and legs and subsequent hemolysis, jaundice, and kidney damage, which may lead to death.

Under chronic exposure conditions, neuropathy mainly of sensorimotor type may develop and cause paresthesias in the extremities and neuralgic pains, but muscle weakness, especially in the fingers, and motor incoordination may also occur. These effects may occur as a late result of an acute exposure or as a result of a long-term exposure to arsenic, where chronic skin symptoms may occur at the same time. A subclinical neuropathy, detectable by neurophysiological methods, has been described in relation to relatively low arsenic exposures. Accidental arsenic exposure from contaminated milk powder caused over 100 deaths in infants and lasting mental retardation and other neurological effects in survivors. Long-term exposure to inorganic arsenic compounds can cause chronic eczema, hyperpigmentation of the skin, and hyperkeratosis, especially on foot soles and palms.

Development of skin cancer may be seen at a later time: squamous cell carcinomas mostly at the hyperkeratoses on the extremities, basal cell carcinomas in any region. Vascular effects may result in Raynaud's phenomenon, acrocyanosis, and necroses (“blackfoot disease”). In addition, epidemiological studies in Taiwan, Chile, and Argentina have shown increased incidence of bladder cancer and lung cancer.⁷ Similar findings have emanated from studies of pesticide production workers, sprayers, smelter workers, residents near polluting industries, and patients treated with arsenicals. The incidence of other cancer forms may be increased as well, though this evidence is less certain. In most studies, the exposures were mixed, and the effects of As(III) and As(V) cannot be separated. Arsenic may act synergistically with tobacco smoke. Teratogenic effects have also been reported.

Prevention

Biological monitoring of arsenic levels in blood is of limited interest, because arsenic is rapidly cleared from the blood. Hair analysis has been employed in forensic medicine, but the significance of external contamination excludes the use of this method in the surveillance of

dust exposures in industry. Measurement of arsenic levels in urine may be used for the evaluation of current exposures, because a major part, about 60% at steady-state, of the absorbed arsenic is excreted in the urine. However, due to the somewhat variable proportion excreted by this route, the daily variations related to the short biological half-life and the contribution of arsenic compounds from food items, urine tests for total arsenic are useful only on a group basis. If the excretion is above 1 mg/L (13 $\mu\text{mol/L}$), the result can be used as an indication of arsenic intoxication. Normally the arsenic content in urine is below 100 $\mu\text{g/L}$ (1.3 $\mu\text{mol/L}$), but levels more than twice that high may be seen after a good seafood meal. After exposure to inorganic arsenic compounds, the urinary arsenic usually consists of no more than 25% inorganic arsenic, one-third of the rest being monomethylarsonate, and two-thirds being dimethylarsinate (cacodylate). Background levels of these compounds would probably be below 20 $\mu\text{g/L}$ (0.27 $\mu\text{mol/L}$), unless exposures from contaminated wells were prevalent. The organoarsenicals from seafood do not affect the urinary excretion of the methylated compounds.

The limit for airborne arsenic and inorganic arsenic compounds is 0.01 mg/m^3 ; for organic compounds, 0.5 mg/m^3 ; and for arsine the limit is 0.05 ppm, which corresponds to 0.2 mg/m^3 . However, on the basis of the carcinogenic effects, the National Institute of Occupational Safety and Health (NIOSH) has recommended a limit of 0.002 mg/m^3 for all arsenic compounds; exposures below this limit would result in minor or undetectable increases of arsenic levels in urine. A WHO/FAO expert group has suggested a limit for daily intake of inorganic arsenic of 0.002 mg/kg body weight. The U.S. Environmental Protection Agency uses a drinking water limit of 10 $\mu\text{g/L}$.

► BERYLLIUM

Beryllium, the fourth lightest element, is extracted from beryl ore and is found at low concentrations in the Earth's crust. Beryllium is used for coating of cathode-ray tubes (e.g., for radar equipment, in electrical or electronic instruments, and in nuclear reactors). Moreover, beryllium is used in many light metal alloys for the space and aircraft industry, and for the nuclear industry. Most of the environmental pollution is due to combustion of fossil fuels.⁸

Most beryllium salts are practically insoluble at neutral pH, and absorption after oral intake is therefore limited. Skin contact may result in allergic dermatitis. Inhalation of beryllium dusts is the major hazard. Once absorbed, excretion is slow. An acute, severe exposure to airborne beryllium may result in an inflammation of mucous membranes and in a chemical pneumonia.

Chronic beryllium disease (sometimes called berylliosis) has similarities to sarcoidosis, and the differential diagnosis may require documentation of beryllium exposure.⁸ This pulmonary granulomatosis can evolve following an acute phase by a long but variable latency period. Often the diagnosis is made several years after cessation of exposure. Cases have occurred in several household contacts and subjects with only short-term exposures. The most frequent symptom is dyspnea at exertion. The chest x-ray usually reveals a mixture of small, rounded, and irregular opacities. Pulmonary function tests show decreased diffusion, later followed by more generalized pulmonary impairment. Granulomas may also occur in the liver and other organs, but the Kveim test for sarcoidosis is negative, while the lymphocyte blast transformation test is positive for beryllium. The course of the disease is irregular, and some form of predisposition seems to affect the pathogenesis. Although steroid treatment is beneficial, no complete recovery has been recorded. Beryllium is regarded a human carcinogen based on epidemiological evidence from refining, machining, and production of beryllium metal and alloys, where beryllium-exposed individuals suffer lung cancer more frequently than expected.⁹

Biological monitoring is of limited interest and plays no role in the prevention of excess beryllium exposures. The limit for occupational beryllium exposure is 0.002 mg/m^3 , but efforts have been made to decrease this limit by a factor of 10. The peak value of 0.025 mg/m^3 is applied for short exposures.

► CADMIUM

Exposures

Cadmium concentration in agricultural soils is increasing because of the deposition of airborne cadmium particles and because of the cadmium content of phosphate fertilizers and sewage sludge used for fertilization. Cadmium is a relatively mobile metal in soils, and many crops retain relatively high cadmium levels. In particular, tobacco leaves are high in cadmium. The total daily intake of cadmium via food varies according to dietary habits, but averages range from less than 10 to more than 50 $\mu\text{g}/\text{day}$. Cereals, mollusks and crustaceans, wild mushrooms, and beef kidney are main sources of increased dietary cadmium exposure.¹⁰

The most important application of this metal is cadmium plating for corrosion treatment of metals, especially iron and steel. Brazing is still carried out with solders containing cadmium. Rechargeable nickel-cadmium batteries are increasingly used in modern-day electronic products. To a limited degree, cadmium is also used in certain copper alloys and in bearing metal. Cadmium rods are used in nuclear power plants. Cadmium sulfide and selenide are used as pigments in enamel, ceramics, glass, plastic, and leather. Many of these uses are now being restricted. However, considerable occupational cadmium exposure may still be a result of various work processes, such as welding or cutting of metals with cadmium-containing coatings, spray-painting with cadmium pigments, or primary production of copper and zinc from cadmium-containing ores. Raw phosphate often contains significant amounts of cadmium, and exposures may occur during the production of phosphate fertilizers. This metal has a melting point of 320°C, and dangerous fumes are generated by rather low temperatures.

Pulmonary absorption depends on particle size and solubility, while 2–10% of oral intake is transferred to the bloodstream. Uptake by the liver induces the synthesis of metallothionein, which binds cadmium. When released to the blood, the complex is subsequently excreted through the kidney glomeruli; most is reabsorbed by the tubulus cells, and an accumulation in the kidney cortex takes place. In general, about one-half of the human body burden of cadmium is located in liver and kidneys. The liver is the main storage organ for cadmium in the body, but the highest concentration is eventually reached in the kidneys. The biological half-life is 10–20 years, and cadmium accumulation in the body therefore seems to occur during the major part of a lifetime.

Effects

Acute cadmium poisoning most frequently occurs after inhalation of cadmium fume, for example, cutting cadmium-plated steel with an oxyacetylene torch. After a latency of a few hours, the first symptoms may suggest metal fume fever, but a toxic pneumonitis then develops. Recovery is often slow and may take months; several years after acute cadmium pneumonitis, progressive pulmonary fibrosis has been observed. Oral cadmium exposure may cause acute poisoning, for example, when large amounts of the metal have been released from solder materials in soft-drink machines or from ceramic glazes of kitchenware.

The chronic form of cadmium poisoning is a result of long-term accumulation in the body, where the kidneys constitute the target organ. The toxic damage mostly seems to occur in the proximal tubuli, but glomerular changes often appear at a later state and may even in some cases be the first indication of cadmium-induced nephropathy. The first sign of kidney dysfunction is usually an increased excretion of low-molecular proteins in the urine, notably β_2 -microglobulin and the more stable α_1 -microglobulin (protein HC). In case of glomerular dysfunction, larger proteins also occur in the urine. Low-level environmental exposure to cadmium is related to increased urinary leakage of small proteins, and subjects above 60 years and patients with diabetes may be at an increased risk of cadmium nephrotoxicity.¹¹

Subsequent losses of protein and minerals, and disturbances of vitamin D metabolism, may lead to skeletal changes as seen most

dramatically in Japan where a large number of cadmium-exposed patients suffered osteomalacia with skeletal pains and pseudo-fractures, the so-called itai-itai disease. Environmental cadmium exposures at low levels are associated with decreased bone mineral density and increased risk of bone fractures. Thus, environmental cadmium pollution may accelerate age-related declines of both renal function and bone density.

Long-term inhalation of cadmium can lead to emphysema, and this outcome may also be of importance in regard to cadmium retention in the lungs of smokers. Experimental animal studies show that pulmonary exposure to cadmium compounds may cause lung cancer, and epidemiological evidence on cancer of the lung, prostate, and kidneys has confirmed that cadmium should be regarded a carcinogenic metal.⁹ Additional animal experiments suggest that this metal may be a teratogen.

Prevention

The cadmium level in the blood is an indication of the current exposure (during the last few months) and is frequently used for biological monitoring. Levels up to 10 $\mu\text{g}/\text{L}$ (89 nmol/L) may occur in heavy smokers, while never-smokers usually show levels below 1 $\mu\text{g}/\text{L}$ (9 nmol/L). For industrial exposures, a recommended limit for blood cadmium is 5 $\mu\text{g}/100\text{ mL}$ (44 nmol/L), but this limit will not protect against kidney damage under long-term exposure conditions. Urinary excretion of cadmium is limited in the beginning, and immediate increases occur only under rather heavy exposures. High urinary cadmium levels are found when the kidneys over a long period have accumulated large amounts of cadmium, which then start to leak. If the exposure continues, tubular and perhaps glomerular dysfunction develops, and relatively large amounts of cadmium are then excreted in the urine. The most recent data from Sweden suggest that the earliest effects may occur at a urine-cadmium excretion below 1 $\mu\text{g}/\text{L}$,¹¹ and levels continuously above this limit should therefore be avoided. β_2 -Microglobulin and protein HC may be assessed in urinary samples as part of monitoring efforts, but excess levels are found only in case of early or imminent kidney damage, that is, when preventive efforts have failed.

The occupational exposure limit in the United States is 0.005 mg/m^3 due to the carcinogenic risk.⁹ Many countries have enacted regulations concerning cadmium release from ceramic glazes and other materials that may leach cadmium to food and beverages. The International Standards Organization (ISO) has adopted a limit for cadmium release from ceramic flatware of 0.17 mg/dm^2 , with higher limits for hollowware. With regard to dietary intake of cadmium, a WHO/FAO expert group several years ago suggested a Provisional Tolerable Weekly Intake (PTWI) limit of 7 $\mu\text{g}/\text{kg}$ body weight per week. Since then, kidney function in the elderly and diabetes patients has turned out to be more vulnerable than expected, and lifelong cadmium accumulation from environmental exposures would seem to eventually cause adverse effects, perhaps substantially below the PTWI. However, even the current PTWI seems already to be exceeded by some population groups, and prevention of cadmium pollution from all sources would therefore seem to be a major environmental priority.

► CHROMIUM

Exposures

Chromium most commonly occurs as trivalent compounds. Divalent compounds are rather unstable, and hexavalent chromates are reduced to trivalent compounds in the presence of oxidizable substances. Only scattered information is available on environmental exposures to chromium. In the United States, daily intake through food is usually below 100 μg , but higher intake occurs in northern Europe. However, the chemical form of chromium present in food and drinking water is largely unknown, but soluble chromates likely predominate.

Occupational exposures to chromium occur in several branches of industry: production of chromium and chromium compounds,

stainless steel and other metal alloys; chromium plating of metals; production of heat-resistant bricks with chromate additives; use of chromates as pigments and bichromates for tanning; welding of chromium-plated metals and chromium-containing alloys; development of photographic emulsions; and production and usage of wood preservatives. The main consumption of chromium is in the steel industry, and stainless steel usually contains between 8% and 18% chromium. In addition, chromate present in cement results in considerable cutaneous exposures.

The gastrointestinal uptake of Cr(VI) is a few percent, while the absorption of Cr(III) is much less; organic complexes of chromium may be more easily absorbed. The fate of inhaled chromium particles and the transfer within the body depends on the particle size and solubility of the compounds. Excretion is mainly via the urine.

Effects

Chromium is an essential trace metal (as glucose tolerance factor) for several species, including humans. Glucose intolerance, weight loss, and peripheral neuropathy in patients undergoing long-term intravenous nutrition may be cured by Cr(III) supplements. Chromium deficiency in humans is otherwise unknown, and the daily chromium need is unclear.

The toxicity of the various chromium compounds varies, partly in relation to the different solubilities.¹² In general, hexavalent compounds are more easily soluble than the trivalent compounds. The chromate ion is strongly oxidizing and is capable of passing through biological membranes. Trivalent chromium is less toxic, apparently due to the lower solubility and lower biological mobility. The major effects include corrosion of skin and mucous membranes, allergic responses, and carcinogenicity.

Long-term inhalation of Cr(VI) compounds in chromium-plating workshops has in the past caused severe corrosion of the nasal mucous membranes with defects in the nasal septum. These effects are now seen more rarely. Chromate may cause circumscribed ulcers (chrome holes) at the knuckles, nail roots, or other exposed skin areas. Even though they may be quite deep, they are almost painless. Healing often takes several weeks and leaves a depressed scar, but the ulcers are apparently not related to development of skin cancer.

Chromium is one of the best known allergens in the occupational environment, and chromate is frequently the most common cause of allergic contact dermatitis among males. Cement eczema is a common occupational disease in construction workers, and chromate is the most frequent cause of allergic hand eczema in occupational health, with high prevalence rates in tanners, furriers, and workers exposed to chromates in photographic laboratories and in relation to wood treatment. Chromate has also been identified as a cause of asthma, probably mediated by a type I allergic reaction. Chromite mining has apparently caused several cases of a benign pneumoconiosis.

Chromium is a well-documented human carcinogen, and occupational exposures resulting from the production of ferrochrome and of chromates have caused an increased frequency of cancer in the respiratory tract.^{12,13} An increased occurrence of lung cancer in welders may be due to the content of insoluble chromates in welding fumes from stainless steel. Although trivalent chromium compounds may be involved in the carcinogenesis, exposures to such compounds have not been shown to cause cancer in epidemiological studies.

Prevention

Biological monitoring of chromium levels in the urine is useful to follow the exposure to soluble, hexavalent chromium compounds. The biological half-time in plasma is a few days. When external contamination of the sample has been avoided, the upper reference level is usually about 0.5 µg/L (10 nmol/L). Plasma chromium levels parallel the urinary excretion, but chromium concentrations in erythrocytes or whole blood reflect longer-term chromate exposures. Exposure to trivalent compounds or sparingly soluble chromates will not result in detectable changes in body fluids available for biological monitoring.

The exposure limit for airborne chromate and chromium acid is a ceiling value of 0.1 mg/m³; for soluble chromic and chromous salts, the limit is 0.5 mg/m³; and for chromium metal and insoluble chromium salts, 1 mg/m³. Cr(VI) compounds are regarded as carcinogenic, and a permissible exposure limit of 0.001 mg/m³ has been suggested by NIOSH. Skin contact with Cr(VI) compounds should be avoided, and any skin contamination should be immediately removed with soap and water. This problem is even more important for patients with chromate allergy who may have to avoid contact with leather products and plastic articles with leachable chromate pigments. The sulfur on matchsticks contains chromate as well. On the other hand, chromium alloys release only insignificant amounts because of oxide formation in the surface layer. In some countries the addition of 0.4% of ferrous sulfate to the cement is required by law, because it effectively reduces the chromate to insoluble Cr(III) compounds. WHO has for many years recommended a drinking water limit of 0.05 mg/L for total chromium, but lower concentrations can easily be maintained in most places.

► COBALT

Human cobalt exposures from natural sources are very limited, and daily intake through food has usually been estimated at somewhat below 50 µg. Cobalt levels in drinking water are usually low and of little concern, and atmospheric levels are frequently undetectable.

Occupational exposures have become prevalent.¹⁴ The most important use is *hard metal*, which consists of various metal carbides (mainly tungsten) cemented by a cobalt binder. Cobalt has also found considerable use in alloys, to which it adds a high melting point, tensile strength, and resistance to corrosion. Cobalt compounds are increasingly used as catalysts, including desiccators in paints. Cobalt pigments are used in ceramic and glass products. The alloys are extensively used in the electrical, automobile, and aircraft industries, and cobalt is also used for electroplating.

Absorption in the gastrointestinal tract varies, but probably averages about 25% for soluble compounds, unless cobalt is ingested in the form of vitamin B₁₂, and in iron deficiency, which increased the absorption of cobalt. Ingestion of excessive amounts of cobalt will induce vomiting and diarrhea.

Cobalt is an essential micronutrient and has important actions as an enzyme activator and as a component of vitamin B₁₂. However, cobalt deficiency has not been documented in humans, but enzootic deficiency is a potential problem in certain regions of the United States, Australia, Scotland, and other parts of the world. Thus, cobalt is added to cattle feed and sometimes to fertilizers.

Respiratory exposure to cobalt dust may lead to airway irritation, asthma, and measurable systemic absorption. Cemented carbide production workers may develop a pneumoconiosis called hard metal lung, frequently following long-term exposures of more than 10 years. The pathogenesis of cobalt-induced pulmonary disease is not known in detail, but some individual hypersensitivity may predispose to the pulmonary reactions. Some studies suggest that cobalt exposure may lead to an increased risk of lung cancer.

Cutaneous exposures to cobalt are common. Small concentrations of this metal are present in cement, and cobalt may contaminate cutting oils and may leach from metal objects. Cobalt allergy is frequent, but occurs frequently in connection with allergy toward nickel or chromate. Hand eczemas in patients with such cross-reactions have a relatively poor prognosis.

An outbreak of cardiomyopathy, sometimes complicated by pericardial effusion, was reported in Quebec City about 1970.¹⁵ This disease occurred exclusively in beer drinkers, and subsequent investigations showed that the local brewery added cobalt sulfate to the beer. The same practice was discovered in Omaha, Minneapolis, and in Brussels, where similar epidemics occurred. Although probably not solely due to the addition of about 1 mg of cobalt to each liter of beer, the epidemics faded after discontinuation of the addition of cobalt. Several similar cases have been linked to industrial cobalt exposures.

Biological monitoring may be of some use.¹⁴ The kinetics of cobalt in the organism show the existence of two fast compartments with half-lives of up to 2 days, while about 10% of absorbed cobalt is excreted much more slowly. Urinary cobalt excretion levels are normally below 2 µg/L (30 nmol/L), unless the individual takes a mineral supplement. Following occupational exposures, urinary excretion levels may be 100-fold the normal upper limit, but the levels may change rapidly due to the short half-life. Thus, more information may be obtained on the average long-term exposure by measuring the cobalt level in urine or blood on Monday morning after an exposure-free period.

Occupational exposures to cobalt metal fume and dust should be limited as much as possible while respecting the current exposure limit of 0.1 mg/m³. Due to the increasing awareness concerning hard metal disease, a limit of 0.05 mg/m³ for cobalt metal, dust, and fume has been proposed by ACGIH. Even this limit may not sufficiently protect a worker with pulmonary hypersensitivity, however.

► COPPER

Copper is a widely used metal that has both beneficial and adverse health effects. This metal is used in electrical equipment, in alloys, and in plumbing and heating systems. Acidic, soft water may leach copper from the tubings. The daily intake through food averages about 1 mg or more. Copper is an essential element that is necessary for various metalloenzymes, and possible signs of copper deficiency in humans have been documented in depletion experiments. Accidental intake of large amounts of this metal results in acute gastrointestinal symptoms. Copper sulfate has therefore been used as an emetic, but the potential absorption of toxic quantities of the metal limits its usefulness. Copper appears to play an etiological role in the development of so-called Indian childhood cirrhosis, but other factors, such as genetic predisposition are thought to be of importance. Anecdotal evidence suggests that infants given formula reconstituted with copper-contaminated tap water can develop a chemical hepatitis, but this possible risk has not been confirmed. Wilson's disease (hepatolenticular fibrosis) causes accumulation of copper in the liver related to insufficient formation of the copper-binding ceruloplasmin; these patients and the heterozygous carriers may be particularly sensitive to excess copper exposures. Also, patients with other pre-existing liver disease or undergoing hemodialysis may be more susceptible to copper storage disease. Occupational exposures to copper fume and fine dust can cause metal fume fever, and copper dust is a respiratory irritant. Serum concentrations are affected by ceruloplasmin levels and increase during pregnancy and during anticonceptive hormone treatment. Excretion is mainly via the bile. The exposure limit for copper dusts or mists is 1 mg/m³, and for copper fume, 0.1 mg/m³, although ACGIH has suggested 0.2 mg/m³ for fumes. WHO recommends a limit for drinking water of 2 mg/L. The recommended daily dietary intake is 2.3 mg for adults.

► IRON

Iron is necessary for life but may also cause toxicity at excess exposures. Iron deficiency with anemia is the most prevalent metal deficiency syndrome in humans, especially among women of the reproductive age groups and certain groups of small children. Several nutrients interfere with iron absorption, but it is always increased in case of deficiency. Ingestion of iron supplements in considerable excess (above 30 mg/kg body weight) may cause acute gastrointestinal lesions followed by metabolic acidosis, toxic hepatitis, and shock. Chronic iron overload, as in hereditary hemochromatosis, leads to hemosiderosis, potential liver cirrhosis, and increased cancer risk. Foundry workers, grinders, and welders are exposed to considerable quantities of iron oxide fume, which accumulates in the lungs and may result in siderosis, a benign pneumoconiosis. Hematite miners have exhibited an excess incidence of lung cancer; although iron may

not be the primary cause, an interaction between the iron dust and other factors, such as radon and asbestos, is possible. The exposure limit for iron oxide fume is 10 mg/m³, but ACGIH has recommended a limit of half as much and 1 mg/m³ for soluble iron salts. Recommendations for daily iron intakes suggest that iron supplements are necessary for large population groups, but the supplement should always be stored in child-proof containers.

Iron pentacarbonyl may be formed when carbon monoxide comes in contact with iron at high partial pressures. This liquid is extremely toxic and, when the vapor is inhaled, results in almost immediate headache, dyspnea, and dizziness. The symptoms then fade, only to return after several hours when pulmonary consolidation and cerebral degeneration are progressing. The ACGIH exposure limit is 0.1 ppm.

► LEAD

Exposures

Lead has a wide spectrum of applications. Metallic lead is used in various alloys, and several inorganic compounds have important uses. Production of organolead compounds, tetraethyl lead and tetraethyllead, as octane boosters in gasoline has now almost ceased. The extensive use of lead resulted in considerable redistributions in the biosphere, particularly as a result of air pollution from leaded gasoline. Calculated natural lead exposures suggest that environmental lead exposures average 10- to 100-fold above typical exposure levels in premetallurgical times. Dietary lead intakes have decreased considerably in many countries as a result of the substitution of lead additives to gasoline. Daily oral intakes of lead are below 100 µg for adults, often averaging about 10 µg. The major sources of environmental lead exposure include: gasoline additives, lead-based paint, lead-soldered food cans, ceramic glazes, and industrial pollution. Drinking water levels may be of particular concern in soft water areas; where lead pipes are still in use, the highest lead concentrations occur in the "first draw" water in the morning.

The melting point for lead is 327°C, and hazardous evaporation results when the temperature exceeds about 500°C. This fact is of importance where lead is melted or molded in factories and workshops. Various inorganic compounds are used as pigments and desiccators, for corrosion treatment and enameling, and as an additive to glass and a stabilizer in polyvinyl chloride (PVC) plastic. Lead compounds that are used in ceramic glazes are usually fritted (i.e., aggregated as larger particles by preheating).

Occupational lead exposure occurs in particular in the following processes: primary production of lead from lead ores; secondary lead production from used automobile batteries and scrap metal; production of batteries; welding and flame cutting of lead-containing or minium-treated alloys; molding of lead-containing alloys in foundries; soldering with lead solder, if the temperature is too high; production of and spray painting with paints containing lead pigments and desiccators; addition of lead stearate as stabilizer in PVC plastic; batch mixing with lead compounds for the production of crystal glass; and grinding and sandblasting of lead alloys and coatings. High exposures have also been documented in instructors from indoor shooting ranges, in workers producing leaded panes, and in gunsmiths.

Inorganic lead compounds are absorbed only to a minor degree in the gastrointestinal tract of adults, usually about 10% or slightly less, somewhat higher during fasting and somewhat lower when excess calcium, phosphate, and phytate are present. However, the immature gastrointestinal tract is relatively permeable to lead, and balance studies in small children have suggested that oral intake may result in absorption rates of 30–50%.

Almost all lead in the blood is bound to the erythrocytes, and the lead content of serum or plasma is so low that it cannot be reliably measured by conventional analytical methods. Measurements therefore refer to the lead content of whole blood (or erythrocytes). Due to the low solubility of lead phosphate, lead accumulates in calcified tissues. About 95% of the lead burden of an adult person is located in

the skeleton, with a very long biological half-life related to the slow tissue remodeling rate. Skeletal lead is more mobile in children. Much less lead is present in the soft tissues, and the half-life is generally about 2 months. The brain probably constitutes an exception: lead that has passed through the blood-brain barrier has a biological half-life of more than a year. The placenta does not constitute any major barrier to lead passage, and the fetus is, therefore, exposed to lead through the mother. Some lead is excreted into the gastrointestinal tract, but the major excretion is via the urine. Only low concentrations of lead have been detected in human milk.

Effects

Lead is an important enzyme inhibitor. Of major clinical importance are the chronic effects on blood cells and the nervous system. Anemia is a typical symptom in classic lead poisoning. Lead inhibits the Na-K-ATPase in the cell membranes of the erythrocytes and thereby makes them less stable, with a shortened life span as a result. Quantitatively less important is the interference with hemoglobin synthesis, several steps of the heme formation being inhibited by lead. Most sensitive is the enzyme aminolevulinic acid dehydratase (ALAD), which is inhibited already at low lead concentrations in the blood at 50 $\mu\text{g/L}$ (0.25 nmol/L) and above. The erythrocyte ALAD activity correlates very closely with the lead content in the blood, but in occupational lead exposure, the activity of this enzyme may become very low. Less sensitive to lead is the incorporation of ferrous ion into protoporphyrin IX to form heme. When this reaction is inhibited, zinc substitutes for iron and the resulting zinc protoporphyrin (ZPP) binds instead of heme to the hemoglobin molecule, thereby rendering it unable to carry oxygen. Each erythrocyte in the blood contains a ZPP amount as a message of the lead exposure at the time when the cell was formed. A blood sample containing erythrocytes that have been formed within the last 4 months or so, and the ZPP concentration in the blood, is, therefore, an indication of the average lead exposure within this time interval. The measurement may be carried out by a portable fluorometer in a few seconds. In adult men, the ZPP concentration increases significantly when the blood-lead concentration averages above 250 $\mu\text{g/L}$ (1.25 nmol/L). In women, the threshold is somewhat lower because of the increased sensitivity related to lower iron stores in the body. In children, the threshold for ZPP increase seems to be about 150 $\mu\text{g/L}$ (0.75 nmol/L). An increased amount of ZPP in the blood can also be caused by iron deficiency alone, but iron deficiency may at the same time make the patient more sensitive to the toxic effects of lead.

Lead affects both the central and the peripheral nervous system. Cases of encephalopathy in adults have been caused by consumption of moonshine whiskey distilled in old car radiators. More insidiously, a chronic toxic encephalopathy may develop. Typically, the lead-poisoned worker is taken to the doctor or the hospital by the wife who is worried about by his failing health and his unbearable irritability. Clinical examination and neuropsychological testing frequently show that attention, concentration, memory, and abstraction are affected. Early effects, detectable by neuropsychological tests, may develop when blood lead concentrations exceed 400 $\mu\text{g/L}$ (2.0 nmol/L) for extensive periods. Prospective studies suggest that decreasing performance may occur in men when a lead level of 300 $\mu\text{g/L}$ (1.5 nmol/L) is exceeded.¹⁶

Children are more susceptible to the central nervous effects, and severe cases of encephalopathy with seizures can still occur, for example, as a result of ingesting of lead-containing paint flakes from peeling walls. More commonly, adverse effects are detected in children with elevated levels of lead in the blood in the absence of any past history of acute lead toxicity. Attention, visuospatial performance, and other brain functions are sensitive to lead toxicity, and decreased results may be detected on IQ tests. Although measurable deficits were thought to occur only at blood-lead concentrations above 100 $\mu\text{g/L}$ (0.5 nmol/L), more recent studies at lower exposure levels have revealed effects also below this limit, and the dose-effect curve may even be steeper at such low exposures.¹⁷

The adult patient with an acute lead poisoning has a weak handshake and a decreased function of the extensor muscles of the

forearm ("lead palsy," Teleky's sign). Decreased nerve conduction velocity has been documented in chronically exposed workers. Related subjective symptoms may include muscle weakness, fatigue, pains in the extremities, and sometimes even tremor. The earliest detectable effects on nerve conduction velocity appear to occur when blood lead levels exceed 400 $\mu\text{g/L}$ (2.0 nmol/L). Children appear to be somewhat more sensitive also with regard to the peripheral nervous system effects.

Acute lead exposure may also affect the kidney function, but this effect appears to be reversible. Symptoms from the gastrointestinal tract include anorexia, dysphagia, constipation, or in some cases diarrhea and occur as a result of chronic exposures as well as acute intoxication. In severe poisoning, colicky pains occur, and several such patients have been subject to surgery for a suspected appendicitis or ulcer. Under chronic exposure conditions and bad oral hygiene, the accumulation of lead sulfide can cause a formation of a blue-gray seam of the gingival edge, the so-called lead seam.

Some studies have suggested that severe lead exposure may result in a decreased life span, in particular due to an increased incidence of stroke. A similar tendency has also been postulated in relation to kidney disease, and kidney cancer has been suggested by animal studies. Although lead may be a weak cancer promoter and augment the development of other disease, current lead exposure levels would probably not cause a detectable increase in cause-specific mortality, although the influence on individual health could be considerable. Teratogenic effects are well documented, and some reports have indicated toxic effects on spermatozoa.

Prevention

The current lead exposure of an individual is best reflected in the lead concentration of whole blood. Prevention of adverse health effects requires that blood lead levels be maintained below 400 $\mu\text{g/L}$ (2.0 nmol/L), and the Occupational Safety and Health Administration (OSHA) lead standard includes the provision that blood lead concentrations should be kept below 300 $\mu\text{g/L}$ (1.5 nmol/L) in male and female workers who intend to have children. The long-term exposure may be evaluated by measuring the ZPP level in the blood, and this test can efficiently be used for screening purposes. Medical surveillance is required as an additional safeguard and must be made available to all employees exposed above the action level of 30 $\mu\text{g/m}^3$ for more than 30 days a year. Blood-lead examination must be carried out at least every 6 months, every 2 months if the blood-lead level exceeds 400 $\mu\text{g/L}$ (2.0 nmol/L). The removal protection provision means that workers with a blood-lead level above 500 $\mu\text{g/L}$ (2.5 nmol/L), or if otherwise indicated by the medical surveillance, should be removed without losing wage or benefits, until the level has returned to 400 $\mu\text{g/L}$ (2.0 nmol/L) or below that level. If the air-lead level cannot be kept below 50 $\mu\text{g/m}^3$, engineering control measures must be initiated. Regular air monitoring is required if levels exceed the action limit of 30 $\mu\text{g/m}^3$. The standard also includes provision for employee information and respirator use.

The goal for the U.S. Centers for Disease Control and Prevention is to reduce children's blood-lead concentrations below 100 $\mu\text{g/L}$ (0.5 nmol/L). If many children exceed this level in a local area, communitywide interventions (primary prevention) should be considered. Interventions for individual children should begin at blood-lead concentrations of 150 $\mu\text{g/L}$ (0.75 nmol/L). These limits appear high in the perspective of recent epidemiological findings,¹⁷ and a wise prevention approach is to minimize lead exposures to the greatest extent possible.

An FAO/WHO expert group has recommended that the weekly oral intake of lead should be below a PTWI of 0.025 mg/kg body weight. This limit is likely protective for adults, but it may be insufficient to prevent adverse effects in children.

The action level set by the U.S. Environmental Protection Agency for lead in drinking water is 15 $\mu\text{g/L}$, and WHO recommends a limit of 10 $\mu\text{g/L}$. Some countries have adopted a limit for lead in wine (250 $\mu\text{g/L}$); milligram quantities may occur in a vintage bottle if the lead cap has been eroded. Lead caps are no longer used. Also, specific limits may apply to ceramic glazes. The lead release is

usually measured by means of a 5% dilute acetic acid test, and the release is measured during boiling for 30 minutes three times. Exposures are also limited by setting standards for lead contents of paints. Major efforts have been initiated to remove old, peeling lead paint as part of restoration of houses with a lead hazard.

► MANGANESE

Manganese has a wide range of applications, ferromanganese being the main product, with 90% of this production used in various metal alloys, including welding rods. Other applications include dry batteries (manganese dioxide) and pigments for the glass and ceramics industry. Methylcyclopentadienyl manganese tricarbonyl (MMT) is increasingly used as an octane-booster in gasoline as other additives are phased out. Occupational exposures to manganese may occur in the primary production and in the various user industries, especially when manganese-containing alloys are welded. Daily intakes through food usually average about 2–3 mg, but may vary considerably, depending on the intake of cereals and rice, which are high in manganese. High levels in drinking water occur in some regions, although low limits are set for technical reasons. Increasing use of MMT in gasoline may cause atmospheric manganese levels above 1 $\mu\text{g}/\text{m}^3$ in cities, and similar levels may be encountered near ferromanganese plants.

The gastrointestinal absorption of manganese appears to be below 5% of that ingested, although higher at lower intakes and in case of iron deficiency; a considerable excretion occurs through the bile, some of which is reabsorbed. Manganese is an essential element in metalloenzymes and as enzyme activator, but deficiency states are unlikely to occur under normal circumstances.

Characteristic, manganese-related diseases appear to be relatively rare. Two different pictures may emerge: pulmonary and neurological pathologies. In acute respiratory exposure to manganese, a chemical pneumonitis may develop with cough, phlegm, fever, and changes on the chest x-ray. Also, manganese aerosols may cause metal fume fever (as described under Zinc). However, pulmonary effects are unlikely to occur at manganese exposures below 0.3 mg/m^3 .

Manganism is a central nervous system disease with clinical manifestations somewhat similar to those of Parkinson's disease. This chronic intoxication has primarily been described in miners, workers in ore processing plants, and foundries. The onset is delayed and sometimes occurs after the exposure has ceased. The first symptoms are nonspecific, such as fatigue, headache, irritability, and memory difficulties. The more characteristic signs then develop insidiously: stiff movements, hoarse and low voice, stiffened facial expression, muscular hypertonia, and tremor. At least partial, and temporary, recovery may be obtained by treatment with L-dopa. The severe manganism appears to affect only a small number of the exposed individuals, and individual vulnerability may, therefore, be of importance. Recent studies have suggested that the early, nonspecific symptoms occur at an increased frequency in welders and other workers with increased exposures to manganese, and perhaps also in subjects with increased environmental manganese exposures. In patients with compromised liver function, manganese may be less effectively excreted, and accumulation in the basal ganglia has been demonstrated, thus suggesting that manganese may contribute to the development of the encephalopathy seen in severe liver disease.¹⁸ Also in regard to this metal, the developing brain may be more vulnerable. Deficits on developmental tests of brain functions were associated with increased manganese concentrations measured in the children's cord blood at birth.¹⁹ This study was carried out in a population without apparent excess exposures and presumably without serious iron deficiency. Although much remains to be learned about manganese toxicity, this metal should prudently be regarded a developmental neurotoxicant.

Biological monitoring for manganese is of some interest and needs further exploration. In the blood, some of the manganese has a half-life of about 1 month. Urine analyses are not useful, except perhaps in case of MMT exposure, but analysis of hair samples has occasionally been used for screening purposes.

The limit for occupational manganese exposures has been lowered by ACGIH to 0.2 mg/m^3 . The WHO drinking water limit of 0.4 mg/L has been determined on the basis of technical considerations. Due to beneficial effects of trace amounts of manganese, a daily intake of about 2.5–5 mg of this metal in the diet has been recommended.

► MERCURY

Exposures

Natural evaporation of mercury is the major source of atmospheric pollution. Cinnabar, that is, mercury sulfide, has been used since ancient times as a pigment and constitutes the most important mercury ore. Inorganic mercury in the aquatic environment tends to sediment, where certain microorganisms are able to methylate mercury, possibly as a means of detoxication. The methylmercury generated then accumulates in fish, particularly in species at the higher trophic levels. Particularly high methylmercury concentrations are reached by marine carnivores. Increased human exposures, therefore, occur in individuals frequently eating fish; the highest exposures seen in the arctic where meat from marine mammals is included in the diet.

Mercury is used for a variety of instruments, including thermometers, manometers, polarographs, and electrical equipment. Mercury is also used for the production of fluorescent light tubes, as a catalyst in chemical industry, including the production of chlorine, and in amalgams for dentistry practice. Mercury may evaporate at room temperature, and the rate depends on the surface area, temperature, and the ventilation. Thus, increased amounts will evaporate if mercury is scattered on the floor as small droplets. The amount that evaporates at 40°C is four times the amount that evaporates at 20°C. At saturation, the air at 20°C contains 15 mg/m^3 , which is more than 100 times the occupational exposure limit.

Mercury compounds are now less frequently used, but some organomercury compounds have important uses. They contain a covalent bond between mercury and carbon, and the organic part of the molecule is often an alkyl group or an alkoalkyl group. The former compounds are more toxic, because they are more easily absorbed and more slowly metabolized. Organomercury compounds have been used as fungicides on seed grains. Methylmercury was extensively used for this purpose in the past, until environmental effects were discovered. Thimerosal is used as a preservative, for example, in vaccines, but this application is now declining due to safety concerns. This compound is metabolized in the body to ethylmercury, which has toxic properties similar to those of methylmercury, but is less stable.

Mercury emissions originate from the various uses of mercury and also from fossil fuel combustion, and some types of coal contain relatively high mercury concentrations. In addition, incineration of municipal and hospital waste may be important point sources.

The various uses of mercury and mercury compounds result in occupational exposures in a range of occupations. Also, the industrial use of mercury may lead to releases to the environment, in particular through sewage water. Localized problems relating to contamination of river systems and bays have been caused by such contamination from chloralkaline plants, paper and pulp industries, and pesticide factories. In the most serious poisoning event, Minamata Bay in Japan became severely contaminated with methylmercury from a factory that used mercury as a catalyst in the production of vinyl chloride.²⁰

Inhalation of metallic mercury results in an almost complete absorption of the vapors in the alveoli. Small amounts are released from dental amalgam fillings, especially from those in the molar teeth that are subjected to the highest pressures during chewing. However, only negligible absorption of the metal takes place in the gastrointestinal tract, unless some is retained, for example, in diverticula or the appendix.

Inorganic mercury compounds from aerosols may be absorbed through the lungs as well, and some absorption (about 5–10%) also takes place in the gastrointestinal tract. A higher absorption rate has been demonstrated in newborn rats, but data on humans is lacking. The organomercury compounds are also absorbed when taken in by this

route, methylmercury almost completely. Occupational exposures are frequently of a mixed type, and absorption patterns may, therefore, vary.

In the blood, inorganic mercury is almost evenly distributed between plasma and erythrocytes, while about 90% of organomercury compounds are bound to the cells. Mercury vapor and methylmercury are lipophilic and may pass biological membranes, including the blood-brain barrier and placenta, and result in considerable deposition in the central nervous system and the fetus, respectively. The vapor dissolved in the blood and tissues rapidly becomes oxidized. Mercuric ions become bound to some extent to metallothionein and accumulate in the kidneys. Excretion takes place mainly through feces and urine, but significant amounts may be eliminated in sweat. The presence of ethanol in the blood influences the equilibrium between dissolved mercury vapor and mercury ions. Thus, after ethanol ingestion, mercury vapor may be detected in the expired air in individuals with high levels of mercuric ions in the blood. When selenium is present in the blood, a complex is formed that results in a longer half-life but also decreased toxicity, as judged from animal experiments. Methylmercury is slowly metabolized in the liver and by gut bacteria and is then eliminated as inorganic mercury.

Effects

Acute poisoning with mercury vapor may cause a severe airway irritation, chemical pneumonitis, and pulmonary edema in severe cases. Ingestion of inorganic compounds results in symptoms of gastrointestinal corrosion and irritation, such as vomiting, bloody diarrhea, and stomach pains. Subsequently, shock and acute kidney dysfunction with uremia may ensue. Cutaneous exposure to mercury compounds may result in local irritation, and mercury compounds are among the most common allergens in patients with contact dermatitis.

Chronic intoxication may develop a few weeks after the onset of a mercury exposure, more commonly if the exposure has lasted for several months or years. The symptoms depend on the degree of exposure and the kind of mercury in question. The symptoms may involve the oral cavity, the nervous system, and the kidneys.

Severe exposure to inorganic mercury causes an inflammation of gingiva and oral mucosa, which become tender and bleed easily. Salivation is increased, most obviously so in subacute cases. Often the patient complains of a metallic taste in the mouth. Especially when oral hygiene is bad, a gray border is formed on the gingival edges.

Mercury may damage both the peripheral and the central nervous system. In exposures to mercury vapor, the central nervous system is the critical organ, and the classic triad of symptoms includes erethism, intention tremor, and the gingivitis described above. The fine intention tremor of fingers, eyelids, lips, and tongue may progress to spasms of arms and legs. A jerky micrographia is typical as well. The changes in the central nervous system result in psychological effects known as erethism: restlessness, irritability, insomnia, concentration difficulties, decreased memory, and depression, sometimes in combination with shyness, unusual psychological vulnerability, anxiety, and total neglect concerning economic problems and daily needs. Newer studies suggest that early stages of erethism may occur, and this syndrome has been dubbed "micromercurialism" by Russian authors. The main problem here appears to be decreased memory, and headache, dizziness, and irritability may also be part of the picture. Similar nonspecific symptoms are described by patients who attribute their ill health to mercury from their dental fillings. Although slight adverse effects are difficult to rule out in susceptible subjects, little evidence is available to support this notion.²¹

Nephrotoxic effects include proximal tubular damage, as indicated by an increased excretion of small proteins in the urine, for example, β_2 -microglobulin. Glomerular damage seems to be caused by an autoimmune reaction to mercury complexes in the basal membrane, and mercury-related cases of nephrotic syndrome have been traced to this pathogenesis.

In children, a different syndrome is seen, the so-called "pink-disease" or acrodynia, diagnosed most frequently in children treated with teething powders that contained calomel and also occasionally seen in children who had inhaled mercury vapor (e.g., from broken

thermometers). A generalized eruption develops, and the hands and feet show a characteristic, scaly, reddish appearance. In addition, the children are irritable, sleep badly, fail to thrive, sweat profusely, and have photophobia. This condition was extremely common until the middle of the twentieth century, when the etiology was finally found and teething powders were phased out.

Intoxications with alkoxalkyl or aryl compounds are similar to intoxications with inorganic mercury compounds, because these organomercurials are relatively unstable. Alkylmercury compounds, such as methylmercury, result in a different syndrome. The earliest symptoms in adults are paresthesias in the fingers, the tongue, and the face, particularly around the mouth. Later on, disturbances occur in the motor functions, resulting in ataxia and dysphasia. The visual field is decreased, and in severe cases the result may be total blindness. Similarly impaired hearing may progress to complete deafness. This syndrome has been caused by methylmercury-contaminated fish in Minamata, Japan and by methylmercury-treated grain used for baking or animal feed in Iraq and elsewhere. Children are more susceptible to the toxic effects of methylmercury than are adults, and congenital methylmercury poisoning may result in a cerebral palsy syndrome, even though the mother appeared healthy or experienced only minor symptoms due to the exposure. In various populations with a high consumption of large marine fish or marine mammals, methylmercury intakes may approach the levels that resulted in such serious disease in Japan and Iraq. While no clear-cut cases of intoxication have been reported in these populations, delays in cognitive development have been reported in children with increased prenatal exposures to methylmercury from the mother's seafood diet.²² Methylmercury may therefore share a developmental neurotoxicity potential with lead, thus causing decrements in IQ levels. Recent evidence suggests that the vulnerability to such toxicity extends into the teenage years.

Although the developing brain is considered the critical target organ in regard to methylmercury, recent evidence has suggested that mercury from fish and seafood may promote or predispose to the development of heart disease. Thus, studies in the United States and Europe have demonstrated a higher risk of cardiovascular death at increased exposures, that is, hair-mercury concentrations above 2 $\mu\text{g/g}$. In this regard, methylmercury seems to counteract the beneficial effect of essential fatty acids in fish. This evidence is yet inconclusive, but deserves attention, because it suggests that a narrow definition of subpopulations at risk, that is, pregnant women and small children, might leave out other vulnerable groups. For preventive purposes, therefore, the population at large should be considered at risk.

Sufficient evidence exists that methylmercury chloride is carcinogenic to experimental animals, but in the absence of comprehensive epidemiological data, methylmercury is considered only a possible human carcinogen (class 2B).⁹

Prevention

Biological monitoring is useful in the diagnosis of mercury exposure and in the control of occupational exposure levels. In the blood, inorganic mercury has a half-life of about 30 days, and methylmercury has a half-life of about twice as long. Unfortunately, blood levels do not reflect mercury retained in the brain where mercury after vapor inhalation has a half-life of several years. Urine levels are usually preferred as an indicator of occupational exposures. Long-term mercury vapor exposures should respect a time-weighted average limit of 25 $\mu\text{g}/\text{m}^3$ and a corresponding urinary mercury excretion limit of 50 $\mu\text{g/g}$ creatinine (28 $\mu\text{mol}/\text{mol}$ creatinine). Induction of slight tremor by mercury vapor has been reported at urinary excretion levels of 50 $\mu\text{g/L}$ (0.25 $\mu\text{mol/L}$) and above. With regard to methylmercury, the earliest effects in adults, such as paresthesias, appear to occur when blood concentrations are above 200 $\mu\text{g/L}$ (1 $\mu\text{mol/L}$). Methylmercury is incorporated in hair, and hair mercury analyses have proved useful for screening, although hair permanent treatment may render the result unreliable. Methylmercury toxicity has been seen at hair levels above 50 $\mu\text{g/g}$ (0.25 $\mu\text{mol/g}$). To protect against developmental neurotoxicity, WHO recommends a PTWI of 1.6 $\mu\text{g/kg}$

body weight, and the U.S. EPA similarly recommends a Reference Dose of 0.1 µg/kg body weight. Taking into account that the former limit is for 1 week, the latter for 1 day, the two limits are fairly similar, and a prudent approach would seem to be to minimize the exposure as much as possible, while maintaining a diet that includes seafood in appropriate quantities. The Reference Dose corresponds to a hair-mercury concentration of about 1 µg/g.²⁰ This level is frequently exceeded in fish-consuming populations, especially if the diet includes predatory fish.

Preventive measures should include the limitation of mercury released from industrial operations to the environment. Important nonindustrial sources are discarded batteries (for cameras and watches), fluorescent light tubes and bulbs, and thermometers. Some countries have instituted a practice of collecting and recycling the mercury from such consumer products. Mercury exposures from dental amalgam fillings should be minimized, but alternative restorative materials should be used only if their safety and durability are known to be superior to amalgam. Thimerosal is being phased out as a pharmaceutical preservative, but still occurs in certain vaccines. A concentration limit of 0.5 mg/kg has traditionally been used for fish and seafood products, but would seem insufficient to ensure that exposures are kept below the Reference Dose while maintaining a diet that includes one or two seafood meals for week. In addition, fish species that may exceed this limit (e.g., swordfish and shark) are usually only required to comply with a limit of 1.0 mg/kg. Because fish contamination cannot easily be controlled, a better way of decreasing methylmercury exposures is to advise the population to eat low in the food chain, preferably smaller and younger fish that contain less mercury.

The current occupational exposure limits are 0.1 mg/m³ as a ceiling value for inorganic mercury and 0.01 mg/m³ for organic (alkyl) mercury. NIOSH has recommended a time-weighted average limit for inorganic mercury at 0.05 mg/m³.

► MOLYBDENUM

The largest deposit of molybdenite, the major molybdenum ore, is in Climax, Colorado. Most of the molybdenum consumption is used in alloys, but various compounds are also employed as catalyst and pigments. Considerable experimental evidence is available on the essential functions of molybdenum, but little information has been gathered on the toxic potentials. The human intake of this metal appears to be below 0.2 mg per day, unless significant contamination occurs. Absorption of molybdenum in food may be about 25–50% in humans, and excretion is mainly through urine; the biological half-life in the blood is probably only a few hours, although some molybdenum may be retained in the liver and other tissues for a longer time. Molybdenum serves a constituent of three oxidases, including xanthine oxidase, but deficiency states have not been reported in humans. Molybdenum poisoning in livestock may produce “teart disease” with anemia, growth retardation, and bone abnormalities, especially if the copper intake is low. In humans, the frequent occurrence of gout-like symptoms in some Armenian villages has been linked to the high intake of molybdenum, possibly via abnormalities of uric acid metabolism. Pulmonary fibrosis has been reported in experimental animals, and a few cases of pneumoconiosis have been seen in workers exposed to sparingly soluble forms of molybdenum. The current ACGIH exposure limits are 0.5 mg/m³ for soluble compounds and 10 mg/m³ for insoluble molybdenum compounds, respectively. A dietary intake of 0.15–0.5 mg of this metal per day has been recommended as safe and adequate for adults.

► NICKEL

Exposures

Nickel is a ubiquitous trace metal, which occurs in nature, but ores of sufficient quality occur only at a few places, notably at Sudbury, Ontario. Nickel is particularly used for alloys but also for surface

treatment of metals, as a catalyst in the electronics industry, and in the production of nickel-cadmium batteries. Nickel exposures occur in the production trades and the various user industries (e.g., when welding stainless steel). The nickel intake through food may average about 0.1–0.2 mg per day, but it varies considerably because high contents may be encountered in legumes, cereals, nuts, and chocolate. Nickel may leach to food and beverages from nickel-plated or nickel-containing kitchen utensils. Gastrointestinal absorption of nickel from food is about 1%, but absorption from an aqueous solution taken on an empty stomach may be about 25%. Internal exposures may result from implantation of orthopedic prostheses and from intravenous infusion of nickel-contaminated solutions.

Effects

Nickel apparently has limited acute toxicity in humans, including airway irritation, and the important adverse effects relate to allergic eczema and respiratory cancers.²³ Nickel carbonyl may cause acute pulmonary disease and systemic toxicity.

Respiratory exposure to nickel compounds in nickel production plants results in an increased risk of nasal and respiratory cancer.¹³ An increased respiratory cancer risk has also been seen in welders, but the contribution by nickel in welding fumes is unclear. Most respiratory cancers in refinery workers have been primary carcinoma of the lung, but nasal cancers may be 100-fold as frequent as otherwise expected. The risk is not limited to sparingly soluble compounds, such as nickel subsulfide, but also relates to easily soluble nickel compounds that may occur as aerosol exposures.

Nickel allergy is the most frequent cause of contact eczema in women. The development of allergy is frequently provoked by earrings, but metal buttons, bracelets, and watches are frequent causes as well. More rarely, the primary allergy develops due to an occupational exposure. However, hand eczema often results as a consequence of exposures at work if nickel allergy is already present, as indicated (e.g., by earlobe dermatitis in the past). Some studies suggest that about 10–15% of women become allergic to nickel, and that almost half of them at some point develop hand eczema, in some cases so severe that the patient has to give up working. A much smaller proportion of the male population appears to be allergic to nickel. Nickel allergy is probably increasing worldwide in prevalence, and it most frequently develops during the teenage years. The hand eczema in a nickel-allergic patient may develop or progress as a result of increased nickel intake through food and beverages.²⁴ In addition, inhalation allergy has resulted in asthmatic symptoms in a few recorded cases.

Nickel carbonyl (Ni(CO)₄) is a liquid that can evaporate at room temperature. Nickel carbonyl is produced in the Mond refining process of nickel. In addition, it may be formed or used in other branches of industry, such as electronics, oil refining, and plastics. After an acute exposure, dyspnea, headache, dizziness, vomiting, and substernal and hypogastric pain may occur, followed by a virtually symptom-free interval of 12–36 hours. Severe pulmonary symptoms then develop, and physical examination suggests pneumonia. The intoxication can lead to cerebral toxicity and death within 3–10 days. Pulmonary cancer has been reported in animal experiments, but the epidemiological evidence is uncertain on this point.

Prevention

Exposure to soluble nickel compounds and nickel carbonyl, which is metabolized to form nickel ions and carbon monoxide, may be evaluated by analysis of nickel concentrations in plasma and urine. The biological half-life in the body and the release from particles retained in the lungs will depend on the solubility of the nickel compounds concerned. Nickel present in the blood seems to be cleared relatively rapidly by the kidneys, and animal experiments suggest a half-life of a few days. Limits for plasma levels must, therefore, depend on the nickel speciation in the exposure. Nickel levels in plasma are usually below 1 µg/L (17 nmol/L) in individuals without occupational exposures, at least when analysis of uncontaminated samples has been carried out by an experienced laboratory.

Limits for occupational exposure are 1 mg/m³ for nickel metal and soluble nickel compounds, and 0.001 ppm for nickel carbonyl. The ACGIH limits are: 1 mg/m³ for nickel metal, nickel sulfide roasting, fumes, and dust; 0.1 mg/m³ for soluble compounds; and 0.05 ppm for nickel carbonyl. NIOSH has recommended that the permissible exposure limit for nickel be reduced to 0.015 mg/m³.

Specific preventive measures apply with regard to nickel-induced contact dermatitis. Primary prevention would mean that nickel-containing or nickel-plated metals should not be used in products that come into contact with the skin. Unfortunately, current fashions and the usefulness of nickel in cheap alloys (including coinage metal) seem to strongly oppose such measures. Contact with such products should be limited, if not totally avoided, in patients who have already developed allergy toward nickel. Many dermatologists have experienced some success in advising their patients to refrain from eating oatmeal, legumes, nuts, and chocolate and from using nickel-plated kitchen utensils. Beverages should not be ingested on an empty stomach. Some countries have enacted legislation concerning the acceptable degree of nickel release from metal objects that may come into contact with the skin. The degree of nickel leaching from white metal objects may be determined by Fisher's test (dimethylglyoxime and ammonium hydroxide), which enables the allergic patient to identify and discard objects that could provoke an outbreak of dermatitis.

► OSMIUM

Environmental exposures are of limited significance, and the information on kinetics in the human body is incomplete. Of main interest is osmium tetroxide (osmic acid), which is used for various laboratory purposes, mainly as a fixative for tissue sections. The highly volatile osmium tetroxide may also be formed by oxidation of the finely divided metal. Inhalation of osmium tetroxide causes immediate irritation of the mucous membranes with cough and shortness of breath. These symptoms may last for several hours after a short exposure. Osmium tetroxide also has corrosive effects on the eyes, as indicated by severe irritation and lacrimation. After these symptoms have ceased, the patient may see large halos around lights until the tissue damage has been completely repaired. Skin contact results in irritant dermatitis. Repeated respiratory exposures have allegedly caused headache, insomnia, chronic airway irritation, and gastrointestinal disturbance. The permissible limit for occupational exposures to osmium tetroxide is 0.002 mg/m³.

► PLATINUM

Platinum is used in jewelry, in dentistry, and in chemical and electrical industries. Platinum compounds are employed in electroplating, in photography, and as a catalyst in the petroleum and pharmaceutical industries. Exposures to hexachloroplatinic acid and platinum tetrachloride are most frequent. When inhaled, the platinum compounds may cause upper airway irritation with violent sneezing, dyspnea, wheezing, and even cyanosis. Platinum rhinorrhea and platinum asthma are more typical clinical pictures that fade away shortly after the worker has left work for the day, and skin contact with chlorinated platinum salts may result in a scaly erythema, sometimes urticaria, and mostly only on hands and forearms.²⁵ These allergic manifestations have been called platinosis. Long-term effects, such as lung fibrosis, are unlikely, but a worker with a past history of platinosis may not be able to work with platinum again without suffering a severe reaction to minute amounts of platinum salts in the atmosphere. Some platinum compounds, notably *cis*-diamino-dichloroplatinum (*cis*-platin), inhibit cell growth in tumors and have therefore been used as cytostatic agents, especially for testicular cancer. Environmental exposures result from industrial emissions and from the use of catalytic converters on automobile exhaust systems. Platinum is employed as a catalyst in catalytic converters on cars. About 1 µg of the metal was lost per kilometer of driving with a pellet-type

catalyst, but much lower losses have been achieved with the newer monolith-type catalysts. The limit for occupational exposures is 0.002 mg/m³ for soluble platinum salts, and ACGIH has adopted a limit of 1 mg/m³ for platinum metal. Limited information exists concerning biological monitoring, but platinum allergy can be diagnosed by specific IgE antibodies.

► SELENIUM

Selenium is often referred to as a metalloid, although it shares some chemical properties with sulfur. Selenium is usually a by-product obtained from primary copper production. This element has found considerable use in semiconductor technology and other electronic applications, in photocopy machines, as pigments in paints and glass, as an ingredient in certain alloys, in antidandruff shampoos, and several other applications. Perhaps the most intensive exposures occur in sulfide ore refineries, but harmful exposures may also result when selenium-containing rectifiers are overloaded or when scrap metal is melted. Environmental selenium exposures vary geographically, with average daily intakes through the diet varying from a low 30–50 µg in Scandinavia, Egypt, and New Zealand to a high of about 300 µg in Venezuela. Increased levels may occur due to emissions from coal combustion and manufacturing industries, but geological factors are generally most important. Some plants concentrate selenium and may contain concentrations up to several thousand parts per million.

Effects of selenium used to be a concern mainly with regard to domestic animals. Acute poisoning (blind staggers) and chronic toxicity (alkali disease) have been known in livestock for over 50 years. Later, selenium deficiency was discovered as the cause of white muscle disease in ruminants, hepatosis dietetica in swine, and exudative diathesis in chickens.

Soluble selenium compounds are almost completely absorbed from the gastrointestinal tract. Absorption through the skin may occur as well. The selenium concentrations in blood and urine seem to reflect recent absorption. Part of the selenium in the blood is associated with a glutathione peroxidase, and the activity of this enzyme is associated with the selenium levels. Selenium compounds are metabolized in the liver, in part by reduction and methylation. Dimethylselenide is an intermediary metabolite that is exhaled when the formation of this compound at high exposures exceeds the further formation of trimethylselenonium ions, which are excreted in the urine. The kinetics depends on the absorption level and perhaps on individual differences and on interfering substances, such as arsenic, cadmium, and mercury.

Inhalation of selenium results in mucous membrane irritation, gastrointestinal symptoms, increased body temperature, headache, and malaise. Garlicy breath from dimethylselenide is frequently present. This symptom was already noted by the housekeeper of Berzelius, who discovered this element. In fact, most of the systemic toxicity may be due to the liberation of this metabolite from the liver. Selenium dioxide forms caustic selenous acid in contact with water and is, therefore, highly irritant and may produce burns and pulmonary edema. The nail beds become tender; deformed nails develop; and skin, teeth, and hair may be dyed red from precipitation of amorphous selenium. Hydrogen selenide is more toxic than hydrogen sulfide; immediate symptoms are related to the irritant properties. Seleniferous food has been related to vague symptoms, but lack of proper reference groups and other deficiencies hamper the interpretation of the data.

Because selenium is an essential trace element, deficiency may occur. The most serious form was first described as Keshan disease, an endemic, juvenile cardiomyopathy in selenium-low areas of China. Low selenium intakes may also predispose to the development of cancer and arteriosclerosis. In addition, clinical improvement has been recorded in other groups of patients, including some on parental nutrition and some with lipidoses of the central nervous system. However, much needs to be discovered in these areas before conclusions concerning minimal daily intakes can be made, although a daily intake of 0.05–0.2 mg is currently recommended.

In regard to prevention of toxic effects, urine-selenium concentrations should be kept below 0.1 mg/L. Analysis of exhaled air for dimethylselenide could be considered but has not been widely applied. The occupational exposure limit is 0.2 mg/m³ for selenium and its inorganic compounds and 0.05 ppm for selenium hexafluoride, an airway irritant. In Finland, where the dietary intake of selenium was among the lowest in the world, selenium has been added to fertilizers to increase the selenium concentration of agricultural products.

► SILVER

Major uses of silver in the past, such as jewelry, silverware, and photographic emulsions, still continue to be important, but a range of other applications have increased the demand due to developments in coatings and alloy technology. Silver solder is also in use, although the adverse effects related to the cadmium content have necessitated a change of ingredients. Argyria is a bluish discoloration of the skin due to deposition of silver metal particles. A localized form is due to penetration of particles through the stratum corneum, but generalized argyria is due to absorption of silver compounds into the body. Argyrosis of the respiratory tract has been diagnosed by bronchoscopy, but ocular argyrosis, especially as evidenced by conjunctival discoloration, may be more easily detected. These signs occur as a result of occupational exposures but may also be caused by oral or dermal pharmaceuticals containing silver; they appear to be relatively benign. The current exposure limit is 0.01 mg/m³ for silver metal and soluble silver compounds, but ACGIH has recommended a limit of 0.1 mg/m³ for silver metal.

► THALLIUM

Thallium has important uses in various industrial processes, including the fabrication of phosphorescent pigments and glassware, and as a catalyst in organic synthesis. Environmental thallium pollution occurs near mines and refineries because zinc, cadmium, and copper ores usually contain thallium. Cement production and coal burning also cause thallium emissions. Historically, extensive application of thallium rodenticides has caused pollution problems and serious poisonings.²⁶

Exposure to thallium from food is normally of no significance. Thallium compounds are without taste and odor; lethal doses may be less than 1 g. Gastrointestinal absorption is almost complete, and uptake through the skin has also led to several cases of intoxication. Within a few days, acute gastrointestinal effects are followed by peripheral neuropathy with muscle weakness and “burning feet syndrome.” The associated mental disturbances include irritability, concentration difficulties, and somnolence. Hair loss (alopecia) occurs about 1–3 weeks after the acute exposure. Thus, the characteristic triad, gastroenteritis, polyneuropathy, and hair loss is seen only at a rather late stage of the intoxication. Characteristic lunular stripes may develop on the nails. In survivors of severe poisoning, some nervous system damage may remain after recovery. Inhalation of thallium-containing dust at work over longer time periods may be associated with vague symptoms of joint pains, anorexia, fatigue, trembling, and with partial hair loss and polyneuropathy. A large-scale study of the population residing near a thallium-polluting cement factory in Germany found that elevated urine-thallium concentrations were associated with polyneuritic symptoms, sleep disorders, headache, fatigue, and other nonspecific symptoms.²⁷

Excretion is mainly via the gastrointestinal tract and the kidney. Urine levels of thallium may remain high for several weeks, although plasma concentrations have decreased. A biological half-life of a couple of weeks seems to apply to humans. A slow excretion takes place through hair and nails, which may provide a profile of recent thallium levels in the body. The limit for occupational exposure to soluble thallium compounds is 0.1 mg/m³.

► TIN

Tin has been used for many centuries in brass and pewter, and current uses also include tin plating, which consumes about half of the total tin production, tin foil, collapsible tubes, and pipes. Cans for food products are often plated with tin on the inner side. To prevent leaching to acidic contents (especially when a can is left open for a few days), tin-lined cans used for food are usually protected with lacquer. The dietary intake of tin is variable, although mostly about 1–4 mg/day. A large number of organotin compounds are in use (e.g., dioctyltin as a stabilizer in PVC, triorganotins as pesticides, in particular fungicides and antifouling agents, and in various compounds as catalysts).

Ingestion of 50 mg of tin results in vomiting, but gastrointestinal absorption is only a few percent. Organotin compounds are more easily absorbed, also through the skin. Inhalation of tin dust is usually not a matter of major concern. However, a benign pneumoconiosis, called stannosis, has been described, where pulmonary function abnormalities are minor, if detectable at all.

The organotin compounds, including dialkyl and trialkyl compounds, are strong skin irritants. The systemic toxicity in experimental animals has been studied in some detail; the neurotoxic potential is higher in trialkyltins than in dialkyltins, and it decreases with the length of the alkyl chains. Some compounds may be immunotoxic, and tributyltin marine antifouling paints may cause serious endocrine disruption in certain marine organisms. Human health effects of seafood contamination by tributyltin are unclear.²⁸ More than 200 human cases of poisoning, half of them fatal, were described after the application of an ointment containing organotin compounds (mainly diethyltin) against staphylococcal infections. The symptoms included headache, vomiting, dizziness, visual disturbances, convulsions, and paresis.

The limit for occupational exposure is 2 mg/m³, and for organotin compounds is 0.1 mg/m³. Biological monitoring seems to be of limited use, although urinary tin excretion may be worth studying more closely. In the preventive measures, eye protection and prevention of skin contact with organotin compounds should be included. Although tributyltin will not be used in marine paints after 2008, the marine contamination will remain for many years. The European Food Safety Authority uses a tolerable daily intake limit for the sum of all organotin compounds of 0.25 µg/kg body weight.²⁸ This limit is likely to be exceeded only in case of frequent intake of heavily contaminated seafood.

► URANIUM

Uranium is a radioactive metal that may cause serious chemical toxicity. Most natural uranium is ²³⁸U, which has a half-life of almost 5 billion years. It is extracted from ores that may contain less than 1% of the metal. The main use is as fuel in nuclear power plants, but small amounts are used as pigments and catalysts. Uranium enrichment to secure fissile uranium results in depleted uranium as a by-product. Because of the high specific gravity (about 1.7 times the one of lead), the depleted uranium is used as a component of munitions in military conflicts, thereby leading to uranium aerosol exposures to munition producers, military personnel, and civilians. Human exposure occurs from production and use of this metal, but uranium may also leach into drinking water from natural deposits, and industrial sources, such as mill tailings. Gastrointestinal absorption varies with solubility, and perhaps 20% of uranium from food and water is absorbed. The tetravalent uranium is oxidized in the organism to hexavalent ions, which are excreted through the glomeruli. At low pH, uranyl ions (UO₂²⁺) will be reabsorbed in the tubuli, where they may cause cell damage or necrosis. Less-soluble uranium compounds from respiratory exposures will tend to accumulate in the lungs. Such accumulation, especially if the uranium is enriched with ²³⁵U, would tend to cause health effects associated with the alpha-radiation. However, the excess cancer risk in uranium miners seems to be mainly due to radon gas and radon progeny. Uranium in drinking water has been linked to

excess excretion of β_2 -microglobulin in the urine as an indication of early tubulus dysfunction, resulting in kidney damage. WHO recommends a drinking-water limit of 9 $\mu\text{g/L}$, based on a high allowance of 50% of the total tolerated daily uranium intake. The standard for occupational exposure to uranium and insoluble compounds is 0.25 mg/m^3 , and for soluble compounds is 0.05 mg/m^3 , while ACGIH has recommended 0.2 mg/m^3 for all uranium.

► VANADIUM

Vanadium is frequently used in various alloys, often in the form of ferovanadium, which accounts for the majority of vanadium consumption. Vanadium oxides are important catalysts in the inorganic and organic chemical industries, and other vanadium compounds are used in the electronics, ceramics, glass, and pigment industries. Vanadium is primarily used for steel production (e.g., for automobile parts, springs, and ball bearings). Occupational exposure to vanadium may also occur at primary production of other metals when the ores contain considerable amounts of vanadium; certain qualities of oil contain much vanadium, and unexpected exposures may occur when servicing burners and filters.

The daily intake through food is usually below 0.1 mg, and gastrointestinal absorption may be less than 1%. Vanadium is an essential element for chickens and rats, but the possible essentiality to humans has not been determined. Environmental exposures have not been reported to cause significant toxicity.

Pentavalent vanadium compounds are more toxic than are the tetravalent compounds. Vanadium pentoxide (V_2O_5) dust and fume result in conjunctivitis, rhinitis, and other irritation of the mucous membranes, and in severe cases, in dyspnea and chemical pneumonitis. Some workers may become particularly sensitive to these actions, while others seem to show some adaptation. Vanadium-induced cough may be particularly bothersome, since it lasts for several days. Chronic bronchitis has been recorded as an apparent long-lasting effect following long-term exposures. Animal studies have indicated that vanadium could induce systemic effects, such as fatty degeneration of liver and kidneys, polycythemia, and cardio-toxicity at high doses. In humans, a lowering of serum cholesterol levels has been demonstrated as well as a reduction of cystine incorporation in fingernails. After oral intake of vanadium, records indicate that the tongue may be covered by a green layer.

Vanadium is efficiently excreted via the urine, and about one-half of the absorbed quantity is excreted within the first two days, but the existence of a slower compartment with a half-life of about several weeks has been suggested. Analysis of urine samples for vanadium may be useful to indicate the acute exposure levels, and levels below 0.5 mg/L (10 nmol/L) are believed to reflect safe exposures. The ceiling limits for occupational exposures to vanadium pentoxide are 0.5 mg/m^3 for dust and 0.1 mg/m^3 for fume, while NIOSH has recommended a limit of 0.05 mg/m^3 for both.

► ZINC

Zinc is a common and essential metal with a low toxic potential. This metal is added to bronze, brass, and various other alloys to add corrosion resistance, and it is used for galvanizing steel and other iron products. In the presence of carbon dioxide and humidity, a surface film of alkaline zinc carbonate is formed, which protects against corrosion. Various zinc compounds are used in the chemical, ceramic, pigment, plastic, rubber, and fertilizer industries, and most frequently used are zinc oxide, carbonate, sulfate, chloride, and some organic compounds. The most significant occupational exposures occur during alloy founding, galvanizing, zinc smelting, and welding, especially of galvanized metals.

The daily intake of zinc varies considerably, seafood and meat being high in zinc, but typically ranges from 10 to 15 mg. Also, soft drinking water may contain high concentrations of zinc leached from the water pipes. The average oral intake from this source is several

milligrams. The gastrointestinal absorption is difficult to evaluate, because the major excretion route is via the gut. The relative zinc absorption varies with the speciation and the presence of phytate, calcium, phosphate, and vitamin D. Under normal circumstances, the absorption is probably about 25–50%, while under zinc deficiency the absorption can increase substantially.

Zinc is an essential metal, and more than 20 zinc-dependent enzymes have been identified. Zinc deficiency in children has resulted in endocrine disturbances with retarded growth and delayed puberty. This condition may be completely cured when zinc therapy is instituted. Acrodermatitis enterohepatica, a rare familial skin disease, has been found to be related to deficient zinc absorption. In addition, recent research has suggested that zinc supplements may be beneficial in certain dermatological conditions and in accelerating wound healing in surgical patients. Zinc also seems to somewhat protect against cadmium toxicity. However, in the occupational setting, the latter metal is a frequent impurity in zinc and may result in serious adverse effects.

Oral zinc poisoning has occurred in a few instances due to zinc release from galvanized food containers. Symptoms included nausea, vomiting, stomach pains, and diarrhea. Inhalation of high concentrations of zinc oxide may cause metal fume fever, a condition that may also be caused by freshly formed oxides of several other metals, including copper, magnesium, manganese, and nickel. This condition is also referred to by other names, such as metal shakes or zinc chills. The metal oxide particles tend to aggregate after their formation and would then be unable to pass through to the lungs as easily; therefore only the freshly formed particles cause the disease. A few hours after the exposure, the first symptoms may be slight feeling of malaise, dry cough and sore throat, and a sweetish, metallic taste in the mouth. About 6–8 hours later, the patient develops an influenza-like syndrome with chills, muscle pains, headache, and medium-grade fever, then follows sweating and recovery. Blood tests show leukocytosis, increased sedimentation rate, and lactate dehydrogenase. Depending on the extent of the exposure, the total attack usually lasts less than 24 hours, and the patient usually returns to work the next morning. Many workers have experienced repeated, almost weekly spells of metal fume fever, and chronic damage could conceivably occur. However, this question is difficult to address, and no evidence currently suggests that repeated attacks of metal fume fever leave sequelae. In fact the patient develops a temporary resistance after each spell, and metal fume fever is, therefore most seen on Mondays, which accounts for the name, Monday morning fever.

Zinc chloride has been in extensive use as a flux in soldering. In contact with water, hydrochloric acid is liberated, and the result is painful burns. Zinc chloride is also used in smoke bombs, and inhalation of the fume has caused corrosive effects in the airways with pulmonary edema and, in the survivors, bronchopneumonia.

Biological monitoring is of dubious value, because the serum zinc concentration appears to be well regulated, and the urine represents only a minor part of the total amount excreted. Metal fume fever seems to be caused by zinc fume levels of 15 mg/m^3 , but only scattered information is available on effects of exposures below that level. The exposure limit for zinc oxide is 2 mg/m^3 , and it is 1 mg/m^3 for zinc chloride. With regard to the beneficial effects, recommended values for daily requirements are 15 mg for adults, 20 mg for pregnant women, and 25 mg for lactating women.

Diseases Associated with Exposure to Chemical Substances

Organic Compounds

Stephen Levin • Ruth Lillis

► ORGANIC SOLVENTS

Organic solvents comprise a large group of compounds (alcohols, ketones, ethers, esters, glycols, aldehydes, aliphatic and aromatic saturated and nonsaturated hydrocarbons, halogenated hydrocarbons, carbon disulfide, etc.) with a variety of chemical structures. Their common characteristic, related to their widespread use in many industrial processes, is the ability to dissolve and readily disperse fats, oils, waxes, paints, pigments, varnishes, rubber, and many other materials.^{1,2}

Solvent exposure affects many persons outside industrial and occupational settings. The use of solvents in household products and in arts, crafts, and hobbies has significantly increased the population that may be affected by repeated exposure. Moreover, the deliberate inhalation of solvents as a form of addiction (“sniffing”) occurs, especially in younger population groups.

Some solvents are well known for their specific toxic effects on the liver, kidney, and bone marrow,³ and a few organic solvents have specific toxicity for the nervous system. Carbon disulfide may induce a severe toxic encephalopathy with acute psychosis;³ methyl alcohol may induce optic neuritis and atrophy; methyl chloride and methyl bromide may cause severe acute, even fatal, toxic encephalopathy. Exposures to *n*-hexane, methyl-*n*-butyl ketone (MBK),^{4,5,6} and carbon disulfide have produced peripheral neuropathy.

Most organic solvents share some common nonspecific toxic effects, the most important of which are those on the central nervous system (CNS). The depressant narcotic effects of organic solvents have long been recognized; numerous members of this heterogeneous group of chemical compounds have been used as inhalation anesthetics (chloroform, ethyl ether, trichloroethylene, etc.).

The sequence of stages of anesthesia achieved with volatile solvents is of interest: the cerebral cortex is affected first, the lower centers of reflex activity in the brain stem and medulla oblongata, which control vital cardiovascular and respiratory functions, are the last to be depressed. This characteristic sequence makes it possible to use volatile anesthetic compounds for medical purposes. The earliest manifestations of the anesthetic effects of solvents are slight disturbances in psychomotor coordination. These may progress to more pronounced incoordination and, if exposure continues, through an excitation stage of longer or shorter duration, to loss of consciousness.

Occupational exposure to solvents may reproduce the entire sequence of medical anesthesia, up to loss of consciousness, and even death through paralysis of vital cardiovascular and respiratory centers. While such severe cases of occupational solvent poisoning are relatively uncommon under normal conditions, they may occur with unexpected accidental overexposure.

The initial manifestations of CNS depression are frequent in workers handling solvents or mixtures of solvents in various industrial processes. A low boiling point, with generation of significant airborne concentrations of vapor, large surfaces from which evaporation may take place, lack of appropriate enclosure and/or exhaust ventilation systems, relatively high temperature of the work environment, and physical exercise required by the actual work performed (increasing the ventilatory volume per minute and thus the amount of solvent vapor absorbed) may all contribute to uptake of sufficient solvent to induce prenarcoctic CNS symptoms.

Early prenarcoctic effects are dizziness, nausea, headache, slight incoordination, paresthesia, increased perspiration, tachycardia, and hot flushes. These symptoms are mostly subjective and transitory, and their causal relationship with solvent exposure has, therefore, often been overlooked. The transitory nature of prenarcoctic symptoms is due to the common characteristics of the metabolic model for solvents: once exposure ceases after the end of the work shift, the body burden of solvents is usually rapidly depleted, mostly eliminated through exhalation. The prenarcoctic symptoms subside as the concentration of solvent in blood and in the CNS decreases.

With exposure to higher concentrations or with longer exposure, more marked incoordination and a subjective feeling of drunkenness may occur. The risk of accidents is increased, even with early prenarcoctic symptoms and more so with more pronounced symptoms.

While acute overexposure of higher magnitude with loss of consciousness is generally accepted as a serious condition (with possible persistent aftereffects, including neurological deficit), the long-term effect of repeated episodes of slight prenarcoctic symptoms has remained unexplored until relatively recently, although it had been recognized that such symptoms are an expression of functional changes in some cortical neurons.

It had been suspected for some time that repeated functional change may lead to permanent impairment of neuronal functions, and various possible mechanisms had been considered, including interference with cell membrane or neurotransmitter functions or even

neuronal loss. Since no regeneration of neurons occurs, neuronal loss can result in permanent, irreversible neurological damage. The diffuse nature of such effects and the lack of major, well-localized neurological deficits have contributed to the relatively slow recognition of chronic, irreversible, solvent-induced neurological impairment.

Repeated exposure to organic solvents may result in the gradual development of persistent symptoms, such as headache, tiredness, fatigue, irritability, memory impairment, diminished intellectual capacity, difficulty in concentration, emotional instability, depression, sleep disturbances, alcohol intolerance, loss of libido, and/or potency. These symptoms, often reported by workers with repeated solvent exposure and mentioned in many studies on chronic effects of solvents, had received relatively little attention until relatively recently, probably because of their nonspecific nature. Nevertheless, the term *toxic encephalosis* was proposed as early as 1947.⁷ More recently, the term *psycho-organic syndrome* has been used for this cluster of symptoms related to long-term solvent exposure. Effects on the CNS, including the diencephalic centers of the autonomic system with their interrelationships with endocrine functions, are probably important components in the development of the syndrome.

The chronic neurotoxicity of solvents related to long-term exposure has received increasing attention. Research has been particularly active in the Scandinavian countries. Epidemiological studies of exposed workers and control groups have significantly contributed to recognition of the association between the psycho-organic syndrome and exposure to solvents; neurobehavioral and electrophysiologic methods, including electroencephalographic (EEG), visual evoked potential (VEP), and nystagmographic investigations, have added objective, quantitative measures for the assessment of CNS functions.

In case-control studies,⁸ neuropsychiatric disease has been found to occur more frequently among solvent-exposed workers than in age-matched controls. In a large study in Denmark, in which solvent-exposed painters were compared with nonexposed bricklayers,⁹ the painters had a relative risk of 3.5 for disability due to cryptogenic presenile dementia. With modern methods of investigation and brain imaging, including computed tomographic (CT) scan, MRI, and cerebral blood flow studies, diffuse cerebral cortical atrophy has been demonstrated in cases of chronic solvent poisoning.^{10,11,12}

Thus recent studies converge to indicate that long-term exposure to solvents may lead to chronic, irreversible brain damage. The clinical expression is that of intellectual impairment and decrements in performance, which can be detected by means of neurobehavioral testing; EEG abnormalities are frequent and characterized mostly by a diffuse low-wave pattern. The underlying pathological changes are represented by cortical atrophy; these changes can be of varying severity, with extreme cases of severe diffuse cerebral and cerebellar cortex atrophy in chronic poisoning due to solvent sniffing addiction.¹³

The axons and myelin sheaths may also be affected by organic solvents. This is well known for peripheral nerves, and peripheral neuropathy has been well documented with exposure to such solvents as carbon disulfide, MBK, and *n*-hexane. Specific CNS effects are also known to occur with carbon disulfide. Other solvents capable of producing peripheral neuropathy such as *n*-hexane and MBK have an effect on both long and short axons, and axonal degeneration of fibers in the anterior and lateral columns of the spinal cord, cerebellar vermis, spinocerebellar tracts, optic tracts, and tracts in the hypothalamus can also occur.

In the past decade, advances in genomics and proteomics has enabled extensive investigation into the mechanisms through which organic compounds exert their toxic and genotoxic effects, pointing to potentially useful biomarkers of exposure and toxicity, as well as possible interventions to protect against the adverse effects of exposure.

► ALIPHATIC HYDROCARBONS

Aliphatic hydrocarbons are mostly derived from petroleum by distillation or cracking; their chemical structure is relatively simple, since they are linear carbon chains of various lengths with a certain number

of hydrogen atoms attached. They are either saturated (alkanes or paraffins) or unsaturated (alkenes or olefins, with one or several double bonds and alkynes or acetylenes, with one or more triple bonds).

The aliphatic hydrocarbons occur in mixtures that have numerous industrial uses: natural gas; heating fuel; jet fuel; gasoline; solvents for a variety of materials such as pigments, dyes, inks, pesticides, herbicides, resins, and plastic materials; in degreasing and cleaning; in the extraction of natural oils from seeds; and increasingly as raw material for the synthesis of numerous compounds in the chemical industry.

Compounds with a low number of carbon atoms are gases (methane, ethane, propane, butane). Compounds with a higher number of carbon atoms (up to eight) are highly volatile liquids at room temperature, whereas those with longer carbon chains have higher boiling temperatures and usually do not generate dangerous air concentrations. Compounds with more than 16 carbon atoms are solids. The only adverse effect attributed to the lower members of the group is the indirect one they might exert when present in high concentrations, displacing oxygen.

Toxic effects of *paraffins* (alkanes) are significant for the highly volatile liquid compounds from pentane through octane. These compounds are potent depressants of the CNS, and overexposure may result in deep anesthesia with loss of consciousness, convulsions, and death. Such high levels of exposure are infrequent under usual circumstances, but they may occur accidentally. Moderate irritation of mucous membranes of the airways and conjunctivae is a common but less severe effect; defatting of the skin might contribute to dermatitis, with repeated contact. Aspiration of liquid mixtures of aliphatic hydrocarbons into the airways or accidental ingestion of such liquids usually results in chemical pneumonitis, often severe and necrotizing.

N-hexane exposure may result in toxic peripheral neuropathy, affecting both the sensory and motor components of peripheral nerves, initially in the lower extremities, but eventually with longer exposure, also in the upper extremities. Paresthesia, numbness, and tingling progressing from distal to proximal, distal hypoesthesia (touch, pain), followed by muscle weakness due to motor deficit, with difficulty in walking and eventual muscular atrophy, and diminished or absent deep tendon reflexes, are the characteristic clinical findings. Electromyographic abnormalities indicating peripheral nerve lesions, including abnormal fibrillation patterns and significant decreases in nerve conduction velocities (sensory and motor) are usually detected. Axonal degeneration and secondary demyelination have been found to be the underlying pathological abnormalities. Abnormalities in visual-, auditory-, and somatosensory-evoked potentials have been reported after experimental *n*-hexane exposure; longer latencies and central conduction times were interpreted as reflecting neurotoxic effects at the level of the cerebrum, brain stem, and spinal cord.¹⁴

N-hexane peripheral neuropathy, first described by Japanese investigators¹⁵ in 1969, has since been repeatedly reported from various European countries and the United States. It has also been reproduced in animal experiments at concentrations as low as 250 ppm. Outbreaks of toxic peripheral neuropathy due to *n*-hexane have continued to be reported. Such cases have occurred in press-proofing workers in Taiwan, associated with exposure to a solvent mixture with a high (60%) *n*-hexane content. The outbreak of peripheral neuropathy cases had been preceded by a gradual change (to a high *n*-hexane content) in the solvent mixture used to clean rollers of press-proofing machines.¹⁶ In an offset printing plant with 56 workers, 20 (36%) developed symptomatic peripheral neuropathy due to exposure to *n*-hexane. Optic neuropathy and CNS involvement were uncommon and autonomic neuropathy was not encountered.¹⁷

Cases of *n*-hexane subacute, predominantly motor, peripheral neuropathy have also been reported in young adults and in children after several months of glue sniffing. Although functional improvement after discontinuation of toxic exposure has been reported, in some cases full recovery has not been observed, even after long-term (16 years) follow-up.^{18,19,20} Experiments involving exposure of rats to high concentrations of *n*-hexane have revealed adverse effects on the seminiferous epithelium; repeated exposures resulted in severe, irreversible testicular lesions.²¹ Cellular changes were observed in the

myocardium as a result of administering *n*-hexane to rats. These cellular changes were considered to be responsible for the decreased threshold for ventricular fibrillation.²² A significant suppression was observed in the serum immunoglobulin (IgG, IgM, and IgA) levels in *n*-hexane-exposed workers.²³ The main *n*-hexane metabolites are 2-hexanol and 2,5-hexanedione, a good biomarker of occupational exposure to *n*-hexane.²⁴ *N*-hexane is metabolized to the gamma-diketone 2,5-hexanedione (2,5-HD), a derivative that covalently binds to lysine residues in neurofilament proteins (NF) to yield 2,5-dimethylpyrrole adducts. Pyrrolylation is an absolute requirement in neuropathogenesis.²⁵ Effects of chronic exposure to *n*-hexane on some nerve-specific marker proteins in rats' central and peripheral nervous systems were studied after high exposure (2000 ppm *n*-hexane for 24 weeks). The level of neuron-specific enolase (NSE), creatine kinase-B (CK-B), and beta-S100 protein decreased significantly in the distal sciatic nerve, while the markers remained unchanged in the CNS.²⁶ *N*-hexane accumulates in adipose tissue where it persists longer (estimated half-life, 64 hours); complete elimination from fat tissue after cessation of exposure has been estimated to require at least 10 days.²⁷

In humans chronically exposed to a mixture of hexane isomers with concentrations ranging from 10 ppm to 140 ppm, the urinary 2,5-hexanedione excretion ranged from 0.4 mg/L to 21.7 mg/L.²⁸ Urinary concentrations of 2,5-hexanedione in subjects not exposed to *n*-hexane or related hydrocarbons were found to range from 0.12 mg/L to 0.78 mg/L.²⁹ The urinary 2,5-hexanedione excretion reaches its highest level 4–7 hours after the end of exposure.³⁰ Biological monitoring to assess worker exposure to toxic chemicals has gained increasing recognition, especially for occupations characterized by highly variable exposure levels. The American Conference of Government Industrial Hygienists has recommended biological exposure indices (BEIs—levels of a biological indicator after an 8-hour exposure to the current threshold limit value [TLV]) for a limited number of widely used chemicals; *n*-hexane is one of these. 2,5-Hexanedione was found to be significantly correlated with a score of electroneuromyographic abnormalities. There is general agreement that, for practical purposes, the urinary concentrations of 2,5-hexanedione can predict the likelihood of subclinical peripheral neuropathy in persons exposed to *n*-hexane.^{31,32} 4,5-Dihydroxy-2-hexanone as a metabolite of *n*-hexane has recently been identified in rats and in humans; it is excreted in amounts that at times exceed those of 2,5-hexanedione. It has been suggested that this metabolite indicates a route of detoxification.³³ While there is no definitive evidence that other aliphatic hydrocarbons, such as pentane, heptane, or octane, have similar effects, some case reports suggest an association. In inhalation exposure of rats to *n*-hexane vapors at 900, 3000, and 9000 ppm, reproductive parameters were unaffected over two generations.³⁴ The potential of commercial hexane to produce chromosome aberrations was evaluated *in vitro* and *in vivo*. No increase in chromosome aberrations was observed in either test system.³⁵ The current OSHA permissible exposure limit (PEL) for *n*-hexane remains at the 500 ppm level adopted in 1971, despite evidence that this level is not protective for workers.

Commercial hexane that had been used in industrial processes where workers had peripheral neuropathy was found to contain 2-methyl pentane, 3-methyl pentane, and methyl cyclopentane, in addition to *n*-hexane. The neurotoxicity of these compounds has been tested in rats, and significant effects on peripheral nerves of a similar type but of lesser magnitude than those of *n*-hexane were detected. The order of neurotoxicity was found to be *n*-hexane > methyl cyclopentane > 2-methyl pentane = 3-methyl pentane.³⁶

Other solvent mixtures, such as one containing 80% pentane, 5% hexane, and 14% heptane, have produced cases of peripheral neuropathy in humans. White spirit mixtures containing more than 10% *n*-nonane have been shown by neurophysiological and morphological criteria to produce axonopathy in rats after 6 weeks of daily exposure. Since the various members of the group are most often used in mixtures, a time-weighted average (TWA) of 100 ppm (350 mg/m³) has been proposed.³

Peripheral neuropathy similar to that associated with hexane has been found to result from exposure to MBK. DiVincenzo et al.³⁷

identified the metabolites of *n*-hexane and of MBK; the similarity of chemical structure between the metabolites of these two neurotoxic agents suggested the possibility of a common mechanism in the very similar peripheral neuropathy.

It is now well established that 2,5-hexanedione is the most toxic metabolite. The biochemical mechanism of 2,5-hexanedione neurotoxicity is related to its covalent binding to lysine residues in neurofilament protein and cyclization to pyrroles. Pyrrole oxidation and subsequent protein cross-linking then lead to the accumulation of neurofilaments in axonal swellings, the histopathologic earmark of gamma-diketone peripheral neuropathy. Massive accumulation of neurofilaments has been shown to occur within the axoplasm of peripheral and some central nervous system fibers.³⁸ MBK has not been shown to cause reproductive toxicity³⁹ and was not mutagenic in the Ames test or in a mitotic gene-conversion assay in bacteria. Mammalian mutagenicity test results were also negative.⁴⁰

Ethyl-*n*-butyl ketone (EBK, 3-heptanone) administered in relatively high doses for 14 weeks by gavage produced a typical central peripheral distal axonopathy in rats, with giant axonal swelling and hyperplasia of neurofilaments. Methyl-ethyl ketone (MEK) potentiated the neurotoxicity of EBK and increased the urinary excretion of two neurotoxic gamma-diketones, 2,5-heptanedione and 2,5-hexanedione. The neurotoxicity of EBK seems to be due to its metabolites, 2,5-heptanedione and 2,5-hexanedione.

Methyl-ethyl ketone is a widely used industrial solvent to which there is considerable human exposure. The potential to cause developmental toxicity was tested in mice. Mild developmental toxicity was observed after exposure to 3000 ppm, which resulted in reduction of fetal body weight. There was no significant increase in the incidence of any single malformation, but several malformations not observed in the concurrent control group were found at a low incidence: cleft palate, fused ribs, missing vertebrae, and syndactyly.⁴¹ MEK potentiates EBK neurotoxicity by inducing the metabolism of EBK to its neurotoxic metabolites.

Commercial-grade methyl-heptyl ketone (MHK, 5-methyl-2-octanone) also produced toxic neuropathy in rats, clinically and morphologically identical to that resulting from *n*-hexane, methyl-*n*-butyl ketone (MBK), and 2,5-hexanedione. The MHK mixture was found by gas chromatography-mass spectrometry to contain 5-nonanone (12%), MBK (0.8%) and C₇–C₁₀ ketones and alkanes (15%), besides 5-methyl-2-octanone. Purified 5-nonanone produced clinical neuropathy, whereas purified 5-methyl-2-octanone was not neurotoxic; given together with 5-nonanone, it potentiated the neurotoxic effect. *In vivo* conversion of 5-nonanone to 2,5-nonanedione was demonstrated.⁴² The toxicity of 5-nonanone was shown to be enhanced by simultaneous exposure to MEK. This effect is attributed to the microsomal enzyme-inducing properties of MEK. The neurotoxicity of methyl-*n*-butyl ketone has been shown to be enhanced by other aliphatic monoketones, such as MEK, methyl-*n*-propyl ketone, methyl-*n*-amyl ketone, and methyl-*n*-hexyl ketone; the longer the carbon chain of the aliphatic monoketone, the stronger the potentiating effect on methyl-*n*-butyl ketone neurotoxicity.⁴³

Neuropathological studies have shown that the susceptibility of nerve fibers to linear aliphatic hydrocarbons and ketones is proportional to fiber length and the diameter of the axon. Fibers in the peripheral and central nervous systems undergo axonal degeneration, with shorter and smaller fibers generally being affected later. The long ascending and descending tracts of the spinal cord, the spinocerebellar, and the optic tracts can be affected. Giant axonal swelling, axonal transport malfunction, and secondary demyelination are characteristic features of this central peripheral distal axonopathy.

The unsaturated *olefins* (with one or more double bonds), such as ethylene, propylene, and butylene, and the diolefins, such as 1,3-butadiene and 2-methyl-1,3-butadiene, mainly obtained through cracking of crude oil, are of importance as raw materials for the manufacture of polymers, resins, plastic materials, and synthetic rubber. Their narcotic effect is more potent than that of the corresponding saturated linear hydrocarbons, and they have moderate irritant effects.

1,3-Butadiene, a colorless, flammable gas, is a by-product of the manufacture of ethylene; it can also be produced by dehydrogenation of *n*-butane and *n*-butene. Major uses of 1,3-butadiene are in the manufacture of styrene-butadiene rubber, polybutadiene rubber and neoprene rubber, acrylonitrile-butadiene-styrene resins, methyl methacrylate-butadiene-styrene resins, and other copolymers and resins. It is also used in the production of rocket fuel. In studies of chronic 1,3-butadiene inhalation, malignant tumors developed at multiple sites in rats and mice, including mammary carcinomas and uterine sarcomas in rats and hemangiosarcomas, malignant lymphomas, and carcinomas of the lung in mice.⁴⁴ An excess of brain tumors following 1,3-butadiene exposure has been found in B6C3F1 mice.⁴⁵ Other important effects were atrophy of the ovaries and testes. Ovarian lesions produced in mice exposed by inhalation to 1,3-butadiene included loss of follicles, atrophy, and tumors (predominantly benign, but also malignant granulosa cell tumors).⁴⁶ A macrocytic megaloblastic anemia, indicating bone marrow toxicity, was also found in inhalation experiments on mice.⁴⁷ Hepatotoxicity has been reported in rats exposed to 1,3-butadiene and its metabolite, 3-butene-1,2-diol, through a depletion of hepatic and mitochondrial glutathione.⁴⁸

Evaluation of the human carcinogenicity of 1,3-butadiene hinges on evidence regarding leukemia risks from one large and well-conducted study and two smaller studies. The smaller studies neither support nor contradict the evidence from the larger study. The larger, United States-Canada study shows that workers in the styrene-butadiene rubber industry experienced an excess of leukemia and that those with apparently high 1,3-butadiene exposure had higher risk than those with lower exposure.⁴⁹ The standardized mortality ratio for non-Hodgkin's lymphoma was found to be increased in a large cohort of employees at a butadiene-production facility. There were, nevertheless, no clear exposure group or latency period relationships.⁵⁰ 1,3-Butadiene is metabolized to 1,2-epoxy-3-butene. This metabolite has been shown to be carcinogenic in skin-painting experiments on mice. 1,3-Butadiene has been found to be mutagenic in *in vitro* tests on *Salmonella* and genotoxic to mouse bone marrow *in vitro* in the sister chromatid exchange (SCE) test. Glutathione-S-transferase theta-1 (GSTT1) and cytochrome P450 2E1 (CYP2E1) polymorphisms have been shown to influence diepoxybutane-induced SCE frequency in human lymphocytes.⁵¹ A second metabolite of 1,3-butadiene is 1,2,3,4-diepoxybutane, also shown to be genotoxic in various test systems *in vitro*.⁵² Binding of ¹⁴C-labeled 1,3-butadiene to liver DNA was demonstrated in mice and rats.⁵³ 1,3-Butadiene is metabolized to several epoxides that form DNA and protein adducts, most resulting from 3-butene-1,2-diol metabolism to 3,4-epoxy-1,2-butanediol.⁵⁴ Butadiene diepoxide, an active metabolite, induces cell cycle perturbation and arrest even with short-term exposure that does not produce other pathologic cellular effects.⁵⁵ The International Agency for Research on Cancer concluded in 1999 that 1,3-butadiene is a probable carcinogen in humans (Group 2A).¹

The National Institute for Occupational Safety and Health has recommended that the present OSHA standard of 1000 ppm TWA for 1,3-butadiene be reexamined, since carcinogenic effects in rodents (mice) have been observed at exposure levels of 650 ppm. To minimize the carcinogenic risk for humans, it was recommended that exposures be reduced to the lowest possible level.

Isoprene (2-methyl-1,3-butadiene), a naturally occurring volatile compound and close chemical relative of 1,3-butadiene, has been studied in inhalation experiments on rats. A mutagenic metabolite, isoprene diepoxide, was tentatively identified in all tissues examined.⁵⁶

The principal member of the series of aliphatic hydrocarbons with triple bonds—*alkynes*—is acetylene (HCCH), a gas at normal temperature. Acetylene is widely used for welding, brazing, metal

buffing, metallizing, and other similar processes in metallurgy. It is also a very important raw material for the chemical synthesis of plastic materials, synthetic rubber, vinyl chloride, vinyl acetate, vinyl ether, acrylonitrile, acrylates, trichloroethylene, acetone, acetaldehyde, and many others.

While the narcotic effect of acetylene is relatively low and becomes manifest only at high concentrations (15%) not found under normal circumstances, the frequent presence of impurities in acetylene represents the major hazard. Phosphine is the most common impurity in acetylene, but arsine and hydrogen sulfide may also be present. The hazard is especially significant in acetylene-producing facilities or when acetylene is used in confined, poorly ventilated areas.

► ALICYCLIC HYDROCARBONS

Alicyclic hydrocarbons are saturated (cycloalkanes, cycloparaffins, or naphthenes) or unsaturated cyclic hydrocarbons, with one or more double bonds (cycloalkenes or cycloolefins). The most important members of the group are cyclopropane, cyclopentane, methylcyclopentane, cyclohexane, methylcyclohexane ethylcyclohexane, cyclohexene, cyclopentadiene, and cyclohexadiene. These compounds are present in crude oil and its distillation products.

Cyclopropane is used as an anesthetic. Most of the members of the group are used as solvents and, in the chemical industry, in the manufacture of a variety of other organic compounds, including adipic, maleic, and other organic acids; methylcyclohexane is a good solvent for cellulose ethers. Their toxic effects are similar to those of their linear counterparts, the aliphatic hydrocarbons, but they have more marked narcotic effects; the irritant effect on skin and mucosae is similar.

► COMMERCIAL MIXTURES OF PETROLEUM SOLVENTS

Mixtures of hydrocarbons obtained through distillation and cracking of crude oil are gasoline, petroleum ether, rubber solvent, petroleum naphtha, mineral spirits, Stoddart solvent, kerosene, and jet fuels. These are all widely used commercial products.

The composition of these mixtures is variable: all contain aliphatic saturated and nonsaturated hydrocarbons, alicyclic saturated and nonsaturated hydrocarbons, and smaller amounts of aromatic hydrocarbons such as benzene, toluene, xylene, and polycyclic hydrocarbons; the proportion of these components varies. The boiling temperature varies from 30°C to 60°C for petroleum ether to 175°C to 325°C for kerosene; the hazard of overexposure is higher with the more volatile mixtures with lower boiling temperatures.

The toxic effects of these commercial mixtures of hydrocarbons are similar to those of the individual hydrocarbons: the higher the proportion of volatile hydrocarbons in the mixture, the greater the hazard of acute CNS depression, with possible loss of consciousness, coma, and death resulting from acute overexposure. Exposure to high concentrations, when not lethal, is usually followed by complete recovery. Nevertheless, irreversible brain damage may occur, especially after prolonged coma. The underlying pathologic change is represented by focal microhemorrhages. The irritant effects on the respiratory and conjunctival mucosae are generally moderate.

Exposure to lower concentrations over longer periods is common; the potential effects of aromatic hydrocarbons, especially benzene, have to be considered under such circumstances. Bone marrow depression with resulting low red blood cell counts and leukopenia with neutropenia and/or low platelet counts can develop, and medical surveillance should include periodic blood counts for the early detection of such effects; cessation of exposure to mixtures containing aromatic hydrocarbons is necessary when such abnormalities occur. Long-term effects of benzene exposure include increased risk of leukemia; therefore, exposure should be carefully monitored and controlled so that the recommended standard for benzene not be exceeded.

Chronic effects on the central and peripheral nervous systems with exposure to commercial mixtures of hydrocarbons have received more attention only in recent years. Since some of the common components of such mixtures have been shown to produce peripheral neuropathy and to induce similar degenerative changes of axons in the CNS, such effects might also result from exposure to mixtures of hydrocarbons. Long-term exposure to solvents, including commercial mixtures of hydrocarbons, has been associated, in some cases, with chronic, possibly irreversible CNS impairment. Such effects have been documented by clinical, electrophysiological, neurobehavioral, and brain-imaging techniques.

Accidental ingestion and aspiration of gasoline or other mixtures of hydrocarbons can occur, mainly during siphoning, and result in severe chemical pneumonitis, with pulmonary edema, hemorrhage, and necrosis.

Gasoline and other hydrocarbon mixtures used as engine fuel have a variety of additives to enhance desired characteristics. Lead tetraethyl probably has the highest toxicity. Workers employed in the manufacture of this additive and in mixing it with gasoline have the highest risk of exposure, and their protection has to be extremely thorough. Ethylene dibromide (EDB) is another additive with important toxicological effects which has received increased attention recently.

Skin irritation, related to the defatting properties of these solvents, and consequent increased susceptibility to infections, is frequent when there is repeated contact with such mixtures of hydrocarbons or with individual compounds. Chronic dermatitis is a common finding in exposed workers; protective equipment and appropriate work practices are essential in its prevention.

Prevention and Surveillance

Exposure to airborne aliphatic hydrocarbons should be controlled so as not to exceed a concentration of 350 mg/m³ as a TWA. This concentration is equivalent to 120 ppm pentane, 100 ppm hexane, and 85 ppm heptane. For the commercial mixtures, a similar TWA has been recommended, except for petroleum ether (the most volatile mixture) for which a TWA of 200 mg/m³ is recommended.³ Exposure to benzene should not exceed the recommended standard of 1 ppm (3.2 mg/m³), given the marked myelotoxicity of benzene and the increased incidence of leukemia. There is a definite need to monitor for the presence and amount of aromatic hydrocarbons in mixtures of petroleum solvents.

Medical surveillance programs should aim at the early detection of such adverse effects as toxic peripheral neuropathy, chronic CNS dysfunction, hematological effects, and dermatitis. Since accidental overexposure may result in rapid loss of consciousness and death (CNS depression), adequate and prompt therapy for such cases is urgent. Education of employees and supervisory personnel concerning potential health hazards, safe working practices (including respirator use when necessary), and first-aid procedures is essential.

► AROMATIC HYDROCARBONS

Aromatic hydrocarbons are characterized by a benzene ring in which the six carbon atoms are arranged as a hexagon, with a hydrogen atom attached to each carbon—C₆H₆. According to the number of benzene rings and their binding, the aromatic hydrocarbons are classified into three main groups:

1. Benzene and its derivatives: toluene, xylene, styrene, etc.
2. Polyphenyls: two or more noncondensed benzene rings—diphenyls, triphenyls.
3. Polynuclear aromatic hydrocarbons: two or more condensed benzene rings—naphthalene, anthracene, phenanthrene, and the carcinogenic polycyclic hydrocarbons (benz[a]pyrene, methylcholanthrene, etc.)

Distillation of coal in the coking process was the original source of aromatic hydrocarbons; an increasing proportion is now

derived from petroleum through distillation, dehydrogenation of cycloparaffins, and catalytic cyclization of paraffins.

Benzene

Benzene is a clear, colorless, volatile liquid with a characteristic odor; the relatively low boiling temperature (80°C) is related to the high volatility and the potential for rapidly increasing air concentrations.

Commercial-grade benzene contains variable amounts—up to 50%—of toluene, xylene, and other constituents that distill below 120°C. More important is the fact that commercial grades of other aromatic hydrocarbons, toluene and xylene, also contain significant proportions of benzene (up to 15% for toluene); this also applies to commercial mixtures of petroleum distillates, such as gasoline and aromatic petroleum naphthas, where the proportion of benzene may reach 16%. Benzene exposure is, therefore, a more widespread problem than would be suggested by the number of employees categorized as handling benzene as such. Many others exposed to mixtures of hydrocarbons or commercial grades of toluene and xylene may also be exposed to significant concentrations of benzene.

Production of benzene has continuously expanded. It is estimated that more than 2 million workers are exposed to benzene in the United States.³ In recent years, there has been increasing concern with respect to benzene in hazardous waste-disposal sites. Benzene has been found in almost one-third of the 1177 National Priorities List hazardous waste sites. Other environmental sources of exposure include gasoline filling stations, vehicle exhaust fumes, underground gasoline storage tanks that leak, wastewater from industries that use benzene, and groundwater next to landfills that contain benzene. Urban structural fires yield benzene as a predominating combustion product.⁵⁷ An important use of benzene in some parts of the world is as an additive in motor fuel, including gasoline. In Europe, gasolines have been found to contain up to 5% benzene; in the United States, levels up to 2% have been reported. An association between acute childhood leukemia and residence near auto repair garages and gasoline stations has been reported.⁵⁸ Environmental levels of benzene in areas with intense automotive traffic have been found to range from 1 to 100 ppb. Urban air in high vehicular traffic zones with high levels of benzene and ultra-fine particulates is associated with elevated levels of chromosome strand breaks and other indicators of oxidative DNA damage in mononuclear blood cells of residents.⁵⁹ DNA and protein adduct levels in liver and bone marrow in mice exposed to benzene showed a dose-dependent increase at doses mimicking human environmental (nonoccupational) exposure.⁶⁰ Consumer products that contain benzene include glues, adhesives, some household cleaning products, paint strippers, some art supplies, and gasoline. Increasing focus has been directed toward the well-documented benzene content of cigarette smoke and the health risks associated with direct smoking and exposure to second-hand smoke.⁶¹

Exposure to benzene may occur in the distillation of coal in the coking process; in oil refineries; and in the chemical, pharmaceutical, and pesticides industries, where benzene is widely used as a raw material for the synthesis of products. Exposure may also occur with its numerous uses as a solvent, in paints, lacquers, and glues; in the linoleum industry; for adhesives; in the extraction of alkaloids; in degreasing of natural and synthetic fibers and of metal parts; in the application and impregnation of insulating material; in rotogravure printing; in the spray application of lacquers and paints; and in laboratory extractions and chromatographic separations. The largest amounts of benzene are used for the synthesis of other organic compounds, mostly in enclosed systems, where exposure is generally limited to equipment leakage, liquid transfer, and repair and maintenance operations. Exposures with the use of benzene as a solvent or solvent component present a more difficult problem, since enclosure of such processes and adequate control of airborne concentrations have not been easily achieved.

Inhalation of the vapor is the main route of absorption; skin penetration is of minor significance. Benzene retention is highest in lipid-rich organs: in adipose tissue and bone marrow, benzene concentrations

may reach a level 20 times higher than the blood concentration; its persistence in these tissues is also much longer. Elimination is through the respiratory route (45–70% of the amount inhaled); the rest is excreted as urinary metabolites.

Benzene is metabolized in the liver to a series of phenolic and ring-opened products and their conjugates, in part by the P450 mixed-function microsomal oxidases; the first intermediate in its biotransformation is benzene epoxide, a precursor of several active metabolites proposed to be responsible for the carcinogenic effect of benzene. The metabolites of benzene include phenol, catechol, hydroquinone, *p*-benzoquinone, and *trans, trans*-muconaldehyde. Recent studies have demonstrated that polymorphisms in NQO1, CYP2E1, and GSTT1 genes and their associated enzymes involved in benzene activation or detoxification, including oxidoreductase 1 (NQO1), CYP2E1, and GSTT1, and P450 enzyme-inducing ethanol consumption,⁶² might contribute to the development of benzene hematotoxicity in exposed workers⁶³ and mice.^{64,65} The role of the aryl hydrocarbon receptor (AhR) is suggested by studies showing the mice lacking AhR exhibit no hematotoxicity after exposure to high concentrations of benzene.⁶⁶

Trans, trans-muconaldehyde (MUC), a six-carbon-diene-dialdehyde, is a microsomal, hematotoxic ring-opened metabolite of benzene. MUC is metabolized to compounds formed by oxidation and reduction of the aldehyde group(s). MUC and its aldehydic metabolites 6-hydroxy-*trans, trans*-2,4-hexadienal and 6-oxo-*trans, trans*-hexadienoic acid are mutagenic in that order of potency. The order of mutagenic activity correlates with reactivity toward glutathione, suggesting that alkylating potential is important in the genotoxicity of these compounds.⁶⁷

The triphenolic metabolite of benzene 1,2,4-benzenetriol (BT) is readily oxidized to its corresponding quinone. During this process, active oxygen species are formed that may damage DNA and other macromolecules. BT increases the frequency of micronuclei formation. BT also increases the level of 8-hydroxy-2'-deoxyguanosine (8-OH-dG), a marker of active oxygen-induced DNA damage. Thus BT can cause structural chromosomal changes and point mutations indirectly by generating oxygen radicals. BT may, therefore, play an important role in benzene-induced leukemia.⁶⁸ Catechol and hydroquinone were found to be highly potent in inducing sister chromatid exchange and delaying cell division; these effects were much more marked than those of benzene and phenol.⁶⁹

Exposure to high airborne concentrations of benzene results in CNS depression with acute, nonspecific, narcotic effects. With very high exposure (thousands of ppm), loss of consciousness and depression of the respiratory center or myocardial sensitization to endogenous epinephrine with ventricular fibrillation may result in death. Recovery from acute benzene poisoning is usually complete if removal from exposure is prompt; in cases of prolonged coma (after longer exposure to high concentrations), diffuse or focal EEG abnormalities have been observed for several months after recovery, together with such symptoms as dizziness, headache, fatigue, and sleep disturbances.

Chronic benzene poisoning is a more important risk, since it can occur with much lower exposure levels. It can develop insidiously over months or years, often without premonitory warning symptoms, and result in severe bone marrow depression. Benzene is a potent myelotoxic agent. Hematologic abnormalities detected in the peripheral blood do not always correlate with the pattern of bone marrow changes. Relatively minor deviations from normal in the blood count (red blood cells [RBCs], white blood cell [WBCs], or platelets) may coexist with marked bone marrow changes (hyperplastic or hypoplastic), and abnormalities are sometimes first found after cessation of exposure. Benzene-induced aplastic anemia can be fatal, with hemorrhage secondary to the marked thrombocytopenia and increased susceptibility to infections due to neutropenia. The number of reported cases of severe chronic benzene poisoning with aplastic anemia gradually decreased after World War II, because of better engineering controls, progressive reduction of the PELs, and efforts to substitute less toxic solvents for benzene in numerous industrial processes.

The mechanism of aplastic anemia appears to involve the concerted action of several metabolites acting together on early stem and

progenitor cells, as well as on early blast cells, to inhibit maturation and amplification. Red blood cell, white blood cell, and platelet counts may initially increase, but more often anemia, leukopenia, and/or thrombocytopenia are found. The three cell lines are not necessarily affected to the same degree, and all possible combinations of hematological changes have been found in cases of chronic benzene poisoning. In some older reports, the earliest abnormalities have been described as reduction in the number of white blood cells and relative neutropenia; in later studies, lower than normal red blood cell counts and macrocytosis with hyperchromic anemia have been found more often to be the initial hematologic abnormalities.^{70,71} Thrombocytopenia has also been frequently reported.⁷² The bone marrow may be hyperplastic or hypoplastic. Compensatory replication of primitive progenitor cells in the bone marrow of mice during benzene exposure has been reported as a response to cytotoxicity among more differentiated cell types.⁷³ All hematologic parameters (total white blood cells, absolute lymphocyte count, platelets, red blood cells, and hematocrit) were decreased among benzene-exposed workers compared to controls, with the exception of the red blood cell mean corpuscular volume (MCV), which was higher among exposed subjects.⁷⁴ In a study of 250 workers exposed to benzene, white blood cell and platelet counts were significantly lower than in 140 controls, even for exposure below 1 ppm in air, the current workplace standard. Progenitor cell colony formation significantly declined with increasing benzene exposure and was more sensitive to the effects of benzene than was the number of mature blood cells. Two genetic variants in key metabolizing enzymes, myeloperoxidase and NAD(P)H:quinone oxidoreductase, influenced susceptibility to benzene hematotoxicity.⁷⁵ In another study, polymorphism in myeloperoxidase was shown to influence benzene-induced hematotoxicity in exposed workers.⁷⁶ Benzene has been shown to suppress hematopoiesis by suppression of the cell cycle by p53-mediated overexpression of p21, a cyclin-dependent kinase inhibitor.⁷⁷

Nitric oxide has been shown to be a contributor to benzene metabolism, especially in the bone marrow, and can form nitrated derivatives that may, in part, account for bone marrow toxicity.⁷⁸ The stromal macrophage that produces interleukin-1 (IL-1), a cytokine essential for hematopoiesis, is a target of benzene toxicity. Hydroquinone, a bone marrow toxin, inhibits the processing of pre-interleukin-1 alpha (IL-1 alpha) to the mature cytokine in bone marrow macrophages.⁷⁹ Benzene and hydroquinone have been demonstrated to induce myeloblast differentiation and hydroquinone to induce growth in myeloblasts in the presence of IL-3.⁸⁰ The stromal macrophage, a target of benzene toxicity, secretes IL-1, which induces the stromal fibroblast to synthesize hematopoietic colony-stimulating factors. The processing of pre-IL-1 to IL-1 is inhibited by *para*-benzoquinone in stromal macrophages of mice.⁸¹

Benzene is an established animal and human carcinogen. Leukemia, secondary to benzene exposure has been repeatedly reported since the 1930s. All types of leukemia have been found; myelogenous leukemia (chronic and acute) and erythroleukemia (Di Guglielmo's disease) apparently more frequently, but acute and chronic lymphocytic or lymphoblastic leukemia is represented as well. Malignant transformation of the bone marrow has been noted years after cessation of exposure, an added difficulty in the few epidemiological studies on long-term effects of benzene exposure. In Italy, with a large shoe-manufacturing industry, where benzene-based glues had been used for many years, at least 150 cases of benzene-related leukemia were known by 1976.⁸² In Turkey, more than 50 cases of aplastic anemia and 34 cases of leukemia have been reported from the shoe-manufacturing industry.⁸³ Epidemiological studies in the United States rubber industry have indicated a more than three-fold increase in leukemia deaths; occupations with known solvent exposure (benzene widely used in the past and still a contaminant of solvents used) showed a significantly higher leukemia mortality than other occupations. Lymphatic leukemia showed the highest excess mortality. The risk of leukemia was much higher in workers exposed 5 years or more (SMR of 2100). Four additional cases of leukemia occurred among employees not encompassed by the definition of the cohort.⁸⁴ In Japan, the incidence of leukemia among Hiroshima and

Nagasaki survivors was found to be significantly increased by occupational benzene exposure in the years subsequent to the bomb.⁸⁵ In a large cohort of 74,828 benzene-exposed and 35,805 nonexposed workers in 12 cities in China, deaths due to lymphatic and hematopoietic malignancies and lung cancer increased significantly with increasing cumulative exposure to benzene.⁸⁶

Experimental studies have demonstrated carcinogenic effects of benzene in experimental animals; in addition to leukemias,⁸⁷ benzene has produced significant increases in the incidence of Zymbal gland carcinomas in rodents, cancer of the oral cavity, hepatocarcinomas, and possibly mammary carcinomas and lymphoreticular neoplasias.⁸⁸ In experimental studies on mice, in addition to a high increase in leukemias, a significant increase in lymphomas was found.⁸⁹ The National Toxicology Program conducted an oral administration experimental study in which malignant lymphoma and carcinomas in various organs, including skin, oral cavity, alveoli/bronchioli, and mammary gland in mice, and carcinomas of the skin, oral cavity, and Zymbal gland in rats were found with significantly increased incidence. Thus NTP concluded that there was clear evidence of carcinogenicity of benzene in rats and mice⁹⁰. The Environmental Protection Agency (EPA) has come to the same conclusion.

The International Agency for Research on Cancer (IARC) has acknowledged the existence of limited evidence for chronic myeloid and chronic lymphocytic leukemia. In addition, it was noted that studies had suggested an increased risk of multiple myeloma,⁹¹ while others indicate a dose-related increase in total lymphatic and hematopoietic neoplasms.

The carcinogenicity of benzene is most likely dependent upon its conversion to phenol and hydroquinone, the latter being oxidized to the highly toxic 1,4-benzoquinone in the bone marrow. Many recent studies have explored the mechanism by which these benzene metabolites act.

The modified base 8-hydroxy-deoxyguanosine (8-OH-dG) is a sensitive marker of DNA damage due to hydroxyl radical attack at the C8 guanine. A biomonitoring study of 65 filling station attendants in Rome, Italy, found the urinary concentration of 8-OH-dG to be significantly correlated with benzene exposure calculated on the basis of repeated personal samples collected during 1 year.⁹² Exposure to low, medium, and high concentrations of benzene resulted in a dose-dependent increase in levels of 8-OH-dG and lymphocyte micronuclei in benzene-exposed workers.⁹³ It has been shown that deoxyribonucleic acid (DNA) adducts (guanine nucleoside adducts) are formed by incubation of rabbit bone marrow with ¹⁴C-labeled benzene; *p*-benzoquinone, phenol, hydroquinone, and 1,2,4-benzenetriol also form adducts with guanine.⁹⁴ The differential formation of DNA adducts by *p*-benzoquinone and hydroquinone and their respective mutagenetic activities have been characterized.⁹⁵

Benzene and its metabolites do not function well as mutagens, but are highly clastogenic, producing chromosome aberrations, sister chromatid exchange, and micronuclei.⁹⁶ Exposure of human lymphocytes and cell lines to hydroquinone has been shown to cause various forms of genetic damage, including aneusomy and the loss and gain of chromosomes. Chromosomal aberrations in lymphocytes of benzene-exposed workers have been well documented;⁹⁷ they were shown to persist even years after cessation of toxic exposure.⁹⁸ The "stable" aberrations are more persistent and have been considered to be the origin of leukemic clones. A more recent study demonstrated an increased incidence of chromosomal aberrations (particularly chromatid gaps and breaks) among long-term Turkish shoe manufacturing workers when compared to a control group.⁹⁹ The occurrence of a significant excess of DNA damage in peripheral lymphocytes of human subjects with occupational exposure to low levels of benzene (12 gasoline station attendants) compared with controls, independent of the ages or smoking habits of the subjects, was demonstrated by the alkaline single cell gel electrophoresis (Comet) assay. Exposed subjects showed an excess of heavily damaged cells.¹⁰⁰ High benzene exposure has been shown to induce aneuploidy of chromosome 9 in nondiseased workers, with trisomy being the most prevalent form, as determined by fluorescence in situ hybridization (FISH) and interphase cytogenetics.¹⁰¹

Cytogenetic effects of benzene have been reproduced in animal models. In rats exposed to 1000 and 100 ppm, a significant increase in the proportion of cells with chromosomal abnormalities was detected; exposure to 10 and 1 ppm resulted in elevated levels of cells with chromosomal abnormalities that showed evidence of being dose-related, although they were not statistically significant.¹⁰² A dose-related increase in the frequency of micronucleated cells in tissue cultures from rat Zymbal glands (a principal target for benzene carcinogenesis in rats) was reported.¹⁰³ A significant increase in sister chromatid exchanges in bone marrow cells of mice exposed to 28 ppm benzene for 4 hours has been reported.¹⁰⁴ Benzene induced a dose-dependent increase in the frequencies of chromosomal aberrations in bone marrow and spermatogonial cells. The damage was greater in bone marrow than in spermatogonial cells.¹⁰⁵ Using fluorescence in situ hybridization with chromosome-specific painting probes (FISH painting), chromatid-type aberrations in mice were significantly increased 24 and 36 hours after a single high-dose benzene exposure, while chromosome-type aberrations were elevated above control values 36 hours and 15 days after exposure, showing that at least part of benzene-induced chromatid exchanges were converted into potentially stable chromosome aberrations.¹⁰⁶

The target cells for leukemogenesis are the pluripotent stem cells or early progenitor cells which carry the CD34 antigen (CD34⁺ cells). Following benzene exposure in mice, aneuploid cells were more frequent in the hematopoietic stem cells compartment than in mature hematopoietic subpopulations.¹⁰⁷ Hydroquinone, a benzene metabolite, increases the level of aneusomy of chromosomes 7 and 8 in human CD34-positive blood progenitor cells.¹⁰⁸ Catechol and hydroquinone have been shown to act in synergy to induce loss of chromosomes 5, 7, and 8 as found in secondary myelodysplastic syndrome and acute myelogenous leukemia.¹⁰⁹ Human CD34⁺ cells have been shown to be sensitive targets for 1,4-benzoquinone toxicity that use the p53 DNA damage response pathway in response to genotoxic stress. Apoptosis and cytotoxicity were dose-dependent, and there was a significant increase in the percentage of micronucleated CD34⁺ cells in cultures treated with 1,4-benzoquinone.¹¹⁰ The role of gene-environmental interaction in benzene-induced chromosomal damage has been investigated: the polymorphic genes GSTM1, GSTT1, and GSTP1, coding for GST, have been shown to exhibit differential metabolism of hydroquinone, associated with different frequencies of micronuclei and sister chromatid exchanges, induced by hydroquinone in human lymphocytes.¹¹¹ Genotype-dependent chromosomal instability can be induced by hydroquinone doses that are not acutely stem cell toxic.¹¹² DNA-protein crosslinking and DNA strand-breaks were induced by *trans*, *trans*-muconaldehyde and hydroquinone, with synergistic interactive effects of the two agents in combination.¹¹³

1,4-Benzoquinone has been shown to inhibit topoisomerase II catalysis, most probably by binding to an essential SH group,¹¹⁴ with a consequent increase in topoisomerase II-mediated DNA cleavage, primarily by enhancing the forward rate of scission. In vitro, the compound induced cleavage at DNA sites proximal to a defined leukemic chromosomal breakpoint.¹¹⁵ 1,4-Benzoquinone and *trans*, *trans*-muconaldehyde were shown to be directly inhibitory, whereas all of the phenolic metabolites were shown to inhibit topoisomerase II activity in vitro following bioactivation using a peroxidase activation system¹¹⁶ and in vivo in the bone marrow of treated mice.¹¹⁷

The effect of p53 heterozygosity on the genomic and cellular responses of target tissues in mice to toxic insult has been demonstrated. Examination of mRNA levels of p53-regulated genes involved in cell cycle control (p21, gadd45, and cyclin G) or apoptosis (bax and bcl-2) showed that during chronic benzene exposure, bone marrow cells from p53^{+/+} mice expressed significantly higher levels of a majority of these genes compared to p53^{-/-} bone marrow cells.¹¹⁸

The ability of the benzene metabolites hydroquinone and *trans*, *trans*-muconaldehyde to interfere with gap-junction intercellular communication, a characteristic of tumor promoters and nongenotoxic carcinogens and shown to result in perturbation of hematopoiesis, has been proposed as a possible mechanism for benzene-induced hematotoxicity and development of leukemia.¹¹⁹ Recent studies suggest that benzene's metabolites, catechol and phenol, may mediate benzene toxicity

through metabolite-mediated alterations in the c-Myb signaling pathway, overexpression of which is believed to play a key role in the development of a wide variety of leukemias and tumors.¹²⁰ Covalent binding of the benzene metabolites *p*-benzoquinone and *p*-biphenylquinone to critical thiol groups of tubulin has been shown to inhibit microtubule formation under cell-free conditions, possibly interfering with the formation of a functional spindle apparatus in the mitotic cell, thus leading to the abnormal chromosome segregation and aneuploidy induction reported for benzene.¹²¹ An effect of MUC, hydroquinone (HQ), and four MUC metabolites on gap-junction intercellular communication has been demonstrated.¹²²

Toxic effects on reproductive organs have received increased attention. In subchronic inhalation studies, histopathological changes in the ovaries (characterized by bilateral cyst formation) and in the testes (atrophy and degenerative changes, including a decrease in the number of spermatozoa and an increase in abnormal sperm forms) have been reported.¹²³ Benzene was shown to be a transplacental genotoxicant in mice, where it was found to significantly increase micronuclei and sister chromatid exchange in fetal liver when administered at a high dose (1318 mg/kg) to mice on day 14 and 15 of gestation.¹²⁴ Levels of pregnandiol-3-glucuronide, follicle-stimulating hormone and estrone conjugate in the urine of female benzene-exposed workers were significantly lower than those in a nonexposed control group.¹²⁵

Exposure to benzene at high concentrations (42.29 mg/m³) induced increases in the frequencies of numerical aberrations for chromosome 1 and 18 and of structural aberrations for chromosome 1 in sperm in exposed workers.¹²⁶

There is little information on developmental toxicity of benzene in humans. Case reports have documented that normal infants without chromosomal aberrations can be born to mothers with an increased number of chromosomal aberrations;¹²⁷ other investigators have reported increases in the frequency of sister chromatid exchanges and chromatid breaks in children of women exposed to benzene and other solvents during pregnancy. In animal experiments *in vivo*, benzene has not been found to be teratogenic; a decrease in fetal weight and an increase in skeletal variants have been associated with maternal toxicity.

The embryotoxicity of toluene, xylene, benzene, styrene, and its metabolite, styrene oxide, was evaluated using the *in vitro* culture of postimplantation rat embryos. Toluene, xylene, benzene, and styrene all have a concentration-dependent embryotoxic effect on the developing rat embryo *in vitro* at concentrations ranging from 1.00 μ mol/ml for styrene, 1.56 μ mol/ml for benzene, and 2.25 μ mol/ml for toluene. There was no evidence of synergistic interaction among the solvents.¹²⁸

The immunotoxicity of benzene in rats was demonstrated by a reduction in the number of B-lymphocytes after 2 weeks of exposure at 400 ppm and a subsequent reduction in thymus weight and spleen B-, CD4⁺/CD5⁺, and CD5⁺ T-lymphocytes at 4 weeks.¹²⁹ Rapid and persistent reductions in femoral B-, splenic T- and B-, and thymic T-lymphocytes, along with a marked increase in the percentage of femoral B-lymphocytes and thymic T-lymphocytes in apoptosis, were induced in mice exposed to benzene at 200 ppm.¹³⁰ *Para*-benzoquinone has been shown to inhibit mitogen-induced IL-2 production by human peripheral blood mononuclear cells.¹³¹ Hydroquinone, in concentrations comparable to those found in cigarette tar, is a potent inhibitor of IL-2-dependent T-cell proliferation.¹³²

Prevention and Control

Prevention of benzene poisoning and of malignant transformation of the bone marrow is based on engineering control of exposure. The TLV for benzene has been repeatedly reduced in the last several decades.^{2,3} In 1987, the OSHA occupational exposure standard for benzene was revised to 1 ppm TWA, with a 5 ppm short-term exposure limit (STEL). The National Institute for Occupational Safety and Health (NIOSH) has recommended that the standard be revised to a TWA of 0.1 ppm, with a 15-minute ceiling value of 1 ppm.

Biological monitoring through measurements of urinary metabolites of benzene is useful as a complement to air sampling for the measurement of benzene concentrations. Elevation in the total

urinary phenols (normal range 20–30 mg/L) indicates excessive benzene exposure, and 50 mg/L should not be exceeded. The urinary inorganic/total sulfate ratio may also be monitored. Biological monitoring is recommended at least quarterly but should be more frequent when exposure levels are equal to or higher than the TWA. A urinary phenol level of 75 mg/L was found in one study to correspond to a TWA exposure to 10 ppm; in other studies the urinary phenol level corresponding to 10 ppm benzene was 45–50 mg/L.

Trans, trans-muconic acid in urine is potentially useful as a monitor for low levels of exposure to benzene. A gas chromatography/mass spectrometry assay was developed that detects muconic acid in urine of exposed workers at levels greater than 10 ng/ml. MUC excretion in urine has been shown to be a sensitive indicator of low levels of exposure to benzene in second-hand tobacco smoke,^{133,134} although interindividual variability rate of metabolizing benzene to MUC may introduce some limitations in the application of this metabolite as an exposure index of low benzene exposure.¹³⁵ *S*-phenylmercapturic acid was reported to be more sensitive than MUC as a biomarker for low levels of workers' exposure to benzene at concentrations less than 0.25 ppm.¹³⁶

Preplacement and periodic examinations should include a history of exposure to other myelotoxic chemical or physical agents or medications and of other hematologic conditions. A complete blood count, a mean corpuscular volume determination, reticulocyte and platelet counts, and the urinary phenol test are basic laboratory tests. The frequency of these examinations and tests should be related to the level of exposure.³ Possible neurological and dermatological effects should also be considered in comprehensive periodic examinations. Adequate respirators should be available and should be used when spills, leakage, or other incidents of higher exposure occur.

In recent years, the possibility of excessive benzene ingestion from contaminated water has received increasing attention. Benzene concentrations in water have been found to range from 0.005 ppb (in the Gulf of Mexico) to 330 ppb in contaminated well water in New York, New Jersey, and Connecticut. In 1985, the EPA proposed a maximum contamination level (MCL) for benzene in drinking water at 0.005 mg/L; this standard was promulgated in 1987.

Toluene

Toluene (methylbenzene, C₆H₅CH₃) is a clear, colorless liquid, with a higher boiling point (110°C) than benzene and, therefore, lower volatility. The production of toluene has increased markedly over the last several decades because of its use in numerous chemical synthesis processes, such as those of toluene diisocyanate, phenol, benzyl, and benzoyl derivatives, benzoic acid, toluene sulfonates, nitrotoluenes, vinyl toluene, and saccharin. More than 7 million tons are produced each year in the United States. Toluene is also used as a solvent, mostly for paints and coatings, and is often a component of mixtures of solvents. Technical grades of toluene contain benzene in variable proportions, reaching 25% in some products.

Hematological effects in workers exposed to toluene have been reported in the past.^{1,2} Such effects were most probably due to the benzene content of toluene or to prior benzene exposure. Animal experiments indicate that pure toluene has no myelotoxic effects. Toluene has been shown to induce microsomal cytochrome P450 and mixed-function oxidases in the liver. Toluene exposure induces P450 isoenzymes CYP1A1/2, CYP2B1/2, CYP2E1, and CYP3A1, but decreases CYP2C11/6 and CYP2A1 in adult male rats. The inductive effect is more prominent in younger than in older animals and in males more than in females. Exposure to toluene does not influence renal microsomal P450-related enzyme activity in rats,¹³⁷ but inhibited mixed-function oxidases in the lung.¹³⁸

Exposure to toluene concentrations higher than 100 ppm results in CNS depression, with prenarctic symptoms and in moderate eye, throat, airway, and skin irritation. These effects are more pronounced with higher concentrations.

Volatile substance abuse has now been reported from most parts of the world, mainly among adolescents, individuals living in isolated communities, and in those who have ready access to such substances.

Solvents from contact adhesives, cigarette lighter refills, aerosol propellants, gasoline, and fire extinguishers containing mostly halogenated hydrocarbons may be abused by sniffing. Euphoria, behavioral changes similar to those produced by ethanol, but also hallucinations and delusions are the most frequent acute effects. Higher doses can result in convulsions and coma. Cardiac or central nervous system toxicity can lead to death. Chronic abuse of solvents can produce severe organ toxicity, mostly of the liver, kidney, and brain.¹³⁹ There is evidence that volatile substance abuse has declined in the United States. In a study of the 6-year period from 1996 through 2001 involving all cases of intentional inhalational abuse of nonpharmaceutical substances, there was a mean annual decline of 9% of reported cases, with an overall decline of 37% from 1996 to 2001. There was, however, no decline in major adverse health outcomes or fatalities.¹⁴⁰

Numerous reports on toluene addiction (sniffing) have indicated that irreversible neurological effects are possible. Severe multifocal CNS damage,^{141,142,143} as well as peripheral neuropathies,¹⁴⁴ with impairment in cognitive, cerebellar, brain stem, auditory, and pyramidal tract function has been well documented in glue sniffers. Diffuse EEG abnormalities are usually present. Cerebral and cerebellar atrophy have been demonstrated by CT scans of the brain; brain stem atrophy has also been reported. MRI imaging following chronic toluene abuse demonstrated cerebral atrophy involving the corpus callosum and cerebellar vermis, loss of gray-white matter contrast, diffuse supratentorial white matter high-signal lesions, and low signal in the basal ganglia and midbrain.¹⁴⁵ Toluene exposure in rats for 11 weeks resulted in a persisting motor syndrome, with shortened and widened gait and widened landing foot splay, and hearing impairment. This motor syndrome resembles the syndrome (e.g., wide-based, ataxic gait) seen in some heavy abusers of toluene-containing products.¹⁴⁶ Toluene can activate dopamine neurons within the mesolimbic reward pathway in the rat, an effect that may underlie its abuse potential.¹⁴⁷ Increased sensitivity to the seizure-inducing properties of aminophylline has been reported in toluene-exposed mice.¹⁴⁸

Subchronic exposure of rats to toluene in low concentrations (80 ppm, for 4 weeks, 5 days/week, 6 hours/day) causes a slight but persistent deficit in spatial learning and memory, a persistent decrease in dopamine-mediated locomotor activity, and an increase in the number of dopamine D2 receptors.¹⁴⁹ Toluene exposure to a dose generally recognized as subtoxic (40 ppm) was reported to have adverse effects on catecholamine and 5-hydroxytryptamine biosynthesis.¹⁵⁰ Selective inhibition by toluene of human GABA(A) receptors in cultured neuroblastoma cells, at concentrations comparable with brain concentrations associated with occupational exposure, has been reported.¹⁵¹

Toluene exposure of rats to concentrations of 100, 300, and 1000 ppm was found to produce a significant increase in three glial cell marker proteins (alpha-enolase, creatine kinase-B, and beta-S100 protein) in the cerebellum. Beta-S100 protein also increased in a dose-dependent manner in the brain stem and spinal cord. The two neuronal cell markers did not show a quantitative decrease in the CNS. This indicates that the development of gliosis, rather than neuron death, is induced by chronic exposure to toluene.¹⁵² Toluene inhalation exposure induced a marked elevation in total glial fibrillary acidic protein, a specific marker for astrocytes, in the hippocampus, cortex, and cerebellum of rats, as well as a significant increase of lipid peroxidation products (malondialdehyde and 4-hydroxyalkenals) in all brain regions. Melatonin administration prevented these increases.¹⁵³ There is evidence that the effects of toluene on neuronal activity and behavior may be mediated by inhibition of NMDA receptors.¹⁵⁴

Progressive optic neuropathy and sensory hearing loss developed in some cases. Alterations in brain stem-evoked potentials and visual-evoked potentials have been demonstrated in relation to the length of occupational exposure to low levels of toluene.¹⁵⁵ Toluene causes broad frequency auditory damage, but this effect is species-specific and most likely occurs in humans at average long-term doses greater than 50 ppm.¹⁵⁶ A morphological study in rats and mice showed the cochlear outer hair cells in the organ of Corti to be mainly affected.¹⁵⁷ Noise exposure enhanced the loss in auditory sensitivity due to toluene,¹⁵⁸ as did concomitant ethanol exposure in studies in

rats.¹⁵⁹ Toluene exposure was also shown to accelerate age-related hereditary hearing loss in one genotype of mice.¹⁶⁰ Concentrations of toluene as low as 250 ppm toluene were able to disrupt auditory function acutely in the guinea pig.¹⁶¹

Hepatotoxic and nephrotoxic effects have also been found in cases of toluene addiction;¹⁶² the possibility that other toxic agents might have contributed cannot be excluded. Long-term exposure to toluene was reported to be associated with proximal renal tubule cell apoptosis.¹⁶³ Sudden death in toluene sniffers has been reported and is thought to be due to arrhythmia secondary to myocardial sensitization to endogenous catecholamines,¹⁶⁴ a mechanism of sudden death similar to that reported with trichloroethylene and other halogenated hydrocarbons.

Adverse developmental effects in offspring of women who are solvent sniffers have been reported. These include CNS dysfunction, microcephaly, minor craniofacial and limb abnormalities,¹⁶⁵ and growth retardation. Developmental disability, intrauterine growth retardation, renal anomalies, and dysmorphic features have been described in offspring of women who abuse toluene during pregnancy. Experimental results¹⁶⁶ confirm adverse developmental effects: skeletal abnormalities and low fetal weight were observed in several animal species (mice, rabbits). In an animal model replicating the brief, high-intensity exposures characteristic of toluene sniffing in humans, brief, repeated, prenatal exposure to high concentrations of toluene were reported to cause growth restriction, malformation, and impairments of biobehavioral development in rats.¹⁶⁷ Prenatal toluene exposure in rats results in abnormal neuronal proliferation and migration, with a significant reduction in the number of neurons within each cortical layer¹⁶⁸ and reduced forebrain myelination¹⁶⁹ in the brains of mature pups. A rapid, reversible, and dose-dependent inhibition of muscarinic receptor-mediated Ca²⁺ signaling has been demonstrated in neural precursor cells taken from rat embryonic cortex. Since muscarinic receptors mediate cell proliferation and differentiation during neural precursor cell development, depression of muscarinic signaling may play a role in toluene's teratogenic effect on the developing nervous system.¹⁷⁰ Prenatal exposure to 1800 ppm toluene increased neuronal apoptosis in the cerebellum of weaned male rats sacrificed 21 days after birth.¹⁷¹

Adverse reproductive effects have been detected in experimental, but not human, studies. In an experimental study on rats receiving toluene by gavage (520 mg/kg body weight during days 6–19 of gestation), no major congenital malformations or neuropathologic changes were found; the number of implantations and stillbirths were not affected. The weight of fetuses and placental weights were reduced, as were the weights of most organs. Prenatal toluene exposure produced a generalized growth retardation.¹⁷² Toluene was not embryotoxic, fetotoxic, or teratogenic for rabbits exposed during the period of organogenesis. The highest concentration tested was 500 ppm.¹⁷³ In rats exposed to toluene at a dose of 6000 ppm, 2 hours/day for 5 weeks, the epididymal sperm counts, sperm motility, sperm quality, and *in vitro* penetrating ability to zona-free hamster eggs were significantly reduced, while no exposure-related changes in the testes weight or spermatogenesis within testes were detected.¹⁷⁴ Conversely, in an earlier study in rats exposed to toluene at 2000 ppm for 90 days, decreases in the weights of the epididymides and in sperm counts were observed, indicating toxicity of toluene to the male reproductive system.¹⁷⁵

Toluene is metabolized to *p*-cresol, a compound shown to produce DNA adducts in myeloperoxidase-containing HL-60 cells.¹⁷⁶ Other toluene metabolites, methylhydroquinone and methylcatechols, have been shown to induce oxidative DNA damage in the rat testis.¹⁷⁷ Nevertheless, toluene has been found to be nonmutagenic and nongenotoxic. There are no indications, from human observations, that toluene has carcinogenic effects; long-term experimental studies on several animal species have been consistently negative.¹⁷⁸

Prevention and Control

The recommended TWA for toluene is 100 ppm. It is important to monitor the benzene content of technical grades of toluene and to control exposures so that the TWA of 1 ppm for benzene is not exceeded. Engineering controls, such as enclosure and exhaust ventilation, are essential for the prevention of excessive exposure; adequate respirators

should be provided for unusual situations, when higher exposures might be expected.³

Biological monitoring of exposure can be achieved by measuring urinary hippuric acid, the main urinary metabolite of toluene. Excretion of hippuric acid in excess of 3 g/L indicates an exposure in excess of 100 ppm. A second important urinary metabolite of toluene is *o*-cresol; as for hippuric acid, the excretion of *o*-cresol reaches its peak at the end of the exposure period (work shift). Interindividual differences in the pattern of toluene metabolism have been found, resulting in variable ratios between urinary hippuric acid and *o*-cresol. For these reasons, biological monitoring should include measurements of both urinary metabolites. Simultaneous exposure by inhalation to toluene and xylene resulted in lower amounts of excreted hippuric acid and methylhippuric acid in urine, while concentrations of solvents in blood and brain were found during the immediate postexposure period. These results strongly suggest mutual metabolic inhibition between toluene and xylene.¹⁷⁹

Preemployment and periodic medical examinations should encompass possible neurological, hematological, hepatic, renal, and dermatological effects. Hematological tests, as indicated for benzene, have to be used because, as noted, variable amounts of benzene may be present in commercial grades of toluene.

Potential environmental toluene exposure is currently also of concern. The largest source of environmental toluene release is the production, transport, and use of gasoline, which contains 5–7% toluene by weight. Toluene in the atmosphere reacts with hydroxyl radicals; the half-time is about 13 hours. Toluene in soil or water volatilizes to air; the remaining amounts undergo microbial degradation. There is no tendency toward environmental buildup of toluene. Toluene is a very common contaminant in the vicinity of waste-disposal sites, where average concentrations in water have been found to be 7–20 µg/L and average concentrations in soil 70 µg/L. The EPA, in a 1988 survey, found toluene in groundwater, surface water, and soil at 29% of the hazardous waste sites tested. Toluene is not a widespread contaminant of drinking water; it was present in only about 1% of groundwater sources, in concentrations lower than 2 ppb.

Xylene

Xylene (dimethylbenzene, C₆H₄[CH₃]₂) has three isomeric forms: *ortho*-, *meta*-, and *paraxylene*. Commercial xylene is a mixture of these but may also contain benzene, ethylbenzene, toluene, and other impurities. With a boiling temperature of 144°C, xylene is less volatile than benzene and toluene. It is used as a solvent and as the starting material for the synthesis of xylydines, benzoic acid, phthalic anhydride, and phthalic and terephthalic acids and their esters. Other uses are in the manufacture of quartz crystal oscillators, epoxy resins, and pharmaceuticals. In a study of two paint-manufacturing plants and 22 spray painting operations (car painting, aircraft painting, trailer painting, and video terminal painting), the main constituents of the mixtures of solvents used were xylene and toluene, with average contents of 46% and 29%, on a weight basis, of 67 air samples.¹⁸⁰ It is estimated that 140,000 workers are potentially exposed to xylene in the United States. As with toluene, early reports on adverse effects of xylene have to be evaluated in light of the frequent presence of considerable proportions of benzene in the mixture.²

Xylene has been shown to induce liver microsomal mixed function oxidases and cytochrome P450 in a dose-dependent manner.¹⁸¹ *m*-Xylene treatment led to elevated P450 2B1/2B2 without significantly depressing P450 2C11, and produced significant increases in activities efficiently catalyzed by both isozymes.¹⁸² The metabolism of *n*-hexane to its highly neurotoxic metabolite 2,5-hexanedione was shown to be markedly enhanced in rats pretreated with xylene. Xylene also increases the metabolism of benzene and toluene. Thus, when present in mixtures with other solvents, xylene can increase the adverse effects of those compounds, which exert their toxicity mainly through more toxic metabolites. The effect on mixed-function oxidases is organ-specific, however, and inhibition of CYP isozymes in the nasal mucosa and lung following *in vivo* inhalation exposure to

m-XYL has been reported,¹⁸³ with potential shifts in the metabolism of the carcinogen benzo-*a*-pyrene toward formation of DNA adducts and toxic metabolites in the lung.¹⁸⁴

Xylene was also found to facilitate the biotransformation of progesterone and 17, β-estradiol in pregnant rats by inducing hepatic microsomal mixed-function oxidases. Decreased blood levels of these hormones were thought to result in reduced weight of the fetuses.¹⁸⁵ Xylene exposure (500 ppm) of pregnant rats on gestation days 7–20 resulted in a lower absolute brain weight and impaired performance in behavioral tests of neuromotor abilities and for learning and memory.¹⁸⁶ The effects of lacquer thinner and its main components, toluene, xylene, methanol, and ethyl acetate, on reproductive and accessory reproductive organs in rats were studied; the vapor from the solvents was inhaled twice a day for 7 days. Both xylene and ethyl acetate caused a decrease in the weights of testes and prostate, and reduced plasma testosterone. Spermatozoa levels in the epididymis were decreased.¹⁸⁷

Acute effects of xylene exposure are depression of the CNS (pre-narcotic and narcotic with high concentrations) and irritation of eyes, nose, throat, and skin. Acute effects of *m*-xylene were studied in nine volunteers exposed at rest or while exercising, to concentrations of 200 ppm TWA, with short-term peak concentrations of 400 ppm or less. Exposure increased the dominant alpha frequency and alpha percentage in the EEG during the early phase of exposure. The effects of short-term *m*-xylene exposure on EEG were minor and no persistent deleterious effects were noted.¹⁸⁸ Exposure to *m*-xylene for 4 weeks at concentration as low as 100 ppm were reported to induce persistent behavioral alterations in the rat.¹⁸⁹

Liquid xylene is an irritant to the skin, and repeated exposure may result in dermatitis. Dermal exposure to *m*-xylene has been shown to promote IL-1 alpha and inducible nitric oxide synthetase production in skin.¹⁹⁰ Hepatotoxic and nephrotoxic effects have been found in isolated cases of excessive exposure. Nephrotoxicity has been demonstrated in rats exposed to *o*-xylene.¹⁹¹ *p*-Xylene reduced cell viability and increased DNA fragmentation in cell culture studies, indicating that long-term exposure may be associated with renal proximal tubule cell apoptosis.¹⁵¹ *p*-Xylene produced moderate to severe ototoxicity in rats exposed at 900 and 1,800 ppm. Increased auditory thresholds were observed at 2, 4, 8, and 16 kHz. The auditory threshold shifts (35–38 dB) did not reverse after 8 weeks of recovery, and losses of outer hair cells of the organ of Corti were found.¹⁹² Myelotoxic effects and hematologic changes have not been documented for pure xylene in humans; the possibility of benzene admixture to technical-grade xylene has to be emphasized. In animal studies, pure xylene was reported to reduce erythrocyte counts, hematocrit and hemoglobin levels, and increase platelet counts in rats.¹⁹³

The TWA for xylene exposure is 100 ppm. The metabolites of *ortho*-, *meta*-, and *paraxylene* are the corresponding methyl hippuric acids. A concentration of 2.05 g *m*-methyl hippuric acid corresponds to 100 ppm (TLV) exposure to *m*-xylene. Prevention, control, and medical surveillance are similar to those indicated for toluene and benzene. Complete blood counts, urinalysis, and liver function tests should be part of the periodic medical examinations.

Styrene

Styrene (vinyl benzene, C₆H₅CH = CH₂), a colorless or yellowish liquid, is used in the manufacture of polystyrene (styrene is the monomer; at temperatures of 200°C, polymerization to polystyrene occurs) and of copolymers with 1,3-butadiene (butadiene-styrene rubber) and acrylonitrile (acrylonitrile-butadiene-styrene, ABS). The most important exposures to styrene occur when it is used as a solvent-reactant in the manufacture of polyester products in the reinforced plastics industry. An estimated 330,000 workers are exposed yearly in the United States.¹⁹⁴ TWA exposures can be as high as 150 to 300 ppm, with excursions into the 1000–1500 ppm range.

The metabolic transformation of styrene is characterized by its conversion to styrene-7,8-oxide by the mixed function oxidases and cytochrome P450 enzyme complex. These reactions have been shown

to be organ-specific; enzymes that metabolize styrene have been demonstrated to differ in the lung and liver.¹⁹⁵ GST polymorphism influences styrene oxide genotoxicity, with susceptibility enhanced in null-type cells (a frequency of approximately 50% in Caucasians).¹⁹⁶ Mandelic acid (MA) and phenyl glyoxylic acid (PGA) are the main urinary metabolites of styrene.

In a mortality study of a cohort of styrene-exposed boat manufacturing workers, significantly increased mortality was found for esophageal cancer and prostate cancer. Among the most highly exposed workers, urinary tract cancer and respiratory disease rates were significantly elevated. Urinary tract cancer rates increased with the duration of employment.¹⁹⁷ Chromosome aberrations and sister chromatid exchanges were reported to be significantly increased in several studies of workers exposed to styrene. In styrene-exposed workers, the frequencies of micronucleated mononucleated lymphocytes, micronucleated binucleated lymphocytes, and micronucleated nasal epithelial cells were reported to be significantly increased when compared with nonexposed controls.¹⁹⁸ Micronuclei levels were shown to be related with end-of-shift urinary concentration of 4-vinylphenol and were modulated by NAD(P)H:quinone oxidoreductase polymorphism; aneuploidogenic effects, evaluated by the identification of centromeres in micronuclei using the fluorescence in situ hybridization technique, were related with before-shift urinary levels of mandelic and phenylglyoxylic acids and were influenced by GST M1 polymorphism.¹⁹⁹ Hemoglobin and O(6)-styrene oxide-guanine DNA adducts were significantly higher in exposed workers as compared to controls and were correlated with exposure measures. 1-Styrene oxide-adenine DNA adducts were detected in workers but not in unexposed controls; adduct levels were affected by both acute and cumulative exposure and were associated with CYP2E1 polymorphisms.²⁰⁰ Epoxide hydrolase polymorphism has also been shown to affect the genotoxicity of styrene-7,8-oxide.²⁰¹ DNA single-strand breaks have been found in workers exposed to styrene at relatively low levels, as determined by urinary excretion of metabolites.²⁰² A significantly higher number of DNA strand breaks in mononuclear leukocytes of styrene-exposed workers compared with unexposed controls, correlated with years of exposure, and a significantly increased frequency of chromosomal aberrations has been reported.²⁰³ Styrene-7,8-oxide has been demonstrated to induce DNA damage, sister chromatid exchanges and micronuclei in human leukocytes *in vitro*, and a strong relationship was found between DNA damage, as measured by the comet assay and cytogenetic damage induced by styrene oxide.²⁰⁴

Styrene-7,8-oxide is a potent carcinogen in mice but not rats. In female mice exposed to styrene, the incidence of bronchioloalveolar carcinomas after 24 months was found to be significantly greater than in controls.²⁰⁵ Styrene-7,8-oxide is mutagenic in several prokaryotic and eukaryotic test systems. It has been shown to produce single-strand breaks in DNA of various organs in mice: kidney, liver, lung, testes, and brain.²⁰⁶ Styrene-7,8-oxide is an alkylating agent and reacts mostly with deoxyguanosine, producing 7-alkylguanine, and with deoxycytidine, producing *N*-3-alkylcytosine. Recent studies have pointed to the even greater toxicity of ring-oxidized metabolites of styrene (4-vinylphenol or its metabolites).²⁰⁷ The International Agency for Research on Cancer (IARC) has classified styrene a possible carcinogen to humans.

Styrene has an irritant effect on mucous membranes (eyes, nose, throat, airways) and skin. Inhalation of high concentrations may result in transitory CNS depression, with pre-narcotic symptoms. Chronic neurotoxic effects have been reported with repeated exposure to relatively high levels in the boat-construction industry, mostly in Scandinavian countries, where styrene is widely used by brush application on large surfaces. EEG changes, performance test abnormalities, and peripheral nerve conduction velocity changes have been reported.²⁰⁸ Peripheral neuropathy has been described following brief but intense exposure.²⁰⁹ Evidence from animal studies indicates that styrene can cause sensorineural hearing loss.²¹⁰ Multiple indicators of oxidative stress were identified in neuronal cells exposed to styrene oxide, suggesting oxidative stress is an important contributor to styrene's neurotoxic effects.²¹¹ Color vision discrimination has been reported to be affected in styrene-exposed workers.²¹²

A case-control study of styrene-exposed rubber-manufacturing workers demonstrated a significant association between recent styrene exposure and acute ischemic heart disease death among active workers.²¹³ Styrene is hepatotoxic and pneumotoxic in mice. Styrene oxide and 4-vinylphenol cause similar toxicities.²¹⁴

Styrene exposure has been reported to be associated with increased serum prolactin levels in exposed workers.²¹⁵ Clinically, hyperprolactinemia is associated with infertility, impotence, and galactorrhea, but at levels in excess of those found in this population. In mice exposed to styrene in the prepubertal period, plasma-free testosterone levels were dramatically decreased following 4 weeks of styrene treatment compared with control group.²¹⁶ The majority of studies have failed to demonstrate developmental or reproductive toxicity resulting from styrene exposure.

Contact allergy to styrene has been reported. Cross-reactivity on patch testing with 2-, 3-, and 4-vinyl toluene (methyl styrene) and with the metabolites styrene epoxide and 4-vinyl phenol has been found.

Prevention

In view of reports of persistent neurological effects with long-term exposure, the present federal standard for a styrene TWA of 100 ppm appears to be too high, and reduction has been suggested. The NIOSH has proposed a TWA of 50 ppm. Biological limits of exposure have been proposed corresponding to a TLV of 50 ppm styrene. At the end of the shift, urinary MA should not exceed 800 mg/g creatinine and the sum of MA + PGA should not be more than 1000 mg/g creatinine. In the morning, before the start of work, the values should not exceed 150 and 300 mg/g creatinine, respectively. Preemployment and periodic medical examinations should assess neurological status, liver and kidney function, and hematological parameters.

▶ HALOGENATED HYDROCARBONS

The compounds in this group result from the substitution of one or more hydrogen atoms of a simple hydrocarbon by halogens, most often chlorine. Simple chlorinated hydrocarbons are used in a wide variety of industrial processes. The majority are excellent solvents for oils, waxes, fats, rubber, pigments, paints, varnishes, etc. In the chemical industry these compounds are used for chlorination in the manufacture of such products as plastics, pesticides, and other complex halogenated compounds.^{1,2} Most are nonflammable; some, such as carbon tetrachloride, have been used as fire extinguishers. (This use has been stopped because of the marked toxicity of carbon tetrachloride and the formation of highly irritant combustion products.) The most widely used simple chlorinated hydrocarbons are as follows:

Monochloromethane (methyl chloride)	CH ₃ Cl
Dichloromethane (methylene chloride)	CH ₂ Cl ₂
Trichloromethane (chloroform)	CHCl ₃
Tetrachloromethane (carbon tetrachloride)	CCl ₄
1,2-Dichloroethane (ethylene chloride)	CH ₂ ClCH ₂ Cl
1,1-Dichloroethane	CHCl ₂ CH ₃
1,1,2-Trichloroethane	CH ₂ ClCHCl ₂
1,1,1-Trichloroethane (methyl chloroform)	CH ₃ CCl ₃
1,1,2,2-Tetrachloroethane	CHCl ₂ CHCl ₂
Monochloroethylene (vinyl chloride)	CHCl = CH ₂
1,2-Dichloroethylene (<i>cis</i> and <i>trans</i>)	CHCl = CHCl
Trichloroethylene	CHCl = CCl ₂
Tetrachloroethylene	CCl ₂ = CCl ₂

Many of the members of this series of compounds have a low boiling point and are highly volatile at room temperature; hazardous exposure levels may develop in a very short time. The application of heat is common in numerous industrial processes; air concentrations of halogenated hydrocarbons increase sharply under such circumstances.

Many industrial solvents are sold as mixtures. These may sometimes contain highly toxic products, and hazardous exposure may

occur without the exposed person's knowledge of the specific chemical composition of the solvent mixture used. Carbon tetrachloride has been generally accepted as the prototype for a hepatotoxic agent; other members of the group have similar or lesser hepatotoxicity.

The majority of the compounds have a narcotic effect on the central nervous system; in this respect they are more potent than the hydrocarbons from which they are derived. Some (chloroform, trichloroethylene) were used as anesthetics until their marked toxicity was recognized. Moderate irritation of mucous membranes (conjunctivae, upper and lower airways) is also a common effect of halogenated hydrocarbons.

With acute overexposure or repeated exposures of a lesser degree, toxic damage to the liver and kidney is common; the severity of these effects is largely dependent on the specific compound and on the level and pattern of exposure. Individual susceptibility may also contribute but is of lesser importance. Halogenated hydrocarbons may produce liver injury and centrilobular necrosis with or without steatosis. They also have marked nephrotoxicity; tubular cellular necrosis is the specific lesion that may lead to anuria and acute renal failure. Many of the fatalities due to acute overexposure to halogenated hydrocarbons have been attributed to this effect, although concomitant liver injury was always present.^{1,2}

The toxicity of many halogenated solvents is associated with their biotransformation to reactive electrophilic metabolites, which can alkylate macromolecules and thus produce organ injury. The microsomal mixed function oxidases and cytochrome P450 complex of enzymes are effective in the biotransformation of halogenated solvents. The role of human microsomal cytochrome P450 IIE1 in the oxidation of a number of chemical compounds has been established. P450 IIE1 is a major catalyst of the oxidation of benzene, styrene, CCl₄, CHCl₃, CH₂Cl₂, CH₃Cl, CH₃CCl₃, 1,2-dichloropropane, ethylene dichloride, ethylene dibromide, vinyl chloride, vinyl bromide, acrylonitrile, and trichloroethylene. Levels of P450 IIE1 can vary considerably among individuals.²¹⁷ The P450 enzyme is highly inducible by ethanol.²¹⁸ Chloroethanes (1,2-dichloroethane, 1,1,1-trichloroethane, and 1,1,2,2-tetrachloroethane) have also been shown to be metabolized by hepatic cytochrome P450.

Food deprivation, more specifically a low intake of carbohydrates, and alcohol consumption enhance the metabolic transformation of the halogenated hydrocarbon solvents chloroform, carbon tetrachloride, 1,2-dichloroethane, 1,1-dichloroethylene, and trichloroethylene. Carbon tetrachloride rapidly promotes lipid peroxidation and inhibits calcium sequestration, glucose-6-phosphatase activity, and cytochrome P450. The urinary excretion of the lipid metabolites formaldehyde, malondialdehyde, acetaldehyde, and acetone was increased after administration of CCl₄. The increased excretion of these lipid metabolites may serve as noninvasive markers of xenobiotic-induced lipid peroxidation.²¹⁹

Pretreatment of rats with large doses of vitamin A potentiates the hepatotoxicity of CCl₄. Vitamin A enhances CCl₄-induced lipid peroxidation and release of active oxygen species from Kupffer cells and possibly other macrophages activated by vitamin A.²²⁰ The *in vivo* formation of PGF₂-like compounds (F₂-isoprostanes) derived from free radical-catalyzed nonenzymatic peroxidation of arachidonic acid has been found to be considerably increased (up to 50-fold) in rats administered CCl₄. F₂-isoprostanes are esterified to lipids in various organs and plasma. The measurement of F₂-isoprostanes may facilitate the investigation of the role of lipid peroxidation in human disease.²²¹

Considerable indirect evidence suggests that the cytokine tumor necrosis factor contributes to the hepatocellular damage resulting from toxic liver injury. By administering a soluble tumor necrosis factor receptor, the mortality from CCl₄ was lowered from 60% to 16% in an experimental study. The degree of liver injury was reduced, as measured by levels of serum enzymes. There was no detrimental effect on liver regeneration. These results suggest that soluble tumor necrosis factor receptor may be of benefit in the treatment of toxic human liver disease.²²²

Cellular phosphatidyl choline hydroperoxide (PCOOH) and phosphatidyl ethanolamine hydroperoxide (PEOOH) were increased more than four times by exposure of cultured hepatocytes to CCl₄,

1,1,1-trichloroethane, tetrachloroethylene, and 1,3-dichloropropene in a concentration of 10 mM. Peroxidative degradation of membrane phospholipids may play an important role in the cytotoxicity of some chlorinated hydrocarbons.²²³

It has been proposed that the nephrotoxicity of some compounds in this group is due to metabolic transformation in the kidney of the glutathione conjugates into the corresponding cysteine conjugates. The cysteine conjugates may be directly nephrotoxic or they may be further transformed in the kidney by renal cysteine conjugate β -lyase into reactive alkenyl mercaptans.

Another toxic effect, more recently identified, is related to the arrhythmogenic properties of halogenated hydrocarbons. These were first reported with chloroform and trichloroethylene used as anesthetics; they have also been found to occur with occupational exposure and, more recently, in persons addicted to the euphoric effects of short-term exposure (solvent sniffers). Ventricular fibrillation secondary to myocardial sensitization to endogenous epinephrine and norepinephrine has been postulated as the mechanism underlying the arrhythmias and sudden deaths. Incorporation of halocarbons in the membrane of cardiac myocytes may block intercellular communication through modification of the immediate environment of the gap junctions. Inhibition of gap junctional communication is possibly a factor in the arrhythmogenic effects of acute halogenated hydrocarbon exposure.²²⁴

The hepatotoxicity of carbon tetrachloride has been studied extensively, both clinically and in various experimental models. The mechanisms of toxic liver injury, the underlying biochemical and enzymatic disruptions, and the corresponding ultrastructural changes have been progressively defined. Hepatic cirrhosis may follow repeated exposure to carbon tetrachloride. Hepatic perisinusoidal cells (PSCs) proliferate and are thought to be the principal source of extracellular matrix proteins during the development of liver fibrosis. The PSCs have been shown to be modulated into a synthetically active and contractile myofibroblast in the course of liver fibrosis.²²⁵

Simultaneous administration of trichloroethylene and carbon tetrachloride (0.05 ml/kg) resulted in a marked potentiation of liver injury caused by CCl₄. Hepatic glutathione levels were depressed only in rats given both TCE and CCl₄. The regenerative activity in the liver appeared to be delayed by TCE.²²⁶ Acetone (A), MEK, and methyl isobutyl ketone (MiBK) markedly potentiate CCl₄ hepatotoxicity and chloroform (CHCl₃) nephrotoxicity. The potency ranking for this potentiating effect is MiBK > A > MEK for hepatotoxicity and A > MEK (MiBK for nephrotoxicity).²²⁷ An unusual type of fibrosis of the liver and spleen, including subcapsular fibrosis and the development of portal hypertension, can result from vinyl chloride exposure.

Liver carcinogenicity has been documented for several compounds of this series. Hepatocellular carcinoma developing several years after acute carbon tetrachloride poisoning has been reported.²²⁸ In other cases long-term exposure, even without overt acute toxicity, may lead to the same end result. In animal studies, carbon tetrachloride has proved a potent hepatocarcinogen.

Chloroform and trichloroethylene have been shown to be hepatocarcinogens in animals.²²⁹ Human data are not available; no long-term epidemiological study has been reported, and the possibility exists that instances of hepatocellular carcinoma may have occurred in workers exposed to these substances without recognition of the etiological link between exposure and malignancy. That this is a possibility has been illustrated by the example of vinyl chloride. Hemangiosarcoma of the liver was identified as one of the possible effects of vinyl chloride exposure in 1974, and many cases have since been reported from various industrial countries. Some of these cases had occurred in prior years, but at that time the link between toxic exposure and malignancy had not been suggested. Only after the etiological association was established, both by the first human cases reported and by results of animal experiments,²³⁰ was information on many other cases published. There are indications that vinyl chloride may induce hepatoma as well as hemangiosarcoma. Vinylidene chloride has also come under close scrutiny, since animal data seem to

indicate a carcinogenic effect. Chemical enhancement of viral transformation of Syrian hamster embryo cells has been demonstrated for 1,1,1-trichloroethane, 1,2-dichloroethane, 1,1-dichloroethane, chloromethane, and vinyl chloride; other chlorinated methanes and ethanes did not show such an effect.²³¹

Exposure to halogenated hydrocarbons and other volatile organic compounds in the general environment, from various sources including contaminated water and toxic waste-disposal sites, has received increasing attention during recent years. Methods have been developed to determine individual exposures with personal monitors to determine ambient air levels and special equipment for the collection of expired air samples in field settings; gas chromatography—mass spectroscopy analysis—has permitted adequate detection and has clarified patterns of relationships between breathing zone concentrations and results of breath analysis.

In a study of students in Texas and North Carolina, air has been found to be the major source of absorption, except for two trihalomethanes, chloroform and bromodichloromethane. Estimated total daily intake from air and water ranged from 0.3 to 12.6 mg, with 1,1,1-trichloroethane at the highest concentrations.²³² Monitoring of airborne levels of mutagens and suspected carcinogens, including linear and cyclic halogenated hydrocarbons, has been undertaken in many urban centers of the United States. Average concentration levels for halogenated hydrocarbons were in the 0 to 1 ppb range. Similar efforts have been undertaken regarding the monitoring of water contamination with halogenated hydrocarbons. Rivers, lakes, and drinking water from various sources have been tested. Analytical methods have been developed for the detection of volatile organic compounds, including chlorinated hydrocarbons, in fish and shellfish. Regional data from Germany indicate that approximately 25% of the groundwater samples contained more than 1 µg/L of a single solvent, most prominent being tri- and tetrachloroethene, 1,1,1-trichloroethane and dichloromethane, but also chloroform. Since the long-term effects of low-level exposure to halogenated hydrocarbon solvents, especially with regard to carcinogenicity and mutagenicity, are not known, it is necessary to monitor current exposures from all possible sources and to reduce such exposures to a minimum to protect the health of the general population.

Carbon Tetrachloride

The production of carbon tetrachloride in the United States has varied from 250 to 400 million kg in recent years. It is currently used mainly in the synthesis of dichlorofluoromethane (fluorocarbon 12) and trichlorofluoromethane (fluorocarbon 11); a small proportion is still applied as a fumigant and pesticide for certain crops (barley, corn, rice, rye, wheat) and for agricultural facilities, such as grain bins and granaries.

Airborne concentrations of carbon tetrachloride in the general environment have been found to vary from 0.05 to 18 ppb. In rural areas, levels of CCl₄ were lower, in the range of 80–120 ppt. The photodecomposition of tetrachloroethylene results in the formation of about 8% (by weight) carbon tetrachloride²³³ and is thought to be possibly responsible for a significant proportion of atmospheric carbon tetrachloride.

Carbon tetrachloride has also been found in rivers, lakes, and drinking water. Through 1983, about 95% of all surface water supplies contained less than 0.5 µg/L; in drinking water, detectable levels (>0.2 µg/L) were present in 3% of 945 samples tested. The toxicity of carbon tetrachloride is enhanced by its metabolic transformation in the liver. Induction of mixed function microsomal enzymes significantly increases CCl₄ toxicity, while inhibition of the enzymatic system decreases its toxicity. The induction of mixed function oxidases can be downregulated by genes that are strongly, rapidly, and transiently induced in most cells on exposure to various stress agents.²³⁴ The toxic effect of carbon tetrachloride is due to a metabolite, a free radical (CCl₃) that appears to produce peroxidation of the unsaturated lipids of cellular membranes. Plasma concentrations of the oxidation products 8-hydroxy-2'-deoxyguanosine, malondialdehyde, and isoprostanes and urinary concentrations of isoprostanes were increased in CCl₄-treated rats.²³⁵ Metabolism of CCl₄ to the more toxic metabolite is thought to occur in the endoplasmic

reticulum. Cytochrome P450 is destroyed in the process. As the metabolite accumulates, carbon tetrachloride can produce disruption of all elements of the hepatocyte-plasma membrane, endoplasmic reticulum, mitochondria, lysosomes, and nucleus result. The consequent cellular destruction is reflected in zonal (centrilobular) necrosis, which can be accompanied by steatosis. The corresponding clinical manifestation is hepatocellular jaundice; in severe cases hepatic failure and death may occur. With lesser exposure, less extensive subclinical pathologic changes may result; nonspecific symptoms, such as fatigability, loss of appetite, and nausea, may be present without jaundice. Food restriction appears to enhance the hepatotoxicity of CCl₄.²³⁶ Elevated serum enzymes (SGOT, SGPT, LDH), bilirubin and sometimes alkaline phosphatase arise in bromsulphalein retention, reduction of prothrombin, and increased urinary urobilin excretion may be found.

Studies have found that 47 different genes were either upregulated or downregulated more than two-fold by the CCl₄ compared with dimethyl formamide, a chemical that does not cause liver cell damage.²³⁷ The expression of genes involved in cell death, cell proliferation, metabolism, DNA damage, and fibrogenesis were upregulated following carbon tetrachloride exposure in mice.²³⁸ Repeated toxic insults may lead to the development of postnecrotic cirrhosis. The renin-angiotensin system²³⁹ and the proinflammatory cytokine tumor necrosis factor-alpha²⁴⁰ have been shown to contribute to carbon tetrachloride-induced hepatic fibrosis. Metallothionein, a small protein involved in the regulation of zinc homeostasis, was shown to improve the recovery of liver fibrosis in a mouse model.²⁴¹ Protection against the hepatotoxic effects of carbon tetrachloride by a wide range of antioxidants has been demonstrated, some by inhibition of overexpression of the IL-6 gene and its associated protein²⁴² or through inhibition of cytochrome P450 system that activates CCl₄ into its active metabolite, the trichloromethyl radical.²⁴³

CCl₄ administration has been shown to cause histopathological damage in the kidney, including glomerular and tubular degeneration, interstitial mononuclear cell infiltration and fibrosis, and vascular congestion in the peritubular blood vessels in the renal cortex. These changes can be prevented by concomitant administration of antioxidants.²⁴⁴ Intraperitoneal administration of CCl₄ has been demonstrated to cause lung injury in mice.²⁴⁵ Chronic exposure to carbon tetrachloride has been demonstrated to cause immunosuppression in mice.^{246,247}

Individual variation in the response to CCl₄ is now better understood. Carbon tetrachloride hepatotoxicity was found to be much less severe in old rats than in young adult rats, as assessed by serum hepatic enzymes and disappearance of hepatic microsomal cytochrome P450.²⁴⁸ Previous mixed-function microsomal enzyme induction has been shown to enhance CCl₄ toxicity through enhanced metabolic transformation to the active intermediate free radical. Alcohols, ketones, and some other chemical compounds enhance carbon tetrachloride toxicity: ethanol, isopropyl alcohol, butanol, acetone, PCBs and PBBs, chlordecone, and trichloroethylene have all been shown to potentiate CCl₄ toxicity, mostly by hepatic enzyme induction. In accidentally exposed workers, chronic ethanol abuse increased the hepatotoxicity of CCl₄.²⁴⁹ Mice without the cytochrome P450 enzyme CYP2E1 are resistant to CCl₄ hepatotoxicity.²⁵⁰

Carbon tetrachloride metabolites form irreversible covalent bonds to hepatic macromolecules, and binding of radiolabeled CCl₄ to DNA also occurs.²⁵¹ Carbon tetrachloride is considered to be an Ames (*Salmonella*) assay negative carcinogen, but has been shown to be a bacterial mutagen under special conditions.²⁵² Experimental evidence of carcinogenicity in mice and rats has accumulated. Liver tumors, including hepatocellular carcinomas, developed in various strains of mice, and benign and malignant liver tumors developed in rats.²⁵³ The carcinogenicity of CCl₄ is thought to derive from its cell proliferative effects.

Prevention and Control

The federal OSHA standard for a PEL for carbon tetrachloride exposure is 2 ppm. Replacement by less toxic substances, engineering controls, and enclosed processes are necessary. Respiratory protection should be available for emergency situations. Medical surveillance

must include careful evaluation of liver and kidney function, central and peripheral nervous system function, and the skin. The World Health Organization has adopted a guideline for permissible CCl_4 concentration of 0.003 mg/L in drinking water.

Chloroform

Chloroform is a colorless, very volatile liquid, with a boiling point of 61°C. Most of the more than 300 million pounds produced annually in the United States is used in the manufacture of fluorocarbons. Chloroform has also been used in cosmetics and numerous products of the pharmaceutical industry; the FDA banned these uses in 1976. Another application of chloroform has been as an insecticidal fumigant for certain crops, including corn, rice, and wheat. Chloroform residues have been detected in cereals for weeks after fumigation. They have also been found in food products, such as dairy produce, meat, oils and fats, fruits, and vegetables, in amounts ranging from 1 to more than 30 mg/kg.

The presence of chloroform in the water of rivers and lakes, in ground water, and in sewage treatment plant effluents has been documented at various locations. In drinking water, concentrations of 5–90 µg/L have been detected. Chlorination of water is thought to be responsible for the presence of chloroform in water.

Chloroform has toxic effects similar to those of carbon tetrachloride, but fewer severe cases have been reported after industrial exposure. Chloroform undergoes metabolic transformation; one of the metabolites has been shown to be phosgene (COCl_2). Metabolism by microsomal cytochrome P450 is obligatory for the development of chloroform-induced hepatic, renal, and nasal toxicity.²⁵⁴ Induction of cytochrome P450 results in increased chloroform hepatotoxicity. MBK and 2,5-hexanedione, the common metabolite of MBK and *n*-hexane enhance chloroform hepatotoxicity by induction of cytochrome P450. Extensive covalent binding to liver and kidney proteins has been found in direct relationship with the extent of hepatic centrilobular and renal proximal tubular necrosis. Affects on immune function have been reported.²⁵⁵ Neither chloroform nor its metabolites had been thought to be directly DNA reactive, although more recent studies have demonstrated adducts formed by oxidative and reductive metabolites of chloroform in vivo in rats.²⁵⁶ In female rat glutathione-depleted hepatocytes, chloroform treatment at high doses resulted in a small dose-dependent increase in malondialdehyde deoxyguanosine adducts and DNA strand breakage.²⁵⁷ A statistically significant increase in the frequency of micronucleated cells was detected in rats given a single p.o. dose of chloroform ($3.32 \times$ baseline).²⁵⁸ Using gas exposure methodology, chloroform has been shown to be mutagenic in *Salmonella*.²⁵⁹ The carcinogenicity of chloroform is, nevertheless, still generally thought to be secondary to induced cytotoxicity and regenerative cell proliferation.^{260,261}

The National Cancer Institute report on the carcinogenic effect of chloroform in animals (hepatocellular carcinomas in mice and renal tumors in rats) draws attention again to the lack of long-term epidemiologic observations. As with other carcinogens, industrial exposure must not exceed the limit of detection, and appropriate engineering methods must be used to protect the health of employees. The NIOSH recommended a ceiling of 2 ppm. Environmental exposure of the general population to chloroform in water and food has also to be reduced to a minimum, given the fact that sufficient experimental evidence for the carcinogenicity of chloroform has accumulated.

Trichloroethylene

Trichloroethylene (TCE) is a colorless, volatile liquid with a boiling point of 87°C. Trichloroethylene was thought to be much less toxic than carbon tetrachloride and was used, to a large extent, to replace CCl_4 in many industrial processes. It is one of the most important chlorinated solvents. Its main applications have been as a dry-cleaning agent and a metal degreaser. In smaller amounts, it is used in extraction of fats and other natural products, in the manufacture of adhesives and industrial paints, and in the chemical industry, mainly in the production of fluorocarbons.

NIOSH has estimated that 3.5 million workers in the United States are occupationally exposed to trichloroethylene; about 100,000 are exposed full time. Trichloroethylene is absorbed rapidly through the respiratory route, and only a relatively small fraction of the amount inhaled is eliminated unchanged in the exhaled air. The metabolic transformation of trichloroethylene has been shown to proceed through formation of a complex with cytochrome P-450; several pathways can then follow:

- Destruction of heme
- Formation of chloral, which can be reduced to trichloroethanol or oxidized to trichloroacetic acid
- Formation of trichloroethylene oxide, which then decomposes into carbon monoxide and glyoxylate
- Formation of metabolites that bind irreversibly to protein, RNA, and DNA

The relative proportion of these four different metabolic pathways can vary. Species differences in TCE metabolism have been demonstrated. Following a single oral dose of TCE of 1.5–23 mmol/kg, peak blood concentrations of trichloroethylene, trichloroacetate, and trichloroethanol were much greater in mice than in rats.²⁶² Studies with human hepatocytes show interindividual differences in the capacity for cytochrome P450-dependent metabolism of TCE and increased CYP2E1 activity may increase susceptibility to TCE-induced toxicity in the human.²⁶³ Dichloroacetate, an inducer of hepatic tumors in mice, has been found to be an important metabolite of TCE in the mouse.²⁶⁴

The levels of protein and DNA adducts vary from species to species, and may contribute to species differences found in carcinogenicity bioassays. In some studies in rodents, no direct evidence of formation of liver DNA adducts could be detected. In other studies, covalent binding to liver and kidney RNA and to DNA in kidney, testes, lung, pancreas, and spleen was found. Chloral hydrate, a metabolite of trichloroethylene, was shown to be mutagenic in vitro and in vivo and induced sister chromatid exchanges and chromosomal aberrations.²⁶⁵ Significant increases in the average frequency of both DNA breaks and micronucleated cells were found in the kidney of rats following a single oral dose of TCE at one half the LD_{50} .²⁶⁶ Dichlorovinylcysteine, a metabolite of TCE thought to be responsible for the nephrocarcinogenicity of trichloroethylene, has been found to induce DNA double-strand breaks followed by increased poly(ADP-ribosylation) of nuclear proteins in cultured renal cells in male Wistar rats.²⁶⁷

In humans, most trichloroethylene is metabolized to trichloroacetic acid and trichloroethanol. The urinary excretion of these metabolites can be used for biologic monitoring of trichloroethylene exposure; trichloroethanol excretion reaches its peak 24 hours after exposure, while trichloroacetic acid reaches its highest urinary level 3 days after exposure. Trichloroethylene has a depressant effect on the CNS; preanesthetic and narcotic symptoms can develop in rapid sequence with high concentrations of vapor. TCE is also an irritant to the skin, conjunctivae, and airways. Acute intentional trichloroethylene exposure was reported to cause neurological and cardiovascular toxicity, with palsies of the third, fifth, and sixth cranial nerves.²⁶⁸

Hepatotoxicity and nephrotoxicity of trichloroethylene are much lower than those of carbon tetrachloride; there are few reports of acute fatal toxic hepatitis and only isolated reports of acute renal failure due to TCE. Among 70 workers exposed to trichloroethylene, significant differences between the exposed and controls were found for urinary levels of the nephrotoxicity markers *N*-acetylglucosaminidase and albumin, and for formic acid.²⁶⁹ In TCE-exposed rats, proximal tubular damage with significantly increased concentrations of *N*-acetyl-beta-D-glucosaminidase and low-molecular-weight-proteins in urine were detected.²⁷⁰

Trichloroethylene can enhance the hepatotoxicity of carbon tetrachloride, possibly potentiating lipid peroxidation. Hepatotoxicity with moderate, long-term exposure has not been found in humans. Severe generalized dermatitis has been reported following TCE exposure; the susceptibility to such skin reactions was influenced by tumor necrosis factor genotype.²⁷¹ TCE, through its metabolite

trichloroacetaldehyde, promotes T-cell activation and related autoimmunity in mice exposed via drinking water.²⁷² Exposure to concentrations of trichloroethylene in the occupational range can accelerate an autoimmune response and can lead to autoimmune disease in mice. The mechanism of this autoimmunity appears to involve, at least in part, activated CD4⁺ T cells that then produced inflammatory cytokines.²⁷³ Cardiac arrest²⁷⁴ and sudden deaths in young workers exposed to TCE have been reported repeatedly and have been attributed to ventricular fibrillation, through myocardial sensitization to increased levels of epinephrine. Recent studies have demonstrated the capacity of TCE to inhibit Ca²⁺ dynamics in cardiomyocytes.²⁷⁵

Chronic effects on the central and peripheral nervous system have been described in TCE-exposed workers.²⁷⁶ Long-term exposure to low concentrations of TCE among people who consumed contaminated drinking water was found to be associated with neurobehavioral deficits.²⁷⁷ TCE has been shown to alter the fatty acid composition of mitochondria in neural cells in the rat.²⁷⁸ VEP amplitudes were significantly decreased in rabbits exposed to TCE via inhalation compared with VEPs obtained prior to exposure; a significant increase in VEP amplitude followed exposure at 700 ppm.²⁷⁹ Persistent mid-frequency hearing loss has been demonstrated in rats exposed to TCE, noted especially at 8 and 16 kHz.²⁸⁰ Cochlear histopathology revealed a loss of spiral ganglion cells.²⁸¹ Brainstem auditory evoked potentials were depressed in TCE-exposed rats, with high-frequency hearing loss predominating.²⁸² Dichloroacetylene, a metabolite of TCE, has been reported to cause trigeminal nerve dysfunction in the rat.²⁸³

Trichloroethylene has been reported to be a hepatocarcinogen in experimental animals. An increased incidence of hepatocellular carcinomas was found in mice, but this effect was not observed in rats, possibly due to differential rates of peroxisome proliferation induction. TCE metabolites were shown to bind to DNA and proteins in a dose-dependent manner in mouse liver.²⁸⁴ Kidney adenocarcinomas, testicular Leydig cell tumors, and possibly leukemia were found to be significantly increased in some experimental studies in rats.

Epidemiological data have accumulated which suggest that TCE may be carcinogenic in humans. In a study of cancer incidence among 2050 male and 1924 female workers in Finland, those who were exposed to TCE had an increased overall cancer incidence when compared with that of the Finnish general population. Excesses of cancer of the stomach, liver, prostate, and lymphohematopoietic tissues were found.²⁸⁵ Among workers exposed for at least 1 year to TCE renal cell/urothelial cancers occurred in excess. Occupational exposure to trichloroethylene was reported to be associated with elevated risk for non-Hodgkin's lymphoma among a large cohort of Danish workers.²⁸⁶ Associations of astrocytic brain tumors with trichloroethylene exposure among workers have been reported.²⁸⁷ A study of cancer mortality and morbidity among 1421 men exposed to TCE found no significant increase in cancer incidence or mortality at any site, but for a doubling of the incidence of nonmelanocytic skin cancer without correlation with exposure categories.²⁸⁸

Trichloroethylene has been shown to induce congenital cardiac malformations in Sprague-Dawley rats when females were given TCE in drinking water before and during pregnancy.²⁸⁹ Residence near trichloroethylene-emitting sites was reported to be associated with an increased risk of congenital heart defects in the offspring of older women.²⁹⁰ Trichloroacetic acid may be the cardiac teratogenic metabolite. Trichloroethylene had no effect on reproductive function in mice at doses up to one-tenth of the oral LD₅₀.²⁹¹ TCE exposure does not produce dominant lethal mutations in mice. Trichloroethylene oxide, an intermediate metabolite of TCE formed by mixed function oxidase metabolism, has been reported to be highly embryotoxic in the Frog Embryo Teratogenesis Assay.²⁹²

Evidence of toxic effects of TCE on male reproductive function has accumulated. Inhalation of TCE by male rats caused a significant reduction in absolute testicular weight and altered marker testicular enzymes activity associated with spermatogenesis and germ cell maturation, along with marked histopathological changes showing depletion of germs cells and spermatogenic arrest.²⁹³ TCE exposure led to impairment of sperm fertilizing ability in mice, attributed to TCE

metabolites, chloral hydrate and trichloroethanol.²⁹⁴ Male rats exposed to TCE in drinking water exhibited a dose-dependent decrease in the ability to fertilize oocytes from untreated females, in the absence of treatment-related changes in combined testes/epididymides weight, sperm concentration, or sperm motility. Oxidative damage to sperm proteins was detected.²⁹⁵ Cytochrome P450-dependent formation of reactive intermediates in the epididymis and efferent ducts and subsequent covalent binding of cellular proteins may be involved in the male reproductive toxicity of TCE in the rat.²⁹⁶ Reduced oocyte fertilizability was found in rats following exposure to trichloroethylene; oocytes from exposed females had a reduced ability to bind sperm plasma membrane proteins.²⁹⁷

Medical surveillance of populations currently exposed or exposed in the past is necessary, with special attention to long-term and potential carcinogenic effects, neurological effects, and liver and kidney function abnormalities. The present federal standard for a permissible level of occupational TCE exposure is 50 ppm. The IARC has classified TCE as probably carcinogenic to humans. A lower exposure limit has been proposed in view of information on carcinogenicity in animals. Exposure of the general population to TCE has received increasing attention. In 1977, the FDA proposed a regulation prohibiting the use of TCE as a food additive; this included the use of TCE in extraction processes in the manufacture of decaffeinated coffee and of spice oleoresins.

Trichloroethylene has been found in at least 460 of 1179 hazardous waste sites on the National Priorities List. Federal and state surveys have shown that between 9% and 34% of water supply sources in the United States are contaminated with TCE; the concentrations are, on the average, 1–2 ppb or less. Higher levels have been found in the vicinity of toxic waste-disposal sites; under such circumstances concentrations of several hundred up to 27,000 ppb have been detected. In 1989 the EPA established a drinking water standard of 5 ppb.

A relationship between trichloroethylene exposure via drinking water during pregnancy and central nervous system defects, neural tube defects, and oral cleft defects was found (odds ratio ≥ 1.50).²⁹⁸ Long-term, low-level exposure to a mixture of common organic groundwater contaminants (benzene, chloroform, phenol, and trichloroethylene) was shown to induce significant increases in hepatocellular proliferation in F344 rats, in the absence of histopathological lesions or an increase in liver enzyme levels in serum.²⁹⁹ Synergy between TCE and CCl₄ when administered in drinking water has been demonstrated in the rat.³⁰⁰

Perchloroethylene

Perchloroethylene (PCE, tetrachloroethylene) is used in the textile industry for dry cleaning, processing, and finishing. More than 70% of all dry-cleaning operations in the United States use PCE. Another important use is in metal cleaning and degreasing. PCE is also a raw material for the synthesis of fluorocarbons. PCE is similar in most respects to trichloroethylene. Its hepatotoxicity, initially thought to be very low, has been well documented, with abnormal levels of liver enzymes after exposure and persistence of elevated urinary urobilinogen and serum bilirubin in asymptomatic persons.

An arrhythmogenic effect of PCE has also been well documented in humans; premature ventricular contractions in young adults were frequent with high blood levels of PCE and disappeared completely after removal from exposure. Alteration of Ca²⁺ dynamics in cardiomyocytes is a common mechanism of cardiotoxic halogenated hydrocarbons' action.³⁰¹

In a collaborative European study, renal effects of PCE exposure in dry cleaners were assessed by a battery of tests, and the findings compared with those of matched controls. Increased high molecular weight protein in urine was frequently associated with tubular alterations, including changes consistent with diffuse abnormalities along the nephron, in workers exposed to low levels of PCE (median 15 ppm). Generalized membrane disturbances were thought to account for the increased release of laminin fragments, fibronectin and glycosaminoglycans, for high molecular weight proteinuria, and

for increased shedding of epithelial membrane components from tubular cells at different locations along the nephron (brush border antigens and Tamm-Horsfall glycoprotein). These findings of early renal changes indicate that dry cleaners need to be monitored for chronic renal changes.³⁰²

Deaths due to massive PCE overexposure have occurred, especially in small dry cleaning establishments. Optic neuritis with residual tunnel vision has been described in an owner of a dry-cleaning shop exposed to PCE.³⁰³ Increases in the brain content of an astroglial protein (S-100) and of glutamine synthetase, a biomarker for astroglial hypertrophy, provide biochemical evidence of astroglial proliferation secondary to neuronal damage. Neurotoxic effects of PCE have been demonstrated in rodents. Effects on color vision in humans have been described. Abnormal chromatic responses and reduced contrast sensitivity were found in a two-and-a-half year-old boy following prenatal exposure to PCE.³⁰⁴

The metabolism of PCE is characterized by a cytochrome P450-catalyzed oxidative reaction that generates tri- and dichloroacetate as metabolites, compounds associated with hepatic toxicity and carcinogenicity. A glutathione conjugation pathway is associated with generation of reactive metabolites selectively in the kidneys and with Perc-induced renal toxicity and carcinogenicity. For biological monitoring of exposure to PCE, measurements of urinary trichloroacetic acid and blood levels of PCE can be used. A blood level of 1 mg/L found 16 hours after exposure corresponds to a TWA exposure of less than 50 ppm. Such an exposure was found to result in no adverse effects on the CNS, liver, or kidney. The excretion of urinary trichloroacetic acid is slow and, therefore, not very useful for biological monitoring. Concentrations of PCE in exhaled air may prove useful after recent exposure.

PCE is an animal carcinogen that produces increased incidence of renal adenomas, adenocarcinomas, mononuclear cell leukemia, and hepatocellular tumors. In chronic inhalation studies, PCE increased the incidence of leukemia in rats and hepatocellular adenomas and carcinomas in mice. Epidemiological studies on workers exposed to PCE are considered inconclusive. Liver cancer and leukemia, of *a priori* concern because of results in experimental animals, have not been found with increased frequency in dry-cleaning personnel. Rates for esophageal cancer and bladder cancer were elevated by a factor of two. The confounding effect of alcohol and cigarette smoking is to be considered, and other solvents may have played a role in bladder cancer incidence.³⁰⁵ The IARC and the EPA have classified PCE as a category 2B carcinogen. The NIOSH has designated PCE as a carcinogen and has recommended that occupational exposure be limited to the lowest feasible limit. In 1986, the ACGIH recommended a TLV-TWA of 50 ppm.

Mutagenicity tests with PCE have been negative. No increase in the rate of chromosomal aberrations or sister chromatid exchange has been found in workers occupationally exposed to PCE. In rats treated by gavage, malformations suggestive of teratogenicity were represented by microphthalmia (TCE, PCE); full-litter resorption and delayed parturition were caused by PCE.³⁰⁶

Contamination of the general environment with PCE has been documented. PCE exposure in 28 dry-cleaning establishments and in 25 homes occupied by dry cleaners in Modena, Italy, showed wide variations in PCE concentrations from establishment to establishment (2.6–221.5 mg/m³, 8-hour TWA personal sampling values). PCE inside the homes were significantly higher than in 29 houses selected as controls; alveolar air samples collected at home suggest that nonoccupational exposure to PCE exists for family members.³⁰⁷ PCE may be formed in small amounts through chlorination of water. It has been found in drinking water in concentrations of 0.5–5 µg/L. In trace amounts, it has also been detected in foodstuffs. The EPA has recommended that PCE in drinking water not exceed 0.5 mg/L.

Methyl Chloroform

Methyl chloroform (1,1,1-trichloroethane) has recently gained widespread use because of its relatively low toxicity. It is mostly used as

a dry-cleaning agent, vapor degreaser, and aerosol vehicle and in the manufacture of vinylidene chloride. Hepato- and nephrotoxicity are low, but narcotic effects and even fatal respiratory depression have been reported. Cardiac arrhythmias due to myocardial sensitization to epinephrine have sometimes led to fatal outcomes. Methyl chloroform, rather than its metabolites, produces the arrhythmias.

Fatal cases of 1,1,1-trichloroethane poisoning have occurred. Intentional inhalation of typewriter correction fluid has resulted in deaths. 1,1,1-trichloroethane and trichloroethylene are the components of this commercial product. Decrease in the availability of toluene-based glues, because of measures to combat glue sniffing, has resulted in abuse of more accessible solvents, such as 1,1,1-trichloroethane. In subchronic inhalation experiments, 1,1,1-trichloroethane was shown to lead to a decrease in DNA concentration in several brain areas of Mongolian gerbils. These results were interpreted as indicating decreased cell density in sensitive brain areas.³⁰⁸

Technical-grade methyl chloroform often contains vinylidene chloride; elimination of this contaminant seems desirable in view of its potential carcinogenic and mutagenic risk.

Vinyl Trichloride

Vinyl trichloride (1,1,2-trichloroethane) is a more potent narcotic and is a potent hepatotoxic and nephrotoxic agent. Significant increases in hepatocellular carcinomas and adrenal pheochromocytomas have been found in mice, but not in rats. DNA adduct formation *in vivo* was found to occur to a greater extent in mouse liver than in rat liver.³⁰⁹ The IARC (1987) has classified 1,1,2-trichloroethane in group 3 (not classifiable as to its carcinogenicity in humans). The EPA (1988) has included 1,1,2-trichloroethane in category C (possible human carcinogen). The permissible level for occupational exposure to 1,1,2-trichloroethane is 10 ppm. The EPA (1987) has recommended that the concentration in drinking water not exceed 3 µg/L.

Tetrachloroethane

Tetrachloroethane (1,1,2,2-tetrachloroethane) is the most toxic of the chlorinated hydrocarbons. It is an excellent solvent and has been widely used in the past in the airplane industry, from which numerous cases of severe and even fatal toxic liver injury have been reported. This has prompted its replacement by other, less toxic solvents in most industrial processes. Toxic liver damage due to tetrachloroethane is known to have been associated with the development of cirrhosis of the liver.

1,1,2,2-Tetrachloroethane has produced hepatocellular carcinomas in mice. In rats, no significant increase in hepatocellular carcinomas was found. It has been recommended by NIOSH that occupational exposure to 1,1,2,2-tetrachloroethane not exceed 1 ppm.

Vinyl Chloride

Vinyl chloride, an unsaturated, asymmetrical chlorinated hydrocarbon, has found widespread use in the production of the polymer polyvinyl chloride. Although its industrial use had expanded in the 1940s and 1950s, it was not until 1973 that its hepatotoxicity and carcinogenicity³¹⁰ were recognized. The acute narcotic effects had long been known: some rather unusual chronic effects had been reported in the 1960s, their main feature being Raynaud's syndrome involving the fingers and hands, skin changes described as similar to those of scleroderma, and bone abnormalities with resorption and spontaneous fractures of the distal phalanges. This syndrome was reported under the name vinyl chloride acroosteolysis.

In 1973 unusual hepatosplenic changes were described in vinyl chloride-exposed workers in Germany. Soon thereafter, the first cases of hemangiosarcoma of the liver were reported in workers of one vinyl chloride-polyvinyl chloride polymerization plant in the United States,³¹¹ and the search for similar cases elsewhere led to the identification of some 90 such otherwise rare tumors in workers of this industry in many industrialized countries.

The nonmalignant pathological changes in the liver are characterized by activation of hepatocytes, smooth endoplasmic reticulum proliferation, activation of sinusoidal cells including lipocytes, nodular hyperplasia of hepatocytes and sinusoidal cells, dilation of sinusoidal spaces, network-like collagen transformation of the sinusoidal walls, moderate portal fibrosis, and subcapsular fibrosis. An increased risk of developing liver fibrosis has been found by ultrasonography in asymptomatic workers who had high exposure to vinyl chloride.³¹¹

Portal hypertension has been the prominent feature in some cases of nonmalignant vinyl chloride liver disease; esophageal varices and bleeding have occurred. Fatty degenerative changes in the hepatocytes and focal necrosis have sometimes been observed and are thought to be more pronounced in cases studied shortly after cessation of toxic exposure.

The dilation of sinusoidal spaces and the proliferative changes of sinusoidal cells are precursors of the malignant transformation and the appearance of angiosarcomas. While the pathological characteristics of hemangiosarcomas may differ, and several types (sinusoidal, papillar, cavernous, and anaplastic) have been described, the biological characteristics are similar, with rapid growth and a downhill clinical course. No effective therapeutic approach has been identified.

Hemangiosarcoma of the liver is a very rare tumor, and therefore the identification of vinyl chloride as the etiologic carcinogen was facilitated. Excess lung cancers, lymphomas, and brain tumors have also been reported in some epidemiological studies. A significant mortality excess in angiosarcoma (15 cases), and cancer of the liver and biliary tract was found in a cohort of 10,173 men who had worked for at least one year in jobs with vinyl chloride exposure. The SMR for cancer of the brain was 180.³¹²

In experimental animals exposed to vinyl chloride, carcinomas of the liver (hepatomas) also occur; sometimes both hemangiosarcoma and hepatoma have been found in the same animal. Malignant tumors of kidney, lung, and brain have also been found with increased incidence. Vinyl chloride is a transplacental carcinogen in the rat. It is metabolically activated by liver microsomal enzymes to intermediates, beginning with chloroethylene oxide, a potent mutagen, that bind covalently to proteins and nucleic acids. Polymorphisms in cytochrome P450 2E1, aldehyde dehydrogenase 2, GSTT1, and a DNA-repair gene, x-ray repair cross-complementing group 1, were shown to influence the risk of DNA damage elicited by vinyl chloride exposure in workers.³¹³

The toxic active metabolite of vinyl chloride is, according to several groups of investigators, most probably the epoxide chloroethylene oxide:

The electrophilic epoxide may react with cellular macromolecules, including nucleic acids; covalent and noncovalent binding occurs. The vinyl chloride epoxide metabolite appears to represent an optimal balance between stability that allows it to reach the DNA target and reactivity that leads to DNA binding and thus to the carcinogenic effect.

Proven sites of alkylation are adenine, cytosine, and guanine moieties of nucleic acids and sulfhydryl groups of protein. Covalent binding with hepatocellular proteins can lead to liver necrosis; it has been observed that after microsomal enzyme induction, high doses of vinyl chloride may result in acute necrosis of the liver.

Binding to DNA is considered potentially important for mutagenicity and carcinogenicity. Ethenocytosine (epsilon C) is a highly mutagenic exocyclic DNA lesion induced by the carcinogen vinyl chloride. 3,N4-ethano-2'-deoxycytidine, 3-(hydroxyethyl)-2'-deoxyuridine, and 3,N4-etheno-2'-deoxycytidine are also formed in

cells treated with vinyl chloride.³¹⁴ 1,N6-ethenodeoxyadenosine (edA) and 3,N4-ethenodeoxycytidine (edC) are two mutagenic adducts associated with exposure to vinyl chloride. Four cyclic theno adducts—1,N6-ethenodeoxyadenine (epsilon A), 3,N4-ethenocytosine (epsilon C), N2,3-ethenoguanine (N2,3-epsilon G), and 1,N2-ethenoguanine (1,N2-epsilon G) have been reported from human cells and tissues treated with the vinyl chloride metabolite chloroacetaldehyde.³¹⁵ Epsilon G, N2,3-ethenoguanine, a cyclic base derivative in DNA, was shown to specifically induce G→A transitions during DNA replication in *Escherichia coli*.³¹⁶ Under normal circumstances, altered DNA molecules are eliminated through physiological enzymatic systems.³¹⁷ With defective function of repair mechanisms, cell populations modified by the toxic metabolite develop with increasing metabolic autonomy and eventual malignant growth. Repair enzyme concentration has been demonstrated to be lower in the target cell population for angiosarcoma, the nonparenchymal cells, than in hepatocytes.³¹⁸ Higher adduct concentrations in young rats may contribute to their greater susceptibility to VC-induced hepatic angiosarcoma as well as their particular susceptibility to hepatocellular carcinoma.³¹⁹ Cytogenetic studies in workers have indicated that vinyl chloride produces chromosomal aberrations.³²⁰ The level of DNA single-strand breaks and other measures of DNA damage were increased in the peripheral lymphocytes of workers with high exposures to vinyl chloride.^{321,322} A decrease in exposure levels in the workplace was associated with a fall in the frequency of sister chromatid exchanges found in the lymphocytes of active workers.³²³

The p53 tumor suppressor gene is often mutated in a wide variety of cancers, including angiosarcoma of the liver. Anti-p53 antibodies have been detected in sera of patients with a variety of cancers and can predate diagnosis of certain tumors such as angiosarcoma, making possible the identification of individuals at high cancer risk among the vinyl chloride-exposed workers.³²⁴ A significant association between cumulative vinyl chloride exposure and anti-p53 expression has been reported among workers,³²⁵ as well as a strong dose-response relationship between Asp13p21 and mutant p53 proteins levels and VC-exposure in workers.³²⁶

Activation of the Ki-ras 2 gene by GC→AT transition at the second base of codon 13 in human liver angiosarcoma associated with exposure to vinyl chloride has been recently reported. Experiments in rats exposed to vinyl chloride and developing liver angiosarcomas and hepatocellular carcinomas showed other sites of mutations affecting the Ha-ras gene in the hepatocellular carcinomas and the N-ras A gene in angiosarcomas. The nature of the ras gene affected by a given carcinogen depends on host factors specific to cell types. The molecular pathways leading to tumors in humans and rats are different, and differences are detected within a given species between different cell types.³²⁷ Mutations of ras oncogenes and expression of their encoded p21 protein products are thought to have an important role in carcinogenesis. In five patients with angiosarcoma of the liver and heavy past exposure to vinyl chloride, four were found to have the mutation (Asp 13 c-Ki-ras) and to express the corresponding mutant protein in their tumor tissue and serum. In 45 VC-exposed workers with no evidence of liver neoplasia, 49% were positive for the mutant p21 in their serum. In 28 age-, gender-, and race-matched, unexposed controls, results were all negative.³²⁸

Prolonged VC exposure at 1100 ppm did not adversely affect embryo-fetal developmental or reproductive capability over two generations in rats.³²⁹ Active research on the metabolic transformations of vinyl chloride has also resulted in a better understanding of the metabolic transformations of other chlorinated hydrocarbons, identification of reactive intermediate products (epoxides), and structural reasons for higher or lower reactivity.

Tetrachloroethylene, 1,2-*trans*-dichloroethylene, and 1,2-*cis*-dichloroethylene have been found not to be mutagenic, while trichloroethylene, 1,1-dichloroethylene, and vinyl chloride are mutagenic. The respective epoxides have been found to be symmetrical and relatively stable for the first group but asymmetrical, unstable, and highly reactive for the second.

The federal standard for exposure to vinyl chloride is 1 ppm for an 8-hour period; the ceiling of 5 ppm should never be exceeded for more than 15 minutes. Air-supplied respirators should be available and are required when exposure levels exceed these limits.

Vinyl Bromide

Vinyl bromide is used in the chemical, plastic, rubber, and leather industries. Experimental studies have shown that vinyl bromide has produced angiosarcoma of the liver, lymph node angiosarcoma, lymphosarcoma, and bronchioloalveolar carcinoma in rats exposed to 50 and 25 ppm by inhalation. Mutagenicity of vinyl bromide has also been reported.^{330,331} DNA damage following vinyl bromide exposure was found in the stomach, liver, kidney, bladder, lung, and brain of mice.³³² On the basis of these data, the NIOSH and OSHA jointly recommended that vinyl bromide be considered a potential carcinogen for humans and be controlled in a way similar to vinyl chloride, with a recommended exposure standard of 1 ppm.

Vinylidene Chloride

Vinylidene chloride (1,1-dichloroethylene or DCE), like other vinyl halides, is used mainly in the plastics industry; it is easily polymerized and copolymerized to form plastic materials and resins with valuable properties. An increased incidence of necrosis of the liver in mice and chronic renal inflammation in rats exposed to vinylidene chloride by gavage has been reported.³³³ DCE undergoes biotransformation by NADPH-cytochrome P450 to several reactive species which conjugate with glutathione (GSH). Further activation of these conjugates occurs in renal tubular cells.³³⁴ DCE requires cytochrome P450-catalyzed bioactivation to electrophilic metabolites (1,1-dichloroethylene oxide, 2-chloroacetyl chloride, and 2,2-dichloroacetaldehyde) to exert toxic effects. Conjugation of GSH with 1,1-dichloroethylene oxide leads to formation of mono- and diglutathione adducts. Species differences were detected; microsomes from mice were sixfold more active than those from rats. The epoxide is the major metabolite of DCE that is responsible for GSH depletion, suggesting that it may be involved in hepatotoxicity of DCE; mice are more susceptible than rats.³³⁵ DCE-mediated mitochondrial dysfunction preceded the onset of hepatotoxicity.³³⁶

1,1-Dichloroethylene (DCE) exposure to mice elicits lung toxicity that selectively targets bronchiolar Clara cells. The toxicity is mediated by its metabolites. The cytochrome P450 enzymes CYP2E1 and CYP2F2 catalyze the bioactivation of DCE to the epoxide in murine lung.³³⁷ An immunosuppressive effect in sera of mice treated with 1,1-dichloroethylene was found, with increased levels of tumor necrosis factor- α and IL-6 thought to contribute to this effect.³³⁸

In experimental studies, vinylidene chloride has been found to be carcinogenic in rats and mice: angiosarcoma of the liver, adenocarcinoma of the kidney, and other malignant tumors have been produced in

inhalation experiments. In a recent study, DCE caused renal tumors in male mice after inhalation. Renal tumors were not observed in female mice or in rats of either sex. Kidney microsomes from male mice bio-transformed DCE to chloroacetic acid. Cytochrome P450 2E1 was detected in male mouse kidney microsomes; the expression of this protein was regulated by testosterone and correlated well with the ability to oxidize *p*-nitrophenol, a specific substrate for cytochrome P450 2E1. In kidney microsomes from rats of both sexes and in six samples of human kidney (male donors), no *p*-nitrophenol oxidase was detected. The data suggest that cytochrome P450 2E1 or a P450 enzyme with very similar molecular weight and substrate specificities is expressed only in male mouse kidney and bioactivates DCE.³³⁹

Workers occupationally exposed to vinylidene chloride have not been shown to have excessively high cancer mortality; nevertheless, the possibility of a carcinogenic risk for humans exposed to vinylidene chloride cannot yet be excluded. Vinylidene chloride has been shown to be mutagenic in several assay systems. Embryotoxicity and fetal malformations have been observed in rats and rabbits after inhalation exposure to maternally toxic concentrations. In studies using a chick model, significantly more embryonic deaths occurred in the DCE-treated group than in controls.³⁴⁰ Vinylidene chloride has not been shown to produce chromosomal aberrations or sister chromatid exchanges. In some experiments, vinylidene chloride has induced unscheduled DNA synthesis in rat hepatocytes and has alkylated DNA and induced DNA repair in mouse liver and kidney; the validity of these results has been questioned. The IARC has concluded that no evaluation of the carcinogenic risk of vinylidene chloride in humans could be made. The recommended exposure standard for vinylidene chloride is 1 ppm.

Ethylene Dichloride

Ethylene dichloride (1,2-dichloroethane, $\text{ClCH}_2\text{-CH}_2\text{Cl}$) is a colorless liquid at room temperature; with a boiling temperature of 83.4°C, it is highly volatile. Ethylene dichloride has a rapidly increasing volume of annual production; approximately 10–13 billion pounds was manufactured in the United States in recent years. Most of it (approximately 75%) is used in the production of vinyl chloride; it has also found applications in the manufacture of trichloroethylene, PCE, vinylidene chloride, ethylene amines, and ethylene glycol. It is a frequent constituent of antiknock mixtures of leaded gasoline and a component of fumigant insecticides. Other uses are as an extractor solvent, as a dispersant for nylon, viscose rayon, styrene-butadiene rubber, and other plastics, as a degreasing agent, as a component of paint and varnish removers, and in adhesives, soaps, and scouring compounds.

The main route of absorption is by inhalation; absorption through the skin is also possible. Ethylene dichloride is metabolized by cytochrome P450; chloroacetaldehyde and chloroacetic acid are the resulting metabolites. Microsomal cytochrome P450 and nuclear cytochrome P450 have been shown to metabolize ethylene dichloride. The possibility that the metabolic transformation of ethylene dichloride by nuclear cytochrome P450 may in part mediate its mutagenicity and carcinogenicity has been considered. Covalent alkylation of DNA by ethylene dichloride has been demonstrated. DNA damage following ethylene dichloride exposure was found in the stomach, liver, kidney, bladder, lung, brain, and bone marrow of mice.³⁴¹

Narcotic and irritant effects occur during or soon after acute overexposure. Studies of workers with prolonged, unprotected exposure to ethylene dichloride found lower neuropsychological functioning in the domains of processing speed; attention; cognitive flexibility; motor coordination and speed; verbal memory; verbal fluency; and visuospatial abilities. These workers also showed disturbed mood and impaired vision.³⁴² Hepatotoxic and nephrotoxic effects become apparent several hours after acute exposure and can be severe, with centrilobular hepatic necrosis, jaundice, or proximal renal convoluted tubular necrosis and anuria; fatalities with high exposure levels have been reported.^{2,3} Chronic ethanol consumption increased 1,2-dichloroethane liver toxicity in rats.³⁴³ A hemorrhagic tendency in acute ethylene dichloride poisoning has also been reported; disseminated intravascular coagulopathy and hyperfibrinolysis have been found in several cases. Experiments on rats and mice fed ethylene

dichloride in corn oil revealed a statistically significant excess of malignant and benign tumors. Glutathione conjugation is important in the metabolic transformation of 1,2-dichloroethane.

The metabolic pathways for 1,2-dichloroethane biotransformation are saturable; saturation occurs earlier after ingestion than after inhalation. Such differences in metabolic transformation have been thought to explain differences in results of experimental carcinogenicity studies, positive after oral administration but negative in inhalation experiments. An increased frequency of sister chromatid exchanges has been found in the lymphocytes of workers with exposure to low levels of ethylene dichloride.³⁴⁴ A statistically significant increase in sister chromatid exchanges was detected in bone marrow cells of mice after acute 1,2-dichloroethane exposure. Ethylene dichloride has been found to be mutagenic in a variety of bacterial systems and to enhance the viral transformation of Syrian hamster embryo cells. Testing for teratogenic effects and dominant lethal effects in mice was negative.³⁴⁵

Environmental surveys conducted by the EPA have detected 1,2-dichloroethane in groundwater sources in the vicinity of contaminated sites in concentrations of about 175 ppb (geometric mean). In a survey of 14 river basins in heavily industrialized areas in the United States, 1,2-dichloroethane was present in 53% of more than 200 surface water samples. In drinking water, the compound has been detected at concentrations ranging from 1 to 64 $\mu\text{g/L}$.³⁴⁶ The OSHA PEL for occupational exposure is 1 ppm. The MCL for drinking water has been regulated by the EPA at 0.005 mg/L. The EPA has classified 1,2-dichloroethane for its carcinogenic potential in group 2B.

Ethylene Dibromide

Ethylene dibromide (1,2-dibromoethane, $\text{BrCH}_2\text{CH}_2\text{Br}$) is a colorless liquid with a boiling point of 131°C. One of the most important uses is in antiknock compounds added to gasoline to prevent the deposition of lead on the engine cylinder. It has also been used as a fumigant for grains, fruit, and vegetables, as a soil fumigant, as a special solvent, and in organic synthesis.

EDB has an irritant effect on the skin, with possible development of erythema, blistering, and ulceration after prolonged contact. It is also a potent eye and respiratory mucosal irritant. Systemic effects include CNS depression; after accidental ingestion, hepatocellular necrosis and renal proximal tubular epithelium necrosis have been reported. Cases of fatal EDB poisoning have been reported. In experimental studies, hepatotoxicity and nephrotoxicity have been found at exposure levels of 50 ppm in all animals tested (rats, guinea pigs, rabbits, and monkeys).

EDB has been shown to produce significant decreases in cytochrome P450 levels in liver, kidney, testes, lung, and small intestine microsomes. Hepatic microsomal mixed-function oxidase activities decreased in parallel with the cytochrome P450 content. Dibromoalkane cytotoxicity is due to lipid peroxidation as well as cytochrome P450-dependent formation of toxic bromoaldehydic metabolites which can bind with cellular macromolecules. Dibromoethane-GSH conjugates also contribute to EDB cytotoxicity.³⁴⁷

The liver toxicity of several halogen compound mixtures has been studied. Carbon tetrachloride (CT) and trichlorobromomethane (TCBM) undergo dehalogenation via the P450-dependent enzyme system. 1,2-dichloroethane (DCE) and 1,2-dibromoethane (EDB) are mainly conjugated with the cytosolic GSH by means of GSH-S-transferase. The mixture TCBM and DBE shows a more than additive action on lipid peroxidation and liver necrosis. TCBM, like CT, reduces hepatic levels of GSH-S-transferase, increasing the amount of EDB available for P450-dependent metabolism, with the production of toxic metabolites. The toxicity of mixtures of halogen compounds can be partly predicted. When their metabolism is quite different, a synergistic toxicity can occur if one pathway interferes with a detoxification mechanism of the other compound.³⁴⁸

EDB exerts a toxic effect on spermatogenesis in bulls, rams, and rats, with oligospermia and degenerative changes in spermatozoa. Effects of EDB on spermatogenesis have been studied in 46 men employed in papaya fumigation; the highest measured exposure was 262 ppb, and the geometric mean was 88 ppb. When compared with a nonexposed reference group, there were statistically significant

decreases in sperm count, in percentage of viable and mobile sperm and in the proportion of sperm with specific morphologic abnormalities.³⁴⁹

A teratogenic effect is suspected; in rats and mice an increased incidence of CNS and skeletal malformations was found to be related to EDB exposure. GSH-S-transferase occurs abundantly in the human fetal liver. 1,2-dibromoethane is metabolized with high efficiency. Significant bioactivation with a possibility of only limited detoxification via cytochrome P450-dependent oxidation suggests that the human fetus may be at greater risk from DBE toxicity than the adult.³⁵⁰ GSH-S-transferase (GST) from human fetal liver was purified and at least five isozymes of GST were found. All the isozymes of GST in human fetal liver metabolized EDB. Bioactivation of EDB by the GST isozyme P-3 resulted in toxicity to cultured rat embryos. The central nervous system, optic and olfactory system, and the hind limb were most significantly affected. A dose-dependent increase of renal malformations was detected in EDB-treated chick embryos.³⁵¹ EDB may be classified as a suspected developmental toxicant in humans.³⁵² The embryotoxic effects of EDB bioactivation, mediated by purified rat liver GST, were investigated using rat embryos in culture. EDB activation caused a significant reduction in general development structures. Most affected were the central nervous system and the olfactory system.³⁵³

The carcinogenicity of EDB has been well documented in several bioassays on rats and mice exposed through various routes, including inhalation of 10 and 40 ppm. An increased incidence of various malignant tumors occurred in one or both sexes of one or both species tested. Among these were tumors of the mammary gland and nasal cavity, alveolar bronchiolar carcinomas, hemangiosarcomas, and tumors of the adrenal cortex and kidney. An epidemiological study³⁵⁴ of a relatively small group of EDB-exposed workers suggests an increase in total mortality and total deaths from malignant diseases in the population with higher exposure.

Mutagenic effects of EDB have been detected in several test systems. EDB is considered to be a bifunctional alkylating agent because of the two replaceable bromine atoms. It may form covalent bonds with cellular constituents; the reaction with DNA is thought to be especially important, with possible covalent cross-links between DNA strands. Irreversible binding of EDB to DNA and RNA has been demonstrated. A complex between reduced glutathione and EDB seems to be implicated in the covalent binding of EDB to DNA; this is unusual in that glutathione seems to play a role in the bioactivation of the carcinogen, as opposed to its more typical detoxification reactions. The major DNA adduct (greater than 95% of the total) resulting from the bioactivation of EDB by conjugation with GSH is S-(2-[N⁷-guanyl]ethyl) GSH. Other adducts are present at much lower levels.³⁵⁵ At least two pathways for 1,2-dibromoethane-induced mutagenicity, dependent on the DNA repair enzyme alkyltransferase, via reaction of EDB with alkyltransferase at its cysteine acceptor site, have been demonstrated.³⁵⁶ Evidence for deregulation by EDB of the genes controlling cell cycling has been reported.³⁵⁷

Environmental exposure of the general population to EDB has recently received increased attention. Several uses of EDB—as an antiknock additive in leaded gasoline, for soil fumigation, fumigation of citrus and other fruit to prevent insect infestation, and treatment of grain-milling equipment—have resulted in contamination of air, water, fruit, grain, and derived products.

EDB has been found in groundwater in areas where it had been extensively used for soil fumigation. In the air of major cities, levels of EDB ranging from 16 to 59 ppt have been detected. Citrus fruits that had been fumigated were found to contain amounts of EDB of several hundred parts per billion; in lychee fruit (imported to Japan from Taiwan) levels varying from 0.14 to 2.18 ppm were detected.³⁵⁸ An important and rather wide-spread contamination problem is that of EDB residues in commercial flour; levels from 8 ppb to 4 ppm were detected. In some ready-to-eat food products levels up to 260 ppb were found.

In 1983, the EPA introduced regulations to discontinue the use of EDB for soil fumigation, grain fumigation, treatment of grain-milling equipment, and postharvest fruit fumigation. In 1984, the EPA recommended guidelines for acceptable levels of the chemical in food for human consumption, based on samplings of grain stocks

and packaged foods in markets. It was recommended that EDB concentrations in grain intended for human consumption not exceed 90 ppb; for flour the residue level should not be higher than 150 ppb, and for ready-to-eat products it should not be more than 30 ppb. These guidelines have been critically reviewed and requests for even lower acceptable levels have been made. The proposed OSHA-TWA standard for EDB exposure is 100 ppb. NIOSH has recommended 45 ppb.

Methyl Chloride and Methyl Bromide

Methyl chloride and methyl bromide are gases at normal temperatures. Methyl chloride (CH_3Cl) is used in the chemical industry as a chlorinating agent but mainly as a methylating agent; it is also used in oil refineries for the extraction of greases and resins, as a solvent in the synthetic rubber industry, and as an expanding agent in the production of polystyrene foam. In recent years, methyl chloride has been used primarily in the production of methyl silicone polymers and resins and organic lead additives for gasoline. Methyl bromide (CH_3Br) is used as a fumigant for soil, grain, warehouses, and ships. Other important uses are as a methylating agent, a herbicide, and a fire-extinguishing agent, a degreaser, in the extraction of oils, and as a solvent in aniline dye manufacture. Currently most of the methyl bromide produced in the United States is used to manufacture pesticides.

Methyl chloride and methyl bromide are irritants; exposure to high concentrations may result in toxic pulmonary edema. They are potent depressants of the CNS; with high exposure, toxic encephalopathy with visual disturbances, tremor, delirium, convulsions, and coma may occur and may be fatal. Inhibition of creatine kinase activities in brain appears to be a sensitive indicator of methyl bromide intoxication, and may be related to genesis of its neurotoxicity.³⁵⁹ Permanent neurological deficits have been reported after recovery from acute toxic encephalopathy caused by methyl chloride and methyl bromide. Hepatotoxic and nephrotoxic effects may also occur.

Fatal poisonings after accidental exposure to high concentrations of methyl bromide, used as a fumigant, have occurred. In California in recent years, the most frequent cause of methyl bromide-related fatalities has been unauthorized entry into structures under fumigation. Toxic acute pulmonary edema, with hemorrhage, has been the most frequently reported lesion in such cases.³⁶⁰

Systemic methyl bromide poisoning developed in nine greenhouse workers after acute inhalational exposure on two consecutive days. Measurements of CH_3Br at the site within hours after the accident suggested that exposure on the second day may have been in excess of 200 ppm (800 mg/m³). Two patients needed intensive care for several weeks because of severe myoclonus and tonic-clonic generalized convulsions which could be suppressed effectively only by thiopental. Prior, subchronic exposure to methyl bromide and high-serum bromide (Br^-) concentrations are likely to have contributed to the severity of the symptoms.³⁶¹ Methyl bromide nonfatal poisoning in a young woman due to leakage of old fire extinguishers was characterized by major action and intention myoclonus on the day following exposure, associated with an initial plasma bromide level of 202 mg/L, 40-fold in excess than the commonly accepted tolerance limit, that decreased slowly to normal levels within 2 months.³⁶² A case of early peripheral neuropathy, confirmed with nerve conduction velocity testing that demonstrated axonal neuropathy, and central nervous system toxicity as a result of acute predominantly dermal exposure to methyl bromide has been reported.³⁶³ Worker and community notification of the hazard whenever fumigation takes place are absolutely necessary.³⁶⁴ Methyl chloride, methyl bromide, and methyl iodide are alkylating agents; all three are direct mutagens in *in vitro* tests. Monohalogenated methanes (methyl chloride, methyl bromide, and methyl iodide) produced DNA adducts 7-methylguanine and O6-methylguanine in exposed rats.³⁶⁵

[¹⁴C]-methyl bromide was administered to rats orally or by inhalation. DNA adducts were detected in the liver, lung, and stomach. [¹⁴C]-3-methyladenine, [¹⁴C]-7-methylguanine, and [¹⁴C]-O6-methylguanine were identified. A systemic DNA-alkylating potential of methyl bromide was thus demonstrated.³⁶⁶

Sister chromatid exchange (SCE) was determined in the lymphocytes of methyl bromide fumigators as an additional biomonitoring parameter. The determination of blood protein adducts can be applied for evaluation of environmental exposure.³⁶⁷ A hitherto unknown GST in human erythrocytes displays polymorphism: three quarters of the population (conjugators) possess, whereas one quarter (nonconjugators) lack this specific activity. Individuals with non-functional GSTT1 entirely lack the capacity to metabolize methyl chloride.³⁶⁸ A standard method for identification of conjugators and nonconjugators with the use of methyl bromide and gas chromatography (head space technique) has been developed. Methyl bromide, ethylene oxide, and dichloromethane (methylene chloride) were incubated *in vitro* with whole blood samples of conjugators and nonconjugators. All three substances led to a marked increase of SCEs in the lymphocytes of nonconjugators. A protective effect of the GST activity in human erythrocytes for the cytogenetic toxicity of these chemicals *in vitro* is thus confirmed.³⁶⁹

The formation of formaldehyde from dichloromethane (methylene chloride) is influenced by the polymorphism of GST theta, in the same way as the metabolism of methyl bromide, methyl chloride, methyl iodide, and ethylene oxide. Carcinogenicity of dichloromethane in long-term inhalation exposure of rodents has been attributed to metabolism of the compound via the GST-dependent pathway. Extrapolation of the results to humans for risk assessment should consider the newly discovered polymorphic enzyme activity of GST theta.³⁷⁰

Methyl chloride has produced a teratogenic effect (heart malformation) in offspring of pregnant mice exposed by inhalation. Methyl chloride and methyl bromide have been shown to produce testicular degeneration. The hemoglobin adduct methyl cysteine has been proposed as a biological indicator of methyl bromide exposure. The NIOSH recommends that methyl chloride and methyl bromide be considered as potential occupational carcinogens. The IARC (1986) found the evidence of carcinogenicity in humans and animals inconclusive. The 1987 TLV for methyl chloride is 50 ppm; for methyl bromide, it is 5 ppm. The U.S. Clean Air Act mandated a phase-out of the import and manufacture of methyl bromide because of its effects on the ozone layer of the atmosphere, beginning in 2001 and culminating with a complete ban, except for quarantine and certain pre-shipment uses and exempted critical uses, in January 2005.

Chloroprene

Chloroprene (2-chloro-1,3-butadiene, $\text{H}_2\text{C} = \text{CCl}-\text{CH} = \text{CH}_2$) is a colorless, flammable liquid with a low boiling point of 59.4°C. The major use is as a monomer in the manufacture of synthetic rubber, neoprene, since it can polymerize spontaneously at room temperature. The annual neoprene production in the United States is approximately 400 million pounds. Inhalation of vapor and skin absorption are the routes of absorption. It is metabolized to the monoepoxides, 2-chloro-2-ethenyloxirane and (1-chloroethenyl)oxirane, a demonstrated mutagen, together with electrophilic chlorinated aldehydes and ketones.³⁷¹ The epoxide intermediate of chloroprene may cause DNA damage in K-ras and H-ras proto-oncogenes of B6C3F1 mice following inhalation exposure. Mutational activation of these genes may be critical events in the pathogenesis of forestomach neoplasms induced in the B6C3F1 mouse.³⁷² Chloroprene is an irritant of skin and mucosa (eyes, respiratory tract); it is a potent CNS depressant and has definite liver and kidney toxicity. In rats, exposure to 80 ppm chloroprene or higher concentrations caused degeneration and metaplasia of the olfactory epithelium and exposure to 200 ppm caused anemia, hepatocellular necrosis, and reduced sperm motility.³⁷³ Hair loss has also been associated with chloroprene exposure in humans.

An excess of lung cancer and skin cancer in workers has been reported by Russian investigators; the mean age of chloroprene-exposed workers with cancer was significantly younger than that in other groups.³⁷⁴ A more recent retrospective cohort mortality study of chloroprene-exposed workers found an elevated risk of liver cancer.³⁷⁵ The methodological limitations of these studies preclude firm conclusions on the carcinogenicity of chloroprene. A cohort study of

chloroprene production and polymerization workers³⁷⁶ gave negative results with regard to lung cancer but raised the possibility of an increased incidence of gastrointestinal cancer and hematopoietic and lymphatic cancer. Methodological difficulties of this latter study make it impossible to reach definitive conclusions.

Chloroprene is classified in Group 2B (possibly carcinogenic to humans) by the International Agency for Research on Cancer on the basis of sufficient evidence for carcinogenicity at multiple organ sites in both mice and rats exposed by inhalation. The results of the studies from China, Armenia, and Russia suggest an excess risk of liver cancer.³⁷⁷ Based on animal experimental studies, chloroprene is listed in the National Toxicology Program's *Report on Carcinogens* as reasonably anticipated to be a human carcinogen.

An immunosuppressive effect of chloroprene is suspected. Chloroprene produces degenerative changes in male reproductive organs. Reproductive capacity in male mice and rats was affected after inhalation of chloroprene in concentrations of 12–150 ppm. Reductions in the number and mobility of sperm and testicular atrophy have been observed in rats after chloroprene exposure. In experiments on rats and mice, it was also found to be embryotoxic.

Although chloroprene has been shown to be mutagenic in several test systems, the genotoxicity of 2-chloro-1,3-butadiene is controversial. A recent mutagenicity study detected a mutagenic effect that occurred linearly with increasing age of chloroprene. Major byproducts of chloroprene, probably responsible for mutagenic properties of aged chloroprene, were identified as cyclic chloroprene dimers.³⁷⁸ Chromosome aberrations have been reported in bone marrow cells of exposed rats. In several groups of chloroprene-exposed workers, an increased incidence of chromosome aberrations in peripheral blood lymphocytes was noted.

Prevention. Occupational exposure to chloroprene should be limited to a maximum concentration of 1 ppm. Protective equipment to exclude the possibility of skin absorption, safety goggles, and air-supplied respirators are necessary to minimize exposure. Medical surveillance must be aimed not only at detection of short-term toxic and irritant effects but also at long-term effects on the CNS, liver and kidney function, reproductive abnormalities, and cancer risk.

Fluorocarbons

Fluorocarbons are hydrocarbons with fluorine, often with additional chlorine or bromine substitution of hydrogen atoms in their molecules. Most of them are nonflammable gases, and some are liquids at room temperature. Contact with open flame or heated metallic objects results in decomposition products, some of which are highly irritant, especially with chlorofluorocarbons (hydrogen fluoride, hydrogen chloride, phosgene, chlorine).

The fluorocarbons are used as refrigerants (Freon is one of the most widely used trademarks), as aerosol propellants, in fire extinguishers, for degreasing of electronic equipment, in the production of polymers, and as expanding agents in the manufacture of plastic foam. The use of perfluorocarbons emulsified in water as blood substitutes (artificial blood) is an area of intensive investigation. Exposure to fluorocarbons in chemical plant operations and production is generally low but highly variable; high exposures can occur in areas without proper ventilation, during tank farm operations, tank and drum filling, and cylinder packing and shipping. Exposure to fluorocarbons can also occur during manufacturing, servicing, or leakage of refrigeration equipment.

The use of fluorocarbons as solvents in the electrical and electronic industry can generate higher exposures, especially when open containers are used. Emissions of fluorocarbons from plastic foams, where they have been entrapped during foam blowing, is another source of exposure. Use of fluorocarbons in sterilization procedures for reusable medical equipment, mostly with ethylene oxide, does not usually generate major exposures. Fluorocarbons, especially trichlorofluoromethane (FC 11), have been used in the administration of certain

drugs by inhalation, mostly sympathomimetics and corticosteroids, for the treatment of asthma.

Fluorocarbons with the widest use are the following:

- Bromotrifluoromethane
- Dibromodifluoromethane
- Dichlorodifluoromethane
- Dichloromonofluoromethane
- Dichlorotetrafluoroethane
- Fluorotrichloromethane
- 1,1,1,2-Tetrachloro-2,2-difluoroethane
- 1,1,2,2-Tetrachloro-1,2-difluoroethane
- 1,1,2-Trichloro-1,2,2-trifluoroethane
- Bromochlorotrifluoroethane
- Chlorodifluoromethane
- Chloropentafluoroethane
- Chlorotrifluoroethylene
- Chlorotrifluoromethane
- Difluoroethylene
- Fluoroethylene
- Hexafluoropropylene
- Octafluorocyclobutane
- Tetrafluoroethylene

Irritative effects of fluorocarbons are mild; after exposure to decomposition products, such effects may be severe. A bronchoconstrictive effect after inhalation of fluorocarbons has been demonstrated to occur at concentrations higher than 1000 ppm. Four cases of toxic pneumonitis due to direct inhalation of industrial fluorocarbon used as a waterproofing spray were reported.³⁷⁹

Narcotic effects occur at high concentrations. Liver and kidney toxicity have been reported with fluoroalkenes, thought to be more toxic than fluoroalkanes. Fatalities have been reported after acute overexposure to high concentrations of fluorocarbons used as refrigerants; in some of these cases simultaneous exposure to methyl chloride or to phosgene (a decomposition product of fluorocarbons) made it difficult to assess the contribution of fluorocarbon exposure to the lethal outcome.

Perfluorooctane sulfonate is a degradation product of sulfonyl-based fluorochemicals that are used extensively in industrial and household applications. It is environmentally persistent, and humans and wildlife are exposed to this class of compounds from several sources. Toxicity tests in rodents have raised concerns about its potential developmental, reproductive, and systemic effects, and exposure to perfluorooctane sulfonate has been shown to affect the neuroendocrine system in rats³⁸⁰ and to increase the permeability of cell and mitochondrial membranes.³⁸¹ Inhibitory effects of perfluorooctane sulfonate on gap junctional intercellular communication, necessary for normal cell growth and function, has been demonstrated in rats.³⁸² A wide range of birth defects, including cleft palate, anasarca, ventricular septal defect, and enlargement of the right atrium, were seen in both rats and mice exposed to this compound,³⁸³ but not in rabbits. A related compound, perfluorooctanoic acid, a potent peroxisome proliferator reported to increase the incidence of hepatic, pancreas and Leydig cell adenomas in rats, caused significant atrophy of the thymus and spleen in mice.³⁸⁴

A significant increase in the number of deaths from bronchial asthma was observed in Great Britain and found to coincide in time with the introduction and use of bronchodilator aerosols with fluorocarbon propellants. After withdrawal of these products from over-the-counter sale, the number of deaths from bronchial asthma decreased significantly.³⁸⁵ Numerous deaths due to inhalation of fluorocarbon FC 11 (trichlorofluoromethane) have occurred. Addiction to fluorocarbon propellants in bronchodilator aerosols has been reported.³⁸⁶

Experimental evidence from studies on various animal species, documenting the arrhythmogenic properties of fluorocarbons, has established that sudden deaths due to cardiac arrhythmias, most probably through a mechanism similar to that identified for many chlorinated

hydrocarbons, can occur with exposure to fluorocarbons. Trifluoriodomethane (CF₃I) and 1,1,2,2,3,3,3-heptafluoro-1-iodopropane (C₃F₇I) were shown to be cardiac sensitizers to adrenaline in dogs.³⁸⁷

Mutagenicity tests were conducted on a series of fluorocarbons in two in vitro systems. Chlorodifluoromethane (FC 22), chlorofluoromethane (FC 31), chlorodifluoroethane (FC 142b), and trifluoroethane (FC 143a) gave positive results in one or two of the tests. Potential carcinogenicity was considered, and limited carcinogenicity bioassays have indicated that FC 31 and FC 133 were potent carcinogens.³⁸⁸ Tetrafluoroethylene, used in the production of Teflon, was shown to have hepatocarcinogenic activity in mice after 2 years of exposure.³⁸⁹ Perfluorooctane sulfonate and perfluorooctanoic acid have been shown to have adverse developmental effects in rodents.³⁹⁰

Fluorocarbons that are lighter than air accumulate at high altitudes, where they may interact with and degrade the ozone layer, leading to penetration to the earth's surface of greater amounts of ultraviolet light. The problem of the ozone layer depletion is thought to be more specifically related to the fully halogenated, nonhydrogenated fluorocarbons, which produce free radical reactions with ozone by photodissociation in the upper atmosphere. Regulatory action has been taken to eliminate the use of fluorocarbon aerosol products in the United States. Other aspects of fluorocarbon use are still under consideration.

▶ ALCOHOLS AND GLYCOLS

Alcohols are characterized by the substitution of one hydrogen atom of hydrocarbons by a hydroxyl (–OH) group; glycols are compounds with two such hydroxyl groups. Both are used extensively as solvents. Under usual industrial exposure conditions, alcohols and glycols do not represent major acute health hazards, mostly because their volatility is much lower than that of most other solvents.

Cases of severe poisoning with methyl alcohol or ethylene glycol are usually caused by accidental ingestion. They have an irritative effect on mucous membranes; the narcotic effect is much less prominent than with the corresponding hydrocarbons or halogenated hydrocarbons. Glycols are liquids with low volatility; the low vapor pressure prevents significant air concentrations, except when the compounds are heated or sprayed. Inhalation or skin contact does not usually result in absorption of toxic amounts; accidental ingestion accounts for the majority of poisoning cases. Glycols are used mainly as solvents and, because of their low freezing point, in antifreeze mixtures.

Methyl Alcohol

Methyl alcohol (methanol, wood alcohol, CH₃OH) is used in the chemical industry in the manufacture of formaldehyde, methacrylates, ethylene glycol, and a variety of other compounds such as plastics, celluloid, and photographic film.^{2,3} It is also used as a solvent for lacquers, adhesives, industrial coatings, inks, and dyes and in paint and varnish removers. It is used in antifreeze mixtures, as an additive to gasoline, and as an antidetonant additive for aircraft fuel. An experimental study of 26 human volunteers exposed for 4 hours to 200 ppm methanol vapor in a randomized, double blind study using a whole-body exposure chamber. No significant differences in serum formate concentrations between exposed and control groups were detected. It was concluded that at 200 ppm, methanol exposure does not contribute substantially to endogenous formate quantities.³⁹¹

Methyl alcohol is a moderate irritant and depressant of the CNS. Systemic toxicity due to inhalation and skin absorption of methyl alcohol has been reported with very high exposure levels because of large amounts being handled in enclosed spaces. Accidental ingestion of methyl alcohol can be fatal; after a latency period of several hours (longer with smaller amounts), neurological abnormalities, visual disturbances, nausea, vomiting, abdominal pain, metabolic acidosis, and coma may occur in rapid sequence.

Toxic optic retrobulbar neuritis is a specific effect of methyl alcohol and may result in permanent blindness due to optic atrophy. In a rat model, functional changes preceded structural alterations. Histopathological changes were most pronounced in the outer retina with evidence of inner segment swelling, photoreceptor mitochondrial disruption, and the appearance of fragmented photoreceptor nuclei in the outer nuclear layer. The nature of both the functional and structural alterations observed is consistent with formate-induced inhibition of mitochondrial energy production, resulting in photoreceptor dysfunction and pathology.³⁹² Bilateral putaminal necrosis is often recognized radiologically in severe methanol toxicity. A case of bilateral putaminal and cerebellar cortical lesions demonstrable on CT and MRI has been reported.³⁹³ Putamen and white matter necrosis and hemorrhage was found at autopsy in a case of fatal methanol poisoning.³⁹⁴ Nephrotoxic effects and toxic pancreatitis have also been reported. Methyl alcohol is slowly metabolized to formaldehyde and formic acid; the extent to which these metabolites are responsible for the specific toxic effects has not been completely clarified. Acute renal injury has been described following acute methanol poisoning.³⁹⁵ Formate metabolism to CO₂ is governed by tissue H₄folate and 10-formyltetrahydrofolate dehydrogenase (10-FTHFDH) levels. 10-FTHFDH was found to be present in rat retina, optic nerve, and brain. It was concluded that, in rats, target tissues possess the capacity to metabolize formate to CO₂ and may be protected from formate toxicity through this folate-dependent system.³⁹⁶

Non-primate laboratory animals do not develop the characteristic human methanol toxicities even after a lethal dose.³⁹⁷ In humans, methanol causes systemic and ocular toxicity after acute exposure. The folate-reduced (FR) rat is an excellent animal model that mimics characteristic human methanol toxicity. Blood methanol levels were not significantly different in FR rats compared with folate-sufficient rats. FR rats, however, had elevated blood and vitreous humor formate and abnormal electroretinograms at 48 hours postdose, suggesting that formate is the toxic metabolite in methanol-induced retinal toxicity.³⁹⁸ Methanol exposure during growth spurt period in rats adversely affects the developing brain, the effect being more pronounced in folate-deficient rats as compared to rats with adequate levels of folate in the diet, suggesting a possible role of folic acid in methanol-induced neurotoxicity.³⁹⁹

In long-term exposure studies with rats, methyl alcohol was demonstrated to be carcinogenic for various organs and tissues.⁴⁰⁰ Methanol is believed to be teratogenic based on rodent studies may result from the enzymatic biotransformation of methanol to formaldehyde and formic acid, causing increased biological reactivity and toxicity. A protective role for the antioxidant glutathione (GSH) has been described.⁴⁰¹ Formaldehyde is the most embryotoxic methanol metabolite and elicits the entire spectrum of lesions produced by methanol.⁴⁰² Cell death plays a prominent role in methanol-induced dysmorphogenesis.⁴⁰³ Methyl groups from (14)C-methanol are incorporated into mouse embryo DNA and protein. Methanol exposure may increase genomic methylation under certain conditions which could lead to altered gene expression.⁴⁰⁴

The management of methanol poisoning includes standard supportive care, the correction of metabolic acidosis, the administration of folic acid, the provision of an antidote to inhibit the metabolism of methanol to formate, and selective hemodialysis to correct severe metabolic abnormalities and to enhance methanol and formate elimination. Although both ethanol and fomepizole are effective, fomepizole is the preferred antidote for methanol poisoning.⁴⁰⁵

Prevention. The federal standard for methanol exposure is 200 ppm.³ Warning signs must be posted wherever methyl alcohol is stored or can be present in the working environment, with emphasis on the extreme danger of blindness if swallowed. Employees' education and training must be thorough. Medical surveillance with attention to visual, neurological, hepatic, and renal functions is necessary. Formic acid in urine and methyl alcohol in blood can be used for the assessment of excessive exposure.

Allyl Alcohol

Allyl alcohol ($\text{H}_2\text{C} = \text{CHCH}_2\text{OH}$) is a liquid with a boiling point of 96.0°C . It is used in the manufacture of allyl esters and of monomers for synthetic resins and plastics, in the synthesis of a variety of organic compounds, in the pharmaceutical industry, and as a herbicide and fungicide.

Absorption occurs through inhalation and percutaneous penetration. Allyl alcohol is a potent irritant for the eyes, the respiratory system, and the skin. Muscle pain underlying the site of skin absorption, lacrimation, photophobia, blurring of vision, and corneal lesions have been reported.² Allyl alcohol exhibits periportal necrotic hepatotoxicity in rats, due to its bioactivation to acrolein and subsequent protein sulfhydryl loss and lipid peroxidation.⁴⁰⁶ This effect is enhanced by exposure to bacterial endotoxins and by caffeine, via increased bioactivation pathways of allyl alcohol involving the P450 mixed-function oxidase system.⁴⁰⁷ The marked irritant properties of allyl alcohol probably prevent greater exposure in humans, which would result in the liver and kidney toxicity found in experimental animals but not reported in humans.

Prevention. The federal standard for PEL to allyl alcohol is 2 ppm. Protective equipment is very important, given the possible skin absorption; the material of choice is neoprene.

Isopropyl Alcohol

Isopropyl alcohol ($\text{CH}_3\text{CHOHCH}_3$, isopropanol) is a colorless liquid with a boiling point of 82.3°C and high volatility. It is used in the production of acetone and isopropyl derivatives. Other important uses are as a solvent for oils, synthetic resins, plastics, perfumes, dyes, and nitrocellulose lacquers and in the extraction of sulfonic acid from petroleum products. Isopropyl alcohol has many applications in the pharmaceutical industry, in liniments, skin lotions, mouthwashes, cosmetics, rubbing alcohol, etc.

Isopropyl alcohol absorption takes place mainly by inhalation, although skin absorption is also possible. The irritant effects are slight; dermatitis has seldom been reported. A fatal neonatal accidental burn by isopropyl alcohol has been reported, however.⁴⁰⁸ Depressant (narcotic) effects have been observed in cases of accidental or intentional isopropyl alcohol ingestion. Coma and renal tubular degenerative changes have occasionally resulted in death. Acetone has been found in the exhaled air and in urine; isopropyl alcohol concentrations in blood can be measured.

In the early 1940s, an unusual clustering of neoplasms of the respiratory tract—malignant tumors of the paranasal sinuses, lung, and larynx—was reported in workers in isopropyl alcohol manufacturing. It was thought that the carcinogenic compounds were associated with the “strong acid process” and especially with heavier hydrocarbon oils (tars) containing polycyclic aromatic compounds.

In the more modern direct catalytic hydration (weak acid process) of propylene, the isopropyl oil seems to contain compounds with lower molecular weight, although the precise composition is not known. Attempts to identify the carcinogen(s) in experimental studies have not been successful,³ and the question of a carcinogen present in the manufacture of isopropyl alcohol is still open.

Prevention. The federal standard for a permissible level of isopropyl alcohol exposure is at present 400 ppm.

Ethylene Chlorhydrin

Ethylene chlorhydrin ($\text{CH}_2\text{ClCH}_2\text{OH}$)—synonyms: glycol chlorhydrin, 2-chloroethanol, β -chloroethyl alcohol—is a very toxic compound.² It is used in the synthesis of ethylene glycol and ethylene oxide and in a variety of other reactions, especially when the hydroxyethyl group ($-\text{CH}_2\text{CH}_2\text{OH}$) has to be incorporated in molecules. Other uses are as a special solvent, for cellulose acetate and esters, resins, waxes, and for the separation of butadiene from

hydrocarbon mixtures. Agricultural applications include seed treatment and application to accelerate the sprouting of potatoes.

Ethylene chlorhydrin is absorbed through inhalation and readily through the skin. It is an irritant to the eyes, airways, and skin. Exposure to high concentrations may result in toxic pulmonary edema. Systemic effects are marked: depression of the CNS, hypotension, visual disturbances, delirium, coma and convulsions, hepatotoxic and nephrotoxic effects with nausea, vomiting, hematuria, and proteinuria. Death may occur as a result of pulmonary edema or cerebral edema. Even cases with slight or moderate initial symptoms may be fatal.

Prevention. The federal standard for the limit of permissible exposure is 5 ppm. The use of ethylene chlorhydrin other than in enclosed systems should be completely eliminated. Protective clothing should use materials impervious to this compound; rubber is readily penetrated and has to be excluded. Protective clothing must be changed regularly so that no deterioration will jeopardize its effectiveness.

Ethylene Glycol

Ethylene glycol ($\text{OHCH}_2\text{CH}_2\text{OH}$) is a viscous colorless liquid, used mainly in antifreeze and hydraulic fluids but also in the manufacture of glycol esters, resins, and other derivatives and as a solvent. CNS depression, nausea, vomiting, abdominal pain, respiratory failure, and renal failure with oliguria, proteinuria, and oxalate crystals in the urinary sediment are manifestations of ethylene glycol poisoning.² In a case of acute ethylene glycol poisoning, the CT scan obtained three days after ethylene glycol ingestion showed low-density areas in the basal ganglia, thalami, midbrain, and upper pons. The neurologic findings were consistent with the abnormalities seen on CT.⁴⁰⁹ In addition, hepatic damage due to calcium oxalate deposition has been reported.^{410,411} Calcium oxalate monohydrate crystals, and not the oxalate ion, is responsible for the membrane damage and cell death observed in normal human and rat PT cells; calcium oxalate monohydrate accumulation in the kidney appears to be responsible for the renal toxicity associated with ethylene glycol exposure.⁴¹² Glycolic acid is the metabolite that is found in the highest concentrations in blood; serum and urine levels of glycolic acid correlate with clinical symptoms.⁴¹³ The active enzyme is alcohol dehydrogenase. It is estimated that 50 deaths occur annually in the United States from accidental ingestion of ethylene glycol. Treatment of ethylene glycol poisoning consists of emergent stabilization, correction of metabolic acidosis, inhibition of further metabolism, and enhancing elimination of both unmetabolized parent compound and its metabolites. The prevention of ethylene glycol metabolism is accomplished by the use of antidotes that inhibit alcohol dehydrogenase. Historically, this has been done with intoxicating doses of ethanol. A recent alternative to ethanol therapy is fomepizole, or 4-methylpyrazole. Like ethanol, fomepizole inhibits alcohol dehydrogenase; however it does so without producing serious adverse effects.⁴¹⁴ Hemodialysis has been successfully used in the treatment of accidental ethylene glycol poisoning by ingestion. The therapeutic use of 4-methyl pyrazole, an alcohol dehydrogenase inhibitor, has been recommended for the management of accidental or suicidal ethylene glycol poisoning.

Prevention.

No federal standard for ethylene glycol exposure has been established. The American Conference of Industrial Hygienists recommended a TLV of 100 ppm. The most important preventive action is to alert employees to the extreme hazard of ingestion. Adequate respiratory protection should be provided wherever the compound is heated or sprayed. Increasing use of glycols as deicing agents for aircraft and airfield runways has generated concern about surface water contamination that may result from runoff. Degradation of ethylene glycol in river water is complete within 3–7 days (depending on temperature); degradation of diethylene glycol is somewhat slower. At low temperatures (8°C or less), both glycols degrade at a minimal rate.⁴¹⁵

Diethylene Glycol

Diethylene glycol is similar in its effects to ethylene glycol; its importance is mainly historical, since more than 100 deaths occurred in the United States when it was used in the manufacture of an elixir of sulfanilamide. Fatal cases were caused by renal proximal tubular necrosis and renal failure.² Diethylene glycol is teratogenic in rodents.⁴¹⁶

► ETHYLENE GLYCOL ETHERS AND DERIVATIVES

The most important alkyl glycol derivatives are ethylene glycol monoethyl ether (EGME), (ethoxyethanol, cellosolve) ($\text{CH}_3\text{CH}_2\text{OCH}_2\text{CH}_2\text{OH}$) and its acetate; ethylene glycol monomethyl ether (methoxyethanol, methyl cellosolve, EGME) ($\text{CH}_3\text{OCH}_2\text{CH}_2\text{OH}$) and its acetate; and ethylene glycol monobutyl ether (butoxyethanol, butyl cellosolve) ($\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{OH}$).² These compounds are colorless liquids with wide applications as solvents for resins, lacquers, paints, varnishes, coatings (including epoxy resin coatings), dyes, inks, adhesives, and plastics. They are also used in hydraulic fluids, as anti-icing additives, in brake fluids, and in aviation fuels. EGME is used in the formulation of adhesives, detergents, pesticides, cosmetics, and pharmaceuticals.

Inhalation, transcutaneous absorption, and gastrointestinal absorption are all possible. These derivatives are irritants for the mucous membranes and skin. The acetates are more potent irritants. Corneal clouding, usually transitory, may occur. Acute overexposure may result in marked narcotic effects and encephalopathy; pulmonary edema and severe kidney and liver toxicity are also possible. At lower levels of exposure, CNS effects result in such symptoms as fatigue, headache, tremor, slurred-speech, gait abnormalities, blurred vision, and personality changes.

Anemia is another possible effect; macrocytosis and immature forms of leukocytes can be found. Exposure to ethylene glycol monomethyl ether has also been associated with pancytopenia. In animal experiments, butyl cellosolve has been shown to produce hemolytic anemia. Exposure to ethylene glycol monomethyl ether and to EGME has been shown to result in adverse reproductive effects in mice, rats, and rabbits. These effects include testicular atrophy, degenerative testicular changes,⁴¹⁷ abnormal sperm head morphology, and infertility in males, effects shown to be antagonized by concomitant exposure to toluene and xylene.⁴¹⁸ The toxic effect of EGME on the male reproductive system may be strongly associated with the disproportion of testicular germ cells, with a depletion of haploid cells and a disproportionate ratio of diploid and tetraploid cells.⁴¹⁹ Glycol ethers produce hemato- and testicular toxicity in animals, which are dependent on both the alkyl chain length and the animal species used. Levels of spermatogenesis-involved proteins were increased by ethylene glycol monomethyl ether, including GST, testis-specific heat shock protein 70-2, glyceraldehyde 3-phosphate dehydrogenase, and phosphatidylethanolamine-binding protein.⁴²⁰ An increased frequency of spontaneous abortions, disturbed menstrual cycle, and subfertility has been demonstrated in EGME-exposed women working in the semiconductor industry.⁴²¹ Ethylene glycol monobutyl ether (2-butoxyethanol) ingestion causes metabolic acidosis, hemolysis, hepatorenal dysfunction, and coma.⁴²² Butoxyacetic acid, formed from ethylene glycol monobutyl ether as a result of dehydrogenase activity, is a potent hemolysin.

2-Methoxyethanol (ME) produces testicular lesions in rats, characterized primarily by degeneration of spermatocytes undergoing meiotic division, with minimal or no hemolytic changes. In guinea pigs, a single dose or multiple (3 daily) doses of 200 mg ME/kg were given, and animals were examined 4 days after the start of treatment. In guinea pigs, spermatocyte degeneration was observed in stage III/IV tubules, but was much less severe than in rats.⁴²³ The stage-specific effect of a single oral dose (500 mg/kg body weight) of ethylene glycol monomethyl ether was characterized during one cycle of seminiferous epithelium in rats. Maximum peritubular membrane damage and germinal epithelium distortion were observed in stages IX–XII. Cell death occurred during conversion of zygotene to pachytene spermatocytes

(stage XIII) and between dividing spermatocytes and step I spermatids (stage late XIII–XIV).⁴²⁴

Exposure of pregnant animals resulted in increased rates of embryonic deaths and in various congenital malformations. The acetate esters of ethylene glycol monomethyl ether and of EGME have produced similar adverse male reproductive effects.

Ethylene glycol monomethyl ether is metabolized to the active compound methoxy-acetic acid, which readily crosses the placenta and impairs fetal development. Pregnant mice exposed to EGME from gestational days 10–17 and offspring were examined on gestational day 18. Significant thymic atrophy and cellular depletion were found in EGME-exposed fetal mice, with decreased $\text{CD4}^+\text{-8}^+$ thymocytes and increased percentages of CD4-8 -thymocytes. In addition, fetal liver prolymphocytes were also sensitive targets of EGME exposure.⁴²⁵

Methoxyacetic acid (MAA), a teratogenic toxin, is the major metabolite of EGME. Electron paramagnetic resonance (EPR) spin-labeling techniques were used to gain insight into the mechanism of MAA toxicity. The results suggested that MAA may lead to teratological toxicity by interacting with certain protein components, that is, transport proteins, cytoskeleton proteins, or neurotransmitter receptors.⁴²⁶ MAA was shown to induce sister chromatid exchanges in human peripheral blood cells.⁴²⁷

A cross-sectional study of 97 workers exposed to ethylene glycol monomethyl ether, with semen analysis in 15, did not reveal abnormalities other than possibly smaller testicular size.⁴²⁸ The occurrence of adverse male reproductive effects in humans cannot be excluded on the basis of this study. Ethylene glycol monomethyl ether, EGME, ethylene glycol *n*-butyl ether and their aldehyde and acid derivatives were tested for mutagenicity with the Ames test, with and without the rat S9 mix. Ethylene glycol *n*-butyl ether and the aldehyde metabolite of ethylene glycol monomethyl ether, methoxyacetaldehyde, were found to be mutagenic in strain *Salmonella typhimurium* 97a, with and without S9 mix.⁴²⁹ Administration of EGME and its metabolite methoxyacetaldehyde (MALD), in concentrations of 35–2500 mg/kg for EGME and 25–1000 mg/kg for MALD, did not cause any chromosomal aberrations in mice after acute or subchronic exposure by the oral route.⁴³⁰

Prevention. Federal standards for PELs are EGME, 200 ppm; EGME acetate, 100 ppm; ethylene glycol monomethyl ether, 25 ppm; ethylene glycol monomethyl ether acetate, 25 ppm; and ethylene glycol monobutyl ether, 50 ppm. The ACGIH has recommended a TLV of 25 ppm for ethylene glycol monomethyl ether and 100 ppm for EGME; this latter TLV was lowered in 1981 to 50 ppm. In 1982 it was proposed that the TWA exposure limits for both these compounds and their acetates be reduced to 5 ppm in view of the testicular effects observed in recent animal studies.

► ORGANIC ACIDS, ANHYDRIDES, LACTONES, AND AMIDES

These compounds have numerous industrial applications. Their common clinical characteristic is an irritant effect on eyes, nose, throat, and the respiratory tract. Skin irritation can be severe, and some of the acids (formic, acetic, oxalic, and others) can produce chemical burns. Accidental eye penetration may result in severe corneal injury and consequent opacities. Toxic pulmonary edema can occur after acute overexposure to high concentrations.

Phthalic Anhydride

Phthalic anhydride ($\text{C}_6\text{H}_4(\text{CO})_2\text{O}$) is a crystalline, needlelike white solid. It is used in the manufacture of benzoic and phthalic acids, as a plasticizer for vinyl resins, alkyl and polyester resins, in the production of diethyl and dimethyl phthalate, phenolphthalein, phthalimide, methyl aniline, and other compounds.

Phthalic anhydride as dust, fumes, or vapor is a potent irritant for the eyes, respiratory system, and skin; with prolonged skin contact, chemical burns are possible. Repeated exposure may result in

chronic industrial bronchitis. Phthalic anhydride is also a potent sensitizing substance: occupational asthma can be severe and hypersensitivity pneumonitis has been reported. Phthalic and maleic anhydrides stimulated vigorous expression of IL-5, IL-10, and IL-13 but relatively low levels of the type 1 cytokines interferon-gamma and IL-12 following topical application to BALB/c strain mice.⁴³¹ Prolonged topical exposure of mice phthalic and maleic anhydrides in each case resulted in the development of a predominantly Th2-type cytokine secretion phenotype, consistent with the ability of these materials to provoke asthma and respiratory allergy through a type 2 (possibly IgE-mediated) mechanism.⁴³² Skin sensitization may result in eczematiform dermatitis.

Prevention. The federal standard for phthalic anhydride is a TLV of 1 ppm. Enclosure of technological processes where phthalic anhydride is used and protective clothing, including gloves and goggles, are necessary, respiratory protection must be available. Periodic examinations should focus on possible sensitization and chronic effects, such as bronchitis and dermatitis.

Maleic Anhydride

Maleic anhydride ($\text{O}=\text{C}-\text{CH}=\text{CH}-\text{C}=\text{O}$) is used mainly in the production of alkyd and polyester resins; it has also found applications for siccatives. Maleic anhydride can produce severe chemical burns of the skin and eyes. It is also a sensitizing substance and can lead to clinical manifestations similar to those described for phthalic anhydride. The 1987 TLV is 0.25 ppm.

Trimellitic Anhydride

Trimellitic anhydride (1,2,4-benzenetricarboxylic acid, cyclic 1,2-anhydride, $\text{C}_9\text{H}_4\text{O}_5$) is used as a curing agent for epoxy resins and other resins, in vinyl plasticizers, polyesters, dyes and pigments, paints and coatings, agricultural chemicals, surface-active compounds, pharmaceuticals, etc. Chemical pneumonitis has been reported after an epoxy resin containing trimellitic anhydride was sprayed on heated pipes. Respiratory irritation after exposure to high concentrations of trimellitic anhydride was reported in workers engaged in the synthesis of this compound. It was also found that in some cases sensitization occurs after variable periods following onset of exposure (sometimes years); allergic rhinitis, occupational asthma, and hypersensitivity pneumonitis can be manifestations of sensitization. Trimellitic anhydride as the etiologic agent in cases of sensitization was confirmed by inhalation challenge tests.⁴³³ Human leukocyte (HLA) Class 2 alleles were demonstrated to be risk factors contributing to individual susceptibility in workers.⁴³⁴ Trimellitic anhydride inhalation challenge of sensitized rats caused challenge concentration-related allergic airway inflammation, asthma-like changes in breathing pattern, and increased nonspecific airway responsiveness.⁴³⁵ Dermal sensitization in mice is associated with increased IgE levels in serum and bronchioalveolar lavage fluid, with increased cell numbers and neutrophils after intratracheal challenge.⁴³⁶ Trimellitic anhydride has been shown to activate rat lymph nodes, with secretion of type 2 cytokines, including the expression of IL-5 and IL-13 cytokines which in the presence of only very low levels of IL-4 may provide for an IgE-independent mechanism for the development of chemical respiratory allergy.⁴³⁷

Prevention. The NIOSH recommended in 1978 that trimellitic anhydride be considered an extremely toxic agent, since it can produce severe irritation of the respiratory tract, including pulmonary edema and chemical pneumonitis; sensitization, with occupational asthma or hypersensitivity pneumonitis can occur at lower levels. Guidelines for engineering controls and protective equipment have been outlined by NIOSH.³ The current OSHA TLV standard is 0.04 mg/m³.

Beta-Propiolactone

Beta-propiolactone ($\text{O}-\text{CH}_2-\text{CH}_2-\text{C}=\text{O}$) is a colorless liquid with important applications in the synthesis of acrylate plastics; it is also used as a disinfectant and as a sterilizing agent against viruses. It is easily absorbed through the skin; inhalation is also important.

Beta-propiolactone is a very potent irritant. In animal experiments it has been found to produce hepatocellular necrosis, renal tubular necrosis, convulsions, and circulatory collapse. Beta-propiolactone is a direct-acting alkylating agent and forms DNA adducts. It is mutagenic in a wide variety of in vitro and in vivo systems, both in somatic and germ cells.⁴³⁸ In several animal studies it has also been shown to be carcinogenic; skin cancer, hepatoma, and gastric cancer have been induced. Reports on systemic or carcinogenic effects in humans are not available.

Beta-propiolactone is included in the federal standard for carcinogens; no exposure should be allowed to occur. The IARC has classified beta-propiolactone as possibly carcinogenic to humans (Group 2B).⁴³⁹ Protective equipment designed to prevent all skin contact or inhalation is necessary; this includes full-body protective clothing and full-face air-supplied respirators. Showers at the end of the shift are absolutely necessary. The 1987 TLV is 0.05 ppm.

N, N-Dimethylformamide

N, N-dimethylformamide, $\text{HCON}(\text{CH}_3)_2$, is a colorless liquid with a boiling point of 153°C. It is miscible with water and organic solvents at 25°C. It has excellent solvent properties for numerous organic compounds and is used in processes where solvents with low volatility are necessary. Its major applications are in the manufacture of synthetic fibers and resins, mainly polyacrylic fibers and butadiene. It is absorbed through inhalation and through the skin and is irritating to the eyes, mucous membranes, and skin.² Adverse effects of absorption include loss of appetite, nausea, vomiting, abdominal pain, hepatomegaly, and other indications of liver injury. Clusters of testicular germ cell tumors have been reported among airplane manufacturing employees and tannery workers.^{440,441} An increased incidence of cancer (oropharyngeal and melanoma) was reported in a cohort of formamide-exposed workers.⁴⁴² DMF exposure was not associated with SCE frequency in peripheral lymphocytes of exposed workers,⁴⁴³ but occupational exposures to acrylonitrile and DMF induced increases in the frequencies of chromosomal aberrations and sister chromatid exchanges in peripheral blood lymphocytes.⁴⁴⁴

Inhalation exposure to DMF increased the incidence of hepatocellular adenomas and carcinomas in rats and the incidence of hepatocellular adenomas, carcinomas, and hepatoblastomas in mice.⁴⁴⁵ Results of in vitro and in vivo genotoxicity assays have been consistently negative.⁴⁴⁶ Dimethylformamide administered to mice and rats 5 days/week for 18 months did not produce effects on estrous cycle. Compound-related morphological changes were observed only in the liver. Centrilobular hepatocellular hypertrophy and centrilobular single-cell necrosis were found in rats and mice.⁴⁴⁷ Dimethylformamide exposure did not result in adverse effects on semen or menstrual cycle in cynomolgus monkeys, exposed for 13 weeks to concentrations up to 500 ppm.⁴⁴⁸ DMF caused cranial and sternebral skeletal malformations in mice⁴⁴⁹ and rats.⁴⁵⁰

N, N-dimethylformamide is metabolized by the microsomal cytochrome P450 into mainly *n*-hydroxymethyl-*n*-methylformamide, which further breaks down to *N*-methylformamide. Measurement of *N*-methylcarbamoylated hemoglobin in blood is a useful biomarker of exposure to *N,N*-dimethylformamide in health-risk assessment.⁴⁵¹ The measurement of the excretion of urinary *N*-acetyl-*S*-(*N*-methylcarbamoyl)cysteine (AMCC) and *N*-methylformamide (NMF) in the urine has been used for biological monitoring in the occupational setting.⁴⁵² The federal standard for a PEL is 10 ppm (30 mg/m³).

N, N'-Dimethylacetamide

N, N'-dimethylacetamide, $\text{CH}_3\text{CON}(\text{CH}_3)_2$, is a colorless liquid that is easily absorbed through the skin. Inhalation is a less important route of absorption, since the volatility is low. *N, N'*-dimethylacetamide is used as a solvent in a variety of industrial processes.

Hepatotoxicity is the most severe adverse effect; hepatocellular degenerative changes and jaundice have been reported in exposed workers. Experimental studies have also indicated hepatotoxicity as the prominent effect in rats and dogs. With high exposure, depressant neurotoxic effects become evident. Dimethylacetamide has been shown, in experiments on rodents, to produce testicular changes in rabbits and rats. Its hepatotoxicity was comparable to and possibly higher than that of dimethylformamide.⁴⁵³ Developmental toxicity (soft tissue and skeletal abnormalities) of dimethylacetamide was detected in rabbits following inhalation exposure.⁴⁵⁴

The federal standard for a PEL is 10 ppm (35 mg/m³). Protective equipment to exclude percutaneous absorption is necessary, as are eye and respiratory protection if high vapor concentrations are possible.

Acrylamide

Acrylamide ($\text{CH}_2 = \text{CHCONH}_2$) is a white crystalline material with a melting point of 84.5°C and a tendency to sublime; it is readily soluble in water and in some other common polar solvents. Large-scale production started in the early 1950s; the major industrial applications are as a vinyl monomer in the production of high-molecular polymers such as polyacrylamides. These have many applications, including the clarification and treatment of municipal and industrial effluents and potable water; in the oil industry (for fracturing and flooding of oil-bearing strata); as flocculants in the production of ores, metals, and coal; as strengtheners in the paper industry; for textile treatment, etc. Acrylamide is of major concern because of its extensive use in molecular biology laboratories, where, in the United States, 100,000–200,000 persons are potentially exposed in chromatography, electrophoresis, and electron microscopy.⁴⁵⁵ Acrylamide is present in tobacco smoke, and concern has arisen regarding human exposures through its presence in some prepared foods, especially high carbohydrate foods cooked at high temperatures, such as French fries and potato chips.⁴⁵⁶

Although the pure polyacrylamide polymers are nontoxic, the problem of residual unreacted acrylamide exists, since up to 2% residual monomer is acceptable for some industrial applications. The FDA has established a maximum 0.05% residual monomer level for polymers used in paper or cardboard in contact with food; similar levels are accepted for polymers used in clarification of potable water. Since acrylamide has cumulative toxic effects, it has been recommended that the general population not be exposed to daily levels in excess of 0.0005 mg/kg.

The initial indication of a marked neurotoxic effect of acrylamide came when a recently introduced acrylamide production method (from acrylonitrile) was first used in 1953; several workers experienced weakness in their extremities, with numbness and tingling, strongly suggestive of toxic peripheral neuropathy. Cases of acrylamide neuropathy have since been reported from Japan, France, Canada, and Great Britain.

Acrylamide is readily absorbed through the skin, which is considered an important route of absorption. Respiratory absorption and ingestion of acrylamide are also important; severe cases of acrylamide poisoning have resulted from ingestion of contaminated water in Japan.

Acrylamide is metabolized to the epoxide glycidamide, metabolically formed from acrylamide by CYP 2E1-mediated epoxidation, and whose adducts to hemoglobin and to DNA have been identified in animals and humans. Dosing rats and mice with glycidamide, typically produced higher levels of DNA adducts than observed with acrylamide. Glycidamide-derived DNA adducts of adenine and guanine were formed in all tissues examined, including both target tissues identified in rodent carcinogenicity bioassays and in nontarget tissues.⁴⁵⁷ This metabolite may be involved in the reproductive and carcinogenic effects of acrylamide. The neurotoxicity of acrylamide and glycidamide were shown to differ in rats, suggesting that acrylamide itself is primarily responsible for peripheral neurotoxicity.⁴⁵⁸

Acrylamide poisoning in occupationally exposed workers has occurred after relatively short periods of exposure (several months to a year). Erythema and peeling of skin, mainly in the palms but also on the soles, usually precede neurologic symptoms; excessive fatigue, weight loss, and somnolence are followed by a slowly progressive symmetrical peripheral neuropathy. The characteristic symptoms include muscle weakness, unsteadiness, paresthesia, signs of sympathetic nervous system involvement (cold, blue hands and feet, excessive sweating), impairment of superficial sensation (touch, pain, temperature) and position sense, diminished or absent deep tendon reflexes in legs and arms, and the presence of Romberg's sign. Considerable loss of muscle strength may occur, and muscular atrophy, usually starting with the small muscles of the hands, has been reported. This toxic neuropathy has a distal to proximal evolution; the earliest and most severe changes are in the distal segments of the lower and upper extremities, and progression occurs with involvement of more proximal segments ("stocking and glove" distribution). Signs indicating CNS involvement are somnolence, vertigo, ataxic gait, and occasionally slight organic mental syndrome. EEG abnormalities have also been described.

Sensory nerve conduction velocities have been found to be more affected than motor nerve conduction velocities; potentials with markedly prolonged distal latencies are described. Recovery after cessation of exposure is slow; it may take several months to 2 years. Workers exposed to acrylamide and *N*-methylolacrylamide during grouting work reported a higher prevalence of symptoms during the exposure period than they did in an examination 16 months later. A statistically significant reduction in the mean sensory NCV of the ulnar nerve was observed 4 months postexposure when compared with the values of a control group, and the mean ulnar distal delay was prolonged. Both measures were significantly improved when measured one year later. Exposure-related improvements were observed from four to 16 months postexposure for both the median (motor and sensory NCV and F-response) and ulnar (sensory NCV, F-response) nerves. A significant reversible reduction in the mean sensory amplitude of the median nerve was also observed, while the mean sensory amplitude of the sural nerve was significantly reduced after 16 months.⁴⁵⁹ Experimental acrylamide neuropathy has been produced in all mammals studied; medium- to large-diameter fibers and long fibers are more susceptible to the primary giant axonal degeneration and secondary demyelination characteristic of acrylamide neuropathy. CNS pathology consists of degenerating fibers in the anterior and lateral columns of the spinal cord, gracile nucleus, cerebellar vermis, spinocerebellar tracts, CNS optic nerve tracts, and tracts in the hypothalamus.

Changes in somatosensory evoked potentials have been found to be useful in the early detection of acrylamide neurotoxicity. They precede abnormalities of peripheral nerve conduction and behavioral signs of intoxication. Deterioration of visual capacity, with an increased threshold for visual acuity and flicker fusion and prolonged latency in VEPs, was reported in monkeys. These abnormalities were detected before overt signs of toxicity became apparent. Acrylamide preferentially damages P retinal ganglion cells in macaques, with marked effects on visual acuity, contrast discrimination, and shape discrimination.⁴⁶⁰

An underlying mechanism of acrylamide peripheral neuropathy has been found to be impaired retrograde transport of material from the more distal parts of the peripheral nerve. The buildup of retrogradely transported material has been shown to be dose-related. Changes in retrograde axonal transport are thought to play an initial and important role in the development of toxic axonopathies, possibly the primary biochemical event in acrylamide neuropathy. Local disorganization of the smooth endoplasmic reticulum, forming a complex network of tubules intermingled with vesicles and mitochondria, is thought to be responsible for the focal stasis of fast-transported proteins. These seem to be the earliest changes detectable in axons damaged by acrylamide. Acrylamide reduced microtubule-associated proteins (MAP1 and MAP2) in the rat extrapyramidal system. The effect was more marked in the caudate-putamen than in other components of the extrapyramidal system. The loss of MAPs occurs first in dendrites and proceeds toward the perikarya. The depletion of microtubule-associated proteins in the extrapyramidal system appears to be an early biochemical event preceding peripheral neuropathy.⁴⁶¹ In addition, acrylamide

also produces necrosis of cerebellar Purkinje cells after high dose (50 mg/kg) administration in rats.⁴⁶² Acrylamide has been found to depress fast anterograde transport of protein, resulting in reduction in delivery of protein to the axon and distal nerve degeneration.⁴⁶³

Acrylamide has been reported to produce effects on neurotransmitter and neuropeptide levels in various areas of the brain. Elevated levels of 5-hydroxyindolacetic acid in all regions of the rat brain were interpreted as being the result of an increased serotonin turnover. Changes in the affinity and number of dopamine receptor sites have also been found. Elevated levels of some neuropeptides were detected mainly in the hypothalamus. Significant decreases in plasma levels of testosterone and prolactin were found after repeated acrylamide administration. In recent studies, acrylamide intoxication was associated with early, progressive nerve terminal degeneration in all CNS regions and with Purkinje cell injury in the cerebellum.⁴⁶⁴

Acrylamide produced testicular atrophy, with degenerative changes in the epithelial cells of seminiferous tubules. Acrylamide treatment produced significant increases in chromosomal structural aberrations in late spermatids-spermatozoa of mice. Chromosomal damage was consistent with alkylation of DNA-associated protamines. A dose-dependent depletion of mature spermatids after treatment of spermatogonia and a toxic effect upon primary spermatocytes were also detected.⁴⁶⁵ Acrylamide (i.p.) produced a meiotic delay in spermatocytes of mice. This was predominately due to prolongation of interkinesis. Acrylamide toxicity appears to increase Leydig cell death and perturb gene expression levels, contributing to sperm defects and various abnormal histopathological lesions including apoptosis in rat testis.⁴⁶⁶ Acrylamide is highly effective in breaking chromosomes in germ cells of male mice, resulting both in early death of conceptuses and in the transmission of reciprocal translocation to live-born progeny. This effect has been demonstrated after topical application and absorption through the skin.⁴⁶⁷ Acrylamide-induced germ cell mutations in male mice require CYP2E1-mediated epoxidation of acrylamide.⁴⁶⁸ Acrylamide exposure in male mice caused a dose-dependent increase in the frequency of morphologic abnormalities in preimplantation embryos. Single-cell eggs, growth retardation, and blastomere lysis were detected after paternal treatment with acrylamide. A more than 100-fold elevation of chromatin adducts in sperm was observed during first and second week after treatment.⁴⁶⁹

The disturbances in cell division caused by acrylamide suggest that acrylamide might induce aneuploidy by interfering with proper functioning of the spindle; errors in chromosome segregation may also occur.⁴⁷⁰ Genotoxic effects of acrylamide and glycidamide have also been detected in several *in vitro* and/or *in vivo* unscheduled DNA synthesis assays.⁴⁷¹ Acrylamide showed mutagenic potency in *Salmonella*, and both the chromosomal aberration assay and micronucleus assay indicated that acrylamide has genotoxic potency; the chromosomal aberration frequencies were observed to be proportional to acrylamide concentrations, and acrylamide significantly increased micronuclei in peripheral blood cells of mice.⁴⁷² The DNA strand breaking effect of acrylamide in rat hepatocytes was enhanced by depletion of glutathione.⁴⁷³ Acrylamide has been shown to exert a wide spectrum of diverse effects on DNA of normal cells, including mostly DNA base modifications and apoptosis, and may also impair DNA repair.⁴⁷⁴ Oncogenicity studies on rats treated with acrylamide in drinking water for 2 years have been positive for a number of tumors (central nervous system, thyroid, mammary gland, uterus in females, and scrotal mesothelioma in males). Acrylamide increased DNA synthesis in the target tissues for tumor development (thyroid, testicular mesothelium, adrenal medulla) in the rat. In contrast, cell growth was not altered in the liver and adrenal cortex (non-target tissues for acrylamide carcinogenesis).⁴⁷⁵

In a mortality study involving a cohort of 371 employees exposed to acrylamide, an excess in total cancer deaths was due to excess in digestive and respiratory cancer in a subgroup that had previous exposure to organic dyes.⁴⁷⁶ IARC has classified acrylamide in Group 2A, probably carcinogenic to humans.⁴⁷⁷

Control and Prevention

Engineering designs that prevent the escape of both vapor and dust into the environment are necessary; enclosure, exhaust ventilation,

and automated systems must be used to minimize exposure. Prevention of skin and eye contact is especially important in handling of aqueous solutions, and closed systems are to be preferred.

Measurements of hemoglobin adducts were developed as a way to monitor exposure to acrylamide and have been successfully applied in a field study of occupationally exposed workers.⁴⁷⁸ A study of 41 workers heavily exposed to acrylamide and acrylonitrile in Xinxiang, China, was undertaken because of frequent signs and symptoms indicating neuropathy. Hemoglobin adducts of acrylamide were significantly correlated with a "neurotoxicity index" based on signs and symptoms of peripheral neuropathy, vibration thresholds, and electroneuromyography measurements.⁴⁷⁹

The present recommended TWA for acrylamide exposure is 0.3 mg/m³. Skin exposure has to be carefully avoided by the use of appropriate protective clothing and work practices. Showers and eye-wash fountains should be available for immediate use if contamination occurs. Preemployment and periodic medical examinations with special attention to skin, eyes, and nervous system are necessary. It is essential that employees be warned of the potential health hazards and the importance of personal hygiene and careful work practices. Frequent inspection of fingers and hands by medical or paramedical personnel is useful in detecting peeling of skin, which usually precedes clinical neuropathy.

► ALDEHYDES

Aldehydes are aliphatic or aromatic compounds with the general structure:

The aldehydes are highly reactive substances and are used extensively throughout the chemical industry. Formaldehyde is a gas that is readily soluble in water; the other aldehydes are liquids. The common characteristic of aldehydes is their strong irritative effect on the skin, eyes, and respiratory system. Acute overexposure may result in toxic pulmonary edema. Sensitization to aldehydes is possible, and allergic dermatitis and occupational asthma can occur. Unlike formaldehyde, gluteraldehyde has not been shown to increase neoplasia in rodent studies.⁴⁸⁰

Formaldehyde

Formaldehyde (HCHO) is a colorless gas with a strong odor, which is readily soluble in water; the commercial solutions may contain up to 15% methanol to prevent polymerization. It has numerous industrial applications in the manufacture of textiles cellulose esters, dyes, inks, latex, phenol, urea, melamine, pentaerythrol, hexamethylenetetramine, thiourea, resins, and explosives and as a fungicide, disinfectant, and preservative. More than half of formaldehyde is used in the United States in the manufacture of plastics and resins: urea-formaldehyde resins phenolic, polyacetal, and melamine resins. Among the many other uses is in the manufacture of 4,4'-methylene dianiline and 4,4'-methylene diphenyl diisocyanate. Some relatively small-volume uses of formaldehyde are in agriculture, for seed treatment and as a soil disinfectant, in cosmetics, deodorants, in photography, and in histopathology.

Formaldehyde has been found to be a relatively common contaminant of indoor air; it originates in urea-formaldehyde resins used in the production of particle board or in urea-formaldehyde foam used for insulation. Such insulation was applied in the United States in approximately 500,000 houses during the period 1975–1980. Concentrations of formaldehyde in residential indoor air have varied from 0.01 to 31.7 ppm.

Significant concentrations of formaldehyde have been found in industrial effluents, mainly from the production of urea-, melamine- and phenol-formaldehyde resins, and also from users of such resins (e.g., plywood manufacturers). In water, formaldehyde undergoes rapid

degradation and, therefore, does not represent a major source of absorption. Formaldehyde is also readily degraded in soil. Bioaccumulation does not occur.⁴⁸¹

Other sources of formaldehyde exposure for the general population are from cigarette smoke (37–73 µg/per cigarette) and from small amounts in food, especially after the use of hexamethylenetetramine as a food additive. Formaldehyde resins applied to permanent-press textiles can emit formaldehyde when stored. Fingernail hardeners containing formaldehyde are a relatively recent addition to the potential sources of formaldehyde exposure. Measurement of formaldehyde levels in the air in office buildings in Taiwan raised concern about increases in lifetime cancer risk.⁴⁸² Japanese anatomy students dissecting cadavers were exposed to formaldehyde levels in excess of the recommended level of 0.5 ppm set by Japan Society for Occupational Health.⁴⁸³ The normal endogenous concentration of formaldehyde in the blood is approximately 0.1 mM in rats, monkeys, and humans.

Absorption occurs through inhalation. Skin and eye contact may result in chemical burns. Guinea pigs exposed by inhalation to formaldehyde (1 ppm for 8 hours) developed increased airway resistance and enhanced bronchial reactivity to acetylcholine, mediated through leukotriene biosynthesis.⁴⁸⁴ Smooth muscle reactivity in the airways was altered, despite absence of epithelial damage or inflammation histologically.⁴⁸⁵ Chronic formaldehyde exposure enhanced bronchoconstrictive responses to ovalbumin antigen challenge in ovalbumin-sensitized guinea pigs.⁴⁸⁶ Acute overexposure to very high concentrations may result in pulmonary edema. Sensitization resulting in allergic dermatitis is not uncommon; occupational asthma is also possible.

With repeated exposures over 10 days, formaldehyde affected the learning behavior and the memory of male and female rats.⁴⁸⁷ Formaldehyde induced oxidative frontal cortex and hippocampal tissue damage in rats; a protective effect of vitamin E against oxidative damage was found.⁴⁸⁸

Formaldehyde carcinogenicity assays have revealed that inhalation exposure to concentrations of 14.3 ppm resulted in a significantly increased incidence of nasal squamous cell carcinomas in rats of both sexes. Induction of nasal carcinomas in rats exhibited a nonlinear relationship with formaldehyde dose, the rates increasing rapidly with increasing exposure concentrations.⁴⁸⁹ Formaldehyde-related increases in cell proliferation are thought to play an important role in formaldehyde carcinogenicity.

In mice only a very small number of squamous cell carcinomas developed, and the incidence was not statistically significant. Dysplasia and squamous metaplasia of the respiratory epithelium, rhinitis, and atrophy of the olfactory epithelium were observed in mice; similar lesions were seen in rats, and goblet cell hyperplasia, squamous atypia, and papillary hyperplasia were also found. A 2-year experimental study on rats investigated the effects of formaldehyde in drinking water. Although pathologic changes in the gastric mucosa were found in the high-dose rats, no gastric tumors or tumors at other sites were detected.⁴⁹⁰

A cohort study of 2490 employees in a chemical plant manufacturing and using formaldehyde found an elevated proportional mortality for digestive tract cancer in white males; the small numbers make it difficult to draw conclusions. No deaths from cancers of the nose or nasal sinuses had occurred. The duration of employment was relatively short. The studies had a very limited power to detect excess mortality from nasal cancer. In a large retrospective cohort mortality study of more than 11,000 workers exposed to formaldehyde in the garment industry, significant excess mortality from cancer of the buccal cavity and connective tissue was found. The incidence of such cancers as leukemia and lymphoma was higher than expected, without reaching the level of statistical significance. Nasopharyngeal cancer mortality was statistically significantly increased in a cohort study of United States industrial workers exposed to formaldehyde, and was also increased in two other U.S. and Danish cohort studies. Five of seven case-control studies also found elevated risk for formaldehyde exposure. Leukemia mortality, primarily myeloid-type, was increased in six of seven cohorts of embalmers, funeral-parlor workers, pathologists, and anatomists. A greater incidence of leukemia in two cohorts of U.S. industrial workers⁴⁹¹ and U.S. garment workers,⁴⁹² but not in a third cohort of United Kingdom chemical workers, has been reported. An IARC Working Group concluded that there is

sufficient evidence in humans that formaldehyde causes nasopharyngeal cancer, but strong but not sufficient evidence for a causal association between leukemia and occupational exposure to formaldehyde. Overall, the Working Group concluded that formaldehyde is carcinogenic to humans (Group 1), on the basis of sufficient evidence in humans and sufficient evidence in experimental animals—a higher classification than previous IARC evaluations.⁴⁹³

Formaldehyde is mutagenic to bacteria, yeast, and *Drosophila*. Recently, formaldehyde-induced mutagenesis has been demonstrated in Chinese hamster ovary cells, primarily point mutations with single-base transversions.⁴⁹⁴ Formaldehyde is metabolized to carbon dioxide and formate. Studies using ¹⁴C-formaldehyde have demonstrated the presence of ¹⁴C-labeled cellular macromolecules.

In microarray studies of the nasal epithelium of rats exposed to formaldehyde by nasal inhalation, multiple genetic pathways were found to be dysregulated by formaldehyde exposure, including those involved in DNA synthesis/repair and regulation of cell proliferation.⁴⁹⁵ Formaldehyde has been reported to react with nucleic acids and has been found to be among the most potent of DNA-protein cross-link inducers, compared with aldehydes with greater carbon chain length.⁴⁹⁶ DNA-protein cross-links were induced, along with cell proliferation, squamous metaplasia and squamous cell carcinomas, in the nasal lateral meatus (a high tumor site in bioassays) of F344 rats exposed to formaldehyde.⁴⁹⁷ DNA damage in human lymphocyte cultures was demonstrated using the comet assay for DNA alterations.⁴⁹⁸

Sister chromatid exchanges in lymphocytes of formaldehyde-exposed anatomy students showed a small but statistically significant increase when compared with preexposure findings in the same persons.⁴⁹⁹ Nasal respiratory cell samples collected from formaldehyde-exposed sawmill and shearing press workers showed a significantly higher frequency of micronucleated cells than found among unexposed controls.⁵⁰⁰ DNA-protein cross-links were found with significantly greater frequency in the white blood cells of 12 formaldehyde-exposed workers than in the white blood cells of 8 unexposed controls.⁵⁰¹ A significant increase in the frequency of micronucleated buccal cells in buccal smears taken from anatomy and pathology staff exposed to formaldehyde has been reported.⁵⁰² Similar findings were reported in a study of mortuary students.⁵⁰³

Evidence has accumulated which indicates that formaldehyde is an important metabolite of a number of halogenated hydrocarbons, mediated through GST theta activity, including dichloromethane, methyl bromide, methyl chloride, and carbon tetrachloride.^{504,505} Formaldehyde administered to male rats at 10 mg/kg body weight/day for 30 days caused a significant fall in sperm motility, viability, and count.⁵⁰⁶ Embryonic viability, increased dysmorphogenesis, and decreased growth parameters were altered in a dose-dependent fashion when mouse and rat embryos were exposed to formaldehyde.⁴⁰²

The federal standard for formaldehyde is 1 ppm (1.2 mg/m³). Engineering controls are essential to control exposure. Protective equipment to prevent skin contact, adequate respirators for situations in which higher exposure could result, proper work practices, and continuous education programs for employees are necessary. The EPA and the OSHA, in their consideration of available epidemiological and toxicological studies, now regard formaldehyde as a possible human carcinogen, although the evidence in humans is limited and controversial.

Acrolein

Acrolein (H₂C = CHCHO), a clear liquid, is used in the production of plastics, plasticizers, acrylates, synthetic fibers, and methionine; it is produced when oils and fats containing glycerol are heated, and it is a component of cigarette smoke. Acrolein is one of the strongest irritants. Skin burns and severe irritation of eyes and respiratory tract, including toxic pulmonary edema, are possible. Inhalation of smoke containing acrolein, the most common toxin in urban fires after carbon monoxide, causes vascular injury with noncardiogenic pulmonary edema containing edematogenic eicosanoids such as thromboxane, leukotriene B₄, and the sulfidopeptide leukotrienes. Thromboxane is probably responsible for the pulmonary hypertension which occurs after the inhalation of acrolein

smoke.⁵⁰⁷ Acrolein caused dose-dependent cytotoxicity to human alveolar macrophages as demonstrated by the induction of apoptosis and necrosis.⁵⁰⁸ Acrolein is produced at the subcellular level by the lipid peroxidation caused by a wide range of agents that cause intracellular oxidative stresses. Acrolein itself acts as a strong peroxidizing agent.⁵⁰⁹ Acrolein has been demonstrated in neurofibrillary tangles in the brain in Alzheimer's disease and is toxic to hippocampal neurons in culture.⁵¹⁰ Acrolein has been implicated in the pathogenesis of atherosclerosis. Glutathione and GST were protective against acrolein-induced toxicity in rat aortic smooth muscle cells,⁵¹¹ and glutathione has been demonstrated to reduce many of the toxic effects of acrolein exposure. Acrolein inhibited T-cell and B-cell proliferation and reduced the viability of mouse lymphocytes in vitro.⁵¹²

Acrolein is embryotoxic and teratogenic in rats and chick embryos after intra-amniotic administration. Initial reactions between acrolein and protein generate adducts containing an electrophilic center that can participate in secondary deleterious reactions (e.g., cross-linking). Inactivation of these reactive protein adducts with hydralazine, a nucleophilic drug, counteracts acrolein toxicity.⁵¹³ Acrolein is genotoxic, causes DNA single-strand breaks, and is a highly potent DNA cross-linking agent in human bronchial epithelial cells.⁵¹⁴ Acrolein forms cyclic deoxyguanosine adducts when it reacts with DNA in vitro and in *S. typhimurium* cultures.

2-Chloroacrolein and 2-bromoacrolein are very potent direct mutagens not requiring metabolic activation in *S. typhimurium* strains.⁵¹⁵ Acrolein was shown to be mutagenic in bacterial systems.⁵¹⁶ Acrolein was not found to be a developmental toxicant or teratogen at doses not toxic to the does, when administered via stomach tube to pregnant white rabbits.⁵¹⁷ Acrolein is not a selective reproductive toxin in the rat.⁵¹⁸

The federal standard for a PEL for acrolein is 0.1 ppm. The IARC has concluded that there is inadequate evidence in humans for the carcinogenicity of acrolein and inadequate evidence in experimental animals (Group 3).⁵¹⁹

Environmentally relevant concentrations of acrolein can induce bronchial hyperactivity in guinea pigs through a mechanism involving injury to cells present in the airways. There is evidence that this response is dependent on leukotriene biosynthesis.⁵²⁰

Other widely used aldehydes are acetaldehyde and furfural. They have irritant effects but are less potent in this respect than formaldehyde and acrolein. Evidence for carcinogenic potential in experimental animals is convincing for formaldehyde and acetaldehyde, limited for crotonaldehyde, furfural and glycidaldehyde, and very weak for acrolein.⁵²¹

► ESTERS

Esters are organic compounds that result from the substitution of a hydrogen atom of an acid (organic or inorganic) with an organic group. They constitute a very large group of substances with a variety of industrial uses in plastics and resins, as solvents, and in the pharmaceutical, surface coating, textile, and food-processing industries.

Narcotic CNS effects and irritative effects (especially with the halogenated esters such as ethyl chloroformate, ethyl chloroacetate, and the corresponding bromo- and iodo-compounds) are common to most esters. Sensitization has been reported with some of the aliphatic monocarboxylic halogenated esters. Some of the esters of inorganic acids have specific, potentially severe toxicity.

Dimethylsulfate

Dimethylsulfate, $(\text{CH}_3)_2\text{SO}_4$, is an oily fluid. It is used mainly for its methylating capacity; it is used as a solvent in the separation of mineral oils and as a reactant in producing polyurethane resins. Absorption is mainly through inhalation, but skin penetration is also possible.

Toxic effects are complex and severe; many fatalities have occurred. After a latency period of several hours, the irritant effects on the skin, eyes, and respiratory system become manifest; toxic pulmonary edema is not unusual. Vesication of the skin and ulceration can occur. Eye irritation usually results in conjunctivitis, keratitis, photophobia, palpebral edema, and blepharospasm. Irritation of the upper airways may also be severe, with dysphagia and sometimes edema of the glottis. Dyspnea, cough, and

shallow breathing are the signs of toxic pulmonary edema. If the patient survives this critical period, 48 hours later the signs and symptoms of hepatocellular necrosis and renal tubular necrosis may become manifest.

At very high levels of exposure, neurotoxic effects are prominent, with somnolence, delirium, convulsions, temporary blindness, and coma. Dimethylsulfate is an alkylating agent. In experimental studies on rats, it has been shown to be carcinogenic. Prenatal exposure has also produced tumors of the nervous system in offspring. The IARC has concluded that there is sufficient evidence of dimethyl sulfate carcinogenicity in animals and that it has to be assumed to be a potential human carcinogen. In inhalation experiments on rodents, embryotoxic and teratogenic effects have also been observed.

The federal standard for a permissible level of dimethylsulfate exposure is 0.1 ppm. Diethylsulfate, methylchlorosulfonate, ethylchlorosulfonate, and methyl-*p*-toluene sulfonate have effects similar to those of dimethyl sulfate, and the same extreme precautions in their handling are necessary. The skin, eyes, and respiratory tract should be protected continuously when there may be exposure to dimethylsulfate or the other esters that have similar effects. Contaminated areas should be entered only by trained personnel with impermeous protective clothing and air-supplied respirators.²

► KETONES

The chemical characteristic of this series of compounds known as ketones is the presence of the carbonyl group. Their general structure is

Ketones are excellent solvents for oils, fats, collodion, cellulose acetate, nitrocellulose, cellulose esters, epoxy resins, pigments, dyes, natural and synthetic resins (especially vinyl polymers and copolymers), and acrylic coatings. They are also used in the manufacture of paints, lacquers, and varnishes and in the celluloid, rubber, artificial leather, synthetic rubber, lubricating oil, and explosives industries. Other uses are in metal cleaning, rapidly drying inks, airplane dopes, as paint removers and dewaxers, and in hydraulic fluids.

The most important members of the ketone group, because of extensive use are as follows:

Acetone	CH_3COCH_3
Methyl-ethyl-ketone	$\text{CH}_3\text{COCH}_2\text{CH}_3$
Methyl- <i>n</i> -propyl ketone	$\text{CH}_3(\text{CH}_2)_2\text{COCH}_3$
Methyl- <i>n</i> -butyl ketone	$\text{CH}_3\text{CO}(\text{CH}_2)_3\text{CH}_3$
Methyl isobutyl ketone	$\text{CH}_3\text{COCH}_2\text{CH}(\text{CH}_3)_2$
Methyl- <i>n</i> -amyl ketone	$\text{CH}_3\text{CO}(\text{CH}_2)_4\text{CH}_3$
Methyl isoamyl ketone	$\text{CH}_3\text{CO}(\text{CH}_2)_2\text{CH}(\text{CH}_3)_2$
Diisobutyl ketone	$(\text{CH}_3)_2\text{CHCH}_2\text{COCH}_2\text{CH}(\text{CH}_3)_2$
Cyclohexane	$\text{C}_6\text{H}_{10}\text{O}$
Mesityl oxide	$\text{CH}_3\text{COCH}=\text{C}(\text{CH}_3)_2$
Isophorone(3,5,5-trimethyl-2-cyclohexen-1-one)	$\text{C}_{10}\text{H}_{14}\text{O}$

Methyl isobutyl ketone is used in the recovery of uranium from fission products. It has also found applications as a vehicle for herbicides, such as 2,4,5-T, and insecticides. Many of the ketones are valuable raw materials or intermediates in the chemical synthesis of other compounds. For example, approximately 90% of the two billion pounds of acetone produced each year is used by the chemical industry for the production of methacrylates and higher ketones.

The major route of absorption is through inhalation of vapor; with some of the ketones, such as MEK and MBK, skin absorption may contribute significantly to the total amount absorbed if work practices allow for extensive contact (immersion of hands, washing with the solvents).

All the ketones are moderate mucous membrane irritants (eyes and upper airways); at higher concentrations CNS depression with

pre-narcotic symptoms progressing to narcosis may occur. A specific neurotoxic effect of MBK, peripheral neuropathy, was reported in 1975⁵²² in workers exposed in the plastic coatings industry. In 1976, similar cases were identified among spray painters. Cases of peripheral neuropathy were also found in furniture finishers exposed to methyl-*n*-butyl ketone (MBK) and in workers employed in a dewatering unit in a refinery, where the exposure was reported to be to MEK.

The toxic sensorimotor peripheral neuropathy caused by MBK exposure is very similar to that caused by other neurotoxic substances such as acrylamide and *n*-hexane. Typically, sensory dysfunctions (touch, pain, temperature, vibration, and position) are the initial changes, affecting the hands and feet. Distal sensory neuropathy can be the only finding in some affected persons; in more severe cases motor impairment (muscle weakness, diminished or abolished deep tendon reflexes) in the distal parts of the lower and then the upper extremities becomes manifest. With progression, and in more severe cases, both the sensory and motor deficits may also affect the more proximal segments of the extremities; muscle wasting may be present in severe cases. Electromyographic abnormalities and slowing of nerve conduction velocity can be detected in the vast majority of cases; these electrophysiological abnormalities are useful for early detection, since they most often precede clinical manifestations. The clinical course is protracted, and cessation of toxic exposure does not result in recovery in all cases; progressive dysfunction was observed to occur for several months after exposure had been eliminated.

Animal experiments have demonstrated that exposure to methyl-*n*-butyl ketone results in peripheral neuropathy in all tested species; moreover, mixed exposure to MEK and MBK (in a 5:1 ratio) resulted in a more rapid development of peripheral neuropathy in rats than exposure to MBK alone, indicating a potentiating effect of MEK. These experimental data are of importance for human exposure, since mixtures of solvents are often used.

MBK produces primary axonal degeneration, with marked increase in the number of neurofilaments, reduction of neurotubules, axonal swelling, and secondary thinning of the myelin sheath. Spencer and Schaumburg⁵²³ have identified similar changes in certain tracts of the CNS, the distal regions of long ascending and descending pathways in the spinal cord and medulla oblongata, and preterminal and terminal axons in the gray matter. For this reason, they have proposed central-peripheral distal axonopathy as a more appropriate term for this type of neurotoxic effect. The “dying back” axonal disease therefore seems not to be limited to the peripheral nerves but to be quite widespread in the CNS. Debate continues regarding the relationship between giant axonal swellings in CNS and PNS tissues, containing neurofilamentous masses, and axon atrophy.⁵²⁴ Recovery from peripheral neuropathy is slow; it is thought that recovery of similar lesions within the CNS is unlikely to occur and might result in permanent deficit, such as ataxia or spasticity.

The predominant metabolite of MBK is 2,5-hexanedione. A similar type of giant axonal neuropathy was reproduced in animals exposed to this metabolite. 2,5-Hexanedione is also the main metabolite of *n*-hexane, another solvent with marked similar neurotoxicity. Other metabolites of MBK are 5-hydroxy-2-hexanone, 2-hexanol, and 2,5-hexanediol; all have been shown to produce typical giant axonal neuropathy in experiments on rats.³ The transformation of MBK to its toxic metabolites is mediated by the liver mixed-function oxidase system. MEK potentiates the neurotoxicity of MBK by induction of the microsomal mixed-function enzyme system.

It is generally accepted that 2,5-hexanedione, the gamma-diketone metabolite of MBK, has the most marked neurotoxic effect of all MBK metabolites. Another ketone, ethyl-*n*-butyl ketone (EnBK, 3-heptanone) has also been reported to produce typical central-peripheral distal axonopathy in rats. MEK potentiated EnBK neurotoxicity; the excretion of two neurotoxic γ -diketones—2,5-heptanedione and 2,5-hexanedione—was increased.

Technical-grade methyl-heptyl ketone (MHK) was also found to produce toxic neuropathy in rats; the effect was shown to be due to 5-nonanone. Metabolic studies have demonstrated the conversion of 5-nonanone to 2,5-nonanedione, MBK, and 2,5-hexanedione. Other γ -diketones—2,5-heptanedione and 3,6-octanedione—have also produced neuropathy.

Nephrotoxic (degenerative changes in proximal convoluted tubular cells) and hepatotoxic effects have been detected in experimental exposure of several animal species to the following ketones: isophorone (at 50 ppm), mesityl oxide (at 100 ppm), mesityl isobutyl ketone (at 100 ppm), cyclohexanone (at 190 ppm), and diisobutylketone (at 250 ppm).

The potential for MEK to cause developmental toxicity was tested in mice. Mild developmental toxicity was observed after exposure to 3000 ppm, which resulted in reduction of fetal body weight. There was no significant increase in the incidence of any single malformation, but several malformations not observed in the concurrent control group were found at a low incidence—cleft palate, fused ribs, missing vertebrae, and syndactyly.⁵²⁵ A recent study of developmental toxicity in rats found no adverse reproductive effects after exposure to 2000 ppm.⁵²⁶

Prevention

Appropriate engineering, mainly enclosure and exhaust ventilation, and adequate work practices preventing spillage and vapor generation are essential to maintain exposure to ketones below the exposure limits. Adequate respiratory protection is recommended for situations in which excessive concentrations are possible (maintenance and repair, emergencies, installation of engineering controls, etc.). Appropriate protective clothing is necessary, and skin contact must be avoided.

All ketones are flammable or combustible, and employees should be informed of this risk as well as of the specific health hazards. Warning signs in the work areas and on vessels and special educational programs for employees, especially new employees, are necessary as part of a comprehensive prevention program.

The NIOSH recommends that occupational exposure to ketones be controlled so that the TWA concentration does not exceed the following exposure limits:

MBK	1 ppm
Isophorone	4 ppm
Mesityl oxide	10 ppm
Cyclohexanone	25 ppm
Diisobutyl ketone	25 ppm
Methyl isobutyl ketone	50 ppm
Methyl isoamyl ketone	50 ppm
Methyl- <i>n</i> -amyl ketone	100 ppm
Methyl- <i>n</i> -propyl ketone	150 ppm
MEK	200 ppm
Acetone	50 ppm

The marked neurotoxicity of at least one member of this group (MBK), the slow recovery in cases of distal axonal degeneration, and the possibility that irreversible damage may occur, possibly also in the central nervous system, indicate the need for appropriate protection and medical surveillance.³ Neurophysiological methods—electromyography and nerve conduction velocity measurements—are indicated wherever MBK, mixtures of MEK and MBK, or other neurotoxic ketones are used. Liver-function tests and indicators of renal function should be included in the periodic medical examination along with the physical examination and medical history.

▶ ETHERS

Ethers are organic compounds characterized by the presence of a –C–O–C– group. They are volatile liquids, used as solvents and in the chemical industry in the manufacture of a variety of compounds. Some of the halogenated ethers are potent carcinogens (see Halogenated Ethers.) While all ethers have irritant and narcotic properties, dioxane (O–CH₂–CH₂–O–CH₂–CH₂) has marked specific toxicity.

Diethylene Dioxide (Dioxane)

Dioxane is a colorless liquid with a boiling temperature of 101.5°C. It has applications as a solvent similar to those indicated for the ethylene glycol ethers; it is also a good solvent for rubber, cellulose acetate and other cellulose derivatives, and polyvinyl polymers. Dioxane has been used in the preparation of histologic slides as a dehydrating agent.

Absorption is mainly through inhalation but also through the skin. Dioxane is slightly narcotic and moderately irritant. The major toxic effect is kidney injury, with acute renal failure due to tubular necrosis; in some cases, renal cortical necrosis was reported. Centrilobular hepatocellular necrosis is also possible.

1,4-Dioxane was not genotoxic *in vitro*, but was an inducer of micronuclei in the bone marrow of rats and a carcinogen for both rats and mice. Together with the previously reported *in vivo* induction of DNA strand breaks in the rat liver, these data raise the possibility of a genotoxic action for 1,4-dioxane.⁵²⁷ Dioxane has been shown to have genotoxic effects in both the mouse bone marrow and liver, inducing micronuclei formed primarily from chromosomal breakage. Dioxane decreased cell proliferation in both the liver and bone marrow.⁵²⁸ Dioxane has been shown to be carcinogenic (by oral administration) in rats and guinea pigs. Several long-term studies with 1,4-dioxane have shown it to induce liver tumors in mice, and nasal and liver tumors in rats when administered in amounts from 0.5 to 1.8% in drinking water.⁵²⁹ IARC in 1999 classified 1,4-dioxane as possibly carcinogenic to humans (Group 2B),⁵³⁰ and The National Toxicology Program in 2002 concluded that 1,4-dioxane is reasonably anticipated to be a human carcinogen.⁵³¹

Prevention

The federal standard for the PEL is 100 ppm; because of the high toxicity, the ACGIH recommended 50 ppm. Protective equipment, appropriate work practices, and medical surveillance are similar to those indicated for the ethylene glycol ethers.

Carbon Disulfide

Carbon disulfide (CS₂) is a colorless, very volatile liquid (boiling temperature, 46°C). It is used in the production of viscose rayon and cellophane.³ Other important applications include the manufacture of carbon tetrachloride, neoprene cement and rubber accelerators, the fumigation of grain, various extraction processes, as a solvent for sulfur, iodine, bromine, phosphorus, and selenium, in paints, varnishes, paint and varnish removers, and in rocket fuel. Absorption is mainly through inhalation; skin absorption has been demonstrated but is practically negligible.

After inhalation at least 40–50% of carbon disulfide is retained, while 10–30% is exhaled; less than 1% is excreted unchanged in the urine. Oxidative metabolic transformation of carbon disulfide is mediated by microsomal mixed-function oxidase enzymes. The monooxygenated intermediate is carbonyl sulfide (COS); the end product of this metabolic pathway is CO₂, with generation of atomic sulfur.⁵³² Atomic sulfur is able to form covalent bonds.

Carbon disulfide is a very volatile liquid, and high airborne vapor concentrations can easily occur; under such circumstances, specific toxic effects on the central nervous system are prominent and may result in severe acute or subacute encephalopathy. The clinical symptoms include headache, dizziness, fatigue, excitement, depression, memory deficit, indifference, apathy, delusions, hallucinations, suicidal tendencies, delirium, acute mania, and coma. The outcome may be fatal; in less severe cases, incomplete recovery may occur with persistent psychiatric symptoms, indicating irreversible CNS damage. Many such severe cases of carbon disulfide poisoning have occurred in the past, during the second half of the nineteenth century in the rubber industry in France and Germany; as early as 1892, the first cases in the rubber industry were reported from the United States. Acute mania often led to admission to hospitals for the insane. With the rapid development of the viscose rayon industry, cases of carbon disulfide poisoning became more frequent, and Alice Hamilton repeatedly called attention to this health hazard in the rubber and rayon viscose industries.⁵³³ The first exposure standard for carbon disulfide in the United States was adopted in 1941. As late as 1946, cases of carbon disulfide psychosis were reported as still being admitted to state institutions for the mentally ill,² often without any mention of carbon disulfide as the etiological agent. Chronic effects of carbon disulfide exposure were recognized later, when the massive overexposures leading to acute psychotic effects had been largely eliminated.

Peripheral neuropathy of the sensorimotor type, initially involving the lower extremities but often also the upper extremities, with distal to proximal progression, can lead in severe forms to marked sensory loss, muscle atrophy, and diminished or abolished deep tendon reflexes. CNS effects can also often be detected in cases of toxic carbon disulfide peripheral neuropathy; fatigue, headache, irritability, somnolence, memory deficit, and changes in personality are the most frequent symptoms.^{2,534} Persistence of peripheral neurotoxic effects over three years after cessation of exposure and even longer persistence of CNS effects have been reported.⁵³⁵ CS₂ exposure was reported to induce polyneuropathy and cerebellar dysfunction, along with parkinsonian features, in viscose rayon plant workers. Brain MRI studies showed multiple lesions in the cerebral white matter and basal ganglia.⁵³⁶ Optic neuritis has often been reported. Constriction of visual fields has been found in less severe cases. CS₂ exposure enhanced human hearing loss in a noisy environment, mainly affecting hearing in the lower frequencies.⁵³⁷

Electromyographic changes and reduced nerve conduction velocity have been useful in the early detection of carbon disulfide peripheral neuropathy.⁵³⁸ Behavioral performance tests have been successfully applied for the early detection of CNS impairment. Neuropsychiatric effects, detected by psychological questionnaires and psychiatric assessment, have been found in workers with occupational exposure to carbon disulfide.⁵³⁹ In rats exposed to CS₂ inhalation (200 and 800 ppm for 15 weeks), auditory brain stem responses were found to be delayed, suggesting a conduction dysfunction in the brain stem.⁵⁴⁰ In CS₂-exposed rats, VEPs (flash and pattern reversal) were shown to be decreased in amplitude with an increase in latency. Repeated exposures had a more marked effect than acute exposure.⁵⁴¹

Carbon disulfide peripheral neuropathy is characterized by axonal degeneration, with multifocal paranodal and internodal areas of swelling, accumulation of neurofilaments, abnormal mitochondria, and eventually thinning and retraction of myelin sheaths. Such axonal degeneration has been detected also in the central nervous system, mostly in long-fiber tracts. A marked reduction in met-enkephalin immunostaining in the central amygdaloid nuclei and the globus pallidus has been measured, with a parallel elevation in the lateral septal nucleus and the parietal cortex. These findings suggest that the enkephalinergic neuromodulatory system could play a role in CS₂ neurotoxicity.⁵⁴² A six-year observational cohort study of the effect of carbon disulfide on brain MRI abnormalities in rayon-manufacturing workers found an increased risk of hyperintense spots in T2-weighted images, which point to so-called silent cerebral infarctions, among the exposed group compared with nonexposed controls.⁵⁴³

Carbon disulfide neuropathy is of the type described as central peripheral distal axonopathy, very similar to those produced by *n*-hexane and methyl-*n*-butyl ketone. Covalent binding of the highly reactive sulfur to enzymes and proteins essential for the normal function of axonal transport is thought to be the mechanism of axonal degeneration leading to carbon disulfide peripheral neuropathy. CS₂ is a member of the class of neuropathy-inducing xenobiotics known as “neurofilament neurotoxics.” Current hypotheses propose direct reaction of CS₂ with neurofilament lysine epsilon-amine moieties as a step in the mechanism of this neuropathy. A lysine-containing dipeptide and bovine serum albumin, when incubated with ¹⁴CS₂, exhibited stable incorporation of radioactivity. A specific intramolecular cross-link was also detected.⁵⁴⁴ Covalent cross-linking of proteins by CS₂ has been demonstrated *in vitro*. In carbon disulfide inhalation studies in rats, carbon disulfide produced dose-dependent intra- and intermolecular protein cross-linking *in vivo*, with cross-linking in neurofilament proteins prior to the onset of lesions, thought to contribute to the development of the neurofilamentous axonal swellings characteristic of carbon disulfide neurotoxicity. Magnetic resonance microscopy demonstrated that carbonyl sulfide, the primary metabolite of CS₂, targets the auditory pathway in the brain. Decreases in auditory brain stem-evoked responses and decreased cytochrome oxidase activity in the posterior colliculus and parietal cortex were reported.⁵⁴⁵ Carbon disulfide interference with vitamin B₆ metabolism has also been considered as a possible mechanism contributing to its neurotoxicity. Carbon disulfide reacts with pyridoxamine *in vitro*, with formation of a salt of pyridoxamine dithiocarbonic acid.

With the recognition of carbon disulfide peripheral neuropathy, efforts to further reduce the exposure limits were made. As the incidence of carbon disulfide peripheral neuropathy decreased, previously unsuspected cardiovascular effects of long-term carbon disulfide exposure, even at lower levels, became apparent. Initially cerebrovascular changes, with clinical syndromes including pyramidal, extrapyramidal, and pseudobulbar manifestations, were reported with markedly increased incidence and at relatively young ages in workers exposed to carbon disulfide. A significant increase in deaths due to coronary heart disease was documented in workers with long-term carbon disulfide exposure at relatively low levels, and this led to the lowering of the TLV to 10 ppm in Finland in 1972.

A higher prevalence of hypertension and higher cholesterol and lipoprotein levels have also been found in workers exposed to carbon disulfide and most probably contribute to the higher incidence of atherosclerotic cerebral, coronary, and renal disease. A high prevalence of retinal microaneurysms was found in Japanese and Yugoslavian workers exposed to carbon disulfide; retinal microangiopathy was more frequent with longer carbon disulfide exposure. A six-year follow-up study of the Japanese cohort demonstrated persistence of elevated prevalences of hypertension, elevated cholesterol and lipoprotein levels, and retinal microaneurysms among the exposed workers compared with controls.⁵⁴⁶

Adverse effects of carbon disulfide exposure on reproductive function and more specifically on spermatogenesis have been reported in exposed workers, with significantly lower sperm counts and more abnormal spermatozoa than in nonexposed subjects. DNA damage induced by carbon disulfide in mouse sperm was detected by the comet assay.⁵⁴⁷ CS₂ exposure in male rayon workers was associated with dose-related increases in miscarriage rates.⁵⁴⁸ The toxic effect on spermatogenesis was confirmed in experiments on rats, where marked degenerative changes in the seminiferous tubules and degenerative changes in the Leydig cells, with almost complete disappearance of spermatogonia, were found. Effects on follicle development and implantation of blastocysts were identified in an embryotoxicity study in mice.⁵⁴⁹

Carbon disulfide has a high affinity for nucleophilic groups, such as sulfhydryl, amino, and hydroxy. It binds with amino groups of amino acids and proteins and forms thiocarbamates; these tend to undergo cyclic transformation, and the resulting thiazolidines have been shown to chelate zinc and copper (and possibly other trace metals), essential for the normal function of many important enzymes. The high affinity for sulfhydryl groups can also result in interference with enzymatic activities.

Effects of carbon disulfide on catecholamine metabolism have been reported. The concentration of norepinephrine in the brain decreased in rats exposed to carbon disulfide, while dopamine levels increased in both the brain and the adrenal glands. The possibility that carbon disulfide might interfere with the conversion of dopamine to norepinephrine has been considered; the converting enzyme dopamine- β -hydroxylase contains copper, and the copper-chelating effect of carbon disulfide probably results in its inhibition.

Carbon disulfide has been shown to produce a loss of cytochrome P450 and to affect liver microsomal enzymes. This effect is thought to be related to the highly reactive sulfur (resulting from the oxidative desulfuration of carbon disulfide), which binds covalently to microsomal proteins.

Intraperitoneal injection of CS₂ in rats produced several high-molecular weight proteins eluted from erythrocyte membranes which were not present in control animals. The high molecular weight proteins were shown to be alpha, beta heterodimers. The production of multiple heterodimers was consistent with the existence of several preferred sites for cross-linking. Dimer formation showed a cumulative dose response in CS₂-treated rats.⁵⁵⁰ CS₂ has been shown to produce inter- and intramolecular cross-linking of the low molecular weight component of the neurofilament triplet proteins.⁵⁵¹ Long-term exposure to carbon disulfide was reported to cause damage to human buccal cell DNA, detected with the comet assay.⁵⁵²

Approximately 70–90% of absorbed carbon disulfide is metabolized. Several metabolites are excreted in the urine. Among these, thiocarbamide and mercaptothiazolinone have been identified. The

urinary metabolites of carbon disulfide have been found to catalyze the iodine-azide reaction (i.e., the reduction of iodine by sodium azide). The speed of the reaction is accelerated in the presence of carbon disulfide metabolites, and this is indicated by the time necessary for the disappearance of the iodine color. A useful biological monitoring test has been developed⁵⁵³ from these observations; departures from normal are found with exposures exceeding 16 ppm. It has been recommended the workers with an abnormal iodine-azide test reaction at the end of a shift, in whom there is no recovery overnight, should be removed (temporarily) from carbon disulfide exposure.

Prevention

The present federal standard for a permissible level of carbon disulfide exposure is 10 ppm. Prevention of exposure should rely on engineering controls, and mostly on enclosed processes and exhaust ventilation. When unexpected overexposure can occur, appropriate³ respiratory protection must be available and used. Skin contact should be avoided, and protective equipment should be provided; adequate shower facilities and strict personal hygiene practices are necessary. Worker education on health hazards of carbon disulfide exposure and the importance of adequate work practices and personal hygiene must be part of a comprehensive preventive medicine program. Medical surveillance should encompass neurologic (behavioral and neurophysiological), cardiovascular (electrocardiogram and ophthalmoscopic examination), renal function, and reproductive function assessment. The iodine-azide test is useful for biological monitoring; it is an integrative index of daily exposure.

► AROMATIC NITRO- AND AMINO-COMPOUNDS

Aromatic nitro- and amino-compounds make up a large group of substances characterized by the substitution of one or more hydrogen atoms of the benzene ring by the nitro- (–NO₂) or amino-(–NH₂) radicals; some of the compounds have halogens (mainly chlorine and bromine) or alkyl radicals (CH₃, C₂H₅, etc.). Substances of this group have numerous industrial uses in the manufacture of dyes, pharmaceuticals, rubber additives (antioxidants and accelerators), explosives, plastic materials, synthetic resins, insecticides, and fungicides. New industrial uses are continuously found in the chemical synthesis of new products.² The physical properties of the aromatic nitro- and amino-compounds influence the dimension of the hazards they may generate. Some are solid, and some are fluids with low volatility; most are readily absorbed through the skin, and dangerous toxic levels can easily be reached in persons thus exposed.

A common toxic effect of most of these compounds is the production of methemoglobin and thus interference with normal oxygen transport to the tissues. This effect is thought to result not through a direct action of the chemical on hemoglobin but through the effect of intermediate metabolic products, such as paraaminophenol, phenylhydroxyl-1-amine, and nitrosobenzene. The microsomal mixed-function oxydase system is directly involved in these metabolic transformations.

Methemoglobin (Met Hgb) results from the oxidation of bivalent Fe⁺² in hemoglobin to trivalent Fe⁺³. Methemoglobin is a ferrihemoglobin (Hgb Fe⁺³OH) as opposed to hemoglobin, which is a ferrohemoglobin. Methemoglobin cannot serve in oxygen transport, since oxygen is bound (as –OH) in a strong bond and cannot easily be detached. The transformation of hemoglobin into methemoglobin is reversible; reducing agents, such as methylene blue, favor the reversion. In humans, methemoglobin is normally present in low concentrations, not exceeding 0.5 g/100 ml whole blood. An equilibrium exists between hemoglobin and methemoglobin, the latter being continuously reduced by intracellular mechanisms in which a methemoglobin reductase-diaphorase has a central place.

The production of methemoglobin after exposure to and absorption of nitro- and amino-aromatic compounds results in hypoxia, especially when higher concentrations of Met Hgb (in excess of 20–25% of total Hgb) are reached. The most prominent and distinctive

symptom is cyanosis (apparent when Met Hgb exceeds 1.5 g/100 ml); most of the other symptoms and signs are due to the effects of hypoxia on the central nervous and cardiovascular systems. With high levels of methemoglobinemia, coma, arrhythmias, and death may occur. After cessation of exposure, recovery is usually uneventful, taking place in a matter of hours or days, depending on the specific compound. Methemoglobinemia develops more rapidly with aromatic amines, such as aniline, than with nitro-aromatic compounds; with the latter, the reversion of methemoglobin into hemoglobin is slower (several days).

While the methemoglobin-forming effect is of an acute type, several significant chronic toxic effects have resulted from exposure to some of the members of this group. Liver toxicity, with hepatocellular necrosis, can be prominent, especially for polynitro-aromatic derivatives. Aplastic anemia is another severe effect, sometimes associated with the hepatotoxic effect, especially with trinitrotoluene.

The major nitro- and amino-aromatic compounds include:

Aniline	$C_6H_5NH_2$
Nitrobenzene	$C_6H_5NO_2$
Dinitrobenzene	$C_6H_4(NO_2)_2$
Trinitrobenzene	$C_6H_3(NO_2)_3$
Dinitrotoluene	$C_6H_3CH_3(NO_2)_2$
Trinitrotoluene	$C_6H_2CH_3(NO_2)_3$
Nitrophenol	$C_6H_4OHNO_2$
Dinitrophenol	$C_6H_3OH(NO_2)_2$
Tetranitromethylaniline (tetryl)	$C_6H_2(NO_2)_3N(CH_3)NO_2$
Toluenediamine	$C_6H_3CH_3(NH_2)_2$
Xylidine	$C_6H_3(CH_3)_2NH_2$
Phenylenediamine	$C_6H_4(NH_2)_2$
4,4'-Diaminodiphenyl methane (methylene dianiline)	$NH_2(C_6H_4)CH_2(C_6H_4)NH_2$

Diazo-positive metabolites (DPM) have been proposed as biological indicators of aromatic nitro- and amino-compound absorption, including that of trinitrotoluene.

Nitrobenzene

Nitrobenzene is a major chemical intermediate used mainly in the production of aniline. It is easily absorbed through the skin and the respiratory route and is known to have resulted in numerous cases of industrial poisoning. Its toxicity is higher than that of aniline, and liver and kidney damage are not unusual, although most often these are transitory. Anemia of moderate degree and Heinz bodies in the red blood cells may also be found. A major part of the absorbed dose is excreted into the urine: 10–20% of the dose is excreted as 4-nitrophenol, the concentration of which may be used for biological monitoring.

Nitrobenzene was tested by inhalation exposure in one study in mice and in two studies in rats. In mice, the incidences of alveolar-bronchiolar neoplasms and thyroid follicular-cell adenomas were increased in males. In one study in rats, the incidences of hepatocellular neoplasms, thyroid follicular-cell adenomas and adenocarcinomas, and renal tubular-cell adenomas were increased in treated males. In treated females, the incidences of hepatocellular neoplasms and endometrial stromal polyps were increased. In a study using male rats only, the incidence of hepatocellular neoplasms was increased. IARC has concluded that nitrobenzene is possibly carcinogenic to humans (Group 2B).⁵⁵⁴

Dinitrobenzene

Dinitrobenzene, especially the meta-isomer, is more toxic than both aniline and nitrobenzene. Liver injury, sometimes severe, may even result in hepatocellular necrosis. Dinitrobenzene is a cerebellar neurotoxicant in rats,⁵⁵⁵ causing gliovascular lesioning in the rat brainstem, with the nuclei of the auditory pathway being particularly affected.⁵⁵⁶ Dinitrobenzene is a testicular toxin, producing a lesion in the seminiferous tubules of the rat.⁵⁵⁷ Germ cell apoptosis in rat testis was evident after administration of 1,3-dinitrobenzene.⁵⁵⁸

Nitrotoluene

The nitrotoluenes can cause liver toxicity and nephropathy in rats. 2-Nitrotoluene decreased sperm motility in mice. O-Nitrotoluene, administered in the feed for up to 2 years, caused clear evidence for cancer at multiple sites in rats and mice, including mesotheliomas, subcutaneous skin neoplasms, mammary gland fibroadenomas, and liver neoplasms in males, subcutaneous skin neoplasms and mammary gland fibroadenomas in females, and hemangiosarcomas and carcinomas of the cecum in both genders.⁵⁵⁹ The cecal tumors have a morphology and a molecular profile of oncogenes and tumor suppressor genes characteristic of human colon cancer.⁵⁶⁰ O-Nitrotoluene causes hemangiosarcomas in mice, probably via p53 and beta-catenin mutations.⁵⁶¹ 2-Nitrotoluene exposure has been shown to be carcinogenic in rats and was associated with hemoglobin and DNA adduct formation.⁵⁶² IARC in 1995 considered the nitrotoluenes not classifiable as to their carcinogenicity to humans (Group 3).⁵⁶³

Dinitrotoluene

Dinitrotoluenes are used primarily as chemical intermediates in the production of toluene diamines and diisocyanates. Exposure to technical-grade dinitrotoluene can cause cyanosis, due to methaemoglobinemia, anemia, and toxic hepatitis. The dinitrotoluenes are skin sensitizers. Hepatotoxicity in animals has been consistently demonstrated.

2,4-Dinitrotoluene was tested by oral administration in mice; tumors of the renal tubular epithelium were observed in males. In studies in rats, the incidence of various tumors of the integumentary system was increased in males. The incidence of hepatocellular carcinomas was increased in treated males and females in one study. The incidence of fibroadenomas of the mammary gland was increased in females in both studies. 2,6-Dinitrotoluene was tested for carcinogenicity in male rats; an increase in the incidence of hepatocellular neoplastic nodules and carcinomas was found.⁵⁶⁴

A cohort study of workers from a munitions factory in the United States found an increased risk for cancer of the liver and gallbladder among workers exposed to a mixture of 2,4- and 2,6-dinitrotoluenes, based on six cases. Recent studies have demonstrated that dinitrotoluene forms adducts with hemoglobin, the levels of which correlated with symptoms of toxicity among exposed workers, suggesting the possible usefulness of adduct assays as a biomonitoring approach.⁵⁶⁵ IARC in 1996 concluded that 2,4- and 2,6-dinitrotoluenes are possibly carcinogenic to humans (Group 2B).⁵⁶⁶

Trinitrotoluene

Trinitrotoluene (TNT) has produced thousands of cases of industrial poisoning. The first reported cases occurred during World War I, and several hundred fatalities were reported from the ammunition industry in Great Britain and the United States. During World War II, there were another several hundred cases and a smaller number of fatalities in both countries.²

Absorption takes place through the skin and also through the respiratory and gastrointestinal routes. 2-Amino-4,6-dinitrotoluene and its isomers are the most common metabolites of 2,4,6-trinitrotoluene; p53 accumulation has been demonstrated in amino-4,6-dinitrotoluene-treated cells, providing evidence of the potential carcinogenic effects of amino-4,6-dinitrotoluene.⁵⁶⁷

Functional disturbances of the gastrointestinal, central nervous, and cardiovascular systems, and skin irritation or eczematous lesions may precede the development and clinical manifestations of toxic liver injury or aplastic anemia. Abdominal pain, loss of appetite, nausea, and hepatomegaly may be the first indications of toxic hepatitis. According to available records, toxic hepatitis developed in approximately one of 500 workers exposed, but the fatality rate was around 30% and higher in some reported series. High urinary coproporphyrin levels are a feature of TNT-induced toxic hepatitis. Acute liver failure may develop rapidly and may be fatal. Massive subacute hepatocellular necrosis has

been found in fatal cases. A chronic, protracted course with development of cirrhosis was observed in other cases. Postnecrotic cirrhosis, becoming clinically evident as long as 10 years after apparent recovery from TNT-induced acute toxic hepatitis, has also been reported. Acute hemolytic anemia has been reported after TNT exposure of workers with glucose-6-phosphate dehydrogenase deficiency. Early equatorial cataracts were described in workers exposed to TNT.

No adequate studies of the carcinogenicity of trinitrotoluene in humans have been reported. The levels of 4-amino-2,6-dinitrotoluene-hemoglobin adducts were found to be statistically significantly associated with the risk of hepatomegaly, splenomegaly, and cataract formation among trinitrotoluene-exposed workers.⁵⁶⁸ Mutagenicity has been demonstrated in a *Salmonella* microsuspension system.⁵⁶⁹ In workers exposed to 2,4,6-trinitrotoluene, increased bacterial mutagenic activity was found in the urine. IARC in 1996 has deemed 2,4,6-trinitrotoluene as not classifiable as to its carcinogenicity to humans (Group 3), due to inadequate evidence in humans and animals.⁵⁷⁰

The effects of TNT on the male reproductive system in Fischer 344 rats included germ cell degeneration, the disappearance of spermatozoa in seminiferous tubules, and a dramatic decrease in the sperm number in both the testis and epididymis. TNT increased the formation of 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-oxodG) in sperm, reflecting oxidative damage, whereas plasma testosterone levels did not decrease.⁵⁷¹

Urinary metabolites of trinitrotoluene are 4-aminodinitrotoluene and 2-aminodinitrotoluene; they can be used for biological monitoring of exposed workers. Complete blood counts, bilirubin, prothrombin, liver enzyme (SGOT, SGPT, etc.) levels, and urinary coproporphyrins have been recommended in the medical surveillance of exposed workers.

Toluylenediamine

Toluylenediamine can produce severe toxic liver damage, with massive hepatic necrosis.

Xylidine

Xylidine has been shown to produce severe toxic hepatitis; post-necrotic cirrhosis has developed in experimental animals.

4,4'-Diaminodiphenylmethane

More than 200 million pounds of 4,4'-diaminodiphenylmethane (methylene dianiline, MDA) are manufactured each year in the United States. It is widely used in the production of isocyanates and polyisocyanates which are the basis for polyurethane foams. Other uses are as an epoxy hardener, as a curing agent for neoprene in the rubber industry, and as a raw material in the production of nylon and polyamideimide resins.

4,4'-Diaminodiphenylmethane was the cause of an epidemic outbreak (84 cases) of toxic hepatitis with jaundice in Epping, England, in 1965 (an episode since known as "Epping jaundice"). The accidental spillage of the chemical from a plastic container and contamination of flour used for bread was the cause of this epidemic. Both the contaminated bread and the pure aromatic amine produced similar lesions in mice.

In 1974, the first industrial outbreak of 13 cases of toxic hepatitis caused by 4,4'-diaminodiphenylmethane was reported. The aromatic amine had been used as an epoxy resin hardener for the manufacture of insulating material. The pattern of illness was similar to that described for the Epping epidemic, with abrupt onset, epigastric or right upper quadrant pain, fever, and jaundice. The duration of the illness ranged from one to seven weeks. Skin absorption had been important in some of the cases.

Another small outbreak of methylene dianiline poisoning occurred when six of approximately 300 men who applied epoxy resins as a surface coat for concrete walls at the construction site of a nuclear power electricity-generating plant contracted toxic hepatitis two days to two weeks after starting work. The clinical picture was similar to the cases previously described. Methylene dianiline has been shown to produce hepatocellular necrosis in all animals tested, although there are species differences. Cirrhosis has developed in rats

and dogs in several experimental series. Nephrotoxicity has also been demonstrated in animal experiments. 4,4'-Diaminodiphenylmethane causes contact allergy. MDA can initiate vascular smooth muscle cell proliferation and vascular medial hyperplasia in rats.⁵⁷²

Limited data suggest that workers in the textile, dye, and rubber industries experience a higher incidence of gallbladder and biliary tract cancer than control groups.³ In view of the very large number of chemicals used, however, a direct association with MDA has not been established. Long-term observations on workers exposed only to chemicals of this group are almost nonexistent, and therefore no firm conclusions can be drawn about its carcinogenicity in humans.

In a chronic feeding experiment on rats and mice, MDA was found to produce thyroid carcinoma, hepatocellular carcinoma, lymphomas, and pheochromocytomas. MDA is specifically activated to DNA-damaging reactive species by hepatocytes and thyroid cells in both rats and humans.⁵⁷³ The NIOSH recommended that MDA be considered a potential human carcinogen and that exposures be controlled to the lowest feasible limit. The IARC concluded that there is sufficient evidence for carcinogenic effect of 4,4'-methylenedianiline in experimental animals to consider it a carcinogenic risk to humans, and The National Toxicology Program in 2002 considered MDA reasonably anticipated to be a human carcinogen.⁵⁷⁴

Dinitrochlorobenzenes

Dinitrochlorobenzenes (DCNBs) are potent skin sensitizers,² via induction of type 1 cytokines interferon-gamma and IL-12,⁵⁷⁵ and are known testicular toxins in animals. Respiratory sensitization is not thought to occur. The toxicity of orally administered dinitrochlorobenzene in mice and rats included lesions affecting the liver, kidney, testis, and hematopoietic system. The liver was the most responsive to DCNB, as evidenced by a dose-related increase in relative liver weight in rats and mice and centrilobular hypertrophy of hepatocytes in mice. The kidney lesion was characterized by hyaline droplets in the renal tubular epithelial cells only in male rats. Testicular and hematopoietic lesions appeared at higher doses.⁵⁷⁶ Dinitrochlorobenzene caused a significant increase in sister chromatid exchange in cultured human skin fibroblasts.⁵⁷⁷ Mutagenicity has been demonstrated in *Salmonella* test systems.⁵⁷⁸

Paraphenylenediamine and Para-aminophenol

Paraphenylenediamine and paraaminophenol are dye intermediates and are used mostly in the fur industry. They are potent skin and respiratory sensitizers. Severe occupational asthma is not unusual in exposed workers.² Paraphenylenediamine was shown to induce sister chromatid exchanges in ovary cells of Chinese hamsters. Paraaminophenol was mutagenic in *E. coli* test systems.⁵⁷⁹ Paraaminophenol causes nephrotoxicity but not hepatotoxicity in the rat. Renal epithelial cells of the rat were shown to be intrinsically more susceptible to paraaminophenol cytotoxicity than are hepatocytes.⁵⁸⁰

4,4'-Methylene-Bis-Ortho-Chloroaniline

4,4'-Methylene-bis-ortho-chloroaniline (MOCA) is used mainly in the production of solid elastomeric parts, as a curing agent for epoxy resins, and in the manufacture of polyurethane foam. Absorption through inhalation and skin contact is possible. In rats, liver and lung cancer have followed the feeding of MOCA. Occupational exposure to MOCA was associated with an increased risk of bladder cancer. MOCA forms adducts with DNA, both in vitro and in vivo. Micronuclei frequencies were higher in the urothelial cells and lymphocytes of MOCA-exposed workers than in controls.⁵⁸¹ An increased frequency of sister chromatid exchange was seen in a small number of workers exposed to MOCA. MOCA is comprehensively genotoxic. DNA adducts are formed by reaction with *N*-hydroxy-MOCA, and MOCA is genotoxic in bacteria and mammalian cells; the same major MOCA-DNA adduct is formed in the target tissues for carcinogenicity in animals (rat liver and lung; dog urinary bladder) as that found in urothelial cells from a man with

known occupational exposure to MOCA. IARC has classified MOCA as probably carcinogenic to humans (Group 2A).⁵⁸² The National Toxicology Program in 2002 listed MOCA as an agent reasonably anticipated to be a human carcinogen. MOCA is included in the federal standard for carcinogens; all contact must be avoided.

Tetranitromethylaniline (Tetryl)

Tetryl is a yellow solid used in explosives and as a chemical indicator.² It can be absorbed through inhalation and skin absorption. It is a potent irritant and sensitizer; allergic dermatitis can be extensive and severe. Anemia with hypoplastic bone marrow has occurred. In animal experiments, hepatotoxic and nephrotoxic effects have been detected.

Prevention and Control

Adequate protective clothing and strict personal hygiene with careful cleaning of the entire body, including hair and scalp, are essential to minimize skin absorption, which is particularly hazardous with this group of substances. Clean work clothes should be supplied at the beginning of every shift. Soiled protective equipment must be immediately discarded. Adequate shower facilities and a mandatory shower at the end of the shift, as well as immediately after accidental spillage, are necessary. Respirators must be available for unexpected accidental overexposure.

Medical surveillance should comprise dermatological examination and hematological, liver, and kidney function evaluation. Workers must be informed of the health hazards and educated and trained to use appropriate work practices and firstaid procedures for emergency situations.

▶ ALIPHATIC AMINES

Aliphatic and alicyclic amines are derivatives of ammonia (NH₃) in which one atom (primary amine) or more hydrogen atoms (secondary or tertiary amines) are substituted by alkyl, alicyclic, or alkanol radicals (ethanolamines). They have a characteristic fishlike odor; most are gases or volatile liquids. They are widely used in industry; one of the most important applications is as “hardeners” (cross-linking agents) and catalysts for epoxy resins. Other uses are in the manufacture of pharmaceutical products, dyes, rubber, pesticides, fungicides, herbicides, emulsifying agents, and corrosion inhibitors.

The amines form strongly alkaline solutions that can be very irritating to the skin and mucosae. Chemical burns of the skin can occur. Skin sensitization and allergic dermatitis have been reported.² Some of the amines can produce bronchospasm, and cases of amine asthma have been documented.² Corneal lesions may result from accidental contact with liquid amines or solutions of amines.

Prevention

Appropriate engineering controls, protective clothing, and eye protection (goggles), air-supplied respirators when concentrations exceeding the federal standard for exposure limits (from 3 to 10 ppm for various amines) are expected, and training programs for employees are necessary to prevent adverse effects due to exposure to these compounds.

▶ ORGANIC NITROSO-COMPOUNDS

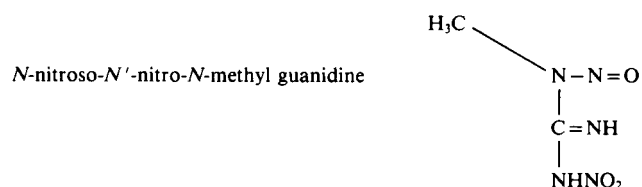

The organic nitroso-compounds comprise nitrosamines and nitrosamides, in which the nitroso-groups (–N = O) are attached to nitrogen atoms

and C-nitroso-compounds in which the nitroso-groups are attached to carbon atoms. Nitrosamines are readily formed by the reaction of secondary amines with nitrous acid (nitrite in an acid medium).

A large number of *N*-nitroso-compounds are known; several examples of dialkyl, heterocyclic, and aryl alkyl nitrosamines with marked toxic activity are shown below, together with two *N*-nitrosamides, *N*-nitrosomethyl urea, and *N*-nitro-*N'*-nitro-*N*-methyl guanidine. The nitrosamines are more unstable in an alkaline medium, yielding the corresponding dialkanes; they are extensively used in synthetic organic chemistry for alkylating reactions.

Toxicological interest in the *N*-nitroso-compounds was first aroused in 1954, when Barnes and Magee⁵⁸³ reported on the hepatotoxicity of dimethylnitrosamine. This compound had recently been introduced into a laboratory as a solvent, and two cases of clinically overt liver damage were etiologically linked to it. A search of the literature at that time revealed only a single short report of the toxic properties of dimethylnitrosamine (DMN). Hamilton and Hardy had reported in 1949 that the use of DMN in an automobile factory had been followed by illness in some of the exposed workers. Experiments on dogs showed DMN to be capable of producing severe liver injury.

As a solvent, DMN is highly toxic and dangerous to handle, although its volatility is relatively low. The absence of a specific odor or irritant properties may favor the absorption of toxic amounts without any warning; contamination of skin and clothes may pass unnoticed.

Information on the industrial uses of nitrosamines is incomplete. A relatively large patent literature indicates many potential applications. The manufacture of rubber, dyes, lubricating oils, explosives, insecticides and fungicides, the electrical industry, and the industrial applications of hydrazine chemistry appear to be the main uses for nitrosamines.

The use of DMN as an intermediate in the manufacture of 1,1-dimethylhydrazine is well known. *N*-nitrosodiphenylamine is used in the rubber industry as a vulcanizing retarder, and dinitrosopentamethylene-tetramine is used as a blowing agent in the production of microcellular rubber.

DMN produced severe liver injury in rats, rabbits, mice, guinea pigs, and dogs. Centrilobular and midzonal necrosis, depletion of glycogen and fat deposition, and dilation of sinusoidal spaces were the prominent changes in the acute stage. Hemorrhagic peritoneal exudate and bleeding into the lumen of the gut were striking features; such changes are not encountered in liver injury caused by carbon tetrachloride, phosphorus, or beryllium. Repeated doses were found to result in fibrosis of the liver. Increases in fibrosis-related gene transcripts, including alpha-SMA, transforming growth factor-beta 1, connective tissue growth factor, tissue inhibitor of metalloproteinase-1, and procollagen I and III, have been identified in the livers of dimethylnitrosamine-intoxicated rats.⁵⁸⁴ DMN was shown to induce, besides typical centrilobular necrosis, veno-occlusive lesions in the liver in animals followed for longer periods after a high, nearly lethal dose. Prolonged oral administration of relatively low doses of dimethylnitrosamine resulted in gross, nodular cirrhosis of the liver; with lower doses, longer survival of the animals was achieved, and several malignant liver-cell-type tumors occurred. Tumor necrosis factor alpha and its receptor were shown to play a role in DMA-related hepatotoxicity in the mouse.⁵⁸⁵

The hepatocarcinogenicity of DMN was reported in 1956.⁵⁸⁶ The metabolic degradation of DMN in the liver proceeds through enzymatic oxidative demethylation, yielding a carcinogenic metabolite. In 1962 Magee and Farber,⁵⁸⁷ by administering ¹⁴C DMN to rats, were able to demonstrate the methylation of nucleic acids in the liver, especially at the N7 site of guanidine. Thus an alteration of the genetic information in the hepatocyte was detected and was considered the basis for the carcinogenic effect. This was the first experimental proof of such a molecular alteration of DNA by a carcinogen.

The discovery of the role of drug-metabolizing microsomal enzymes in the biotransformation of DMN into a carcinogen opened an important field of investigation. Similar pathways were found to be effective for another compound of this group, diethylnitrosamine.⁵⁸⁹ The activation of DMN via microsomal metabolism occurs in the hepatocytes, although liver tumors arise from non-parenchymal cells, suggesting intercellular transport of the carcinogenic metabolites.⁵⁸⁸

The acute hepatotoxic effect of *N*-nitroso compounds is also caused by the alkylating intermediate metabolites. The acute toxicity is due to alkylation of proteins and enzymes, while the carcinogenic effect is related to the alkylation of nucleic acids. Several fundamentally important observations were also made by Druckrey and coworkers:⁵⁸⁹

1. A carcinogenic effect of a single dose of some of these compounds was demonstrated (tumors developed after various latency periods), and the kidney, liver, esophagus, stomach, and CNS were the main organs in which the primary tumors were detected.
2. The site of the primary malignant tumor was found to be, for certain compounds, in a clear relationship with the administered dose.
3. DMN was shown to be a more potent carcinogen than diethylnitrosamine.
4. The transplacental carcinogenicity of DMN was demonstrated; hepatocarcinogenicity was detected in offspring of treated pregnant rats.

5. Di-*n*-butyl-nitrosamine induced hepatocellular carcinoma and cirrhosis of the liver when administered orally in relatively high amounts. With the gradual decrease of the dose, fewer hepatocellular carcinomas and more cancers of the esophagus and the urinary bladder were found. Diamylnitrosamine resulted in hepatocellular carcinoma when given in high doses. Subcutaneous injections resulted in squamous cell and alveolar cell carcinoma of the lung, in addition to relatively few hepatocellular carcinomas. This finding was thought to be important since it indicated that lung cancer can develop not only after inhalation of carcinogens but also as a result of absorption of carcinogens through other routes.

Cyclic *N*-nitroso compounds (*N*-nitroso-pyrrolidine, -morpholine, -carbethoxy-piperazine) were also found to produce hepatocellular carcinomas. Heterocyclic nitrosamines (*N*-nitrosoazetidine, *N*-nitrosohexamethyleneimine, *N*-nitrosomorpholine, *N*-nitroso-pyrrolidine, and *N*-nitrosopiperidine) result in characteristic hepatic centrilobular necrosis; they have also been shown to produce a high incidence of tumors of the liver and other organs. The earliest change in the liver is the development of foci of altered hepatocytes, demonstrated histochemically by changes in the activities of glucose-6-phosphate dehydrogenase and glycogen phosphorylase, and in the glycogen content. Proliferating cells have been detected by immunohistochemical reaction for proliferating cell nuclear antigen. The number and size of foci of altered hepatocytes increased in a time- and dose-related manner.⁵⁹⁰

Pancreatic cancer developed in Syrian hamsters after subcutaneous administration of three nitrosamines, including *N*-nitro-2,6-dimethylmorpholine. *Ras*-oncogene activation was investigated in bladder tumors of male rats given *N*-butyl-*N*-(4-hydroxybutyl) nitrosamine. Enhanced expression of p21 was detected in all tumors. The tobacco-specific nitrosamine 4-(methylnitrosamine)-1-(3-pyridyl)-1-butanone (NNK) is a potent carcinogen in laboratory animals. Analysis of DNA for *K-ras* mutation showed G (A transition of codon 12 of the *K-ras* oncogene in tumor cells derived from pancreatic duct cells treated with NNK.⁵⁹¹

In human esophageal cancers, no *ras* gene mutations but a relatively high prevalence of p53 gene mutations have been reported. A high prevalence of point mutations in *Ha-ras* and p53 genes was found in *N*-nitrosomethylbenzylamine (NMBA)-induced esophageal tumors in rats. The prevalent mutations were G → A.⁵⁹² The carcinogenic properties of *N*-nitroso compounds are associated with their ability to alkylate DNA, in particular to form O6-alkylguanine and O4-alkylthymine.⁵⁹³ The carcinogenicity of NMBA has been shown to be reduced by dietary factors (e.g., strawberries, blackberries, grape seed extract) that decrease the formation of DNA-damaging intermediates.⁵⁹⁴

The dialkylnitrosamines, stable compounds, are decomposed only by enzymatic action and result in cell damage after having undergone an enzymatic activation process in organs that have adequate enzymatic systems. The toxic, mutagenic, teratogenic, and carcinogenic effects of nitroso-compounds all depend on this biologic activation by enzymatic reactions. Inhibition of hepatic microsomal enzymatic systems by a protein-deficient diet has been shown to result in a decrease in dimethylnitrosamine toxicity, confirming that the hepatotoxic effect is dependent on microsomal enzymatic activation.

The predominant effect of the dialkylnitrosamines is liver injury, the characteristic lesion being a hemorrhagic type of centrilobular necrosis. This specificity of action is related to the fact that these compounds require metabolic transformation-activation for their toxic effect. The enzymatic systems effective for these metabolic transformations are present in highest amounts in the microsomal fraction of the liver, but also in the kidney, lung, and esophagus. Species differences have been documented; these metabolic differences parallel differences in the main site of effects— toxic, carcinogenic, or both.

In contrast to the relative chemical stability of nitrosamines, the nitrosamides show varying degrees of instability. Many of these compounds yield diazoalkanes when treated with alkali, and they are extensively used in the synthetic chemical industry.

The nitrosamides differ in their effects from the nitrosamines; they have a local irritation effect at the site of administration; some have marked local cytopathic action, sometimes resulting in severe tissue necrosis. *N*-methyl-*N*-nitrosomethane causes severe necrotic lesions of the gastric mucosa and also periportal liver necrosis. In addition to their local action, some of the nitrosamides have a radiomimetic effect on organs with rapid cell turnover, with the bone marrow, lymphoid tissue, and small intestine being injured most. Several substances of the nitrosamide group are known to induce cancer at the site of chronic application.

Morpholine is widely used in industry as a solvent for waxes, dyes, pigments, and casein; it has also found applications in the rubber industry.

As an anticorrosive agent and as an emulsifier (after reaction with fatty acids), morpholine is used in the manufacture of cleaning products. Long considered a relatively nontoxic substance, morpholine was also used in the food industry, in the coating of fresh fruit and vegetables (fatty acid salts of morpholine), and for anticorrosive treatment of metals (including those to be used in the food industry). Industrial occupational exposure and household exposure are therefore quite frequent. Absorption of morpholine through the oral route may, in the presence of nitrites from alimentary sources, result in the production of hazardous gastric levels of nitrosamine. In the rubber industry, efforts have been made to replace amino-compounds that can generate *N*-nitrosamines in accelerators with “safe” amino components. Derivatives of the dithiocarbamate and sulfenamide class were synthesized and found to be suitable for industrial application.

The organic *N*-nitroso-compounds are characterized by marked acute liver toxicity; chronic absorption of smaller amounts has been shown to result in cirrhosis in experimental animals. Initial reports of human cases of postnecrotic cirrhosis, however, have not been followed by other reports on human effects. Suitable epidemiological data are not yet available on the real incidence of toxic liver damage, cirrhosis of the liver, hepatocellular carcinoma, and other malignant tumors in industrially exposed populations. Altered p53 expression has been demonstrated in the early stages of *N*-nitrosomorpholine-induced rodent hepatocarcinogenesis.⁵⁹⁵ Ethanol has been shown to enhance the hepatocarcinogenesis of *N*-nitrosomorpholine, related to increased ornithine decarboxylase activity and cell proliferation in enzyme-altered lesions.⁵⁹⁶

The presence of nitrosamines in cutting oils has been reported.¹ The formation of nitrosamines had been suspected, since nitrites and aliphatic amines are known constituents of some cutting fluids. Concentrations of nitrosamines up to 3% have been found in randomly selected cutting oils; metal machining operators using cutting oils may, therefore, be significantly exposed to nitrosamines. Semisynthetic cutting oils and the synthetic cutting fluids most often contain amines as a soluble base and nitrites as additives. NIOSH estimated that almost 800,000 persons are occupationally exposed in the manufacture and use of cutting fluids, and issued guidelines for industrial hygiene practices in an effort to minimize skin and respiratory exposure.

Environmental Nitrosamines

The possibility that exposure to compounds of the nitrosamine group may occur in situations other than the industrial environment was revealed by an outbreak of severe liver disease in sheep in Norway in 1960. Severe necrosis of the liver was the main pathologic feature.

The sheep had been fed fish meal preserved with nitrite. This suggested that nitrosamines may have resulted from the reaction between secondary and tertiary amines present in the fish meal and the nitrites added as a preservative. The presence of dimethylnitrosamine at levels of 30–100 ppm was detected. Subsequently, the presence of nitrosamines in small amounts in food for human consumption has been documented. Smoked fish, smoked sausage, ham and bacon, mushrooms, some fruits, and alcoholic beverages (from areas in Africa with a high incidence of esophageal cancer) have been shown to contain various amounts of nitrosamines (0.5–40 µg/kg).

Nitrosamines can be formed in the human stomach from secondary amines and nitrites. The methylation of nucleic acids of the stomach, liver, and small intestine in rats given ¹⁴C methyl urea and sodium nitrite simultaneously was also demonstrated, and malignant liver and esophageal tumors in rats have resulted from simultaneous feeding of morpholine or *N*-methylbenzylamine and sodium nitrite. Several bacterial species—*E. coli*, *E. dispar*, *Proteus vulgaris*, and *Serratia marcescens*—can form nitrosamines from secondary amines. The bacterial reduction of nitrate to nitrite in the human stomach has been shown.

Tobacco-specific nitrosamines have been identified and have received considerable attention. Nicotine and the minor tobacco alkaloids give rise to tobacco-specific *N*-nitrosamines (TSNAs) during tobacco processing and during smoking (≤ 25 µg/g) and in mainstream smoke of cigarettes (1.3 TSNA/cigarette). In mice, rats, and hamsters, three TSNAs, *N*'-nitrosornicotine (NNN), 4-(methyl-nitrosamino)-1-(3 pyridyl)-1-butanone (NNK), and 4-(methyl-nitrosamino)-1-(3 pyridyl)-1-butanol (NNAL), are powerful carcinogens; two TSNAs are moderately active carcinogens and two TSNAs appear not to be carcinogenic. The TSNAs are procarcinogens that require metabolic activation. The active forms react with cellular components, including DNA, and with hemoglobin. The Hb adducts serve as biomarkers in smokers or tobacco chewers, and the urinary excretion of NNAL is an indicator of TSNA uptake. The TSNAs contribute to the increased risk of upper digestive tract cancer in tobacco chewers and lung cancer in smokers. In laboratory animals, DNA adduct formation and carcinogenicity of tobacco-specific *N*-nitrosamines are closely correlated.⁵⁹⁷ The high incidence of cancer of the upper digestive tract in the Indian subcontinent has been causally associated with chewing of betel quid mixed with tobacco. Betel quid is the source of four *N*-nitrosamines from the Areca alkaloids; two of these are carcinogenic.⁵⁹⁸ Human cytochrome P450 2A subfamily members play important roles in the mutagenic activation of essentially all betel quid-related *N*-nitrosamines tested.⁵⁹⁹

TSNAs NNN and NNK are metabolites of nicotine and are the major carcinogens in cigarette smoke. In fetal human lung cells exposed to NNN and NNK, a dose-dependent increase in DNA single-strand breaks was observed. In combination with enzymatically-generated oxygen radicals, strand breakage increased by approximately 50% for both NNN and NNK.⁶⁰⁰ Tobacco-specific nitrosamine NNK produces DNA single-strand breaks (SSB) in hamster and rat liver. DNA SSB reached a maximum at 12 hours after treatment and persisted 2–3 weeks, reflecting deficient repair of some DNA lesions.⁶⁰¹ Chromosomal abnormalities were significantly more frequent in the peripheral blood lymphocytes of women following in vitro exposure to NNK compared with those of men, suggesting a greater risk of tobacco-related malignancy for women.⁶⁰² NNK injected subcutaneously or instilled intratracheally into pregnant hamsters resulted in high incidence of respiratory tract tumors in offspring; target organs included the adrenal glands and the pancreas. The results suggested that NNK, at doses comparable to the cumulative exposure during a 9-month period in women, is a potent transplacental carcinogen in hamsters.⁶⁰³

Evidence of nitrosamine-induced DNA damage was found in the increased levels of 8-oxodeoxyguanosine and 8-hydroxydeoxyguanosine (8-OH-dG) in tissue DNA of mice and rats treated with the tobacco-specific nitrosamine NNK. These lesions were detected in lung DNA and liver DNA, but not in rat kidney (a nontarget tissue). These findings support the role of oxidative DNA damage in NNK lung tumorigenesis.⁶⁰⁴ NNK produced pulmonary tumors in adult mice treated with

a single dose (100 mg/kg i.p.). Progression of pulmonary lesions was noted from hyperplasia through adenomas to carcinomas (to 54 weeks). DNA was isolated from 20 hyperplasias and activation of the K-ras gene was found in 17 lesions, 85% of the mutations involving a GC → AT transition within codon 12, a mutation consistent with base mispairing produced by the formation of the O6-methylguanine adduct.⁶⁰⁵ NNK stimulated cell proliferation in normal human bronchial epithelial cells and small airway epithelial cells in culture, through activation of the nuclear factor κB, which in turn up-regulated cyclin D1 expression.⁶⁰⁶ 4-(Methylnitrosamino)-1-(3 pyridyl)-1-butanone (NNK) is a potent carcinogen in adult rodents and variably effective transplacentally, depending on species. NNK was tested in infant mice; at 13–15 months, 57% of NNK-exposed male offspring had hepatocellular tumors; a lower occurrence (14%) was found in female offspring. In addition, primary lung tumors were also found in 57% of males and 37% of females. These results call attention to the possibility that human infants may be especially vulnerable for tumor initiation by tobacco smoke constituents.⁶⁰⁷

The number of lung tumors and fore-stomach tumors in mice given 6.8 ppm *N*-nitrosodiethylamine was considerably increased when ethanol 10% was also added. Ethanol increased lung tumor multiplicity 5.5-fold when *N*-nitrosopyrrolidine was given. It is thought that coadministered ethanol increases the tumorigenicity of nitrosamines by blocking hepatic first-pass clearance.⁶⁰⁸

Numerous epidemiological studies have established that asbestos causes occupational lung cancer and mesothelioma; a cocarcinogenic effect of cigarette smoking on the incidence of lung cancer in asbestos workers has been well documented. In an experimental study on rats, chrysotile asbestos was administered intratracheally, *N*-bis(hydroxypropyl)nitrosamine (DHPN) was injected intraperitoneally, and the animals were exposed to smoke from 10 cigarettes/day for their entire life span. Lung tumors were detected in one of 31 rats receiving only asbestos; they occurred in 22% of rats receiving DPNH alone and in 60% of the rats receiving DPNH and asbestos. Thus the cocarcinogenic effect of tobacco-specific nitrosamines was clearly demonstrated in an animal model.⁶⁰⁹

The Areca-derived 3-(methylnitrosamino)propionitrile (MNPN) when tested on mouse skin produced multiple distant tumors in the lungs. When applied by swabbing the oral cavity, strong organ-specific carcinogenicity resulted in nasal tumors, lung adenomas, liver tumors, and papillomas of the esophagus, with relatively few oral tumors.⁶¹⁰

Certain environmentally relevant nitrosamines specifically induce malignant tumors in the urinary bladder in several animal species. Butyl-3-carboxypropylnitrosamine, methyl-3-carboxypropylnitrosamine, and methyl-5-carboxypropylnitrosamine were found to be beta-oxidized by mitochondrial fractions to butyl-2-oxopropylnitrosamine, or methyl-2-oxopropylnitrosamine. By this reaction, water-soluble carboxylated nitrosamines of low genotoxic potential are converted into rather lipophilic 2-oxopropyl metabolites, with high genotoxic and carcinogenic potency.⁶¹¹

In northeast Thailand the consumption of raw freshwater and salt-fermented fish results in repeated exposure to liver fluke (*Opisthorchis viverrini*) infection and ingestion of nitrosamine-contaminated food. A high prevalence of cholangiocarcinoma is known to exist in this region. The Syrian golden hamster receiving subcarcinogenic doses of dimethylnitrosamine (DMN) and infection with flukes developed cholangiocarcinomas. Nitrosamines are considered to be genotoxicants, while liver flukes are assumed to play an epigenetic role.⁶¹² Samples of food frequently consumed in Kashmir, a high-risk area for esophageal cancer, revealed high levels of *N*-nitrosodimethylamine, *N*-nitrosopiperidine, and *N*-nitrosopyrrolidine in smoked fish, sun-dried spinach, dried mixed vegetables, and dried pumpkin.⁶¹³

A reduction of the high exposures to *N*-nitrosamines in the rubber and tire industry is possible by using vulcanization accelerators that contain amine moieties that are both difficult to nitrosate, and, on nitrosation, yield noncarcinogenic *N*-nitroso compounds. The toxicological and technological properties of some 50 benzothiazole sulfenamides derived from such amines have been evaluated.⁶¹⁴

Laboratory research conducted over the last 30 years has identified the organic nitroso-compounds as some of the most potent carcinogens, mutagens, and teratogens for a variety of animal species. The possibility of nitrosamine formation from nitrites (or nitrates) and secondary or tertiary amines in the stomach and the possibility of a similar effect attributable to microorganisms normally present in the gut and frequently in the urinary tract suggest a potential hazard for the population at large.

The identification of tobacco-specific nitrosamines and of nitrosamines in betel and in food stuffs in areas with high cancer incidence emphasizes the growing importance of this group of chemical carcinogens.

► EPOXY COMPOUNDS

Epoxy compounds are cyclic ethers characterized by the presence of an epoxide ring.

These ethers, with an oxygen attached to two adjacent carbons, readily react with amino, hydroxyl, and carboxyl groups and also with inorganic acids to form relatively stable compounds. The epoxide group is very reactive and can form covalent bonds with biologically important molecules. Industrial applications have expanded rapidly in the manufacture of epoxy resins, plasticizers, surface-active agents, solvents, etc.

Most epoxy resins are prepared by reacting epichlorhydrin with a polyhydroxy compound, most frequently bisphenol A, in the presence of a curing agent (cross-linking agents—"hardeners," mainly polyamines or anhydrides of polybasic acids, such as phthalic anhydride). Catalysts include polyamides and tertiary amines; diluents such as glycidyl ethers, styrene, styrene oxide, or other epoxides are sometimes used to achieve lower viscosity of uncured epoxy resin systems.

Epoxy compounds can adversely affect the skin, the mucosae, the airways, and the lungs; some have hepatotoxic and neurotoxic effects. Most epoxy compounds are very potent irritants (eyes, airways, skin), and they can produce pulmonary edema. Skin lesions can be due to the irritant effect or to sensitization. Respiratory sensitization can also occur. Carcinogenic effects in experimental models have been demonstrated for several epoxy compounds.

Epichlorhydrin

Epichlorhydrin (1-chloro-2,3-epoxypropane, CH₂OCH-CH₂Cl) is a colorless liquid with a boiling point of 116.4°C. The most important uses are for the manufacture of epoxy resins, surface-active agents, insecticides and other agricultural chemicals, coatings, adhesives, plasticizers, glycidyl ethers, cellulose esters and ethers, paints, varnishes, and lacquers.^{2,3}

Absorption through inhalation and skin is of practical importance. Epichlorhydrin is a strong irritant of the eyes, respiratory tract, and skin. Obstructive airway disease was found related to epichlorhydrin exposure in workers; GST polymorphism influenced the risk of airway obstruction.⁶¹⁵ Skin contact may result in dermatitis, occasionally with marked erythema and blistering. Skin sensitization with allergic dermatitis has also been reported. Severe systemic effects have been reported in a few cases of human overexposure: these included nausea, vomiting, dyspnea, abdominal pain, hepatomegaly, jaundice, and abnormal liver function tests.

In experimental studies, nephrotoxic effects have been found; an adverse effect on liver mixed-function microsomal enzymes has also been reported. In experiments on rats, epichlorhydrin was found to

significantly decrease the content in cytochrome P450 of microsomes isolated from the liver, kidney, testes, lung, and small intestine mucosa.

An excess of lung cancer was observed among a small number of workers employed in the production of epichlorohydrin. A nested case-control study within this population found a weak association between epichlorohydrin and lung cancer. Another nested case-control study based on the same cohort found a weak association with central nervous system tumors. A small excess of lung cancer was observed in another cohort, but in a third no excess of cancer was observed. In a case-control study of lung cancer nested within another cohort of chemical workers, a significantly decreased risk of lung cancer was associated with epichlorohydrin exposure. All results were based on relatively small numbers.

Epichlorohydrin by mouth caused papillomas and carcinomas of the forestomach, and by inhalation, induced papillomas and carcinomas of the nasal cavity in rats. It produced local sarcomas in mice after subcutaneous injection and was active in a mouse-lung tumor bioassay by intraperitoneal injection.⁶¹⁶

Epichlorohydrin is considered a bifunctional alkylating agent; it reacts with nucleophilic molecules by forming covalent bonds; crosslinking bonds may also be formed. These chemical characteristics are believed to be of importance for their carcinogenic, mutagenic, and reproductive effects. Epichlorohydrin forms adducts with DNA.⁶¹⁷ Chromosomal aberrations have been found in exposed workers. Workers with high epichlorohydrin exposure also had significantly higher sister chromatid exchange frequencies than those with low or no exposure.⁶¹⁸ Epichlorohydrin exposure *in vitro* had significant effects on sister chromatid exchange frequencies in the lymphocyte cultures of human subjects.⁶¹⁹

Several experimental studies suggest that interference with male reproductive function can result from epichlorohydrin exposure. In rats, epichlorohydrin was found to produce progressive testicular atrophy, reduction of sperm concentration, and an increase in the number of morphologically abnormal spermatozoa. Testicular function was studied in epichlorohydrin-exposed workers; no effects were demonstrated. Epichlorohydrin did not produce teratogenic effects in rats, rabbits, or mice.

Prevention

The recommended standard³ for exposure to epichlorohydrin is 2 mg/m³ (0.5 ppm), with a ceiling of 19 mg/m³ (5 ppm) not to exceed 15 minutes. IARC concluded in 1999 that epichlorohydrin is probably carcinogenic to humans (Group 2A).

Ethylene Oxide

Ethylene oxide (1,2-epoxyethane, H₂COCH₂), is a colorless gas used in the organic synthesis of ethylene glycol and glycol derivatives, ethanalamines, acrylonitrile, polyester fibers, and film and surface-active agents; it has been used as a pesticide fumigant and for sterilization of surgical equipment. Ethylene oxide is highly reactive and potentially explosive; it is relatively stable in aqueous solutions or when diluted with halogenated hydrocarbons or carbon dioxide.

Ethylene oxide is a high-volume production chemical; production capacity in the United States was 6.1 billion pounds a year in 1981. Exposure to ethylene oxide is very limited in chemical plants, where it is produced and used for intermediates, mostly in closed systems. Maintenance and repair work, sampling, loading and unloading, and accidental leaks can generate exposure.

Although only a small proportion of ethylene oxide is used in health care and medical equipment manufacturing industries, and even less for sterilization of equipment in medical care facilities, NIOSH has estimated that more than 75,000 employees in sterilization areas have been exposed; concentrations as high as hundreds of parts per million were found on occasion, mostly in the vicinity of malfunctioning or inadequate equipment.

Absorption occurs through inhalation. Ethylene oxide is a strong irritant, especially in aqueous solutions. Severe dermatitis and even

chemical burns, marked eye irritation, and toxic pulmonary edema have occurred with high concentrations. The presence of lens opacities in combination with loss of visual acuity was found to be significantly increased among sterilization workers exposed to ethylene oxide, when compared with unexposed controls.⁶²⁰ Allergic dermatitis may develop. With high levels of exposure, CNS depression with drowsiness, headaches, and even loss of consciousness have occurred. Six workers accidentally exposed acutely to ethylene oxide experienced nausea, vomiting, chest tightness, shortness of breath, dizziness, cough, and ocular irritation. One worker had transient loss of consciousness.⁶²¹ A number of cases of sensory motor peripheral neuropathy have been reported in personnel performing sterilization with ethylene oxide. Removal from exposure resulted in gradual improvement over several months. A cluster of 12 operating-room nurses and technicians developed symptoms after a five-month exposure to high levels of ethylene oxide in disposable surgical gowns. All patients reported a rash on the wrist where contact was made with the gowns, headaches, and hand numbness with weakness. About 10 of 12 patients complained of memory loss. Neurologic evaluation revealed neuropathy on examination in 9 of the 12 patients, elevated vibration threshold in 4 of 9, abnormal pressure threshold in 10 of 11, atrophy on head MRI in 3 of 10, and neuropathy on conduction studies in 4 of 10. Neuropsychological testing demonstrated mild cognitive impairment in four of six patients. Sural nerve biopsy in the most severely affected patient showed findings of axonal injury.⁶²² The distal axonal degenerative changes have been shown in rats exposed to 500 ppm for 13 weeks. In rats chronically exposed to ethylene oxide (500 ppm for 6 hours/day, 3 days/week for 15 weeks), the distal portions of the sural nerve showed degenerative changes in myelinated fibers and fewer large myelinated fibers in the distal peroneal nerve, with a decrease in the velocity of anterograde axonal transport.⁶²³

Studies of sterilization personnel have found that mortality from lymphatic and haematopoietic cancer was only marginally elevated, but a significant trend was found, especially for lymphatic leukemia and non-Hodgkin's lymphoma, in relation to estimated cumulative exposure to ethylene oxide. For exposure at a level of 1 ppm over a working lifetime (45 years), a rate ratio of 1.2 was estimated for lymphatic and hematopoietic cancer. Three other studies of workers involved in sterilization (two in Sweden and one in the United Kingdom) each showed nonsignificant excesses of lymphatic and haematopoietic cancer. In a study of chemical workers exposed to ethylene oxide at two plants in the United States, the mortality rate from lymphatic and hematopoietic cancer was elevated, but the excess was confined to a small subgroup with only occasional low-level exposure to ethylene oxide. Six other studies in the chemical industry (two in Sweden, one in the United Kingdom, one in Italy, one in the United States, and one in Germany) were based on fewer deaths. Four found excesses of lymphatic and hematopoietic cancer (which were significant in two), and in two, the numbers of such tumors were as expected from control rates.⁶²⁴

Ethylene oxide has been shown to be mutagenic in several assay systems including human fibroblasts.⁶²⁵ Covalent binding to DNA has been demonstrated. Sterilization plant workers have been shown to exhibit evidence of DNA damage. DNA strand breaks, alkali-labile sites of DNA and DNA cross-links were seen in excess in peripheral mononuclear blood cells, compared to findings in unexposed controls.⁶²⁶ The frequency of hemoglobin adducts and sister chromatid exchanges (SCEs) in peripheral blood cells increased with cumulative exposure to ethylene oxide among hospital workers.⁶²⁷ Increased frequencies of HPRT mutants, chromosomal aberrations, micronuclei, and sister chromatid exchanges have been reported among sterilization plant workers.⁶²⁸ Chromosomal aberrations and sister chromatid exchange have been found to occur with significantly increased frequency in workers exposed to ethylene oxide at concentrations not exceeding a TWA of 50 ppm (but with occasional excursions to 75 ppm). Exposures near or below 1 ppm among workers in a hospital sterilization unit were associated with increased hemoglobin adduct formation and SCEs, independent of smoking history.⁶²⁹ In general,

the degree of damage is correlated with level and duration of exposure. The induction of sister chromatid exchange appears to be more sensitive to exposure to ethylene oxide than is that of either chromosomal aberrations or micronuclei. In one study, chromosomal aberrations were observed in the peripheral lymphocytes of workers two years after cessation of exposure to ethylene oxide, and sister chromatid exchanges six months after cessation of exposure.⁶³⁰

Adverse reproductive effects (reduced numbers of pups per litter, fewer implantation sites, and a reduced ratio of fetuses to number of implantation sites) were observed in rats exposed to 100 ppm ethylene oxide. An increased proportion of congenital malformations (mostly skeletal) was also reported. The effect occurred predominantly when exposure occurred during the zygotic period rather than during organogenesis.⁶³¹ Genotoxic effects on male germ cells in postmeiotic stages have been demonstrated in both *Drosophila* and the mouse.⁶³² Significant effects on fetal deaths and resorptions, malformations, crown-to-rump length, and fetal weight were found in ethylene oxide exposed female mice.⁶³³ Testicular damage following ethylene oxide exposure in rats has been reported, with specific but reversible injury to Sertoli cells.⁶³⁴ Women hospital employees exposed to ethylene oxide were found to have a higher incidence of miscarriages than a comparison group.

In 1981, the NIOSH recommended that ethylene oxide be regarded in the workplace as a potential carcinogen and that appropriate controls be used to reduce exposure. This recommendation was based on the results of a carcinogenicity assay, clearly indicating that ethylene oxide can produce malignant tumors in experimental animals. In a chronic inhalation study, mononuclear cell leukemias and peritoneal mesotheliomas were found to be significantly increased in ethylene oxide-exposed rats; both were dose-related and occurred at concentrations of 33 ppm. Ethylene oxide induced uterine adenocarcinomas in mice in a two-year inhalation study.⁶³⁵

A mortality study of workers in a Swedish ethylene oxide plant⁶³⁶ showed an increased incidence of total cancer deaths, with leukemia and stomach cancer accounting for most of these excess cancer deaths. Other chemical exposures (including some well-known carcinogens) had also been possible in that plant. An excess of leukemia was also found in another plant in which 50% ethylene oxide and 50% methyl formate were used for sterilization of hospital equipment.⁶³⁷ The small number of observed deaths and the complex chemical exposures do not allow definitive conclusions regarding the human evidence of ethylene oxide carcinogenicity, although it is entirely consistent with the experimental data. A more recent study of the mortality experience among 18,254 United States sterilization plant workers (4.9 years average exposure duration and 16 years of follow-up), with 8-hour TWAs averaging 4.3 ppm, reported a significant trend toward increased mortality with increasing length of time since first exposure for all hematopoietic cancers; among men, but not women, there was a significant increase in mortality from hematopoietic cancers.⁶⁴² A recent follow-up study of this cohort revealed an internal exposure-response trend for hematopoietic cancers limited to males (15-year lag). The trend in hematopoietic cancer was driven by lymphoid tumours (non-Hodgkin's lymphoma, myeloma, lymphocytic leukemia), which also had a positive trend with cumulative exposure for males with a 15-year lag.⁶³⁸

The current (1987) TLV for ethylene oxide is 1 ppm. IARC has concluded that ethylene oxide is carcinogenic to humans (Group 1).⁶²²

Glycidyl Ethers

Glycidyl ethers are characterized by the group:

Their most important use is for epoxy resins; diglycidyl ether of bisphenol A is one of the basic ingredients used to react with epichlorhydrin. Glycidyl ethers are also used as diluents, to reduce the

viscosity of uncured epoxy resins systems. These find applications in protective coatings, bonding materials, reinforced plastics, etc. The NIOSH estimates that about one million workers are exposed to epoxy resins; it is difficult to reach an accurate estimate of the number exposed to glycidyl ethers, but it is probably around 100,000 workers. Evidence has accumulated indicating that the epoxy resin glycidyl methacrylate is genotoxic and forms DNA adducts.

Glycidyl ethers are irritants for the skin and mucosae; dermatitis and sensitization have been reported. In experimental studies, an adverse effect on spermatogenesis and testicular atrophy has been the result of glycidyl ether exposure of several species (rats, mice, rabbits) to concentrations as low as 2–3 ppm. A potent effect on lymphoid tissue, including atrophy of the thymus and of lymph nodes, low white blood cell counts, or bone marrow toxicity have also been reported in rats, rabbits, and dogs. Information on immunosuppressive or myelotoxic effects in humans is not available, and the possibility that such effects have not been detected in the past cannot be excluded. The present federal standard for PELs are listed below:

Allyl glycidyl ether	5 ppm
<i>N</i> -Butyl glycidyl ether	25 ppm
Diglycidyl ether	0.1 ppm
Isopropyl glycidyl ether	50 ppm
Phenyl glycidyl ether	1 ppm

IARC has classified phenyl glycidyl ether as possibly carcinogenic to humans (Group 2B), based on evidence of carcinogenicity in animals.^{639,640}

Polychlorinated Biphenyls

Richard W. Clapp

The group of chemicals termed polychlorinated biphenyls is part of the larger class of chlorinated organic hydrocarbon chemicals. There are 209 individual compounds (congeners) with varying numbers and locations of chlorine on the two phenyl rings, with varying degrees of toxicity and adverse human and ecological effects.¹ Some of the PCBs are structurally similar to dioxins and furans and these congeners may cause similar health effects.² The higher chlorinated PCBs are particularly persistent in the environment,³ although not all potential congeners were manufactured and there was a shift toward lower-chlorinated PCB mixtures in later years. In 1976, the U.S. Congress passed the Toxic Substances Control Act which led to the ban of production of PCBs in the United States.

PCBs were first produced by the Monsanto Company in the late 1920s in two U.S. states for use in electrical products; initially, polychlorinated biphenyls were found to have properties that made them desirable in electrical transformers and capacitors, because of their insulating and low flammability characteristics.⁴ Subsequently, PCBs were used in hydraulic fluids, microscope oil, paints, surface coatings, inks, adhesives, in carbonless copy paper, and chewing gum, among other products. Because of leaks in the production process, and spills or leaks from transformers and other products, fires and incineration of PCB products, and improper disposal of PCB-containing wastes in landfills, there is widespread contamination from PCBs in the environment and wide distribution in the food chain and human adipose tissue.¹ There have been some dramatic examples of leakage and spills, including the Hudson River, in New York, and the New Bedford Harbor, in Massachusetts, and the town of Anniston, Alabama among many other examples. Indeed, PCBs have been found in mammalian blood and adipose tissue samples throughout the world,⁵ including remote Arctic populations with limited industrial production or use of these compounds.⁶ The likely source of PCB exposure in these remote settings is ingestion of PCBs accumulated through the food chain, especially in fish and marine mammals.

Because of the many adverse health effects and widespread distribution of PCBs in the environment, these compounds have not been made in the United States since 1977⁷ and are being phased out under the recent Stockholm Convention on Persistent Organic Pollutants (POPs). There are environmental and occupational exposure limits for PCBs in the United States that set allowable levels in workplaces, in drinking water sources, during transport or disposal, discharge into sewage treatment plants, and in food consumed by infants and adults. The current OSHA occupational limits are 1 mg/m³ for PCB mixtures with 42% chlorine and 0.5 mg/m³ for mixtures with 52% chlorine over an 8-hour day. Presumably, these limits would protect workers exposed during spills of old equipment containing PCBs. The U.S. Food and Drug Administration recommends that drinking water not contain more than 0.5 parts per billion PCBs and that foods such as milk, eggs, poultry fat, fish, shellfish, and infant formula not contain more PCBs than 3 parts per million or 3 mcg/g on a lipid basis.¹

PCBs are chemically similar to other compounds such as dioxins and furans and human exposures are often to mixtures of these related compounds. For example, in transformer fires such as the one that occurred in the Binghamton, New York State Office building,⁸ or in two major contaminated rice oil poisoning incidents in Japan⁹ and Taiwan^{10,11} the exposures were to a combination of PCBs, dioxins (PCDDs), dibenzofurans (PCDFs), and possibly some other chlorinated compounds. This makes the determination of the causes of the health effects observed in these situations complex.

► CHEMICAL PROPERTIES OF PCBs

PCBs were produced by the catalyzed addition of chlorine to the basic double benzene ring structure; any number of chlorine atoms from 1 to 10 can be added, typically resulting in mixtures of dozens of congeners in commercial mixtures. These mixtures can be oily or solid, and colorless to light yellow, with no characteristic smell or taste. The commercial products were primarily six or seven mixtures classified by their percentage of chlorine. The major manufacturer, Monsanto, called its PCB product Aroclor and assigned identifying numbers based on the chlorine content of the congener mixtures.¹ Other manufacturers, such as Bayer in Europe, used other names and numbering schemes (Clophen A60, Kanechlor 500, etc.). These products resist degradation in the environment and have low solubility in water, but they are soluble in oils and certain organic solvents. They are lipophilic and, therefore, bio-accumulate in fatty tissue in humans and other species.

► GLOBAL CONTAMINATION

Beginning with the production of PCBs in Anniston, Alabama in the late 1920s, later production in other part of the United States and Europe in the middle of the last century, and extending beyond the curtailment of production for nearly all uses in 1977, there have been many examples of environmental contamination by these persistent compounds. In Sweden, widespread PCB contamination was documented in the 1960s, and in North America, surveys documented contamination of human breast milk and fish around the Great Lakes beginning in the 1970s. Two major episodes of PCB poisoning from contaminated rice oil occurred in 1968 in Japan and in 1979 in Taiwan.

Cohorts of PCB-exposed manufacturing workers were established and follow-up studies were conducted in the United States,¹² Italy,¹³ and Sweden¹⁴ in the 1970s and considerable human and environmental exposure was described in the areas where these plants were located. For example, the Hudson River in New York and the Housatonic River in Massachusetts have been contaminated by PCBs from manufacturing plants in Hudson Falls and Pittsfield. These rivers have had fish consumption warnings posted for decades

because of the high concentrations of PCBs found there. More recently, studies of offspring of mothers exposed to PCBs through their diet, primarily through fish consumption, have been conducted around the Great Lakes in North America¹⁵⁻¹⁹ and in Europe²⁰ and these have added to the literature about health effects in children. The health effects identified in these recent studies include disruption of reproductive function, neurobehavioral and developmental deficits in newborns and children exposed to PCBs in utero, systemic effects such as liver disease, effects on the thyroid and immune systems.^{21,22}

Mechanisms of Toxicity

The primary mechanism of toxicity for dioxin-like coplanar PCBs appears to be the induction of gene product expression after initial binding to the aryl hydrocarbon (Ah) receptor in the intracellular cytosol of mammalian cells. The most sensitive effects of this process are the alteration of cytochrome P450 1A1 and 1A2 expression, and induction of ethoxyresorufin O-deethylase (EROD) which produce a series of downstream effects.¹ These can result in a variety of adverse responses in different tissues which may vary by sex and developmental stage in different animal species. Other PCBs appear to be estrogenic and affect reproductive and endocrine systems. PCB effects on the neurological system may occur through other mechanisms that are not currently understood. Furthermore, although PCB mixtures appear to have both tumor initiating and promoting capabilities in experimental animal studies, the mechanism of carcinogenicity is not currently known.

Human Health Effects

The earliest reports of adverse human health effects of PCBs were dermal effects in exposed workers who were diagnosed with rashes and chloracne. Typically, the exposures are to mixtures of PCBs and other chlorinated compounds, making it difficult to isolate the effects specific to PCBs. For example, the two major outbreaks of PCB poisoning, with clinical syndromes called Yusho and Yu-cheng, were examples of mixed exposures to cooking oil contaminated with PCBs and other chlorinated compounds such as polychlorinated dibenzofurans.²³ Nevertheless, these two episodes provided much early evidence of PCB-related health effects including chloracne, other skin abnormalities, hyperpigmentation, swelling of the eyelids, and eye discharge. Furthermore, the offspring of PCB-exposed mothers exhibited dark skin pigmentation, pigmented nails, and abnormal dentition. Chronic effects of PCB poisoning in Yusho victims included headache, joint swelling and pain, numbness of extremities, irregular menstruation, and low birth weight in offspring. Children also were found to have growth retardation and various other developmental effects which were later investigated in other studies.²⁴

Worker cohorts exposed to PCBs in manufacturing capacitors and transformers were followed and several types of cancer were found to be elevated. For example, deaths due to melanoma of skin were increased (24 observed/13.7 expected) in capacitor workers and transformer workers. Lymphoma (10 observed/5.7 expected) and brain cancer (13 observed/3.7 expected) deaths were also increased in transformer workers, and liver and biliary tract cancer deaths were elevated in some capacitor workers' studies.⁷ Electrical workers with potential exposure to PCBs have also been shown to have excess deaths due to melanoma of skin^{12,25} and brain cancer.²⁶ These studies of workers were the scientific basis for the current classification of PCBs as "probable" human carcinogens.²⁷

Other studies of PCB and cancer in nonoccupationally-exposed persons indicated increased incidence of non-Hodgkin's lymphoma.^{28,29} A recent Swedish study of testicular cancer suggested that risk is increased by prenatal exposure to two subgroups of estrogenic and enzyme-inducing PCBs.³⁰ A number of studies of breast cancer cases have been carried out, with equivocal results.³¹ Some breast cancer studies estimated exposure from fat or blood samples taken shortly before diagnosis,³² and some also combined all congeners or looked

at large groups of PCB congeners.³³ More recently, one study looked at specific congeners and found increased risk in women with higher blood concentrations of the dioxin-like PCBs.³⁴ Another study of breast cancer suggested that exposure to PCBs was associated with an increased risk of the disease in women with a specific CYP1A1 polymorphism (the m2 genotype).³⁵

Abnormal thyroid function has been found in offspring of Dutch women exposed to PCBs, dioxins, and furans, and there is increasing evidence that exposure during the perinatal period can result in learning and cognitive development during childhood.³⁶ Strong correlations between Great Lakes fish consumption and PCB levels in umbilical cord blood and breast milk have been found. Menstrual cycle length and time-to-pregnancy have been investigated in relation to Lake Ontario fish consumption with inconsistent results, but newborn neurological development was abnormal in offspring of women in the high exposure category.³⁷

► PUBLIC HEALTH IMPACTS OF ENVIRONMENTAL EXPOSURE

The health impacts of low-level environmental exposure are controversial. Studies of low-dose effects are sometimes contradictory, as in the case of blood pressure and serum PCB levels. Similarly, some studies of neurobehavioral effects in offspring of PCB-exposed mothers have been questioned.³⁸ Nevertheless, the effect on memory, attention, and IQ in children on a population level is significant enough to warrant limiting exposure to PCBs through the food chain. Clinicians seeking to provide guidance to worried patients, for example, should inquire about dietary fish consumption and residence near potential PCB contamination sites.

Exposure in the United States can be reduced by adherence to current regulations governing disposal of PCB-containing waste. The primary consideration is safe transport of PCB-containing waste and either burial in an approved landfill, incineration at temperatures greater than 1500°C or, preferably, chemical treatment and dechlorination of the PCBs.³⁹

International efforts to manage and dispose of PCBs are underway and are being coordinated by the United Nations Environment Program.⁴⁰ The Stockholm Convention on Persistent Organic Pollutants took effect in May, 2004 and required the participating parties to eliminate the use of PCBs by 2025 and accomplish environmentally sound PCB waste management worldwide by 2028. The first steps toward establishing inventories of PCBs and standard methods for phasing out and eliminating wastes are already being taken. A critical parallel effort is adherence to the Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal. As these efforts move forward, the global PCB pollution caused by past uses and practices can be expected to diminish and human exposures and health effects will decline further.

Polychlorinated Dioxins and Polychlorinated Dibenzofurans

Yoshito Masuda • Arnold J. Schechter

Polychlorinated dibenzo-p-dioxins (PCDDs) have been described as the most toxic man-made chemicals known. They are synthetic, lipophilic, and very persistent. They are also relatively controversial. Toxicological studies of 2,3,7,8-tetrachlorodibenzo-p-dioxin (2,3,7,8-TCDD), which is known as the most toxic congener among PCDDs and usually called Dioxin, demonstrate dose-dependent toxic responses to other PCDDs and related chemicals such as the polychlorinated dibenzofurans (PCDFs), which frequently accompany polychlorinated biphenyls (PCBs). (Both PCDFs and PCBs are chemically and biologically similar to PCDDs.) However, the findings from human studies, at least until recently, have been less consistent.

The animal health effects include but are not limited to: death several weeks after dosing, usually accompanied by a “wasting” or loss of weight syndrome; increase in cancers (found in all animal cancer studies); increased reproductive and developmental disorders including fetal death in utero, malformations, and in offspring dosed in utero, endocrine disruption with altered thyroid and sex hormone blood levels; immune deficiency sometimes leading to death of new born rodents, especially following dosing with infectious agents; liver damage including transient increase in serum liver enzymes as well as the characteristic lesions of hepatocytes to chlorinated organics, enlarged cells, intracytoplasmic lipid droplets, increase in endoplasmic reticulum, enlarged and pleomorphic mitochondria with altered structure of the cristae mitochondriales and enlarged dense intramitochondrial granules; central nervous system and peripheral nervous system changes including altered behavior and change in nerve conduction velocity; altered lipid metabolism with increase in serum lipids; and skin disorders including rash and chloracne (acne caused by chlorinated organic chemicals). Some effects are species specific. Other findings have been reported but with less frequency or consistency.¹

Findings reported in some human studies are similar to those from animal studies. These include an increase in cancers of certain types, including soft tissue sarcomas, Hodgkin’s lymphoma, non-Hodgkin’s lymphoma, lung cancer, and liver cancer; adverse reproductive and developmental effects following intrauterine and nursing exposure such as lower birth weight and smaller head circumference for gestational age, decreased cognitive abilities, behavioral impairment, and endocrine disruptions including altered thyroid hormone levels; immune deficiency; liver damage; altered lipid metabolism with increase in serum lipids; altered nerve conduction velocity; altered sex ratio in children born to dioxin-exposed women (more females than males); increase in diabetes or altered glucose metabolism in exposed chemical workers and sprayers of dioxin-contaminated Agent Orange herbicide; and behavioral changes including anxiety, difficulty sleeping, and decrease in sexual ability in males.¹⁻¹⁰ Some of the human health effects are subtle such as those reported in the

Dutch studies. These effects are not likely to be detected by the clinician on individual patients but only in a larger population-based study. Skin disorders including rash and chloracne are also observed in some exposed persons.

PCDDs and PCDFs are not manufactured as such, but are usually found as unwanted contaminants of other synthetic chemicals or as products of incineration of chlorinated organics. PCDDs consist of two benzene rings connected by a third middle ring containing two oxygen atoms in the para position. PCDFs have a similar structure but the middle connecting ring contains only a single oxygen atom. PCBs consist of two connected biphenyl rings with no oxygen. When chlorine atoms are in the 2, 3, 7, and 8 positions, PCDDs and PCDFs are extremely toxic. The most toxic congener, 2,3,7,8-TCDD is defined as having a “Dioxin toxic equivalency factor” (TEF) of 1.0; other toxic PCDDs and PCDFs have TEFs from 0.00001 to 1¹¹ (Table 29-1). PCDDs and PCDFs without chlorines in the 2, 3, 7, and 8 positions are devoid of dioxinlike toxicity. Some PCBs also have dioxin-like toxicity as shown in Table 29-1. The Dioxin toxic equivalency (TEQ) approximates the toxicity of the total mixture. The TEQ is determined by multiplying the measured level of each congener by the congener’s TEF and then adding the products. The total Dioxin toxicity of a mixture is the sum of the TEQs from the PCDDs, the PCDFs, and the dioxin-like PCBs. There are characteristic levels and patterns of PCDD and PCDF congeners found in human tissues which correspond to levels of industrialization and contamination in a given country. At the present time, seven toxic PCDD and 10 toxic PCDF congeners as well as 12 PCBs can usually be identified in human tissue in persons living in more industrialized countries. The measurement of the individual congeners is done by capillary column gas chromatography coupled to high-resolution mass spectrometry. Extraction, chemical cleanup, and the use of known chemical standards have markedly improved specificity and sensitivity of such measurements in recent years.

Intake of 1–6 pg/kg body weight (BW)/day of TEQ of dioxin-like chemicals (PCDDs, PCDFs, and PCBs) is characteristic of adult daily intake in the United States at the present time.¹² Intake of TEQ is mostly from food, especially meat, fish, and dairy products. Fruits and vegetables have very low levels of Dioxins, which are from surface deposition. Air and water contain very low levels of the fat-soluble Dioxins and are believed to usually contribute little to human intake, as food intake has been demonstrated in several studies to result in more than 90% of human exposure. Nursing infants in the United States consume approximately 35–65 pg/kg BW/day of TEQ during the first year of life. The U.S. Environmental Protection Agency (EPA) has used a value of 0.006 pg/kg BW/day of TEQ over a 70-year lifetime as a dose believed to possibly lead to an excess of one cancer per 1 million population. The EPA Dioxin Reassessment

TABLE 29-1. PCDD, PCDF, AND PCB CONGENERS WITH TEF

*Data from the report of an expert meeting (1997) at the World Health Organization. Source: Van den Berg M, Birnbaum L, Bosveld ATC, et al. Toxic equivalency factors (TEFs) for PCBs, PCDDs, PCDFs for humans and wildlife. Environ Health Perspect. 1998;106:775-92.

draft document is considering a change from 0.006 to 0.01 pg/kg BW/day of TEQ as a cancer reference dose. Some European countries and Japan use values between 1 and 10 pg/kg BW/day of TEQ as their reference value or tolerable daily intake (TDI). These different values are all based on review of the same published animal and human literature and each involves certain assumptions and safety factor considerations including extrapolation between animal species and from animals to humans. From a public health perspective, however, it is noteworthy that the U.S. daily intake of Dioxins, especially in the presumably more sensitive nursing infant, exceeds reference values.¹³⁻¹⁵

The PCBs, which, unlike PCDDs and PCDFs, were deliberately manufactured, are also found in most countries as environmental contaminants in humans, wildlife, and environmental samples. They were used as electrical and thermal insulating fluids for electrical transformers and capacitors, as hydraulic fluids in carbonless copying paper, and in microscope oil. Higher levels are found in more industrialized countries. One of the most well-known PCB and PCDF contaminations is the rice oil poisoning (the 1968 Yusho incident) in Japan where PCBs and PCDFs contaminated rice oil used for cooking. We describe this incident in detail later because it clearly documented the human toxicity of dioxinlike chemicals as early as 1968. An almost identical incident, known as Yucheng, occurred in Taiwan in 1979.

Dioxins became of concern because of a number of well-known incidents. One of the most well-known is the spraying of Agent Orange herbicide in Vietnam. Repeated spraying of concentrated solutions of 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), the latter contaminated with the most toxic Dioxin, 2,3,7,8-TCDD, over jungles and rice crops in the south of Vietnam between 1962 and 1971 during the Vietnam War has been a

concern to those exposed: the Vietnamese and U.S. Vietnam veterans. Jungles were sprayed to deprive enemy troops of cover, and crops were sprayed to deprive enemy troops and civilians of food. Areas around base camps as well as naval areas were sprayed for similar reasons. Elevated Dioxin levels have been found in fat tissue, blood, and milk decades afterward in Vietnamese exposed to Agent Orange and in some exposed American Vietnam veterans.^{16,17} The highest levels of Dioxins in breast milk ever measured were in Vietnamese women who were nursing during the spraying of Agent Orange. The half-life of elimination of 2,3,7,8-TCDD is believed to be between 7 and 11 years in humans. Vietnamese studies concerning adverse reproductive consequences and increases in cancers following potential exposure to Agent Orange are limited. Other well-known PCDD and PCDF incidents include the Seveso, Italy, explosion of 1976; Times Beach, Missouri; Love Canal, New York; the Binghamton State Office Building PCB transformer fire incident of 1981; the rice oil poisoning incidents in Japan (Yusho) and in Taiwan (Yucheng); the Coalite exposures in England; Nitro, West Virginia; several German industrial exposures; and the Ufa, Russia, exposures.¹

Recent epidemiology studies from the United States, Europe, and Japan show increased rates of cancer in workers who were more highly exposed to dioxinlike chemicals and also in consumers of the contaminated rice oil. In addition, one German study of chemical workers exposed to PCDDs found an increase in mortality from ischemic cardiovascular disease as well as from cancer in the more highly exposed members of one German cohort of chemical workers.¹⁸⁻²² Recent Dutch studies found reproductive and developmental alterations in children born to women in the general population with higher levels of TEQs. These latter examinations are among the first studies to document human health effects of Dioxins at levels found in the general population in industrial countries.^{4,6} The levels of Dioxins in the Dutch population are similar to but slightly higher than those found in the United States and other industrial countries.

Rogan and coworkers have previously described developmental findings in North Carolina children born to women in the general population with higher levels of PCBs. They have also described more striking and persistent findings in children whose mothers had high levels of PCBs and PCDFs from the Taiwan Yucheng rice oil poisoning.²³⁻²⁷

Recent research has documented the discovery of a Dioxin receptor in the cytoplasm of human as well as other mammalian cells. The Dioxins, which appear not to be directly genotoxic, but which can initiate or promote cancer as shown in all animal studies investigating Dioxins and cancer, bind with the aryl hydrocarbon (Ah) receptor in the cytoplasm. The complex then moves into the nucleus. The exact mechanisms by which the many adverse health outcomes are achieved is not known.²⁸

To illustrate the human health consequences of PCDF exposure, we review the Yusho incident, which has provided a substantial amount of public health and medical information.¹⁰ Yusho, which means "oil disease" in Japanese, occurred in Western Japan in 1968. This poisoning was caused by ingestion of commercial rice oil (used for home cooking), which had been contaminated with PCBs, PCDFs, polychlorinated quaterphenyls (PCQs), and a very small amount of PCDDs. About 2000 people became ill and sought medical care. The marked increase of PCDFs in the rice oil is believed to have occurred in the following way. Although PCBs are usually contaminated with small amounts of PCDFs, the commercial PCBs used as a heat-transfer medium for deodorizing rice oil were heated above 200°C and the PCBs were gradually converted into PCDFs and PCQs. The PCBs with increased PCDF concentration leaked into the rice oil through holes formed in a heating pipe because of inadequate welding.²⁹

Yusho patients ingested more than 40 different PCDF congeners in the rice oil, but only a small number of PCDF congeners persisted in their tissues. High concentrations of 2,3,4,7,8-pentachlorodibenzofuran (2,3,4,7,8-pentaCDF), up to 7 ppb, were observed in tissue samples in 1969, a year after the incident.³⁰ Although the levels of PCDF congeners declined significantly, elevated levels of PCDF congeners did, however, continue for a substantial period of time. In 1986, the levels of PCDF congeners were observed up to 40 times higher than those of

the general population, and at the present time they are still elevated. PCDF concentrations in the liver were almost as high as those in adipose tissue, but PCB concentrations were much lower in the liver than in the adipose tissue, so partitioning was not simply a passive process. In calculating the toxic contribution of PCDDs, PCDFs, and PCBs in a Yusho patient using the TEF, 2,3,4,7,8-pentaCDF was found to have accounted for most of the dioxin-like toxicity from TEQs in the liver and adipose tissue of patients.

The toxicity of individual congeners of PCDFs and PCBs was compared to 2,3,7,8-TCDD toxicity by the use of the TEFs. Total TEQ in the rice oil was calculated to be 0.98 ppm, of which 91% was from PCDFs, 8% from PCBs, and 1% from PCDDs. Thus, more than 90% of the dioxin-like toxicity in Yusho was considered to have originated from PCDFs rather than the more plentiful PCBs. Therefore, at the present time Yusho is considered to have been primarily caused by ingestion of PCDFs.²⁹

On an average, the total amounts of PCBs, PCQs, and PCDFs consumed by the 141 Yusho patients surveyed were 633, 596, and 3.4 mg, respectively. During the latent period, the time between first ingestion of the oil and onset of illness, the average total amounts consumed were 466, 439, and 2.5 mg of PCBs, PCQs, and PCDFs, respectively. The smallest amounts consumed which caused Yusho were 111, 105, and 0.6 mg of PCBs, PCQs, and PCDFs, respectively. In Yusho, it took on average about 3 months for clinical effects to be readily detected.

Most patients were affected within the 9-month period beginning February 1968, when the contaminated rice oil was shipped to the market from the Kanemi rice oil producing company, to October 1968, when the epidemic of Yusho was reported to the public. Prominent signs and symptoms of Yusho are summarized in Table 29-2.

TABLE 29-2. PERCENT DISTRIBUTION OF SIGNS AND SYMPTOMS OF YUSHO PATIENTS EXAMINED BEFORE OCTOBER 31, 1968

Symptoms	Males N = 98	Females N = 100
Increased eye discharge	88.8	83.0
Acnelike skin eruptions	87.6	82.0
Dark brown pigmentation of nails	83.1	75.0
Pigmentation of skin	75.3	72.0
Swelling of upper eyelids	71.9	74.0
Hyperemia of conjunctiva	70.8	71.0
Distinctive hair follicles	64.0	56.0
Feeling of weakness	58.4	52.0
Transient visual disturbance	56.2	55.0
Pigmented mucous membrane	56.2	47.0
Increased sweating of palms	50.6	55.0
Itching	42.7	52.0
Numbness in limbs	32.6	39.0
Headache	30.3	39.0
Stiffened soles in feet and palms of hands	24.7	29.0
Vomiting	23.6	28.0
Swelling of limbs	20.2	41.0
Red plaques on limbs	20.2	16.0
Diarrhea	19.1	17.0
Hearing difficulties	18.0	19.0

Pigmentation of nail, skin, and mucous membranes; distinctive follicles; acneiform eruptions; increased eye discharge; and increased sweating of the palms were frequently noted. Common symptoms included pruritus and a feeling of weakness or fatigue.³¹

The most notable initial signs of Yusho were dermal lesions such as follicular keratosis, dry skin, marked enlargement and elevation of the follicular orifice, comedo formation, and acneiform eruption.³² Acneiform eruptions developed in the face, cheek, jaw, back, axilla, trunk, external genitalia, and elsewhere (Fig. 29-1). Dark pigmentation of the corneal limbus, conjunctivae, gingivae, lips, oral mucosa, and nails was a specific finding of Yusho. Severity of the dermal lesions was proportional to the concentrations of PCBs and PCDFs in the blood and adipose tissue. The skin symptoms diminished gradually in the 10 years after the onset, probably related to the decreasing PCDF concentrations in the body, while continual subcutaneous cyst formation with secondary infection persisted in a relatively small number of the most severely affected patients.

The most prominent ocular signs immediately after onset were hypersecretion of the Meibomian glands and abnormal pigmentation of the conjunctiva. Cystic swelling of the meibomian glands filled with yellow infarctlike contents was observed in typical cases³³ (Fig. 29-2). These signs markedly subsided in the 10 years after the onset of Yusho. Eye discharge was a persistent complaint in many patients.

A brownish pigmentation of the oral mucosa was one of the characteristic signs of Yusho. Pigmentation of the gingivae and lips was observed in many victims during 1968 and 1969. This pigmentation persisted for a considerable period of time and was still observed in most patients in 1982. Radiographic examination of the mouth of

Figure 29-1. Acneiform eruption on the back of a Yusho patient (female, age 33, photographed in December, 1968). The photograph from Dr Asahi. (Source: Adapted from Asahi M, Urabe H. A case of "Yusho"-like skin eruptions due to halogenated PCB-analogue compounds. *Chemosphere*. 1987;16:2069-72.)

Figure 29-2. The lower eyelid of a 64-year-old Yusho patient, 13 years after onset. White cheesy secretions were noted from the ducts of the Meibomian glands when the eyelid was manually squeezed. The photograph from Dr Ohnishi. (Source: Adapted from Ohnishi Y, Kohno T. *Ophthalmological aspects of Yusho*. In: Kuratsune M, Yoshimura H, Hori Y, Okumura M, Masuda Y, eds. *YUSHO: A Human Disaster Caused by PCBs and Related Compounds*. Fukuoka, Japan: Kyushu University Press; 1996:206–9.)

Yusho patients demonstrated anomalies in the number of teeth and in the shape of the roots and marginal bone resorption at the roots.

Irregular menstrual cycles were observed in 58% of female patients in 1970. This was not related to elevation of Yusho tissue levels. Thyroid function was investigated in 1984, 16 years after onset. The serum triiodothyronine and thyroxine levels were significantly higher than those of the general population, while thyroid-stimulating hormone levels were normal. The serum bilirubin concentration in the

patients correlated inversely with the blood levels of PCBs and serum triglyceride concentration, characteristically increased in the poisoning. Marked elevation of serum triglyceride was one of the abnormal laboratory findings peculiar to Yusho in its early stages. Significant positive correlation was observed between serum triglyceride levels and blood PCB concentrations in 1973. Significantly elevated levels of triglycerides persisted in Yusho patients for 15–20 years after exposure to PCBs and PCDFs.

From the follow-up data of three Yucheng patients and five Yusho patients,³⁴ fat-based concentrations of TEQ and PCBs in the Yusho patients with severe grade illness were estimated to have decreased from 40 ppb and 75 ppm, respectively, in 1969, to 0.6 ppb and 2.3 ppm, respectively, in 1999 (Fig. 29-3). Estimated median half-lives of three PCDFs and six PCBs were 3.0 and 4.6 years, respectively, in the first 15 years after the incident, and 5.4 and 14.6 years, respectively, in the following 15 years. Typical Yusho symptoms of acneiform eruption, dermal pigmentation, and increased eye discharge were very gradually recovered with lapse of 10 years. However, enzyme and/or hormone-mediated sign of high serum triglyceride, high serum thyroxin, immunoglobulin disorder, and others are persistently maintained for more than 30 years.³⁵ Blood samples of 152 residents in Fukuoka, where several hundreds Yusho patients are living, were examined in 1999 for TEQ and PCB concentrations.³⁶ Their mean levels were 28 pg/g lipid (range 9.2–100) and 0.4 ug/g lipid (range 0.06–1.7), respectively. Mean values of TEQ and PCBs in Yusho patients were only six and two times higher, respectively, than those in controls in 1999 as shown in Fig 29-3.

A statistically significant excess mortality was observed for malignant neoplasm of all sites. This was also the case for cancer of the liver in males. However, excess mortality for such cancer was not statistically significant in females. It is still too early to draw any firm conclusion from this mortality study. However, the Yusho rice oil poisoning incident was one of the first to demonstrate human health effects caused by the dioxinlike PCDFs and PCBs. These effects are somewhat similar to those noted in laboratory animals and wildlife from PCDD, PCDF, or PCB exposure.¹⁰

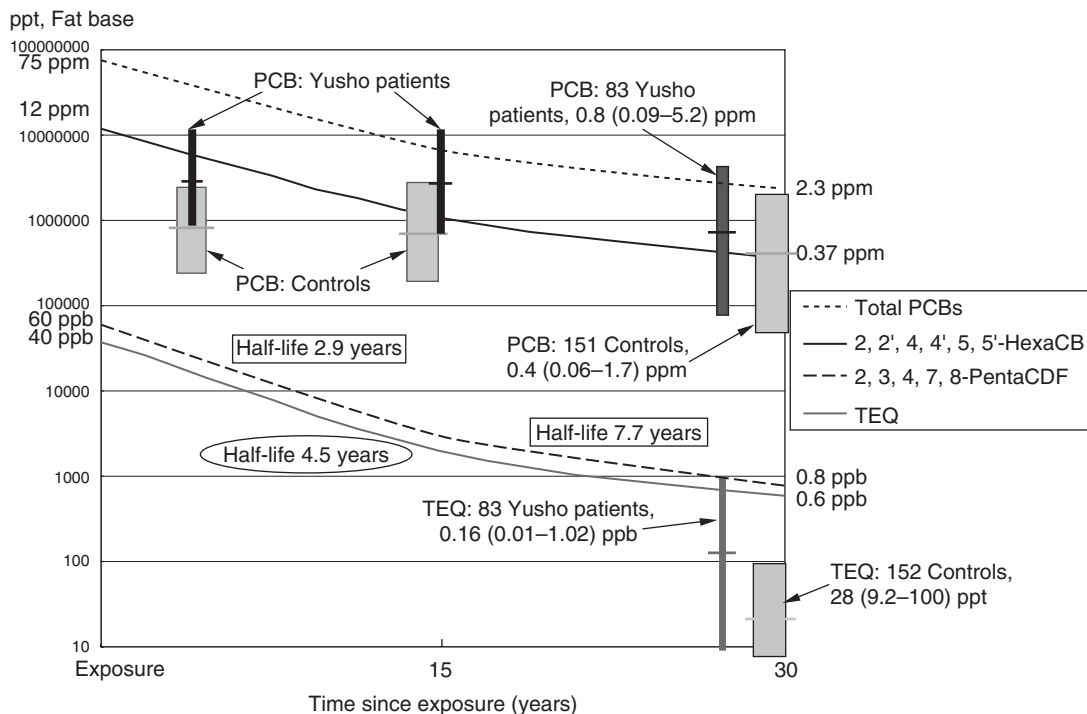

Figure 29-3. Estimated changes of PCB/TEQ concentrations in Yusho patients from 1969 to 1999 for 30 years. (Source: Adapted from Masuda Y. *Fate of PCDF/PCB congeners and changes of clinical symptoms in patients with Yusho PCB poisoning for 30 years*. *Chemosphere*. 2001;43:925–30; Masuda Y. *Behavior and toxic effects of PCBs and PCDFs in Yusho patients for 35 years*. *J Dermatol Sci*. 2005;1:511–20.)

Reduction of PCDDs, PCDFs, and related chemicals in the environment can be and has been addressed in a variety of ways. One way is preventing the manufacture of certain chemicals such as PCBs. Another is banning the use of certain phenoxyherbicides such as 2,4,5-T, which is contaminated with the most toxic Dioxin, 2,3,7,8-TCDD. Improved municipal, toxic waste, and hospital incinerators that produce less Dioxin is another approach, as is not burning certain chlorine-containing compounds, such as the very common polyvinyl chlorides. The use of unleaded gasoline avoids chlorinated scavengers found in leaded gasoline, which may facilitate formation of Dioxins. Cigarette smoke contains a small amount of Dioxins. Cessation of smoking and provision of smoke-free workplaces, eating establishments, airports, etc. helps prevent Dioxin formation and exposure. In Europe, over the past decade, PCDD and PCDF levels appear to be declining in human tissue including breast milk and blood. This decline coincides in time with regulations and enforcement of regulations designed to decrease PCDD and PCDF formation, especially with respect to incineration. Since intrauterine exposure cannot be prevented on an individual basis, and breast-feeding, which involves substantial Dioxin transfer to the child, is otherwise desirable, worldwide environmental regulations with strong enforcement are clearly indicated as a preventive public health measure.

Brominated Flame Retardants

Daniele F. Staskal • Linda S. Birnbaum

► INTRODUCTION

The incidence of fire-related injuries, deaths, and economic damages has decreased over the past 25 years, partly because of fire prevention policies requiring flame retardant chemicals in many industrial products. Brominated flame retardants (BFRs) have routinely been added to consumer products for several decades to reduce fire-related incidents. They represent a major industry involving high-production chemicals with a wide variety of uses, yet all BFRs are not alike and often the only thing that they have in common is the presence of bromine. Concern for this emerging class of chemicals has been raised following a rapid increase of levels in the environment, wildlife, and people in combination with reports of developmental, reproductive and neurotoxicity, and endocrine disruption. Despite these concerns, little information is available on their sources, environmental behavior, and toxicity. Because of limited knowledge, few risk assessments have been completed.

► PRODUCTION AND USE

More than 175 different types of flame retardants are commercially available and can be generally divided into classes that include halogenated organic (usually brominated or chlorinated), phosphorus- or nitrogen-containing, and inorganic flame retardants. The BFRs are currently the largest market group because of their low cost and high efficiency. Some, such as the polybrominated biphenyls (PBB), are no longer being produced because of recognized toxicity and accidental poisoning.¹ “Tris-BP” was also removed from the market after its original use as a flame retardant on children’s clothing because it was shown to have mutagenic and nephrotoxic effects.²

Over 75 BFRs are recognized; however, five BFRs constitute the overwhelming majority of BFR production. Tetrabromobisphenol A (TBBPA), hexabromocyclododecane (HBCD), and three commercial mixtures of polybrominated diphenyl ethers, or biphenyl oxides, known as decabromodiphenyl ether (DBDE), octabromodiphenyl ether (OBDE), and pentabromodiphenyl ether (PentaBDE), are used as additive or reactive components in a variety of polymers. The spectrum of final applications is very broad, but includes domestic and industrial equipment such as: TVs, mobile phones, computers,

Note: The information in this document has been subjected to review by the National Health and Environmental Effects Research Laboratory, U.S. Environmental Protection Agency, and approved for publication. Approval does not signify that the contents reflect the views of the Agency, nor does mention of trade names or commercial products constitute endorsement or recommendation for use. Partial funding provided by the NHEERL-DESE Training in Environmental Sciences Research, EPA CT 826513.

furniture, insulation boards, carpet padding, mattresses, and upholstered textiles. About 90% of electrical and electronic appliances contain BFRs. Information on global production and usage of BFRs is supplied by the Bromine Science and Industrial Forum.³

► ENVIRONMENTAL PREVALENCE

Global environmental studies indicate that these chemicals are ubiquitous in sediment and biota and undergo long range transport.^{4,5} All of the major BFRs (PBDEs, HBCD, and TBBPA) have been documented in air, sewage sludge, sediment, invertebrates, birds, and mammals (including humans). Environmental trends show that levels are increasing and that often the specific congener patterns found in biota do not mimic what is used in commercial products. This suggests breakdown or transformation of the flame retardant products during manufacture, use, disposal, or during biomagnification in the food web. Full documentation and specific concentrations in the various media can be found in special issues of the journals *Chemosphere*⁴ and *Environment International*.⁵

► HEALTH EFFECTS

No known health effects have been reported in humans following exposure to BFRs currently in production; however, no investigative studies have been conducted. PBB and Tris-BP, two BFRs with known human health effects, are no longer produced. Proposed health effects of BFRs are based on fish and mammalian toxicity data primarily available for the five major BFRs. Thorough reviews and extended references for toxicological studies can be found in the provided references.^{1,2,4-9}

PBDEs. There are 209 potential PBDE congeners, of which approximately 25 are found in commercial mixtures ranging from trisubstituted up to the fully brominated deca-congener. The lower brominated congeners tend to be well absorbed following oral ingestion, are not well metabolized, and primarily distribute to lipophilic tissues in the body and, therefore, appear to have a long half-life in humans (>2 years). These also appear to be the most toxic congeners. Both the technical PBDE products as well as individual congeners can induce phase I and phase II detoxification enzymes in the liver. Several of the individual congeners have been tested in a variety of developmental neurotoxicity studies in rodents. Mice dosed during critical windows of development demonstrate effects on learning and memory that extend into adulthood. Rodents have also been exposed to PBDEs using a standardized protocol which detects endocrine disruption during puberty and results demonstrate that both male and female rats are sensitive to their effects.¹⁰ The most consistently reported

effect following exposure to PBDEs in animal studies is an accompanying decrease in circulating thyroid hormones. This could be particularly harmful during development as small changes in these essential hormones have been associated with cognitive deficits in children. DecaBDE is the only BFR that has been extensively studied for cancer effects.⁶ The results of the 2-year bioassays concluded that there was some evidence of carcinogenicity in rodents demonstrated by an increased incidence of hepatocellular and thyroid gland follicular cell adenomas or carcinomas.

TBBPA. Rodent studies indicate that TBBPA is not acutely toxic and has a low rate of absorption paired with a high rate of metabolism; long term exposure data are unavailable. The majority of adverse effects of TBBPA have been found in vitro, demonstrated by damage to hepatocytes, immunotoxicity in culture, and neurotoxicity in cerebellar granule cells. Disruption of thyroid homeostasis appears to be the primary toxic effect in rodent studies, further adding evidence to the endocrine disruption potential of the BFRs.

HBCD. Toxicity data for HBCD is extremely limited; however, a handful of studies have shown effects on circulating thyroid hormones as well as developmental neurotoxicity following a single neonatal exposure.

► HUMAN EXPOSURE

Environmental sources of TBBPA, HBCD, and PBDEs have not been isolated, but are believed to include leaching from a wide range of final consumer applications (e.g., plastics and foam). These chemicals have all been detected in air, water, soil, and food. Body burdens (blood, adipose, and breast milk) have also been established, indicating that most people have low-level exposures. While it is generally assumed that the major route of exposure for adult humans is through dietary intake, primarily through foods of animal origin, there is increasing evidence that suggests indoor dust and indoor air may also play major roles. Nursing infants are believed to receive the highest daily exposure as breast milk may have relatively high concentrations of these chemicals; a concerning trend since these chemicals appear to be most toxic to developing systems.

► REGULATIONS

Regulations vary among countries; some areas, such as Europe, banned the use of some PBDEs in mid-2004. There are currently no federal regulations in the United States; however, individual states have legislation banning or restricting the use of some of the mixtures. The sole U.S. producer of the PentaBDE and OctaBDE mixtures voluntarily phased out production at the end of 2004. DecaBDE, HBCD, and TBBPA are part of the High Production Volume (HPV) initiative through the International Council of Chemical Associations in which the chemical industry will provide data, hazard assessments, and production information for these chemicals. Up-to-date information on regulatory action can be found on the Bromine Science and Environmental Forum website.³

Multiple Chemical Sensitivities

Mark R. Cullen

► INTRODUCTION

During the 1980s a curious clinical syndrome emerged in occupational and environmental health practice characterized by apparent intolerance to low levels of man-made chemicals and odors. Although still lacking a widely agreed upon definition or necessarily permanent designation,¹ the disorder idiosyncratically occurs in individuals who have experienced a single or recurring episodes of a typical chemical intoxication or injury such as solvent or pesticide poisoning or reaction to poor indoor air quality. Subsequently, an expansive array of divergent environmental contaminants in air, food, or water may elicit a wide range of symptoms at doses far below those which typically produce toxic reactions. Although these symptoms are not associated with objective impairment of the organs to which they are referable, the complaints may be impressive and cause considerable dysfunction and disability for the sufferer.

Although such reactions to chemicals are doubtless not new, there is an unmistakable impression that multiple chemical sensitivities, or MCS as the syndrome is now most frequently called², is occurring and presenting to medical attention far more commonly than in the past. Although no longitudinal data are available, it has become prevalent enough to have attracted its own group of specialists—clinical ecologists or environmental physicians—and substantial public controversy. Unfortunately, despite widespread debate over who should treat patients suffering with the disorder and who should pay for it, research has progressed only modestly in the last two decades. Neither the cause(s), pathogenesis, optimal treatment, nor strategies for prevention have been adequately elucidated.

This sorry state of affairs notwithstanding, MCS is clearly occurring and causing significant morbidity in the workforce and general populations. It is the goal of the sections which follow to describe what has been learned about the disorder in the hope of improving recognition and management in the face of uncertainty and stimulating further constructive scientific engagement of this timely problem.

Definition and Diagnosis

Although, as noted, there has yet to be general consensus on a single definition of MCS, certain features can be described which allow differentiation from other well-characterized entities.² These include:

1. Symptoms appear to begin after the occurrence of a more typical occupational or environmental disease such as an intoxication or chemical insult. This 'initiating' problem may be one episode such as a smoke inhalation, or repeated, as in solvent

intoxication. Often the preceding events are mild and may blur almost imperceptibly into the syndrome which follows.

2. Symptoms, often initially very similar to those of the initiating illness, begin to occur after reexposures to lower levels of the same or related compounds, in environments previously well tolerated, such as the home, stores, etc.
3. Generalization of symptoms occurs such that multiple organ-system complaints are involved. Invariably these include symptoms referable to the central nervous system such as fatigue, confusion, headache, etc.
4. Generalization of precipitants occurs such that low levels of chemically diverse agents become capable of eliciting the responses often at levels orders of magnitude below accepted TLVs or guidelines.
5. Work-up of complaints fails to reveal impairment of organs which would explain the pattern or intensity of complaints.
6. Absence of psychosis or systemic illness which might explain the multiorgan symptoms.

While not every patient will fit this description in its entirety, it is very important to consider each point before "labeling" a patient with MCS or including them in any study population. Each of the criteria serves to rule out other disorders with which MCS may be confused: panic or a related somatization disorder, classic sensitization to environmental antigens (e.g., occupational asthma), pathologic sequelae of organ system damage (e.g., reactive airways dysfunction syndrome after a toxic inhalation), or a masquerading systemic disease (e.g., cancer with paraneoplastic phenomena). On the other hand, it is important to recognize that MCS is not a diagnosis of exclusion nor should exhaustive and therapeutically disruptive (see below) tests be required in most cases. While many variations will be encountered, MCS has a quite unmistakable character which should allow prompt recognition in skilled hands.

In practice the most difficult diagnostic problems with MCS fall into two categories. The first occurs with patients early in their course in whom it is often challenging to separate MCS from the more clear-cut occupational or environmental health problem that usually precedes it. For example, patients who have experienced untoward reactions around organic solvents may find that their reactions are persisting even when they have been removed from high exposure areas or after these exposures have been abated; clinicians may assume that high exposures which could be remedied are still occurring and pay direct attention to that, an admirable but unhelpful error. This is especially troublesome in the office setting where MCS may be seen as a complication of nonspecific building related illness (NSBRI). Whereas the office worker with NSBRI typically responds promptly to steps which improve indoor air quality, a patient who has acquired MCS may continue to experience symptoms despite the far lower exposures involved. Again, attempts to further improve the air quality may be frustrating to patient and employer alike.

*Note: *The term Idiopathic Environmental Intolerance has recently been introduced by some investigators.*

Later in the disorder, confusion often is created by patient reactions to chronic illness. The MCS patient who has been symptomatic for many months is often depressed and anxious as are many medical patients with chronic diseases to which they have not adapted. This may lead to a focus exclusively on psychiatric aspects in which the chemically stimulated symptoms are viewed as a component. Without diminishing the importance of recognizing and treating these complications of MCS nor the evidence that MCS itself has psychological origins, the underlying symptomatic responses to chemical exposures, and the belief system that engenders, must be recognized to facilitate appropriate management. Focusing exclusively on psychological aspects while ignoring the patient's perception of his or her illness is therapeutically counterproductive.

Pathogenesis

The sequence of events which leads in some individuals from a self-limited episode or episodes of occupational or environmental illness to the development of potentially disabling symptomatic responses to very low levels of ubiquitous chemicals is presently unknown. Presently there are several theories which have been offered, including the following:

1. The clinical ecologists and their adherents initially attributed the illness to immune dysfunction caused by excessive cumulative burden of xenobiotic material in susceptible hosts.^{3,4} According to this view, such factors may include relative or absolute nutritional deficiencies (e.g., vitamins, anti-oxidants, essential fatty acids, etc.) or the presence of subclinical infections such as candida or other yeasts, or other life stresses. In this view, the role of the "initiating" illness is important only insofar as it may contribute heavily to this overload.
2. Critics of clinical ecology have invoked a primarily psychological view of the disorder, characterizing it in the spectrum of somatoform illnesses.^{5,6} Variations of this view include the concept that MCS is a variant of classic posttraumatic stress disorder or a conditioned ("nocebo") response to an unpleasant experience. In these views, the initiating illness plays an obviously more central role in the pathogenesis of the disorder. Host factors may also be important, especially the predisposition to somatize.
3. More recently, several theories have emerged which invoke a synthesis of biologic and neuropsychologic mechanisms. Central in these theories is the role of altered chemoreception of odor and irritation stimuli in the nose⁷ resulting in altered CNS responses to otherwise minimally noxious stimuli. A model of sensitization or "kindling" of limbic pathways, analogous to mechanisms postulated to explain drug addictions and other CNS adaptations, has also been proposed.⁸ The rich network of neural connections between the nasal epithelium and the CNS provide an intriguing theoretical basis for these hypotheses.

Unfortunately, despite considerable literature generated on the subject, little compelling clinical or experimental science has been published to conclusively prove any of these views. Limitations of published clinical studies include failure to rigorously define the population on which tests have been performed and problems with identifying appropriately matched groups of referent subjects for comparison. Neither subjects of research nor observers have been blind to subjects' status or research hypotheses. In the end, much of the published data must be characterized as anecdotal.

Problematically still, legitimate debate over the etiologic basis of the disorder has been heavily clouded by dogma. Since major economic decisions may hinge on the terms in which an individual case or cases generally are viewed (e.g., patient benefit entitlements, physician reimbursement acceptance etc.), many patients as well as their physicians may have very strong views of the illness which have inhibited scientific progress as well as patient care. It is essential to an understanding of MCS itself that the above theories are extant and

often well known to patients who often have very strong views themselves. As such MCS differ markedly from other environmentally related disorders like progressive massive fibrosis in miners in which uncertainty about pathogenesis has not interfered with efforts to study the problem or manage its victims.

That notwithstanding, recent reports have shed light on several of these possibilities. Evidence is mounting that the immunologic manifestations earlier reported are spurious; controlled analyses have failed to show consistent patterns of difference in a wide range of immune functions.⁹ While our rapidly expanding knowledge of immunology implies that differences may emerge based on future science, for now this theoretical consideration seems least relevant to MCS pathogenesis. On the other hand, studies of the physiologic and psychophysical responses of nasal epithelium in affected subjects suggest this "organ"—viewed as the upper respiratory epithelia and their neural connections in the CNS—as a more reasonable consideration as the locus of injury or abnormal response. Regarding psychological theories, delineation of the limitations of previous studies,¹⁰ and newer contributions,¹¹ speak to the high likelihood that psychological phenomena are at least involved, if not central to the pathogenesis of MCS.

Epidemiology

Several populational studies have appeared since the last edition, enhancing our knowledge of responses of large populations to low-level chemical exposures and clinical MCS. Kreutzer et al, surveying a representative group of Californians, reports a cross-sectional rate of self-report MCS by almost 6%, many of whom reported being diagnosed for same by a physician.¹² Using a different instrument, Meggs found slightly under 4% claimed to be chemically sensitive in North Carolina.¹³ In a survey of military and reserve personnel from Iowa active during the Persian Gulf Conflict of 1990–91, Black and colleagues reported over 5% of returning veterans met stringent questionnaire criteria for MCS; 2.6% of those Iowan military who did not serve in the war area also met the case definition.¹⁴

Some patterns are apparent from these and other sources.¹⁵ Compared to other occupational disorders, women are affected more than men. MCS appears to occur more commonly in midlife (especially fourth and fifth decades), although no age group appears exempt from risk. While previous clinical reports had suggested that the economically disadvantaged and nonwhites were underrepresented, population-based data suggests that SES is not an important predictor, nor was race/ethnicity. Neither classic allergic manifestations nor any familial factor has proved important to date.

In addition to these demographic features, some insights may be gleaned about the settings in which the illness occurs. Although many develop after nonoccupational exposures, e.g., in cars, homes, etc., several groups of chemicals appear to account overwhelmingly for the majority of initiating events—organic solvents, pesticides, and respiratory irritants. While this may be a function of the broad usage of these materials in our workplaces and general environment, the impression is that they are overrepresented. The other special setting in which many cases occur is in the so-called tight building, victims NSBRI occasionally evolving into classic MCS. Although the two illnesses have a great deal in common, their epidemiologic features readily distinguish them. NSBRI typically affects most individuals sharing a common ("sick") environment and responds characteristically to environmental improvement; MCS occurs in isolation and does not abruptly respond to quantitative modifications of the environment.

A final issue of considerable interest is whether MCS is, in fact, a truly new disorder or whether it has only recently come to attention because of widespread interest in the environment as a source of human disease. Views on this are split, largely along the same lines as opinion regarding the pathogenesis of the disorder. Those who suspect a primarily biologic role for environmental agents, including the clinical ecologists, would argue that MCS is uniquely a twentieth century phenomenon with rapidly rising incidence because of increased

chemical contamination of the environment.¹⁶ Contrarily, those who invoke primarily psychological mechanisms have argued that only the societal context of the disease is in any sense new. According to this view, the social perception of the environment as a hostile agent has resulted in the evolution of new symbolic content to the age-old problem of psychosomatic disease, changing the perception of patient and doctor but not the fundamental disease mechanism.^{17,18}

Natural History

Although MCS has yet to be subjected to careful clinical study sufficient to delineate its course or outcome, anecdotal experience with large numbers of patients has shed some preliminary light on this issue which may be of great importance in appropriate management. Based on this information, the general pattern of illness appears to be one of initial progression as the process of generalization evolves, followed by cyclical periods of ameliorations and exacerbations. While these cycles are generally perceived by the patient to be related to improvement or contamination of his or her environment, the pattern seems to have some life of its own as well, although the basis for it is far from clear.

Once the disorder is established, there is a tendency for more chronic symptoms to supervene as well, with less obvious temporal relationship to exposures. The two most typical patterns are fatigue—many patients meet clinical criteria for chronic fatigue syndrome—and muscle pain, clinically indistinguishable from fibromyalgia in many cases.¹⁹ The overlap among the three disorders, both clinically and epidemiologically, has encouraged the thinking that they may share a common final pathway or even pathogenesis, but this has not been proved.

This disease history has two important ramifications. First, other than during the early stages in which the process initially emerges, there is little evidence to suggest that the disease is in any sense progressive.¹⁵ Patients do not tend to deteriorate from year to year, nor have obvious complications such as infections or organ system failure resulted. There is no evidence of mortality from MCS, although many patients become convinced that progression and death are inevitable based on the profound change in perception of health which the disorder engenders.

While this observation may provide the basis for a sanguine prognosis and reassurance, it has been equally clear from described clinical experience that true remission of symptoms is also rare. While various good outcomes have been described, these are usually premised on improved patient *function* and *sense of well-being*, rather than reduced reactivity to environmental stimuli. The underlying tendency to react adversely to chemical exposures continues, although symptoms may become sufficiently tolerable to allow return to a near-normal lifestyle.

In sum, MCS would appear to be a disorder with well-defined upper and lower bounds in outcome. While neither limit has been confirmed by large well-characterized series, it is probably not premature to include this assumption in planning treatment and assisting in vocational rehabilitation.

Clinical Management

Very little is known about treatment of MCS. A vast array of modalities have been proposed and tried, but none has been subjected to the usual scientific standards to determine efficacy: a controlled clinical trial. As with other aspects, theories of treatment follow closely the theories of pathogenesis. Clinical ecologists, convinced that MCS represents immune dysfunction caused by excessive body burdens of xenobiotics, focus much of their attention on reducing burden by strict avoidance of chemicals; some have advocated extreme steps resulting in complete alterations in patient lifestyle. This approach is often accompanied by efforts to determine “specific” sensitivities by various forms of skin and blood testing—none as yet validated by acceptable standards—and utilizing therapies akin to desensitization with a goal of inducing “tolerance.” Coupled with this are a variety of strategies to bolster underlying immunity with dietary supplementation and other metabolic supports. A most radical approach involves efforts to eliminate toxins from the body by chelation or accelerated turnover of fat (where some toxicants are stored).

Those inclined to a more psychological view of the disorder have explored alternative approaches consistent with their theories. Supportive individual or group therapies and more classic behavioral methods have been described.²⁰ However, as with the more biological theories, the efficacy of these approaches remains anecdotal.

Although none of these modalities is likely to be directly dangerous, limitations to present knowledge would suggest that they would best be reserved for settings in which well-controlled trials are being undertaken. In the meantime, certain treatment principles have emerged which can be justified based on present knowledge and experience. These include:

1. Taking steps to limit to the extent possible the search for the mysterious “cause” of the disease is an important first aspect of treatment. Many patients will have had considerable work-up by the time MCS is considered and will equate, not irrationally, extensive testing with extensive pathology. Uncertainty feeds this cycle as well as the patients’ common underlying fear that they have been irrevocably poisoned.
2. Whatever the theoretical proclivity of the clinician, it is crucial that the existing knowledge and uncertainty about MCS be explained to the patient, including specifically that the cause is unknown. The patient must be reassured that the possibility of a psychological basis does not make the illness less real, less serious, or less worthy of treatment. Reassurance that the disease will not lead inexorably to death, as many patients imagine, is also valuable, coupled with caution that with current knowledge *cure* is an unrealistic treatment objective.
3. Steps to remove the patient from the most obviously offensive aspects of their environment are almost always necessary, especially if the patient still lives or works in the same environment where the initiating illness occurred. While radical avoidance is probably counterproductive given the goal of improving function, protection from daily misery is important for establishing a strong therapeutic relationship which the patient needs. In general, this requires some vocational change which will also require attention to sufficient benefits to make this choice viable for the patient. For cases which occur as a consequence of an occupational illness, however mild, workers’ compensation may be available; most jurisdictions do not require detailed understanding of disease pathogenesis but can be invoked viewing MCS as a complication of a disorder which is accepted by local convention as work related.
4. Having established this foundation of support, subsequent therapy should be targeted at improved function. Obviously psychological problems, like adjustment difficulties, anxiety or depression, should be treated aggressively, as should coexistent pathology like atopic manifestations. Unfortunately, since these patients do not tolerate chemicals readily, nonpharmacologic approaches may be necessary. Beyond these measures, patients need direction, counseling, and reassurance in order to begin the challenging process of adjusting to an illness without established treatment. To the extent consistent with tolerable symptoms, patients should be encouraged to expand the range of their activities and should be discouraged from passivity, dependence, or resignation which intermittently recur throughout the course of the illness. It is worth emphasizing that there are no data to suggest, let alone prove, that intermittent chemical exposures capable of inducing transient symptoms otherwise adversely modify the future course of the illness.
5. Although it is appropriate to provide patients with all available factual information about MCS as well as fairly representing the view of the clinician, it must be recognized that many patients will get desperate and will try available alternative treatment modalities, sometimes several at once or in a sequence. It is probably not reasonable to strongly resist such efforts or to undermine a therapeutic relationship on this account but rather to hold steadily to a single coherent perspective treating such “treatments” as yet another troublesome aspect of a troublesome condition.

Prevention

It goes without saying that primary prevention cannot be seriously considered, given present knowledge of the pathogenesis of the disorder or the host factors which render certain individuals susceptible to it. At this time, the most reasonable approach is to reduce the opportunities in the workplace and ambient environment for the kinds of acute exposures which would appear to precipitate MCS in some hosts, especially solvents and pesticides. Reduction in the proportion of poorly ventilated offices would also appear likely to help.

Secondary prevention would appear to offer some greater control opportunity although no intervention has been studied. On the possibility that psychological factors may play a role in victims of environmental mishaps, careful early management of individuals exposed to toxic substances would seem advisable, even if that exposure was relatively trivial, the prognosis from a biologic perspective is good. For example, patients seen in clinics or emergency rooms after acute exposures should have some exploration of their reactions to the events and should probably receive close follow-up where undue fears of long-term effects or recurrence are expressed. Equally important, efforts must be made on behalf of such patients to ensure that preventable recurrences do not occur since this may be an important pathway leading to MCS by whichever mechanism is truly responsible.

Pulmonary Responses to Gases and Particles

Kaye H. Kilburn

This chapter defines the functional zones of human lung, describes responses to occupationally polluted air, reviews the adverse health effects caused by environmental air pollution, and considers indoor air pollution.

► FUNCTIONAL ZONES OF HUMAN LUNG

The lungs' two regions are the conducting airways and the gas-exchanging alveolar zone. In the former, a mucociliary escalator removes deposited particles. The alveolar zone, which includes alveolarized respiratory bronchioles and alveolar ducts, lacks this ability¹ (Fig. 32-1). The two zones differ greatly in defenses and susceptibility to damage. For example, water-soluble gases such as sulfur dioxide and ammonia adsorb to water in proximal conducting airways, while relatively insoluble ozone and nitrogen dioxide damage the nonmucous-covered alveolar zone (Table 32-1). The airways selectively filter particles. Thus large particles (50 μm in diameter) lodge in the nose or pharynx, but particles less than 10 μm (and usually less than 5 μm) reach the alveolar zone.² Fungal spores with diameters of 17–20 μm affect only proximal conducting airways (Fig. 32-2), while the 1 μm diameter spores of *Micropolyspora faeni* affect alveoli as well (Fig. 32-3). As a first approximation, reactions to particles can be predicted from their size, which is best defined by the mean median diameter, and from solubility in water. The site of lodgment of fibers and fibrils is predicted from aerodynamic diameter, not from length.

► OCCUPATIONAL POLLUTED AIR

Acute Alveolar Reactions

Asphyxiant Gases

Asphyxiant gases, divide into groups (1) represented by carbon dioxide, methane, and fluorocarbons that displace oxygen from alveoli to cause death, and carbon monoxide that combines with hemoglobin more avidly than oxygen and (2) chemical reactive poisons for mitochondrial cytochromes, hydrogen cyanide, hydrogen sulfide, and sodium azide. Their properties, exposure sources, toxicity, and applicable standards for occupational exposure in the United States are listed in Table 32-1. Carbon dioxide stimulates respiration at concentrations less than 10% but depresses it at higher concentrations and is anesthetic and lethal. Hazards occur when people go into poorly ventilated chambers, often underground. For example, carbon dioxide, methane, ammonia, and hydrogen sulfide are generated from manure collected from cattle feeding lots or from sewage and in

wells, pits, silos, holds of ships, or abandoned mine shafts. Workers entering these areas often collapse after a few breaths. Tragically, the first person to attempt rescue often dies of asphyxiation before it is realized that the exposure is lethal.

Arc welding is hazardous in small compartments, since it does not require oxygen but burns organic material with oxygen to produce carbon monoxide; if the space is poorly ventilated, lethal quantities of carbon monoxide accumulate. Methane, as coal damp, is an asphyxiant and an explosion hazard for miners. Community contamination with hydrogen sulfide has occurred from coal seams in Gillette, Wyoming, from evaporative (salt crystallization) chemistry in Trona, California, and from hydrocarbon petroleum refining in Ponca City, Oklahoma, Lovington and Artesia, New Mexico and Nipoma, California. However, the most serious incident of this type was the Bhopal, India, disaster of 1984. Methyl isocyanate (used in manufacturing the insecticide carbaryl (Sevin)) escaped from a 21-ton liquid storage tank, killing more than 2300 people and injuring more than 30,000.

Hydrogen sulfide inhalation has produced nausea, headache, shortness of breath, sleep disturbances, and throat and eye irritation at concentrations of 0.003–11 mg/m^3 during a series of intermittent air pollution episodes. Hydrogen sulfide concentrations of 150 ppm quickly paralyzes the sense of smell, so that victims may be unaware of danger. Instantaneous death has occurred at levels of 1,400 mg/m^3 (1000 ppm) to 17,000 mg/m^3 (12,000 ppm). As the level of hydrogen sulfide increases in the ambient environment, symptoms vary from headache, loss of appetite, burning eyes, and dizziness at low concentrations, to low blood pressure, arm cramps, and unconsciousness at moderate concentrations, to pulmonary edema, coma, and death at higher concentrations. The recommended occupational standard for carbon dioxide is 0.5%, but for carbon monoxide it is 50 ppm for an 8-hour workday, with a single exposure to 200 ppm considered dangerous for chronic as well as acute impairment of the central nervous system (CNS). Since hydrogen sulfide is highly toxic even at low concentrations, the Occupational Safety and Health Administration (OSHA) has not set a time-weighted average for an 8-hour day. Instead, 20 ppm has been set as a maximum 15-minute exposure. New federal regulations are under review.

Oxidant Gases

A potent oxidizing agent, ozone is a bluish pungent gas generated by electrical storms, arcs, and ultraviolet light. Ozone and nitrogen oxides are important in environmental air pollution. At high altitudes, the ozone shield protects the earth against solar radiation. Excess ozone is found aboard high-flying long-distance aircraft, particularly over the North Pole if cabin adsorption is inadequate or absent. Otherwise exposure to

oxidant gases occurs mainly from welding, near generation of electricity, and in the chemical industry (Table 32-1). Nitrogen dioxide has a pungent odor seen in fuming nitric acid, silos containing alfalfa, and manufacture of feeds, fertilizers, and explosions. Although ozone and nitrogen dioxide irritate mucous membranes and the eyes, greater damage is produced in the distal zone of the lung, the respiratory bronchioles, and alveoli ducts. These gases enter alveolar epithelial cells, produce swelling, and secondarily affect the capillary endothelial cells. The thin alveolar membranes are made permeable to plasma fluids and proteins, which leads to pulmonary edema after exposure to large concentrations. Exposure to nitrogen oxides, principally nitrogen dioxide generated in silos by silage, in animal feed processing, and in nitrocellulose film fires in movie theaters, caused subacute necrotizing bronchiolitis in victims who survive acute pulmonary edema. Sulfur dioxide may also cause alveolar edema but is extremely irritating; so unless doses are unbearably high, the nose and upper airways reduce the concentrations reaching alveoli.

Irritant Gases

The irritant gases include fluorine, bromine, and chlorine, hydrochloric acid, hydrogen fluoride, phosgene (and chlorine, which were poison gases used in World War I), sulfur dioxide, ammonia, and dimethyl sulfate. Oxides of vanadium, osmium, cadmium, and platinum as finely divided fumes act like gases. The sources are generally industrial processing, although inadvertent production may occur. In addition, bromine and chlorine are injected to sterilize municipal water supplies, so that large amounts of concentrated gas are transported into and stored in densely populated cities. One desulfurization processes for petroleum uses vanadium pentoxide as a catalyst for hydrogen sulfide, and although portions of this are regenerated, workplace and environmental exposures occur. When liquid ammonia is injected into soil industrial use in making amphetamines or fertilizers, workers may be exposed to large quantities.

Irritant gases in large quantities damage alveolar lining cells and capillary endothelial cells, causing alveolotoxic pulmonary edema; when removal of fluid by lymphatic drainage fails they may also severely damage the epithelial surfaces of airways. Edema fluid moves up into the terminal bronchioles and hence into the conducting airways, to be ascultated as rales.

Recent observations show that the brain is the target of chlorine, hydrochloric acid, ammonia, formaldehyde, and hydrogen sulfide. Sensitive measurements show impaired balance, reaction time, visual fields, verbal recall, problem solving, and decision-making and high frequencies of headache, memory loss, dizziness, and other symptoms.³

Particles

Particles causing alveolar edema include small fungal spores such as *M. faeni*, bacterial endotoxins, and metal fumes (particles), particularly vanadium pentoxide, osmium, platinum, cadmium, and cobalt. Particles of hyph and spores may be generated from vegetable crops used as food, fiber, or forage; as aerosols from sewage or animal fertilizer; or from petroleum desulfurization. Acute inhalation of high concentrations produces pulmonary edema, noted clinically in minutes to hours.

Mixtures

Mixtures created by combustion of fuel, such as diesel exhaust in mines and welding fumes, particularly in compartments with limited ventilation, may reach edemagenic levels of ozone, nitrogen dioxide, formaldehyde, and acrolein. Again, if combustion or arcing takes place in spaces without adequate ventilation, pulmonary edema, or acute airways obstruction is more likely.

Therapy

Physiological therapy of pulmonary edema is oxygen delivered under positive pressure by mask or endotracheal tube that restores oxygen to alveoli blocked by foaming to improve systemic oxygenation. Diuretics and fluid restriction, or adrenal corticosteroids are secondary measures. Speed is crucial. If breathing is impaired or the patient is unconscious, intubation and artificial ventilation are lifesaving.

Control

Personnel must don self-contained breathing apparatus or air supply respirators before entering areas where harmful gases may collect and work in such areas only with adequate provision for air exchange. Would-be rescuers of afflicted individuals should wear an individual air or oxygen supply and be attached to a safety harness by which they can be retrieved safely by fellow workers. Appropriate advice and rules should be posted for personnel and reviewed frequently.

TABLE 32-1. PROPERTIES, SOURCES, AND TOXICITY OF COMMON GASES

Name	Formula	Color and Odor	Health Effects			OSHA [TWA] ^a (ppm)	IDLH ^b (ppm)
			Sources of Exposure	Acute	Chronic		
■ Asphyxiant Gases							
Carbon dioxide	CO ₂	c, ol	M, We, FC	A, H, D, Ch		5000	50,000
Carbon monoxide	CO	c, ol	CS, T, FC	A, H, Cv, Co		50	1500
Methane	CH ₄	c, olf	Ng, D	A

Color and Odor: c, colorless; f, flammable; gy, green, yellow; o, odorless; p, polymerizes; po, pungent; rb, red-brown; re, rotten eggs; so, sweet.

AC, aircrew; Ae, animal excreta; Af, agrifertilizer; CM, chemical manufacture; CS, cigarette smoke; D, dumps; EA, electric arcs; FC, fuel combustion;

M, mining; Ng, natural gas; P, petroleum drilling, refining; S, stratosphere; T, tunnels; W, welding; We, wells.

Health Effects: A, asphyxiant; AO, airways obstruction; AOL, acro-osteolysis; B, burns, skin; Ca, cancer; Ch, cough; Co, coma; Cv, depressed heart rate; D, dizziness; H, headache; L, liver; Mm, mucous membrane irritation; Np, neuropsychological toxin; Pe, pulmonary edema; T, tearing; Tp, tracheal pain.

^aTWA, time-weighted average.

^bIDLH, level of immediate danger to life or health.

Prevention

Opportunities for gas leakage and accumulation should be minimized by industrial hygiene surveillance; the above advice postulates that every effort has been made to reduce leakage and maximize avoidance.

Chronic Alveolar Disease

Extrinsic allergic alveolitis, lipoproteinosis, and granulomatous alveolitis are disorders of the alveolar cells and spaces caused by inhalation of chemically active particles.

Nongranulomatous Alveolitis (Allergic Pneumonitis)

The original description of extrinsic allergic alveolitis, or farmer's lung, implicated inhalation of fungal spores and vegetable material from hay or grain dust,⁴ that recruited cells to alveoli. Some exposed farmers developed shortness of breath. Frequently, they had precipitating serum antibodies to crude preparations of fungi. However, antibodies were also found in asymptomatic farmers. Farmer's lung occurred in areas where animal feeds were stored wet, with the consequent enhanced generation of fungal spores. Classic descriptions came from Northwest England,⁵ Scotland, and the north-central U.S. dairy states.⁶ Both the size of the spores, less than 7 μm to be respirable but less than 3 μm to reach alveoli, and their solubility influence the disorder. Fungal toxins, including endotoxins, are important in the pathogenesis of farmer's lung, and hypersensitivity may be responsible for part of the pathological picture. Whether this is type IV allergy or also type III is not clear. Initial high-dose exposure to spores

frequently produces both airway narrowing and acute pulmonary edema⁷ (Fig. 32-3) requiring hospitalization and oxygen therapy. After repeated exposure and development of precipitating antibodies, many cells may be recruited into alveoli. This pneumonitis can be lethal with repeated heavy exposure. Or the reaction may clear completely during absence from exposure. Adrenal corticosteroids frequently help resolve the acute phase but do not affect the chronic fibrotic stage.

Molds and Mycotoxin

Previously mold and mycotoxin disease occurred at work but infantile hemosiderosis was linked to be a mold, *Stachybotrys chartarum*, growing on Cleveland homes with excess humidity in the 1990s (CDC 1994, CDC 1997, Etzel 1998, Dearborn 2002). A decade later, mold disease of adults and children appears nationwide with greatest prevalence in a swath across the deep south from Florida and Texas to Arizona and California (Kilburn 2003). Patients developed headaches, fatigue, memory loss, impaired concentration, dizziness, and deficient balance together with flulike nasal and pulmonary congestion and phlegm tinged with blood. They saw black mold growing on walls, floors, and ceiling, smells were musty and they felt better away from home. An infant mouse model replicated findings in human infants (Yiki et al 2001.) Numerous school rooms were affected and teachers and children sickened. Mold growth was seen on lift samples and confirmed by culture. Indoor air samples showed more colony-forming units than did outdoor air samples. Molds included *Stachybotrys chartarum* or *atra*, *Aspergillus-penicillin*, *Cladosporium*, and other genera. Patients had serum antibodies to molds and mycotoxins particularly trichothecenes

Figure 32-2. Effects of exposure to thermophiles.

and satratoxins but not aflatoxin, but neither patterns nor titers distinguish affected patients from asymptomatic control subjects. For a general source see Straus 2004. Neurobehavioral testing found impaired balance, slowed reaction time, decreased strength, excess errors distinguishing colors and visual field defects. Hearing and blink reflex latency were usually not affected. Verbal recall for stories, cognition for problem solving and multitasking, and perceptual motor function were frequently impaired as was the ability to see missing items in pictures (Kilburn 2003). The abnormalities resembled those produced by exposures to hydrogen sulfide, chlorpyrifos,⁸ and chlorine.⁹

Berylliosis

Beryllium, a dense, corrosion-resistant metal, produces fulminant chemical pneumonia when inhaled as a soluble salt in large doses. Inhalation of fumes or fine particles leads to chronic granulomatous alveolitis. Originally beryllium disease was interpreted as an accelerated sarcoidosis.¹⁰ First recognized in workers making phosphores for fluorescent lamps, berylliosis is recognized pathologically by noncaseating granuloma with giant cells and the absence of necrosis. Specific helper-inducer T cells accumulate in the lung, identifying berylliosis as a hypersensitivity disease.¹¹ Insidious shortness of breath was accompanied by characteristic x-ray changes, which led to hospitalization in a tuberculosis sanitarium. Patients with accelerated sarcoidosis were brought to the attention of Dr Harriet Hardy, who isolated beryllium as the cause from 42 materials used by the original workers.¹⁰ Subsequently, the problem was recognized in workers from other fluorescent light and electrical factories that used beryllium nitrate phosphores. Some patients with advanced disease died. Those with less advanced berylliosis gradually improved but had residual interstitial fibrosis.¹² Because beryllium is irreplaceable in nuclear reactors and in exotic alloys for spacecraft, exposure to beryllium fumes continues for engineers and skilled workers.

Lipoproteinosis

In this disorder, alveolar spaces are filled with neutral lipids resembling pulmonary surfactant and its apoproteins.¹³ Inorganic particles and *Mycobacterium tuberculosis* have been causally associated.¹⁴ Thus areas of lipoproteinosis are frequently found in lung biopsies or in lungs at autopsy from workers exposed to silica¹⁵ and to many other particles. Diagnosis is made by sampling alveolar fluids by mini-bronchial lavage through the fiberoptic bronchoscope or by lung biopsy. Treatment is removal by lung lavage.

Both granulomatous and nongranulomatous alveolitis occur from inhaling moldy plant debris. Animal experiments suggest that granulomas may be due to poorly digestible complex chitins, which are complex carbohydrates forming the walls of spores and of plant cells.¹⁶ Chronic farmer's lung may produce lipoproteinosis¹⁷ and pulmonary fibrosis.

Fibrosis

Chronic interstitial fibrosis occurs after exposure to hard metal (tungsten carbide), silicon carbide, rare earths, copper (as sulfate in vineyard sprayer's lung), aluminum, beryllium, and cadmium may follow a granulomatous sarcoidlike response. Aluminum has been associated with fibrosis in workers making powdered aluminum for paints,¹⁸ but is infrequent and must be differentiated radiographically or by lung biopsy from asbestosis and silicosis.

Powdered tungsten and carbon are fluxed with cobalt to make hard metal. Animals exposed to cobalt alone show the lesions seen in workers,¹⁹ of proliferation of alveolar and airway cells.²⁰ Similar to berylliosis, removing the worker from exposure leads to prompt improvement; reexposure causes exacerbation. Its similarity to farmer's lung or alveolar lipoproteinosis suggests that lung lavage may be helpful. Adrenal corticosteroids help reverse the airways obstruction. Cadmium is unusual in producing both pulmonary edema (acute respiratory distress syndrome), particularly when fumes are generated from silver (cadmium) soldering and pulmonary fibrosis, which is fine and non-nodular in cadmium refinery workers.²¹ Because of the frequency of asbestos exposure and asbestosis among metal smelting and refinery workers,²² caution is advised in attributing pulmonary fibrosis to cadmium alone. Nodular infiltrates resembling those of berylliosis, hard metal disease, and silicosis have been reported among dental technicians and workers machining alloys of exotic metals. Because these illnesses occur infrequently among exposed workers (e.g., only 12.8% of 425 workers exposed to hard metal had radiographic evidence of disease),²³ individual immune response or susceptibility factors appear to be important.

Asthma, Acute Airway Reactivity

Acute airway narrowing, or asthma, is defined by shortness of breath or impaired breathing usually accompanied by wheezing that is relieved spontaneously or with therapy. Its spectrum includes acute responses that develop within a few minutes of exposure in a sensitized individual and those needing several hours of exposure to reach their peak, as with cotton dust.²⁴ Asthma is the fastest growing lung disease of the twenty-first century. Although the causes are not agreed upon, chemical exposures are important at work and at home. It is estimated that asthma increased by 60% in the 1980s.²⁵ Asthma currently affects 5–10% of children in the United States and 5–10% of adults.²⁶ African Americans are three times more likely to die of asthma than are whites.²⁵ They are also frequent victims of environmental inequality, meaning living in chemical "soups." Asthma is a disease of increasing mortality in the United States and across the world, particularly in developed countries such as Sweden, Denmark, and New Zealand.

Figure 32-3. Effects of exposure to pigeon proteins.

In 1979, the mortality in the United States was 1.2 per 100,000 and it had risen to 1.5 in 1983–1984.²⁷ In African Americans, the corresponding figures were 1.8 in 1979 and 2.5 in 1984. Possible causes of this startling increase in asthma were not identified nor reasons why this disease became epidemic. Many authors²⁵ have elaborated on the mechanisms, in a sea of multiple and complex causes. Air pollution and the synthetic chemical triggers for asthma have increased manyfold in the past 50 years, while buildings and homes have become tighter containers for them. The prevention of asthma, which is the most effective control measure, depends on reducing exposures to ambient air pollution and other chemical causes.^{28,29}

Because the processing of cereal grains and flour maximizes opportunities for exposure, farmers, grain handlers, millers, and bakers probably constitute the largest worldwide group with reactive airways disease.^{30,31} Fortunately, exposures that produce the highest prevalence of airways reactivity, as to diisocyanates and cotton dust, have been controlled in the United States or use reduced.³² An estimated 8 million workers in the world are exposed to welding gases and fumes. Such exposure produces symptoms but practically no acute airway response and relatively mild impairment of function. This is detectable 10 or 11 years after beginning of exposure and is greater in cigarette smokers.³³

Diagnosis

Acute or reactive airway response is recognized by an increased resistance to expiratory flow by contraction of smooth muscle or swelling in airway walls causing tightness in the chest, shortness of breath, and wheezing, quickly or insidiously. Nonproductive cough is frequent, but as mucus secretion is stimulated, the cough becomes productive. Generalized wheezing is heard low and posterior as the lung empties during forced expiration. Alternatively, scattered localized wheezing may be heard. The lungs' appearance on chest x-ray film is usually normal with abnormalities seen only from preexisting disease. Occasionally, severe hyperinflation causes increased radiolucency and low and flattened diaphragms, suggesting emphysema. A second exception is accentuated venous markings and a prominent minor lung fissure, suggesting pulmonary edema. Symptoms occur within a few hours of beginning work, are more frequent on Monday or the first day back after a holiday, and gradually increase during the work shift.²⁴ The diagnosis is confirmed by finding decreased expiratory flow when comparing measurements at the middle or end of the shift with those made before entry to the workplace. Cross-shift decrements at work are optimal but a laboratory exposure challenge may be substituted^{4,7} with workers' exposure long enough to simulate the workplace.

Mechanisms

Acute airway responses may be nociceptive, inflammatory, or immune. The reactive segment of a workforce includes but is not limited to atopic individuals, those with IgE antibodies. In the instance of toluene diisocyanate (TDI), which has been well studied, reactivity to low doses does not appear to correlate with atopic status.³⁴ Etiologies of many workplace exposures are imperfectly understood because flour and dusts from cotton, grain, coal, and in foundries are complex mixtures. Single agent-specific causes include metal fumes from zinc, copper, magnesium, aluminum, osmium, and platinum, endotoxins from Gram-negative bacteria and possibly fungal toxins. Many organic, naturally occurring food, fodder, and fiber plant products contain endotoxin. Concentrations increase with senescence of plants and thus are maximal at harvest time, as with cotton and for rye after frost.

Causal Agents

To cover comprehensively, the occupational exposures of importance is an encyclopedic job. However, Table 32-2 provides an index of the categories of materials and types of reactions that depended on patient reports and descriptive epidemiology. Causative agents are logically grouped so the reader can add new materials and reactions to them. Such reports have been published infrequently in the last decade.

Control, Surveillance, and Prevention

The first principle of control and prevention is to reduce exposure for all workers by improved industrial hygiene. This controlled byssinosis (cotton dust disease) in the United States. Since 1973, as dust was reduced in cotton textile mills so that after 15 years there was debate on whether byssinosis had existed. In contrast, it continues to be a problem in the waste cotton industry³⁵ and in developing countries³⁶ lacking adequate engineering controls. The second principle of control and prevention is to remove reactive individuals from exposure. Reactivity is judged from symptoms or objectively from impaired function after challenge. Often individuals who react sharply to inhaled agents select themselves out of work. Because removing impaired workers from cotton textile mills did not improve their function, at least in the short term, byssinosis needs longitudinal surveillance added to the acute shift exposure so that workers with accelerated functional deterioration in 6 or 12 months are removed from exposure before they have suffered impairment that interferes with their ability to work. Annual and semiannual surveillance by pulmonary function testing was mandated by the cotton dust standards invoked in 1978³⁷ under the 1970 amendments to the Occupational Health and Safety Act (OSHA).

Chronic Airway Disease: Chronic Bronchitis

Definition

Chronic bronchitis is defined by the presence of phlegm or sputum production for more than 3 months of 2 succeeding years. Chronic bronchitis is the most common respiratory disease in the world.³⁸

Effects of Cigarette Smoking

The prevalence of chronic bronchitis is mainly due to smoking cigarettes, a plague of the twentieth century after World War I. Although the habit is on the wane in the United States, it is entrenched in Europe and has taken developing nations by storm, where the peak prevalence of cigarette smoking may not yet have been reached. Certainly there is no evidence that *not smoking* has become the accepted social behavior, as it has in the United States. Chronic bronchitis has such a high prevalence in blue collar cigarette smokers, particularly 20 years or more after they start smoking, that it often takes careful analysis to uncover occupational chronic bronchitis.³⁹

Occupational effects are best assessed by studying large populations of individuals who have never smoked.⁴⁰ Alternately, effects of cigarette smoking and occupational exposure can be partitioned by adjusting predicted function values for expiratory flows for duration of smoking using standard regression coefficients.⁴¹ Similarly, accelerated functional deterioration or increased prevalence of symptoms across years of occupational exposure after adjusting for the cumulative effects of smoking may show the effects of occupational exposure. Considering the additive effects of cigarette smoking to occupational dusts and fumes and atmospheric air pollution, a decrement in forced expiratory volume in one second (FEV₁) exceeding 21–25 mL/year in a person who has never smoked, is excessive. Cigarette smoking alone in men increases the age-associated decrement 40% or 9 mL/year.⁴¹ Women show no such effect, probably because they smoke fewer cigarettes daily but still show increased lung cancers. In groups of men, who smoke decrements in FEV₁ of more than 30 mL/year suggest occupational or environmental exposures. Airborne particle burdens increase age-related decrements.

Occupational Exposures

Occupational exposure to many dusts including those containing silica, coal, asbestos, and cotton (including flax and hemp) dust, and exposures during coking, foundry work, welding, and papermaking increase the prevalence or lower the age of appearance of chronic bronchitis. Although it is clear that high exposures to silica and to asbestos produce characteristic pneumoconiosis, lower doses cause airways obstruction. Symptoms and airways obstruction from cotton and other

vegetable dusts have been well studied for more than a century.⁴² In the 1960s studies in British textile mills (using American-grown cotton), the severity of this Monday-morning asthma (byssinosis) and of shortness of breath and tightness in the chest correlated with concentrations of respirable cotton dust in workplace air.⁴³ Similarly, exposure to welding gases and fumes accelerates reductions in expiratory flows.³³ Shipbuilding, construction, and coal mining associated with asbestosis and to a lesser extent with silicosis, are also strongly correlated with

chronic bronchitis.^{44,45} The common thread is inhalation of respirable particles with inflammation stimulated by one or more chemically active species contained or absorbed and work in foundries.⁴⁶ Clinical signs are cough with mucus coming from goblet cell hyperplasia in small airways and to hyperplasia of mucous glands in large bronchi and exertional dyspnea due to small airways obstruction.⁴⁷

Although inhalation of 200–400 ppm of sulfur dioxide by rats or guinea pigs models chronic bronchitis, these levels exceed, by two

orders of magnitude for workers in smelting or metal roasting operations or by three orders of magnitudes for most ambient air pollution exposures. The important difference is that human exposures include quantities of respirable particles. Similarly, exposure to chlorine, fluorine, bromine, phosgene, and vapors of hydrogen fluoride and hydrogen chloride produce bronchitic reactions. Discontinuous pulses of damage produce cycles of injury and repair rather than chronic bronchitis.

Gases are adsorbed on particles in many occupational exposures, such as welding, metal roasting, smelting operations, and foundries especially where compressed air jets are used for cleaning. Gas molecules adsorbed on particles deposit in small airways.² This deposition is studied in animal models with gases and pure carbon. Carbon, by itself an innocuous particle, adsorbs gas molecules and in the lining creates a nidus of damage because the particle is difficult to remove and the adsorbed gas molecules leach into cells.⁴⁸ Perhaps the best examples are the adsorption of ozone, nitrogen dioxide, and hydrocarbons on respirable particles⁴⁰ in Los Angeles, Mexico City, Athens, and other cities^{28,29} where large amounts of fossil fuel are combusted with limited atmospheric exchanges because of mountains, prevailing winds, and weather conditions.

The prevalence of occupational chronic bronchitis has declined in the postindustrial era in the United States, Great Britain, and Northern Europe. Byssinosis and chronic bronchitis from cotton dust have been on the wane since the early 1970s.^{49,50} A similar decline in prevalence in workers in foundries, coke ovens, welding, and other dusty trades is attributed to improved air hygiene often dictated by economic or processing imperatives.⁴⁴⁻⁴⁶ Workers in Eastern Europe, China, India, Southeast Asia, and South America are now plagued by these “solved” problems.

Natural History

The natural history of chronic bronchitis in urban dwellers has been investigated since the early nineteenth century.^{51,52} Chronic inhalation of polluted air stimulates mucus production, cough with phlegm, which define chronic bronchitis epidemiologically.⁵³ Chronic bronchitis identified by cough and sputum was studied in more than 1,000 English civil servants and transport workers over a decade.^{53,54} Approximately the same proportion were symptomatic at the end of the decade as at its beginning, although some individuals had left and others had entered the symptomatic group over the interval.⁵⁴

Chronic bronchitis prevalence increases with age in both females and males. The male predominance may be entirely due to cigarette smoking. The latent period before deterioration of expiratory airflow may be long if chronic bronchitis begins in childhood or early adulthood but short if it begins in late middle age.^{53,54}

Chronic bronchitis may begin with an abrupt onset of bronchitis, unassociated with cigarette smoking or occupational exposure.⁵⁵ More common in women, preceded by a viral or chemical respiratory illness and more likely to respond to treatment with broad-spectrum antibiotics. Afterward there is chronic phlegm production and more rapid than expected airflow limitation with deterioration of pulmonary function. When shortness of breath accompanies the cardinal symptoms, airflow limitation is generally present, and the yearly decrements in function are usually twice as large as predicted. For many individuals who smoke and have had an insidious onset of shortness of breath, expiratory airflow declines more steeply after age 50.⁵⁴

Epidemiology

Since the early 1960s, atmospheric air pollution has been recognized as an important cause of chronic bronchitis.⁵⁶ Studies in London⁵⁴ Groningen, The Netherlands,⁵⁷ Cracow, Poland,⁵⁸ firmly established that episodic severe pollution increased mortality and that chronic levels of atmospheric air pollution were associated with increased prevalence and morbidity from chronic bronchitis. Mortality from asthma and chronic bronchitis fell in Japan when sulfur dioxide air pollution decreased.⁵⁹ In 1986, restudy of Italian schoolchildren showed that previously reduced expiratory flows rose to levels of controls when air pollution decreased.⁶⁰

Control Measures

Control measures for chronic bronchitis depend on avoiding exposure—to cigarette smoke, to contaminated respirable particles in coal mines, smelters, and foundries, and to worldwide air pollution from fossil fuel combustion. Poverty often associates with more asthma and chronic bronchitis and residence in cities, near freeways and fuel building. As the standard of living rises, the prevalence of chronic bronchitis falls.²⁸ Control ultimately depends on improving the population's general health and curtailing its exposure to respirable particles.

Surveillance

Effects of a personal, occupational, or atmospheric air pollution control program are best assessed by surveying symptoms and pulmonary functional performance of samples of the affected population. Most essential data—the prevalence of chronic bronchitis and measurement of expiratory airflow—are easily obtained and can be appraised frequently. Decreasing exposure reduces the prevalence of cough and phlegm and the rate of deterioration of expiratory airflow.

Prevention

The prevention of chronic bronchitis essentially centers on avoiding generation of respirable particles into the human air supply. Cigarette smoking cannot be condoned. Air filtration helps but enclosing particle generation away from human noses, as in cotton textile mills is best. Socioeconomic measures include cleaner combustion of fossil fuels, reduction of human crowding, provisions for central heating, and improved standard of living.

Neoplastic Disease of Airways

Lung cancer from occupational exposure to uranium (radon), asbestos, chromate pigments, and arsenic was described before the worldwide epidemic of lung cancer from cigarette smoking. Unfortunately, early reports often failed to mention cigarette smoking, delaying secure attribution of cause until the study of large numbers of individuals who had never smoked. The causal linkage of asbestos to lung cancer without smoking is firm. The histological types including adenocarcinoma, squamous cell, undifferentiated and small-cell or oat-cell carcinoma are the same as seen in the general population. One sentinel disorder is small-cell carcinoma, after exposure to chloromethyl ethers.

The association of lung cancer with exposure to polycyclic aromatic hydrocarbons in coke oven workers and roofers is established and follows Percival Pott's attribution of the scrotal skin cancers in chimney sweeps to coal tar in London, over 200 years ago. Similarly, the occupational exposures to radon, radium, and uranium in mining and metalworking cause lung cancers. A recent example is uranium-mining Navajo Indians on the Colorado Plateau, who, despite a low prevalence of smoking and a low consumption of cigarettes among those who smoked, had a tenfold increase (observed over expected) in lung cancer.⁶¹ Sentinel nasal sinus cancers and excessive lung cancers have resulted from exposure to the nickel refining in calcination of impure nickel and copper sulfide to nickel oxide or in the carbonyl process.⁶²

Lung cancer may be caused by other exposures to nickel, to chromium, and to arsenic, but the data are less convincing than for asbestos and radon.⁶³ In recent studies of copper smelter workers and aluminum refinery workers, it may be asbestosis which had a prevalence between 8% and 25% using the International Labor Organization (ILO) criteria for x-ray diagnosis.²²

The factor common to higher pulmonary disease prevalence and lung cancer mortality among metal smelter workers was asbestos used for heat insulation; for patching of calciners, retorts, and roasters; and for heat protection for personnel. The contribution of asbestos must be taken into account before attributing cancer or irregular opacities in the lung to the useful metals.

► ENVIRONMENTAL AIR POLLUTION

History

The famous fogs along the Thames in the City of London chronicled by Sir Arthur Conan Doyle in the Sherlock Holmes stories 100 years ago underscored a problem from the beginning of the Industrial Revolution with John Evelyn's description in 1621. Death from such exposure ambient air pollution were first recognized in the Meuse Valley of Belgium during a thermal inversion in December 1930.⁵⁶ Sixty people died. In Donora, Pennsylvania, a town of about 14,000 people along the Monongahela River with steel mills, coke ovens, a zinc production plant, and a chemical plant manufacturing sulfuric acid, a continuous temperature inversion created a particularly malignant fog that caused many illnesses and 20 deaths in October 1948. Deaths occurred from the third day. In December 1952, a particularly vicious episode in London produced excessive deaths in infants, young children, and elderly persons with cardiorespiratory disease. High particle loads were 4.5 mg/m³ for smoke and 3.75 mg/m³ for sulfur dioxide. A 1953 episode in New York City underscored this twentieth century plague. Repeated in Tokyo, Yokohama, New Orleans, and Los Angeles they led to investigation of the health effects of environmental air pollution in the 1960s and early 1970s.

Air pollution swept across the Northern Hemisphere between November 27 and December 10, 1962. Excessive respiratory symptoms were observed in Washington, D.C., New York City, Cincinnati, and Philadelphia. London had 700 excess deaths due to high sulfur dioxide levels, and in Rotterdam, sickness, absenteeism, and increased hospital admissions occurred, with a fivefold increase in sulfur oxides. Hamburg, West Germany, reported increased sulfur dioxide and dust and increased heart disease mortality. In Osaka, 60 excess deaths were linked to high pollution levels.

Currently, several cities stand out. Mexico City, the world's capitol of air pollution, with extreme levels of pollution at an altitude of 7,000 feet is an enclosed valley with over 25 million people. Athens, located like Los Angeles with a mountain backdrop to prevailing westerly winds, has experienced such serious pollution as to jeopardize some of its monuments of antiquity. Adverse health effects from air pollution have been observed in São Paulo and Cubatao, Brazil, which have many diesel vehicles, a heavy petrochemical industry, and fertilizer plants. Brazil is experimenting with ethyl alcohol as fuel for internal combustion engines. As more countries industrialize and automobilize, the lessons of Donora, London, and New York are ignored in Bangkok and Beijing.

Sources

The major source of air pollution is fossil fuel combustion.⁶³ During this century, automotive gasoline-based transportation has become the predominant contributor, with a shift from coal for space heating and industrial production. In fact, the internal combustion automobile engine is the major source of both particles and gases, including hydrocarbons. The interaction of atmospheric gases with hydrocarbons under sunlight (photocatalysis) produces ozone and nitrogen dioxide. Adding these to the direct products of combustion in air produces the irritating acrid smog, coined for the mixture of smoke and fog. Thus, the horizon of many cities shows a burnished copper glow from nitrogen oxides. The smog in Los Angeles has remained practically static for 30 years; efforts to ameliorate the problem have simply kept pace with the additional population and its motor vehicle exhaust.^{64,65} Now Bakersfield, Fresno, and Riverside have more bad air days than does Los Angeles.

In certain areas, such as the Northeastern United States, industrial processing, coking, steel production, as well as paper mills and oil refineries contribute their selective and somewhat specific flavor to the problem.⁶⁶ As in occupational exposures, the particles are of respirable size and adsorb gases. Fly ash, from the combustion of coal in power stations, from space heating, and in industry consists of fused glass spheres with adsorbed metals and acidic gases.⁶⁷ Adsorbed chemicals increase particle toxicity and their size determines the

zones injured in the lung.⁶⁸ Hypertension, coronary artery occlusive disease, and myocardial infarction all link to nanoparticles of fly ash in the air.⁶⁷⁻⁶⁹ From inflammation in the lungs, nanoparticles effects⁷⁰ spread to arteries and arterioles causing hypertension. The role of inflammation due to particle burdens on coronary artery disease worldwide has been developed in the past decade.⁷¹ Even children cancer rates, climbing in developed countries have climbed since 1970 throughout Europe.⁷² More childhood cancers were correlated with Chernobyl. Air pollution is also linked to genetic alterations in infants in New York.⁷³

Waste incineration has increased the burden in the air, and greater population has nearly exhausted available canyons and open spaces for landfills for garbage around major cities. Although it appears that selective incineration under properly controlled conditions may help solve the solid waste problem, it increases the burden of particles and gases in the atmosphere unless carefully controlled.⁷⁴ Moreover, nature may be responsible for freak episodes of air pollution. In 1986, release of carbon dioxide from Lake Nyos in West Africa killed 1700 people as they slept, and already the lake may be partly recharged.⁷⁵

Regulated Pollutants

Since 1970 in the United States, carbon monoxide, hydrocarbons, sulfur dioxide, nitrogen oxides, and ozone have been regulated by the Environmental Protection Agency (EPA). In various urban areas, ozone and oxidant concentrations have been defined above which occupants are alerted to limit physical activity. Although the respirable particles, particularly flyash, hydrocarbons, and coated carbon particles from diesel engines, are the principal components of visible pollution, recently considerable attention has focused on acids and chlorofluorocarbons.⁷⁶

Chlorofluorocarbons manufactured as refrigerants and used to power "convenience" aerosols liberate chlorine into the stratosphere, where it combines with ozone to reduce the shield against ultraviolet radiation.^{76,77} The combination of loss of the ozone shield and carbon dioxide from increased combustion of fuel and destruction of tropical rain forests, among other causes, has raised atmospheric carbon dioxide, leading to global warming, the so-called greenhouse effect.^{77,78} This constitutes an entirely different but potentially very serious complication of environmental air pollution. Northern Europeans, particularly in Sweden, Norway, and the city of Cologne, West Germany, have been greatly concerned with the problem of acid rain, which is precipitation of large amounts of acidic gases combined with water.⁷⁹ The acidity of these solutions has etched limestone buildings and acidified lakes and reservoirs, killing aquatic life and changing natural habitats. Ozone loss (which increases the risk of skin cancer),⁸⁰ acid rain, and global warming are likely to produce future human health problems.

Modifiers

The effects of particles and gases in the atmosphere are lessened by wind and rain dilution and made worse by thermal inversion. Studies in Tokyo showed that the heat worked with ozone to produce respiratory symptoms in schoolchildren.^{28,29,69} Unpremeditated experiments show that stopping automotive transportation in a city such as New York, for a day or two, ameliorates problems from rising levels of air pollutants. Thus it appears obvious that a clean transportation in urban areas would greatly reduce air pollution. Because combustion of diesel fuel and gasoline in automobiles and trucks is the major problem, designing cleaner engines and fuels are essential to improving air quality.⁸¹ Alternate fuels emphasizing methanol and ethanol alone or mixed with gasoline may be important and are included in the EPA plans for clearer air for the United States in this decade. Prudence is essential. One additive methyl-*n*-butyl ether increased respiratory illnesses in winter and asthma and ruined some engines. Organified manganese MMT has also caused human toxicity. Almost 20 years of retrofit (regressive) engineering, the installation of catalytic converters, has been less satisfactory. Although they have kept air pollution from increasing in Los Angeles, it is unclear whether this technology would help in Mexico City, Athens, or São Paulo.

Effects

Toxicity is determined by particle size, adsorption, and respiratory deposition profiles.⁸² Respirable particles are those capable of depositing beyond the ciliated conducting airways of the human lung.^{1,2} Air pollution causes symptoms, impaired pulmonary function, respiratory diseases, and mortality. Acute symptoms, including eye irritation, nasal congestion, and chest tightness, appear to be due to the oxidant gases, aldehydes, and hydrocarbons largely in the gaseous phase, including peroxyacetyl nitrate.⁸³ In the most sensitive 7–10% of the population, exposure to these gases decreases expiratory air flow, with wheezing and cough. Symptoms increase with exercise and are usually relieved within a few hours of removal from exposure.

Large studies of European populations exposed to air pollution have shown that airways obstruction varied on days of greater or lesser levels of sulfur dioxide and particles.^{57,60} However, the question of reversibility is unanswered. Whether, or how quickly, airflow limitation is relieved by removal from exposure has not been tested. Meanwhile, to assume that the effects resemble those of cigarette smoking with irreversible airways obstruction, it is justified.

The prevalence of chronic bronchitis in the exposed population is one of the most reliable indicators of exposure to the gases and particles of atmospheric air pollution.⁸³ A number of classic studies—Grottingen, The Netherlands; Cracow, Poland; London; Tokyo; and Los Angeles—have shown that prevalence of chronic bronchitis rises with the level and duration of air pollution.⁸⁴ This is best studied in individuals who have never smoked and in children. The production of excess mucus, to necessitate coughing for its removal, appears to be essentially a protective mechanism for the respiratory tract. Both clinical and experimental data show goblet cell metaplasia in small airways⁴⁷ and goblet cell and mucous gland hyperplasia in large conducting airways. This latter finding is the consistent pathological accompaniment of chronic bronchitis in autopsies from exposed populations.⁸⁵

Deaths from the air pollution disasters, and from current levels of air pollution, struck infants who died of pneumonia and adults with cardiorespiratory disease, particularly chronic bronchitis and emphysema. Recent genetic effects on newborns⁷³ and excess cancer rates in children extend this range.⁷² Those with precarious respiratory function are highly susceptible to additional insult and by analogy constitute, in the picturesque lumberjack terms, “standing dead timber,” susceptible to the “strong wind” provided by a prolonged period of increased air pollution.

Other results of severe air pollution include the retardation of children’s mental development from airborne lead,⁸⁶ which constituted the principal reason for first reducing lead tetraethyl and similar additives and finally removing them from gasoline and motor fuel in the United States during the 1970s. The clear inverse relationship between lead and population intelligence is being verified again in Mexico City.⁸⁷ Myocardial infarction from acute coronary artery occlusion is a twentieth century epidemic disease^{76,88} that reached a first zenith in the 1960s when with lung cancer deaths were linked to cigarette smoking.⁸⁸ Unfortunately in the United States, cigarette smoking has fallen but myocardial infarction rates continue to climb. Fine particles, nanoparticles from air pollution fossil fuel combustion, acute inflammation in arterioles and arterioles that is the nidus for inflammatory cells and followed plaque formation, cholesterol deposit, rupture, and occlusion.^{69–71,88}

► INDOOR AIR POLLUTION

Living Agents

Illness and excessive symptoms from indoor exposures to sick buildings have increased rapidly in a generation. Illness associated with exposure indoors has been observed repeatedly^{89,90} and reviewed at length.^{91,92} Sometimes as in Pontiac, Michigan, investigations into bacterial and fungal contamination had fruitful results. For example, legionnaire’s disease was discovered from an investigation of

illnesses occurring at a convention of the American Legion at the Bellvue Stratford Hotel in Philadelphia. Its etiology was a bacterium since named *Legionella pneumophila*.⁹³ Episodes of the tight building syndrome became more frequent after the energy crisis of 1973 but many investigations failed to find a bacterial or fungal source so the search turned to chemical contamination.

Sources of Chemicals

Indoor air receives gases, vapors, and some particles generated by the activities therein (Table 32-3). Their concentrations reflect the amounts generated or released in the volume, the number of air exchanges, and the purity of makeup air. Thus, human effluents, chiefly carbon dioxide and mercaptans, combine with combustion products of space heating and cooking, cigarette smoke, and contributions from air-conditioning systems. Added to these are outgassing of building construction, adhesive, and decorating materials to make a potent witches’ brew. If the building has sufficient of air exchanges, the concentration gradient may be reversed and the building atmosphere made hospitable. On the other hand, reducing the air exchanges to conserve heat or cold can build up noxious odors, vapors, and gases. Location of air intakes, types of filtration, and refrigeration and heating systems may all decrease the quality of indoor air and increase volatile organic chemicals (VOCs). New evidence shows that pesticides such as chlordane and organophosphates such as chlorpyrifos sprayed indoors in xylene water, can cause excessive neurobehavioral symptoms and measurable brain injury.³

A causal analysis of personal factors and indoor air quality in Sweden found that total hydrocarbon concentrations plus smoking, psychosocial factors, and static electricity were significantly correlated with eye, skin, and upper airway irritation, headache, and fatigue.⁹⁴ Hyperactivity, as well as sick leave due to airway diseases, were important chronic effects in this study but atopy, age, and sex were not correlated with symptoms. The studies were extended to 129 teaching and maintenance personnel of six primary schools in Uppsala,⁹⁴ a Swedish city 50 km from Stockholm. All buildings had elevated carbon dioxide levels of more than 800 ppm, indicating a poor air supply. Mean indoor VOCs ranged from 70 $\mu\text{g}/\text{m}^3$ to 180 $\mu\text{g}/\text{m}^3$. Arithmetic mean was 130 $\mu\text{g}/\text{m}^3$, aromatics mean was 39 $\mu\text{g}/\text{m}^3$, while formaldehyde was below the detection limit of 10 $\mu\text{g}/\text{m}^3$. Chronic sick building symptoms were not related to carbon dioxide levels, but instead were correlated with VOCs, as well as to wall-to-wall carpeting, hyperactivity, and psychosocial factors.

Formaldehyde. Because many building materials are bonded with formaldehyde phenol resins, formaldehyde which also is a constituent of cigarette smoke and permanent press fabrics, has been consistently found in indoor air,⁹⁵ and most studies find it a major contaminant. Thus, prohibition of smoking indoors makes air safer as well as more pleasant. Cooking with natural gas generates nitrogen oxides that rival formaldehyde in their capacity to irritate.

Asbestos. During the late 1970s and early 1980s, concern for release of asbestos from construction materials into indoor air stimulated measurement of fiber levels.⁹⁶ Generally, these have been well below occupational levels, usually between 0.01 and 0.0001 fibers/mL. However, during repair or renovation of home or school heating systems, with maximal conservation of air, levels may reach 0.2–1.0 fibers/mL. The experience with asbestos has raised concerns about bystander exposure to fibrous glass that has been widely used in insulation.

Freon and Chlorofluorocarbons. The leakage of freon, a refrigerant used in air-conditioning systems, is particularly noxious because phosgene, a poison gas used in World War I, is generated at ignition points such as electric arcs, burning cigarettes, and open flames. This problem was first identified aboard nuclear submarines, which remained submerged for long periods. Phosgene was generated at the

New York: The Society; 1981: 48, which states: "If the air is thought to contain any contaminant not listed (in various tables), guidance on acceptable exposure . . . should be obtained by reference to the standards of the Occupational Safety and Health Administration. For application to the general population the concentration of these contaminants should not exceed 1/10 of the limits that are used in industry . . . In some cases, this procedure may result in unreasonable limits. Expert consultation may then be required . . . These substances are ones for which indoor exposure standards are not yet available." *Contaminants marked "O" have odors at concentrations sometimes found in indoor air. The tabulated concentrations do not necessarily result in odorless conditions.

burning tips of cigarettes. Paint solvents contributed most to indoor pollution on board these vessels so regulations prohibit painting less than 30 days before putting to sea.

Radon. Another concern indoors is radon and daughter products, which may concentrate in indoor air due to building location (e.g., the granite deposits of Reading Prong in Pennsylvania, New York, and New Jersey) or be released from concrete and other building materials.⁹⁷ As with asbestos, the human health hazards of large exposures to radon products are well known from the miners of Schneeberg, Germany, and Jacy-mov, Czechoslovakia. The long-term health impact of low doses of radon products from basements, particularly from building materials or the substrata of rock, is poorly understood.⁹⁸ Thus decisions as to legislation and rule making have wavered in the breezes of indecision.

In summary, living organisms bacteria, molds and their products cause disease in buildings spread by heating and air-conditioning systems. Also, solvents such as trichloroethylene that are widespread contaminants of culinary water and dispersed into the air by showering and other water use, cause chronic neurobehavioral impairment.^{99–101} Low-level exposures appear to cause these cancer effects after latent periods of 20 or 25 years.⁷²

Effects

Symptoms. Initially, temporary ill effects from indoor exposure begin minutes to hours after exposure and diminish or disappear in a

few hours or overnight after leaving the building. They recur on reentry. Symptoms include fatigue, feeling of exhaustion, headache, and sometimes anorexia, nausea, lack of concentration, and lightheadedness. As occupants talk about their problems, irritability and recent memory loss may be noted along with the irritation of eyes and throat. Although demonstrating physiological changes may be difficult because of slight changes, interpretation may be aided by comparing exposed peoples' observed functions to those predicted.⁹⁹ As the methods for proving these diagnoses have improved, concerns over possible mass hysteria, or "crowd syndrome" have eased. Recommended investigational methods for these problems were all aided by follow-up measurements, so subjects are their own controls.

Investigation. Use a standard inventory of symptoms and obtain information on as many occupants of a structure as possible. Affective disorder inventories such as the profile of mood states are useful. This information should be accompanied by mapping of affected and unaffected subjects' work areas and their locations in the building. Air sampling should recognize chemical groups such as aldehydes, solvents, mercaptans, oxidant gases, chlorofluorocarbons (freons), carbon monoxide, pesticides (organochlorines and organophosphates) mold and mycotoxins plus bacteria and endotoxins. The decision to use physiological tests for pulmonary or neurological function should be made after reviewing the exposures and the symptom inventories.

Control and Prevention

Provision for adequate air exchange with entrainment of fresh air not contaminated by motor vehicle exhaust or effluents from surrounding industrial activities is most prudent for prevention. Removal of contaminants in air by hoods with back- or down-draft suction works for welding, painting, and similar operations. Internal filtration of air removes particles in cotton textile mills and metal machining operations but is rarely useful in indoor pollution, where total particle burdens are rarely more than 0.2 or 0.3 mg/m³ and nanoparticles and VOCs are incriminated. On high-altitude aircraft, activated charcoal absorbers for ozone are workable, as they are on submarines. However, the cost of these for buildings, compared with cost for air exchanges, is prohibitively high. Freon, formaldehyde, solvents, and asbestos should be controlled to as low levels as possible in the indoor environment. These concerns compete with energy conservation. The problems of indoor air pollution in "sick buildings," especially neurobehavioral impairment associated with VOCs and pesticides, molds and mycotoxins demand attention as workers are forced to retire early for neurobehavioral disability.

Pesticides

Marion Moses

Pesticides are among the few toxic substances deliberately added to our environment. They are, by definition, toxic and biocidal, since their purpose is to kill or harm living things. Pesticides are ubiquitous global contaminants found in air, rain, snow, soil, surface and ground water, fog, even the Arctic ice pack. All living creatures tested throughout the world are contaminated with pesticides—birds, fish, wildlife, domestic animals, livestock, and human beings, including newborn babies.

The term *pesticide* is generic, and different classes are named for the pest they control: insecticides (e.g., ants, aphids, beetles, bugs, caterpillars, cockroaches, mosquitoes, termites), herbicides (e.g., weeds, grasses, algae, woody plants), fungicides (e.g., mildew, molds, rot, plant diseases), acaricides (mites, ticks), rodenticides (rats, gophers, vertebrates), piscicides (fish), avicides (birds), and nematocides (microscopic soil worms).

► HISTORY

Use of sulfur and arsenic as pesticides dates back to ancient times. Botanicals such as nicotine (tobacco extract) date from the sixteenth century, and pyrethrum (from a type of chrysanthemum) since the nineteenth century. In the United States, Paris green (copper-aceto-arsenite) was first used in 1867 to control the Colorado potato beetle. In 1939 there were 32 pesticide products registered in the United States, primarily inorganic compounds containing arsenic, copper, lead, mercury, nicotine, pyrethrums, and sulfur.

Widespread use of petrochemical-based synthetic pesticides began in the 1940s. Swiss chemist Paul Mueller discovered the insecticidal properties of dichlorodiphenyltrichloroethane (DDT) in 1939. Dusting of allied troops during World War II to kill body lice averted a typhus epidemic, making it the first war in history in which more soldiers died of wounds than of disease. DDT was marketed for commercial use in the United States in 1945. German scientists experimenting with nerve gas during World War II synthesized the first organophosphate insecticide, parathion, marketed in 1943. The phenoxy herbicides 2,4-dichlorophenoxy acetic acid (2,4-D) and 2,4,5-trichlorophenoxy acetic acid (2,4,5-T) were introduced in the 1940s, carbaryl and other *N*-methyl carbamate insecticides in the 1950s, the synthetic pyrethroid insecticides in the 1960s, and genetically modified products (plant-incorporated protectants, PIPs) in the 1990s.

The first serious challenge to synthetic pesticides was the 1962 publication of *Silent Spring* by wildlife biologist Rachel Carson.¹

She documented environmental persistence, bioaccumulation in human and animal tissues, severe toxic effects on birds, fish, and other nontarget species, and potentially devastating ecological, wildlife, and human health effects of DDT and related chlorinated hydrocarbon insecticides.

In 1970, authority for administration and enforcement of the federal pesticide law was transferred from the U.S. Department of Agriculture to the newly created Environmental Protection Agency (EPA).

► PRODUCTION AND USE

In 2001 there were 18 major basic producers of pesticides in the United States, 100 smaller producers, 150–200 major formulators, 2000 smaller formulators, 250–300 major distributors, 16,900 smaller distributors and establishments, and 40,000 commercial pest control companies.

In 2002, average production of conventional pesticides (herbicides, insecticides, fungicides, rodenticides, and fumigants) in the United States was 1.6 billion pounds. Exports averaged 400 million pounds, and imports 100 million pounds. Total sales were \$9.3 billion, including exports of \$1.6 billion, and imports of \$1.0 billion.

The United States is the world's largest pesticide user, accounting for 24% of the estimated 5 billion pounds used worldwide. About 5 billion pounds of other chemicals regulated as pesticides were used in 2001—approximately 2.6 billion pounds of chlorine compounds, 797 million pounds of wood preservatives, 363 million pounds of disinfectants, and 314 million pounds for other uses.²

California, which accounts for 25% of all U.S. pesticide use, mandates reporting of all agricultural and commercial pesticide use, including structural fumigation, pest control, and turf applications. It does not require reporting of home and garden use and most industrial and institutional uses. Total use reported in 2004 was 175 million pounds.³

EPA broadly classifies pesticides as general or restricted use. Some pesticides may be general for some uses, and restricted for others. Restricted-use pesticides must be applied by a state-certified applicator or by someone under the supervision of a certified applicator. The states vary enormously in the quality of their education and training programs for pesticide applicators. Usually one person on each farm or in each company is certified, most often a supervisor or manager. In actual practice, most workers applying pesticides are not certified and work “under the supervision of a certified applicator.” Many are minimally or poorly trained, and turnover is high.

Agricultural Use

By the 1950s, synthetic chemical pesticides were major pest control agents in agriculture in the United States. In 2001, agriculture accounted for 76% of conventional pesticide use (herbicides, insecticides, and fungicides) with major use in corn, soybeans, and cotton. Of the estimated average 722 million pounds used, almost 60% were herbicides, 21% insecticides, 7% fungicides, and 14% all other types. The top 15 pesticides used in 2001 were glyphosate, atrazine, metam sodium,

acetochlor, 2,4-D, malathion, methyl bromide, dichloropropene, metolachlor-s, metolachlor, pendimethalin, trifluralin, chlorothalonil, copper hydroxide, and chlorpyrifos (Lorsban).

In California, almost 90% of reported use is in agriculture. Sulfur, favored by both conventional and organic farmers, accounted for 30% of use (53.2 million pounds) in 2004. Pesticides other than sulfur for which 1 million or more pounds were used were petroleum oils (unclassified), metam sodium, methyl bromide, 1,3-dichloropropene, mineral oil, glyphosate, chloropicrin, copper sulfate, sulfuryl fluoride, copper hydroxide, petroleum distillates, sodium chlorate, chlorpyrifos, calcium hydroxide, propanil, diuron, trifluralin, propargite, and maneb. Eight crops accounted for 58% of use: grapes, almonds, process tomatoes, strawberries, carrots, oranges, cotton, and rice.

Agricultural pesticide use in Canada and Western Europe is similar to that of the United States. Patterns in Latin America, the Asia-Pacific region, and Africa are similar to those of the 1950s with insecticides accounting for 60–80% of use and herbicides 10–15%.

Nonagricultural Use

Major nonagricultural uses of pesticides include wood preservation; lawn, landscape, and turf maintenance; rights-of-way (highways, railroads, power lines); and structural, industrial, public health, and home and garden use.

Wood Preservatives

About 797,000 million pounds of wood preservatives are used annually in the United States. The largest single use is creosote on railroad ties. Pentachlorophenol and copper-chromium-arsenate are used for preservation of utility poles, dock pilings, and lumber for construction purposes.

Home and Garden

The EPA estimates that 102 million pounds of active ingredient pesticides were used in the home and garden sector in 2001, about 11% of conventional pesticide use. The most common were 2,4-D, glyphosate (Roundup), pendimethalin, diazinon, MCPP, carbaryl (Sevin), malathion, DCPA, and benefin.² All residential use of diazinon was banned in 2004.

Lawn, Landscape, Turf, Golf Courses

If home lawns were a single crop, it would be the largest in the United States, covering some 50,000 square miles (the size of Pennsylvania). The use of lawn and turf pesticides is widespread and about \$30 billion is spent annually.⁴ About 40% of lawns are treated, with 32 million pounds applied by householders themselves, and an additional 38 million pounds by commercial firms. Herbicides account for 70% of use, insecticides 32%, and fungicides 8%.

There are about 14,000 golf courses in the United States, and many are intensively chemically managed, especially those used year round in southern states. Herbicides and fungicides are the most widely used.

Maintenance of Right-of-Way

Herbicides are extensively used for maintenance of rights-of-way along highways, power transmission lines, and railroads. County and state agencies can be major users. The California Transportation Agency (CalTrans) is the largest single pesticide user in the state, treating 25,000 miles of highway with herbicides annually.

Structural Use

A major nonagricultural use of pesticides is pest control in homes, apartments, offices, retail stores, commercial buildings, sports arenas, and other structures. Common practice is to contract for regular spraying for cockroaches, ants, and other indoor pests. Subterranean and dry-wood termites are major structural pests. Estimates are that one million termite treatments of 500,000 households occur annually in the United

States. About 20% of all termite jobs are in Texas alone, where estimates are that consumers spend more than \$1 billion annually for services. About 30 million homes were treated with chlordane for subterranean termites before it was banned in 1988. Chlorpyrifos (Dursban), which largely replaced chlordane, is itself under restriction for subterranean termite control, being replaced by other chemicals including imidacloprid (Premise), fipronil (Termidor), and chlorfenapyr (Phantom). Baiting systems are also increasing in use including sulfluramid (Terminate, Firstline), hexaflumuron (Sentricon), hydramethylnon (Subterfuge), and diflubenzuron (Advance, Exterra). The fumigant sulfuryl fluoride (Vikane) has replaced methyl bromide for tenting structures for control of dry-wood termites.

Over-the-Counter Products

About 71 million pounds of pesticides were sold directly to the consumer as aerosols, foggers, pest strips, baits, pet products, and lawn and garden chemicals in 1993.² Home use pesticides include the herbicides 2,4-D, glyphosate (Roundup), and simazine; home use insecticides include carbaryl (Sevin), dichlorvos (DDVP), methoxychlor, malathion, pyrethrins, pyrethroids, and propoxur (Baygon), and the fungicides, maneb, captan, benomyl, and chlorothalonil (Daconil). The organophosphates diazinon and chlorpyrifos (Dursban) were the most widely used insecticides until banned for indoor and outdoor home use and direct sale to consumers in 2001.

Industrial Use

Fungicides are widely used as mildewcides; preservatives and antifoulants in paints, glues, pastes, and metalworking fluids; and in fabrics for tents, tarpaulins, sails, tennis nets, and exercise mats. Carpets are routinely treated with insecticides for protection against insects and moths. Pesticides are used in many consumer products including cosmetics, shampoos, soaps, household disinfectants, cardboard and other food packaging materials, and in many paper products. The pulp and paper products industry uses large amounts of slimicides. Water for industrial purposes and in cooling towers is treated with herbicides and algicides to prevent growth of weeds, algae, fungi, and bacteria. Canals, ditches, reservoirs, sewer lines, and other water channels are similarly treated. The EPA estimates that 111 million pounds of active-ingredient conventional pesticides, about 13% of the total, were used in the industrial/commercial government sector market in 2001. The most commonly used in 2001 were 2,4-D, glyphosate, copper sulfate, penidmethalin, chlorothalonil, chlorpyrifos, diuron, MSMA, triclopyr, and malathion.

Public Health Use

The major public health use of pesticides in the United States is the treatment of drinking water and sewage. In 2001, the EPA estimated that 2.6 billions pounds of chlorine/hypochlorites were used for water treatment, 1.57 billion pounds for disinfection of potable and wastewater, and 1 billion pounds for disinfection of recreational water.

There has been an increase in mosquito control pesticide spraying in the United States in response to West Nile Virus. Common practice is to spray ultra low volume (ULV) formulations using less than three ounces per acre of a synthetic pyrethroid insecticide (usually permethrin or d-phenothrin), or the organophosphates malathion or naled. Ground applications are also used. The Centers for Disease Control and Prevention has issued a fact sheet for the public regarding larvicides and adulticides, and recommendations for repellents.⁵

Malaria Control

Worldwide, the biggest public health use of pesticides is in malaria control. DDT is still in use in some countries, but ULV spraying of synthetic pyrethroids is more widely used. Pyrethroid impregnated bed nets, shown to reduce childhood mortality and morbidity, are being used as a preventive measure in many countries.⁶ Cost, distribution, and the need for net retreatment every 6–12 months are barriers to full implementation in endemic areas. The U.S. Centers for Disease Control and Prevention is testing several nets that

theoretically retain lethal concentrations of insecticide for the life of the net, 3–5 years.⁷

Aircraft Use

Cargo holds, passenger cabins, and other areas of aircraft are sprayed with a wide variety of insecticides. A controversial policy is the spraying of occupied cabins with aerosol insecticides, usually synthetic pyrethroids. U.S. airlines have abandoned this practice within U.S. borders, but spray them on international flights to countries that require it by law, including Australia and the Caribbean.

Active and Inert Ingredients

Pesticide products are mixtures of active and inert ingredients. The Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) defines an active ingredient as one that prevents, destroys, repels, or mitigates a pest, or is a plant regulator, defoliant, desiccant, or nitrogen stabilizer. It must be identified by name on the label with its percentage by weight. In 2000, there were about 900 active ingredient pesticides registered by the EPA. The total number of registered products is not known because the EPA allows multiple registrations of the same active ingredient in brand-name products under different “house labels.” Estimates are that 100,000 to 400,000 registered products are on the market—many being similar products formulated by different companies. Table 33-1 lists the major classes and types of chemicals used as pesticides in the United States.

Inert ingredients are all other ingredients not active as a pesticide in the product, including solvents, surfactants, carriers, thickeners, wetting/spreading/dispersing agents, propellants, microencapsulating agents, and emulsifiers. “Inert” does not mean nontoxic, since inert ingredients can be chemically and biologically active, and some are classified as both active and inert. Isopropyl alcohol, for example, may be an active ingredient in antimicrobial pesticide in some products, and an inert ingredient used as a solvent in others. Typical solvents include xylene, deodorized kerosene, 1,1,1-trichloroethane, methylene chloride, and mineral spirits. Over-the-counter aerosol pesticide products may contain carcinogenic solvents such as trichloroethylene and methylene chloride as “inert” ingredients.

There are 1200 inert ingredients registered with the EPA, categorized into four lists, based on potential adverse effects on human health. List 1 has nine ingredients of toxicological concern which are the only inerts required to be named on the label: isophorone, adipic acid, bis(2-ethylhexyl) ester, phenol, ethylene glycol monoethyl ether, phthalic acid, bis(2-ethylhexyl) ester, hydroquinone, and nonylphenol. List 2 contains 55 potentially toxic inerts with a high priority for testing. The largest number of ingredients is on List 3, about 1500 of unknown toxicity. List 4A contains 160 inerts generally regarded as safe. List 4B contains 310 ingredients with sufficient data to conclude that current use will not adversely affect public health or the environment. When an inert reaches List 4B, no further regulatory action is anticipated.

Except for List 1, pesticide registrants can withhold the names of inert ingredients and list only percentages, because of industry claims of confidentiality based on the FIFRA trade secret provisions. Environmental groups filed a lawsuit in federal court against the EPA in 1994 under the Freedom of Information Act, demanding public disclosure of inert ingredients. The court ruled in 1996 that pesticide companies must disclose inert ingredients in six pesticide products: Aatrex 80W (atrazine), Weedone LV4 (2,4-D), Roundup (glyphosate), Velpar (hexazinone), Garlon 3A (triclopyr), and Tordon 101 (picloram and 2,4-D).

Pesticide Formulations

There are four basic types of pesticide formulations: (a) foggers, bombs, and aerosols, (b) liquids and sprays, (c) powders, dusts, and granules, and (d) baits and traps.

Contaminants. Many technical pesticide products contain pesticide metabolites and process contaminants. Pesticides manufactured from chlorinated phenols, such as 2,4-D and pentachlorophenol, contain dibenzodioxins and dibenzofurans. Hexachlorobenzene contaminates the fungicides chlorothalonil, dacthal, pentachloronitrobenzene, and pentachlorophenol. DDT is a contaminant of the miticide dicofol (Kelthane). Many pesticides are contaminated with nitrosoamines, including trifluralin, glyphosate, and carbaryl. The ethylenebisdithiocarbamate fungicides contain the metabolite ethylene thiourea (ETU),

TABLE 33-1. PESTICIDE RESIDUES IN BLOOD AND URINE: U.S. ADULTS 1999–2003

*Paradichlorobenzene (mothballs).

[†]Not calculated because too many samples were below the limit of detection.

[‡]Also found in tobacco smoke and certain polyaromatic hydrocarbons.

[§]Metabolite of several pesticides including lindane and hexachlorobenzene.

[¶]3,5,6-trichloro-2-pyridinol major metabolite of chlorpyrifos.

Source: Third National Report on Human Exposure to Environmental Chemicals. CDC. July 2005. <http://www.cdc.gov/exposurereport/>.

and carbon disulfide is a biodegradation product. Lengthy storage can also increase the toxicity of contaminants and metabolites in pesticide formulations, including sulfotepp in diazinon, and isopropylmalathion and *O,O,S*-trimethylphosphorothioate in malathion.

Intermediates. Pesticide intermediates can be highly toxic. Methylisocyanate (MIC), the chemical that poisoned and killed thousands of people in Bhopal, India, in 1984, is an intermediate in the manufacture of the *N*-methyl carbamate insecticides aldicarb (Temik) and carbaryl (Sevin).

► EXPOSURE TO PESTICIDES

Occupational Exposure to Pesticides

The EPA estimates there are 351,600 pest control operator/exterminator professionals certified to apply pesticides commercially; and 965,692 certified private applicators, most of whom are individual farmers. Pesticide law allows noncertified applicators to work “under the supervision of” a certified applicator. Thus, there are thousands more noncertified applicators working with commercial pest control firms and on farms. There is no estimation of their actual numbers, or of their qualifications and training.

Those who handle concentrated formulations—mixers, loaders, and applicators—have the highest exposure. Batch processing used in pesticide manufacturing requires little direct contact, and exposures are usually lower.

Farm workers who cultivate and harvest crops are exposed to dislodge able pesticide residues on leaf surfaces, on the crop itself, in the soil, or in duff (decaying plant and organic material that collects under vines and trees). Field workers are exposed to overspray from crop-dusting aircraft and drift from airblast and other ground rig sprayers. Farm worker families, especially migrant workers, who often live in camps, are surrounded by fields that are sprayed.

Children’s Exposures

Children’s exposures to pesticides are magnified by their greater likelihood of direct exposure from skin contact with contaminated floors, carpets, lawns, and other surfaces due to their crawling, toddling, and exploring activities. They can swallow significant amounts from ingesting contaminated house dust, and mouthing and chewing pesticide-contaminated objects. Their higher respiratory rate, larger skin surface for their size, and less mature immune and detoxifying systems put them at greater risk than adults at comparable exposure levels.

Farm worker children are at high risk of exposure because they may work in the fields or be taken to the fields by their parents and exposed to pesticide drift from nearby fields and from take-home contamination by their parents.^{8,9}

Absorption of Pesticides

Pesticides are readily absorbed through the skin, the respiratory tract (inhalation), and the gastrointestinal tract (ingestion). The eyes can be

a significant route of exposure in splashes and spills. The rate of absorption of pesticides into the body is product specific and depends on the properties of the active ingredient pesticide and the inert ingredients in a particular formulation.

The skin, not the respiratory system as is commonly believed, is the chief route of absorption. Fumigants, which are in the form of gases, which accounts in part for their greater toxicity, are a notable exception. Inhalation can be an important route of exposure in the home from the use of aerosols, foggers, bug bombs, and moth control products, but the dermal route is still the most important route, especially in children.

A new method to estimate residue transfer of pesticides by dermal contact and indirect ingestion uses riboflavin (vitamin B₂), a highly fluorescent, water soluble, nontoxic tracer compound as a surrogate for pesticide residues. Coupled with video imaging and computer quantification, the system measures transfer of pesticide residues to the skin. It is especially useful in estimating surface-to-skin and skin-to-mouth residue transfer in children from carpets, upholstery, and other surfaces inside the home.^{10,11}

Biomonitoring

A biomonitoring program of the U.S. general population, which began in 1999–2000 by the Centers for Disease Control and Prevention (CDC), used blood and urine samples from participants in the National Health and Nutrition Examination Survey (NHANES). The CDC’s first report of the findings, *The National Report on Human Exposure to Environmental Chemicals*, was issued in 2001. The only pesticide data in that report were urinary dialkylphosphate metabolites (DAPs). The second report, with the same title, was issued in 2003. It included much more data on pesticides, including selected organophosphate, organochlorines, *N*-methyl carbamates, herbicides, and pest repellents and disinfectants. Table 33-1 summarizes selected data in adults from the 2003 report. Racial differences are most striking with DDE residues. Levels in Mexican Americans were 311% greater than in whites, and 228% greater than in blacks. Levels in blacks were 36% greater than in whites, and 44% lower than in Mexican Americans. DDT is still widely used in Mexico for malaria control, but efforts to ban use are in progress.¹²

► TOXICOLOGY

The U.S. EPA ranks pesticides into four categories based on acute toxicity (Table 33-2).

Most of the rest of the world uses the World Health Organization (WHO) classification (Table 33-3).

Organophosphates

Organophosphates are responsible for the majority of occupational poisonings and deaths from pesticides in the United States and throughout the world. There are many reports of severe poisoning and fatalities from accidental and suicidal ingestion of these compounds. Even less toxic organophosphates can be deadly. Malathion

TABLE 33-2. ENVIRONMENTAL PROTECTION AGENCY PESTICIDE TOXICITY CATEGORIES BY MEDIAN LETHAL DOSE (LD₅₀) IN MG/KG BODY WEIGHT IN THE RAT*

Toxicity Class and Signal Word Required on Label	Oral (mg/kg)	Dermal (mg/kg)	Inhalation (mg/L)	Effects	
				Eye	Skin
I Highly toxic DANGER	<50	<200	<0.2	Corneal opacity (irreversible)	Corrosive
II Moderately toxic WARNING	50–500	200–2000	0.2–2	Corneal opacity (reversible 7 days)	Severe irritation
III Minimally toxic CAUTION	500–5000	2000–20,000	2–20	Irritation	Moderate irritation
IV Least toxic CAUTION	>5000	>20,000	>20	No irritation	Mild irritation

*The median lethal dose (LD₅₀) is the amount that will kill 50% of the exposed animals. The lower the median lethal dose, the more hazardous the chemical.

TABLE 33-3. WORLD HEALTH ORGANIZATION—RECOMMENDED CLASSIFICATION OF PESTICIDES BY HAZARD BY MEDIAN LETHAL DOSE (LD₅₀) IN MG/KG BODY WEIGHT IN THE RAT*

Hazard Class	Oral		Dermal	
	Solids	Liquids	Solids	Liquids
IA Extremely hazardous	<5	<20	<10	<40
IB Highly hazardous	5–50	20–200	10–100	40–400
II Moderately hazardous	50–500	200–2000	100–1000	400–4000
III Slightly hazardous	>500	>2000	>1000	>4000

*The median lethal dose (LD₅₀) is the amount that will kill 50% of the exposed animals. The lower the median lethal dose, the more hazardous the chemical.

contaminated with a toxic isomerization product, isomalathion, caused five deaths and 2800 poisonings in Pakistan malaria sprayers in 1975.

In the state of Washington there were 26 reports of severe poisoning in workers applying Phosdrin (mevinphos) in 19 different apple orchards in 1993. The state banned the pesticide in 1993 and the federal EPA banned it in 1995.

In 1989 in Florida, 185 farm workers were severely poisoned when sent to work in a cauliflower field 12 hours after it had been sprayed with Phosdrin, when the legal reentry interval was 4 days. Phosdrin was banned in 1994. Severe poisonings have occurred from wearing laundered uniforms previously contaminated with parathion, which was banned in 2002.

Providing emergency care to patients who attempt suicide by ingesting organophosphate insecticides can result in poisoning. Two emergency medical technicians were poisoned after mouth-to-mouth resuscitation to an attempted suicide victim who ultimately died. Ten hospital emergency room workers and paramedics were symptomatic after contact with a patient who ingested an organophosphate insecticide, requiring temporary closing of the emergency department.¹³

Signs and symptoms of organophosphate poisoning occur soon after exposure, from minutes to hours. Mild poisoning results in fatigue, headache, dizziness, nausea, vomiting, chest tightness, excess sweating, salivation, abdominal pain, and cramping. In moderate poisoning the victim usually cannot walk, has generalized weakness, difficulty speaking, muscular fasciculations, and miosis. Central nervous system effects also occur, including restlessness, anxiety, tremulousness, insomnia, excessive dreaming, nightmares, slurring of speech, confusion, and difficulty concentrating. Coma and convulsions accompany severe poisoning, which can result in death without proper treatment.¹⁴

The organophosphates are readily metabolized and excreted, and with early and proper treatment most poisoned workers will recover. In accidental or suicidal ingestion, recovery depends on the amount ingested, the interval before emergency resuscitation, and the appropriateness of treatment. While recovery appears to be complete, long-term neurological effects can occur (vide infra).

Organophosphates are similar to nerve gas and exert their toxic action by inhibition of the enzyme acetylcholinesterase at synaptic sites in muscles, glands, autonomic ganglia, and the brain, resulting in a build-up of the neurotransmitter acetylcholine. Enzymes that hydrolyze choline esters in humans are found in red blood cells (RBCs) (“true” cholinesterase) and plasma (“pseudocholinesterase”) derived from the liver. Decreased activity of RBCs and plasma cholinesterase is an indicator of excess absorption of organophosphates, and testing activity levels is an excellent tool for monitoring worker exposure, and diagnosing poisoning.

A 10–40% reduction in cholinesterase activity usually results in latent poisoning without clinical manifestations. A 50–60% reduction usually results in mild poisoning. A reduction of 70–80% results in moderate poisoning, and 90% or more indicates severe poisoning that can be fatal without treatment.

The rate of reduction in cholinesterase activity is an important determinant of poisoning. A rapid reduction over a few minutes or hours can produce marked signs and symptoms, which can be minimal or absent for a gradual drop of the same magnitude over a period of days or weeks. In worker-monitoring programs, a reduction in RBC enzyme activity of 25% or more, or in plasma cholinesterase of 40% or more from a pre-exposure or “baseline” level, is evidence of

excess absorption. Workers should be removed from further exposure until recovery of activity to at least 80% of baseline.

Atropine, which blocks the effects of acetylcholine, is the antidote for organophosphate pesticide poisoning. Pralidoxime (2-PAM), if given within 24–48 hours of exposure, can reactivate cholinesterase and restore enzyme function. After this time, “aging” of the enzyme-pesticide complex occurs, making it refractory to reactivation.^{15,16}

Genetic factors, especially paraoxonase (PON1) activity levels, can affect metabolism and detoxification of organophosphates and may account for differing susceptibility to poisoning,^{17,18} especially in children.¹⁹

Alkylphosphate metabolites of organophosphates are excreted in the urine and can be useful as a measure of recent absorption in exposure assessment and biomonitoring. Levels peak within 24 hours of exposure and usually are not detectable 48 hours or more after exposures ceases.

Action on Chlorpyrifos. First marketed in 1975, chlorpyrifos has become one of the most widely used organophosphates in the United States. Registered under the trade name Dursban and Lorsban, it is found in hundreds of “house label” products. In April 1995, the EPA fined the basic manufacturer, DowElanco, \$732,000,000 for failing to report to the agency adverse health effects known to the company over the past decade. An EPA review of chlorpyrifos for reregistration resulted in an agreement with the registrant for withdrawal of flea control, total release foggers, paint additive, and pet care (shampoos, dips, sprays) products.

N-Methyl-Carbamate Insecticides

The N-methyl-carbamate insecticides are similar to the organophosphates in their acute toxic effects and mechanism of action. However, the inhibition of acetylcholinesterase is readily reversible. Signs and symptoms appear earlier, and workers are more likely to remove themselves from excess exposure. Except for an aldicarb (Temik)-related tractor accident death of a farm worker reported in 1984, there are no deaths from occupational exposure reported in the United States, but there are reports from other countries.²⁰

Atropine is also the antidote for N-methyl-carbamate poisoning, but 2-PAM is not recommended unless there is concomitant exposure to an organophosphate. Testing RBC and plasma cholinesterase activity is less useful in poisoning with the carbamates because carbamylation of the enzyme, unlike phosphorylation, is readily reversible, and can occur *in vitro* during transport of the specimen to the laboratory. Poisoning of grape girdlers in California with prolonged exposure to methomyl (Lannate)-contaminated soil was unusual in the occurrence of significant depression of cholinesterase activity.

Chlorinated Hydrocarbon Insecticides

Most organochlorine insecticides including DDT, aldrin, endrin, dieldrin, chlordane, heptachlor, and toxaphene (Table 33-4), are no longer used in the United States. They are central nervous system stimulants, and in toxic doses cause anxiety, tremors, hyperexcitability, confusion, agitation, generalized seizures, and coma that can result in death. Those in current use—dienochlor, endosulfan (thiodan), and methoxychlor—are readily metabolized and excreted and do not persist in the environment.

TABLE 33-4. PESTICIDES BANNED OR SEVERELY RESTRICTED IN THE UNITED STATES BY YEAR AND ACTION TAKEN

Alar (daminozide)	1990	Ban food use, nursery/plants allowed
Aldrin/Dieldrin	1974	Ban all use except termites
	1989	Termite use cancelled
Azinphosmethyl	2002	Cancellation 23 crop uses
	2005	Cancellation 9 crop uses; time-limited registration 10 remaining crop uses*
Bendiocarb (Ficam)	2001	All use voluntary cancellation
Benomyl (Benlate)	2002	All use voluntary cancellation
BHC	1978	All use cancelled
Cadmium	1987	Home lawn, golf fairway use cancelled
	1990	Golf tees/greens use cancelled
Calcium arsenate	1989	Non-wood uses cancelled
Captafol	1987	All use cancelled
Captan	1999	Residential lawn use cancelled, sod farms, golf courses allowed
CCA†	2003	Residential use cancelled
Chlordimeform	1989	All use cancelled
Chlordane	1978	All use except termites cancelled
	1988	Termite use cancelled
Chlorpyrifos	2001	Ban OTC sales directly to the public
Clopyralid	2002	Ban lawn/turf Washington, California
Cyanazine	1999	All use cancelled
Cyhexatin	1987	All use cancelled
DBCP	1979	Ban all use except pineapple in Hawaii
	1989	Pineapple use cancelled
DDT	1972	Ban all use except health emergencies
Diazinon	1986	Ban golf courses, sod farms
	2001	Ban OTC sales directly to the public
	2002	Ban all indoor use
	2004	Ban all outdoor nonagricultural use
Dicofol	1998	Residential use cancelled
Dinoseb	1986	Ban all use after emergency suspension
Endrin	1985	All use cancelled
EPN	1983	Mosquito larvacide use cancelled
	1987	All use cancelled
Ethylene dibromide	1984	Grain fumigant use cancelled
	1987	Payapa fumigation use cancelled
	1989	Citrus export fumigation use cancelled
Fenamiphos	2002	Voluntary phase-out all uses
Folpet	1999	Ban except paints/coatings/sealants
Fonofos	1999	All use cancelled
Heptachlor	1983	Most seed treatment use cancelled
	1988	Most termite use cancelled
	1994	Most remaining uses cancelled
	1995	Technical product export cancelled
	1999	Ban fire ant use, domestic production
Hexachlorobenzene	1984	All use cancelled
Kepone	1977	All use cancelled
Lead arsenate	1987	All use cancelled
Lindane (γ -HCH)	1986	Ban indoor smoke fumigation use
	1990	Many uses cancelled; seed treatment, lice/scabies use allowed
Mancozeb	1992	Home garden, turf, fruit use cancelled
Mirex	1977	Cancelled except pineapple in Hawaii
	1987	All use cancelled
Monocrotophos	1988	All use cancelled
Nitrofen (TOK)	1983	All use cancelled
Parathion	1991	All use cancelled except nine field crops
	2002	All use cancelled
Phosdrin	1994	All use cancelled
2,4,5-T, Silvex	1979	Emergency suspension
	1985	All use cancelled
Sodium arsenite	1989	Ant bait use cancelled; grapes, seed okra, cotton use allowed
	1993	All use cancelled
Toxaphene	1982	Cancelled except in P. Rico, Virgin I
	1990	All use cancelled
Vinclozolin	2005	Lettuce use cancelled; phaseout all other uses
Zineb	1990	All use cancelled

*Almonds, apples, blueberries, brussel sprouts, cherries, crab apples, nursery stock, parsley, pears, pistachios, and walnuts.

†Chromated copper arsenate, a wood preservative.

Lindane. The only persistent chlorinated hydrocarbon insecticide still on the market in the United States is lindane (γ -hexachlorocyclohexane, γ -HCH). It is available by prescription only for lice and scabies (formerly available over-the-counter as Kwellly, now discontinued). Generalized seizures have occurred in children and adults from dermal application for lice and scabies. Prescriptions for lindane have decreased 67% from 1998 to 2003 when the Food and Drug Administration (FDA) required dispensing it in 1–2 ounce single-use packets. CDC recommends that lindane should not be used for persons weighing less than 110 pounds (50 kg), that treatment should not be repeated, and that it should not be tried unless other treatments have failed.²¹

Kepon. The most serious outbreak of chlorinated hydrocarbon poisoning in the United States occurred at a plant manufacturing chlordane (Kepon) in Hopewell, Virginia, in 1974. The plant was closed in 1975, and the registration cancelled in 1976, but a consumption advisory is still in effect for Kepon-contaminated fish in the St. James River estuary.

Hexachlorobenzene. More than 3000 cases of acquired porphyria cutanea tarda occurred in Turkey in the late 1950s from consumption of hexachlorobenzene-treated wheat seed illegally sold for food use. Turkey banned hexachlorobenzene in 1959, and all use

was cancelled in the United States in 1984. Hexachlorobenzene is a contaminant of Dacthal, chlorothalonil, pentachloro-nitrobenzene, and pentachlorophenol.

Pyrethrums/Pyrethrins/Synthetic Pyrethroid Insecticides

Pyrethrums are crushed petals of a type of chrysanthemum that contains insecticidal chemicals called pyrethrins. Pyrethrin formulations contain the active pyrethrins, which is a solvent extracted from the flowers, and are more acutely toxic than pyrethrums. Pyrethroids are synthetic analogs of natural pyrethrins. The synergist piperonyl butoxide is added to most pyrethrin and pyrethroid formulations to prolong their residual action.

Pyrethrins and pyrethroids slow the closing of the sodium activation gate in nerve cells. Pyrethroids with the alpha-cyano moiety (cyfluthrin, lambda-cyhalothrin, cyphenothrin, cypermethrin, esfenvalerate, fenvalerate, fenpropathrin, fluralinate, tralomethrin) are more toxic than those without this functional group (permethrin, *d*-phenothrin, resmethrin).

The pyrethrins and pyrethroids are readily metabolized and excreted and do not bioaccumulate in humans or in the environment. They are less acutely toxic than most organophosphate insecticides; most are in toxicity categories III and IV (Table 33-5). Many household aerosols and pet care products contain pyrethrins and synthetic

pyrethroids and piperonyl butoxide, and they are widely used by exterminators for treatments of homes and buildings.

Characteristic symptoms of exposure to synthetic pyrethroids are transient facial and skin paresthesias and dysesthesias such as burning, itching, and tingling sensations which disappear soon after exposure ceases and can be exacerbated by sweating and washing with warm water. Signs and symptoms of mild to moderate poisoning include dizziness, headache, nausea, anorexia, and fatigue. Severe poisoning results in coarse muscular fasciculations in large muscles of the extremities and generalized seizures. Recovery is usually rapid after exposure ceases. There are no specific antidotes to poisoning, and treatment is supportive.²²

Pyrethrins cross-react with ragweed and other pollens. Members of this class of chemicals, including the synthetic pyrethroids, are potential allergens and skin sensitizers.

Fatalities. A fatality in a child was associated with sudden irreversible bronchospasm from use of a pyrethrin shampoo.²³ A 43-year-old woman with a history of asthma and ragweed allergy experienced an anaphylactic reaction after using a pyrethrin lice shampoo.²⁴ A 36-year-old woman with a history of asthma developed severe shortness of breath 5 minutes after she began washing her dog with a 0.05% pyrethrin shampoo, and was in cardiopulmonary arrest within 5 minutes.

Phenolic and Cresolic Pesticides

These highly toxic pesticides include pentachlorophenol, dinitrophenol (DNOC), and dinocap. They are uncouplers of oxidative phosphorylation, and poisoning produces anorexia, flushing, severe thirst, weakness, profuse diaphoresis, and hyperthermia, which can progress to coma and death. Aspirin is contraindicated in treatment. Many occupational deaths have occurred from these compounds, as well as deaths in infants in a newborn nursery in France where sodium pentachlorophenolate was mistakenly added to a wash solution for diapers.

Herbicides

Glyphosate (Roundup, Rodeo), the most widely used herbicide in the United States, is much less acutely toxic than paraquat, the herbicide it primarily replaced, and is sold over-the-counter. Occupational illnesses, mostly irritant and skin reactions, involving glyphosate products are among the most frequently reported in agricultural and landscape maintenance workers in California.²⁵ Ocular effects are reported in factory workers.²⁶ A toxic inert ingredient in some formulations, polyoxyethylenamine (POEA), is linked to fatalities from accidental or suicidal ingestion.²⁷

Action on Glyphosate. New York State charged Monsanto, the registrant of glyphosate, with deceptive and misleading advertising, challenging unsubstantiated safety and health claims for Roundup and other products. In 1996, the company agreed to discontinue the use of terms such as “biodegradable” and “environmentally friendly.”

Atrazine, the second most widely used herbicide, is also not acutely toxic, is sold over-the-counter, and is used for lawn and turf management in some states. It is persistent in soil, is a widespread groundwater contaminant, and causes mammary cancer and other tumors in rodents. Atrazine is under review by the EPA as an endocrine disruptor.

The widely used chorophenoxy herbicides including 2,4-D, dicamba, and MCPA are also not acutely toxic, but can be fatal if ingested.²⁸

Paraquat and Other Bipyridyls

Unlike most herbicides which have a relatively low acute toxicity, paraquat (Gramoxone) is an epithelial toxin and can cause severe injury to the eyes, skin, nose, and throat, resulting in ulceration, epistaxis, and severe dystrophy or complete loss of the fingernails. Acute poisoning, from suicidal or accidental ingestion, can result in hepatic and renal

failure; the patient may recover only to die of asphyxiation due to a relentlessly progressive pulmonary fibrosis. Death usually occurs 1–3 weeks after ingestion, depending on the dose and treatment. Dermal exposure to paraquat has also caused fatal pulmonary fibrosis. Deaths have been reported in farmers and landscape maintenance workers and from application to the skin for treatment of lice and scabies. There is no antidote to paraquat poisoning, and most patients who absorb or ingest an amount sufficient to cause severe organ toxicity do not survive.²⁹ Its toxic action is most likely due to lipid peroxidation from reaction with molecular oxygen to form a superoxide ion. Diquat, a related compound used mainly for aquatic weed control, is much less toxic.

Fumigants

Fumigants are among the most toxic pesticide products. As gases, they are rapidly absorbed into the lungs and distributed throughout the body. Most are alkylating agents, mutagens, and carcinogens and are neurotoxic and hepatotoxic. They are responsible for many deaths, especially methyl bromide. The central nervous system, lungs, liver, and kidneys can be severely affected. Pulmonary edema can occur and is a frequent cause of death.

Methyl Bromide. Severe neurotoxic and behavioral effects, including toxic psychosis, can result from poisoning with methyl bromide. Mental and behavioral changes can occur soon after acute poisoning or from low-level chronic exposure. There are many reports of permanent sequelae after recovery from acute methyl bromide poisoning. Anxiety, difficulties in concentration, memory deficits, changes in personality, and other behavioral effects occur and can be progressive and irreversible.

Methyl bromide is a potent ozone depleter. The United States is a signatory to the Montreal Protocol, an international agreement to phase out all use of the fumigant by 2001. The phaseout was extended to 2005 and then waived for agricultural uses in the United States.

Fungicides

Most of the widely used fungicides are in toxicity category IV, the least acutely toxic. Many cause contact dermatitis and can be potent allergens and sensitizers (vide infra). Many are also known or suspect carcinogens—including benomyl, captan, chlorothalonil, maneb, and mancozeb.

Insect Repellents

N,N-diethyl-*m*-toluamide (deet, OFF!, Skintastic), developed by the military for troops in the field, was first marketed in 1954, and is estimated to be used by 30 million people annually. It is applied directly to the skin, and use has been increasing, especially for children, because of concerns regarding ticks that carry Lyme disease, and mosquitoes that carry West Nile virus.

Deet is neurotoxic, and signs and symptoms of mild poisoning include headache, restlessness, irritability, crying spells in children, and other changes in behavior. Severe poisoning results in toxic encephalopathy, with slurring of speech, tremors, generalized seizures, and coma. Generalized seizures have occurred in children when used according to label directions, and fatalities in children and adults within hours of repeated dermal exposure. Anaphylactic shock, though rare, has also been reported, resulting in a requirement for the signal word “Warning” on the label.

Surveillance Data

The number of pesticide-related illnesses and deaths in the United States is unknown. Annual data are available from the Poison Control Center Toxic Exposure Surveillance System (TESS) and from the California Pesticide Illness Surveillance Program (PISP), but there is no systematic national collection. Reports are also available from the

National Center for Health Statistics, and from the Sentinel Event Notification System of Occupational Risk (SENSOR), a collaboration between National Institute of Occupational Safety and Health (NIOSH) and seven states.

In 2003, TESS reported 99,522 pesticide-related incidents, 4.2% of total reports. About 51% of the incidents were in children less than 6 years old. There were 41 fatalities, including 16 suicides.³⁰ In California PISP, 1232 reports were investigated in 2003, of which 803 were suspected or confirmed. Agricultural pesticide use accounted for 405 of the cases and nonagricultural pesticides for 395, of which 69% were occupational. Eight were admitted to hospitals and 70 lost time from work.³¹

SENSOR reported 1009 cases of acute pesticide-related illness from 1998 to 1999, with a rate of 1.17 incidents per 100,000 full time equivalents (FTEs). The rate in agriculture of 18.2 FTEs was 34 times higher than the nonagriculture rate of 0.53. Insecticides were responsible for 49% of all illnesses, which were of low severity in 69.7% of cases, moderate in 29.6%, and severe in 0.4% (four cases), with three fatalities.³²

Reentry Poisoning

Dermal absorption of dislodgeable residues on crops they are harvesting has caused systemic poisoning of thousands of farm workers. California is the only state that enforces mandatory reporting of pesticide illness, so most information on reentry poisonings is from that state. The earliest poisoning incidents were in crops with high foliar contact such as grapes, peaches, and citrus, that had been sprayed with Toxicity I organophosphates such as parathion, phosdrin, and azinphos-methyl (Guthion).

One of the largest outbreaks of pesticide-related dermatitis in California occurred in 1986, among 198 farm workers picking oranges sprayed with propargite (Omite-CR). About 52% of the workers sustained severe chemical burns. No violations of reentry intervals or application rates were found. A new inert ingredient that prolonged residue degradation had been added to the formulation, and subsequent field degradation studies showed that the proper reentry interval should have been 42 days, not 7. Omite-CR was banned for any use in California but is still used in other states.

The establishment of waiting periods before workers could be sent into the fields, called reentry intervals or restricted entry intervals (REIs), decreased poisoning in California to 117 in 1993, compared to an average of 168 from 1989 through 1992. Prior to 1989, the average number of field residue cases per year had been 279.

Drift Episodes

Drift is the movement of pesticides away from the site of application. Approximately 85–90% of pesticides applied as broadcast sprays drift off target and can affect birds, bees, fish, and other species, as well as human beings. Significant concentrations can drift a mile or more; lower concentrations can drift many miles depending on droplet size, wind conditions, ambient temperature, and humidity.

Pesticide exposures to bystanders and community residents from drift are increasing with the building of residential housing adjacent to agricultural fields and golf courses. Off-gassing and drift from fields where methyl bromide, chloropicrin, and metam sodium are used to fumigate the soil have resulted in evacuation of residents in surrounding communities. Problems are increasing in urban areas with increasing chemical treatment of lawns, sports areas, parks, and recreation areas.

The state of California reported 256 drift-related exposures in 2003, involving 33 episodes. One episode resulting from improper soil injection of chloropicrin was responsible for 166 of the cases. In 2002 there were 478 exposures involving 39 episodes. A law enacted in California in 2005, prompted by rural agricultural drift incidents, requires responsible parties to pay for emergency medical treatment for injures to innocent bystanders, and offers incentives to provide immediate medical aid before cases are litigated.

Developing Countries

The majority of pesticide poisonings and deaths are in low-income and developing countries, which account for 25% of pesticide use, 50% of acute poisonings, and 75% of deaths. WHO estimates that the total number of acute unintentional poisonings annually in the world is between 3 and 5 million cases, with 3 million severe poisonings and 20,000 deaths.

WHO estimates that intentional poisonings number 2 million with 200,000 resulting in death by suicide. Suicide is reported to be responsible for most deaths, but this may be due to biased reporting, minimization of occupational hazards, and faulty assumptions resulting in inappropriate blame being attributed to victims. A South Africa study found that hospital and health authorities greatly underestimate occupational cases and overestimate suicides. Assumptions that a lack of awareness is responsible for most poisonings was not borne out when reporting was supervised and intensified, and reports increased almost tenfold during an intervention period. The risks for women were underestimated during routine notifications.³³

In most countries there is easy access to pesticides, poor regulation and enforcement, and inadequate or unavailable medical facilities, and even government distribution programs which can contribute to poisonings. A survey of six Central American countries found 98% underreporting of pesticide poisoning, estimating 400,000 poisonings per year (1.9% of the population) of which 76% were work related.^{34,35,36} Suicide is reported as the fifth leading cause of death in China and 58% are from ingesting pesticides.

Phasing out WHO Class I and II pesticides (USEPA Toxicity Category I) would greatly reduce acute poisoning and death where pesticides are readily available and where laws and policies are insufficient to protect workers and the public.^{37,38}

► HEALTH EFFECTS

Asthma

Exposure to pesticides can trigger or exacerbate asthma, induce bronchospasm, or increase bronchial hyperreactivity. Pesticides that inhibit cholinesterase can provoke bronchospasm through increased cholinergic activity. At high doses, certain pesticides can act as airway irritants. Low levels that are insufficient to cause acute poisoning can trigger severe reactions in those without a previous diagnosis of asthma. Pesticides linked to asthma, wheezing, and hyperreactive airway disease include the antimicrobials chlorine and chloramine; the fumigants metam sodium and ethylene oxide; the fungicides captafol, chlorothalonil, maneb/mancozeb, and other ethylenbis-dithiocarbamates; the herbicides alachlor, atrazine, EPTC, and paraquat; and the insecticides carbofuran, chlorpyrifos, dichlorvos, malathion, pyrethrins, pyrethrum, and synthetic pyrethroids.

The Children's Health Study, a population-based study in southern California, found that children diagnosed by the age of five were more likely to have asthma if exposed to pesticides.³⁹ Wheezing in Iowa farm children was associated with herbicide exposure, but most studies show farmers' children to be at lower risk of allergic disease, including hay fever.⁴⁰ A study in New Zealand found no adverse effects on asthmatic children from community spraying of the biological insecticide *Bacillus thuringiensis* (BT). In a pesticide fire, respiratory symptoms in the affected surrounding community were highest in preschool children and asthmatics.

Work Related

SENSOR found that 3.4% of 534 cases of work-related asthma in Michigan and New Jersey, reported from 1995 to 1998, were pesticide related. From 1993 to 1995, 2.6% of 1101 cases of occupational asthma reported in California, Massachusetts, Michigan, and New Jersey were pesticide related.⁴¹ Dyspnea and cough were found in over 78% of workers on apricot farms where large amounts of sulfur were used.⁴² Outdoor

workers exposed to pesticides had an increase in asthma mortality.⁴³ Decreased risk was found in animal farmers in Denmark, Germany, Switzerland, and Spain who had a lower prevalence of wheezing, shortness of breath, and asthma than the general population.⁴⁴

No increase in asthma emergency room visits to public hospitals was found in New York City during urban spraying of pyrethroid pesticides for West Nile Virus control.⁴⁵ Some household aerosol sprays trigger symptoms and impair lung function in asthmatics,⁴⁶ and use of mosquito coils inside the home was associated with a higher prevalence of asthma.^{47,48}

Swimming Pools

Swimming pools are treated with sodium hypochlorite, which is 1% chlorine. A major chlorination by-product (trihalomethane) found in the air of indoor chlorinated pools is nitrogen trichloride. Increase in asthma was found in children who regularly attend indoor pools,⁴⁹ and bronchial hyperresponsiveness and airway inflammation in swimmers with long-term repeated exposure during training and competition.⁵⁰ Serum levels of Clara cell protein, an anti-inflammatory biomarker, are significantly lower in children who are indoor pool swimmers.⁵¹ Air contamination can trigger asthma in pool workers who do not enter the water.

Chronic Health Effects

Epidemiological studies in populations with occupational and environmental exposure to pesticides show increased risk of cancer, birth defects, adverse effects on reproduction and fertility, and neurological damage. The increased risk can occur without any evidence of past acute health effects or poisoning and from long-term exposure to low levels not considered toxicologically significant. Constraints in chronic disease epidemiology of pesticides include difficulty in assessing and documenting exposure; simultaneous exposure to other pesticides (and inert ingredients); the changing nature of exposures over time; and potential additive and synergistic effects from multiple exposures, especially in exposures to the fetus, infants, and children at critical periods in development.

Data Sources

Data are now being reported from the Agricultural Health Study (AHS), a prospective cohort of 52,395 farmers, 4916 licensed commercial applicators, and 32,347 spouses of farmer applicators from Iowa and North Carolina, with data collection from 1993 to 1997, and continuing surveillance conducted by the National Cancer Institute (NCI).^{52,53} The NCI also collects data from farmer/farm worker studies in five northeastern states, six southern states, seven midwestern states, and six western states. The Midwest Health Study conducted by NIOSH collects data from Iowa, Michigan, Minnesota, and Wisconsin.

The National Health Information Survey household survey of the U.S. civilian noninstitutionalized population, conducted annually since 1957, includes pesticide use data. The NOMS (National Occupational Mortality Surveillance) is a collaborative study of NIOSH, NCI, and the National Center for Health Statistics using pooled death certificate data from 26 states. Useful data are also available from the NHATS (National Human Adipose Tissue Survey) of fat tissue collected from 1967 to 1983 of 20,000 autopsy cadavers and surgical patients for analysis of 20 organochlorine pesticides.

Potential adverse long-term effects of pesticides include cancer in adults and children, and effects on the nervous and reproductive systems. In the discussion that follows, only studies in which potential pesticide exposure was included as a risk factor and in which the findings were statistically significant are included.

Pesticides and Cancer

A large number of pesticide-active ingredients are known or suspect animal carcinogens. Based on the evidence for cancer in humans, the

EPA classifies pesticides into seven categories: A, human carcinogen; B, probable human carcinogen; C, possible human carcinogen; D, not classifiable as to human carcinogenicity; E, no evidence of carcinogenic risks to humans; L, likely, and NL, not likely human carcinogenesis. Epidemiological studies done in the United States and other countries report significant increased risk of certain cancers with occupational pesticide exposure in children and adults.

Cancer in Children

Pesticide use in the home has shown the most consistent increase in risk for several childhood cancers in the United States and other countries. In most studies, the risk is higher in children younger than five, and for use during pregnancy. Parental occupation as a farmer or farm worker has been shown to increase risk for certain kinds of cancers.^{54,55,56}

Parental Occupational Exposure. Increased risk of *bone cancer* was found in California for paternal pesticide exposure, and in Australia for maternal exposure; of *brain cancer* for parental exposure in the United States/Canada and in Norway and Sweden; of *Hodgkin's disease* in children of Iowa farmer applicators; of *kidney cancer* for parental exposure in England/Wales; of *leukemia* for periconceptual exposure in the United States/Canada; for maternal exposure during pregnancy in China and Germany; and for parental exposure in Sweden; of *neuroblastoma* in New York related to paternal creosote exposure, and maternal insecticide exposure; and in the children of Iowa farmer applicators; of *non-Hodgkin lymphoma* for maternal exposure during pregnancy in Germany.

*Home Exposure.*⁵⁷ Increased risk of *bone cancer* was found in California/Washington for home extermination (boys only); of *brain cancer* in Los Angeles for use of pet flea/tick foggers and sprays; in Missouri for use of bombs/foggers, pet flea collars, any termite treatment, garden diazinon and carbaryl use, yard herbicides, and pest strips; in Denver for pest strip use; in Washington state for home use during pregnancy; of *leukemia* in California for professional extermination in the third trimester, any use three months prior, during, and 1 year after pregnancy; in Los Angeles for parental garden use (higher if maternal), and for indoor use once a week or more; in Denver for pest strip use; in the United States/Canada for maternal home exposure and postnatal rodent control; in England/Wales for propoxur mosquito control; in Germany for home garden use; of *neuroblastoma* in the United States/Canada for garden herbicides; of *non-Hodgkin lymphoma* in Denver for home extermination; in the United States/Canada for frequent home use for home extermination, and in Germany for professional home treatment; of *soft tissue sarcoma* in Denver for yard treatment; of *Wilm's tumor* in the United States/Canada for home extermination.

Environmental Exposure. Increased risk of *hematopoietic cancer (leukemia/lymphoma)* was found in the Netherlands for swimming in a pesticide-polluted pond; of *leukemia* for maternal residence in a propargite use area in California, and within one-half mile of dicofol and metam sodium use.

Cancer in Adults^{58,59,60}

Farmers. Increased risk of *brain cancer* was found in U.S. applicators, in women in China, and men in Italy; of *colorectal cancer* in Italy; of *kidney cancer* in Canada and Italy; of *leukemia* in Illinois, Iowa, Minnesota, Nebraska, Denmark, France, Italy, and Sweden; of *liver/biliary cancer* in the United States; of *lung cancer* in Missouri, and in the Agricultural Health Study cohort related to use of chlorpyrifos, metolachlor, pendimethalin, and diazinon; of *malignant melanoma (skin)* in Norway and Sweden; of *multiple myeloma* in the Agricultural Health Study cohort in U.S. midwest states and in Norway; of *non-Hodgkin lymphoma* in U.S. midwest states, in New York (women), in Wisconsin; and in Canada, Italy, and Sweden; of *pancreatic cancer* in

Iowa, Louisiana and Italy; of *prostate cancer* in the Agricultural Health Study cohort applicators related to use of methyl bromide; in Canada and in Italy related to use of dicofol and DDT. North Dakota farmers with prostate cancer who did not use pesticides had a median survival 8 months longer than users; of *soft tissue sarcoma* in Kansas; of *stomach cancer* in Italy; and of *testicular cancer* in Swedish farmers using deet repellent. Glyphosate exposure was not associated with increased risk in the Agricultural Health Study.⁶¹

Farm Workers. Increased risk of *Hodgkin's disease* was found in Italy; of *leukemia* in California; in wives of pesticide-licensed farmers in Italy; of *lung cancer* in heavily exposed men and women in Costa Rica; of *malignant melanoma (skin)* in Australia and Scotland; of *multiple myeloma* in the United States; and of *non-Hodgkin lymphoma* in California.

Pesticide Applicators. Increased risk of *bladder cancer* was found in the United States; of *colorectal cancer* in Iceland; of *leukemia* in the United States, of Australia, and in Iceland (women); of *liver/biliary cancer* in DDT malaria sprayers in Italy; of *multiple myeloma* in DDT malaria sprayers in Italy⁶² and herbicide applicators in the Netherlands; of *pancreatic cancer* in U.S. aerial applicators and Australian DDT malaria sprayers; of *prostate cancer*⁶³ in Florida and Sweden; of *soft tissue sarcoma* in herbicide sprayers in Europe and Canada; and of *testicular cancer* in Florida pest control operators.

Factory Workers. Increased risk of *bladder cancer* was found in workers manufacturing the carcinogenic pesticide chlordimeform in Denmark and Germany, and in a U.S. bladder cancer cohort; of *kidney cancer* in Michigan pentachlorophenol workers, in an international herbicide cohort; of *leukemia* in U.S. alachlor workers, and U.S. formaldehyde workers; of *liver/biliary cancer* in DDT workers; of *lung cancer* in Alabama herbicide workers, in California diatomaceous earth workers, in Illinois chlordane workers, in Michigan DBCP workers, and in an English pesticide cohort; of *non-Hodgkin lymphoma* in U.S. atrazine and arsenic workers, and German and Swedish phenoxy herbicide workers; of *nasal cancer* in U.S. chlorophenol workers, in English herbicide workers, in European male and female formaldehyde workers, and in Filipino formaldehyde workers; of *soft tissue sarcoma* in Alabama herbicide workers, in U.S. chlorophenol workers, in Denmark pesticide workers, and in herbicide workers in Europe and Canada; of *stomach cancer* in Maryland arsenical workers; and of *testicular cancer* in methyl bromide workers in Michigan.

Other Occupational Exposure. U.S. Agricultural extension agents were at increased risk for brain cancer, colorectal cancer, Hodgkin's disease, kidney cancer, leukemia, multiple myeloma, non-Hodgkin lymphoma, and prostate cancer. U.S. forestry soil conservationists were at increased risk for colorectal cancer, kidney cancer, multiple myeloma, non-Hodgkin lymphoma, and prostate cancer. Golf course superintendents were at increased risk for brain cancer, colorectal cancer, multiple myeloma, and prostate cancer.

Increased risk of *bladder cancer* was found for pesticide exposure in Spain; of *Hodgkin's disease* in Swedish creosote workers; of *lung cancer* in China; of *non-Hodgkin lymphoma* in herbicide-exposed forest workers, and pesticide exposure in Australia and Sweden; of *pancreatic cancer* in Spain related to DDT exposure; of *soft tissue sarcoma* in Sweden related to phenoxy herbicide exposure; and of *stomach cancer* related to herbicide exposure in Sweden.

Home Exposure. Increase in risk of *lung cancer* was found in China; of *nasal cancer* in the Philippines for the daily burning of insecticide coils; of *prostate cancer* for home and garden use in Canada; and of *soft tissue sarcoma* for self-reported herbicide use in the United States.

Environmental Exposure. Increased risk of *brain cancer* was found in women in Massachusetts living near cranberry bogs; of *pancreatic*

cancer for residents in a dichloropropene use area in California; of *soft tissue sarcoma* from community chlorophenol contamination in Finland; of *soft tissue sarcoma* in men living near hexachlorobenzene emissions in Spain (*thyroid cancer* also increased); and of *stomach cancer* in a high pesticide use village in Hungary.

Breast Cancer (Female)

Early studies finding an increase in the risk of breast cancer associated with serum and fat levels of the DDT metabolite DDE and other pesticides were not always supported by larger cohort and case-control studies, especially those using historical samples gathered before diagnosis. Levels in the body at the time of cancer diagnosis may not reflect actual past exposures, and body stores depend on intake, changes in body size, and metabolism, among other conditions.⁶⁴⁻⁶⁶ A summary of the findings of pesticide-related studies in which the findings were statistically significant follows.

Serum and Fat (Adipose) DDE. Increased risk related to DDE levels in serum was found in New York, in North Carolina blacks, and in Belgium, Canada, Columbia, and Mexico; and to fat levels in Connecticut, New York, and Germany. Decreased risk related to serum DDE levels was found in California, Maryland, New England, New York, and Brazil; and to fat levels in five European countries (Germany, Spain, Netherlands, northern Ireland, Switzerland). No association with DDE serum levels was found in California, in a U.S. meta-analysis, in Missouri, in the Nurses' Health Study, in Long Island, NY, in Denmark, or Vietnam; and with fat levels in Connecticut, in a national U.S. study, and in Sweden and Vietnam.

Other Pesticide Serum and Fat Levels. Increased risk related to serum hexachlorobenzene was found in Missouri, to β -HCH (isomer found in lindane) in Connecticut, and to serum dieldrin in Denmark; and to β -HCH in autopsy fat in Finland, to breast fat aldrin and lindane in Spain, and to hexachlorobenzene in postmenopausal women with ER+ tumors in Sweden. No association was found related to serum chlordane and dieldrin in Long Island, NY, to transnonachlor in New York, to β -HCH in Connecticut and Norway, and to breast fat levels in Connecticut of oxychlordane, transnonachlor, and hexachlorobenzene.

Estrogen Receptor Status. Two studies found an increase in risk related to estrogen receptor-positive tumors—a national U.S. study related to DDE levels and a Swedish study related to hexachlorobenzene levels in postmenopausal women. A study in Canada found an increase in risk related to DDE and estrogen receptor-negative tumors. No association with estrogen receptor status was found in two Connecticut studies of DDE and oxychlordane, and one of DDE in Belgium.

Occupational Exposures. A few studies have been done of occupation as a risk factor for breast cancer. Increased risk was found in farmers in North Carolina, and no association with atrazine exposure in Kentucky. Decreased risk was found for Florida licensed pest control operators, and in a national study of applicators.

Environmental Exposure. Increased risk was found in Kentucky for residing in a triazine herbicide area. Decreased risk was found in California for residing in areas of agricultural use of probable human carcinogens and mammary carcinogens. No association was found for California teachers living within a half mile of agricultural pesticide use.

Neurological Effects

Although there is a dearth of data on chronic neuropathological and neurobehavioral effects of pesticides, available studies show adverse effects in two areas: long-term sequelae of acute poisoning and organophosphate-induced delayed neuropathy.

Long-term Sequelae of Acute Poisoning

The percentage of acutely poisoned individuals who develop clinically significant sequelae is not known. Early reports document that organophosphate pesticides can cause profound mental and psychological changes.⁴⁴

Follow-up studies in persons poisoned by organophosphates suggest that long-term neurological sequelae occur even though recovery appeared to be complete. Even single episodes of severe poisoning may be associated with a persistent decrement in function. Neuropsychological status of 100 persons poisoned by organophosphate pesticides (mainly parathion), an average of 9 years prior, was significantly different from that in control subjects in measures of memory, abstraction, and mood. Twice as many had scores consistent with cerebral damage or dysfunction, and personality scores showed greater distress and complaints of disability.⁴⁵

Other studies find that auditory attention, visual memory, visual-motor speed, sequencing, problem solving, motor steadiness, reaction time, and dexterity are significantly poorer among the poisoned cohort. Complaints of visual disturbances were found in 10 of 117 individuals 3 years after occupational organophosphate poisoning (mainly from parathion and phosdrin). One-fourth of workers poisoned 10–24 months after hospitalization for acute organophosphate poisoning had abnormal vibrotactile thresholds.

Parkinson's Disease

An association between pesticide exposure and Parkinson's disease was first suggested in 1978. The role of toxic chemicals in the human pathology of the disease was highlighted in 1983 with a report of parkinsonism in an addict exposed to MPTP (1-methyl-4-phenyl-1,2,3,6-tetra-hydropyridine), a street drug contaminant. The toxic mode of action of the insecticide rotenone leading to degeneration of dopaminergic neurons is similar to MPTP and has become the first animal model of pesticide-induced Parkinson's disease.⁶⁷ Heptachlor, and perhaps other organochlorine insecticides, exerts selective effects on striatal dopaminergic neurons and may play a role in the etiology of idiopathic Parkinson's disease. Low doses of permethrin can reduce the amount of dopamine transporter immunoreactive protein in the caudate-putamen, and triadimefon induces developmental dopaminergic neurotoxicity. As more pesticides are studied, many are shown to predispose dopaminergic cells to proteasomal dysfunction, which can be further exacerbated by environmental exposure to certain neurotoxic compounds like dieldrin.

Examination of the brain of addicts decades after MPTP exposure shows activated microglia—cells in areas of neural damage and inflammation—suggesting that even a brief toxic exposure to the brain can produce long-term damage. It is postulated that certain pesticides may produce a direct toxic action on the dopaminergic tracts of the substantia nigra and contribute to the development of Parkinson's in humans based on genetic variants (vide infra), exposure conditions, family history, and other factors. Silent neurotoxicity produced by developmental insults can be unmasked by challenges later during life as well as the potential for cumulative neurotoxicity over the life span.

Human Studies^{68,69}

Farmers. Increased risk of Parkinson's disease related to pesticide exposure was found in farmers in Italy and Australia, and in women in China, and in Taiwan. A nonsignificant increase in risk was found in Washington State for self-reported crop use of paraquat and other herbicides. No association was found for exposure to herbicides/pesticides in Kansas, to agricultural fungicides in Michigan, to insecticides/herbicides/rodenticides in India, to insecticides/herbicide and paraquat use in Canada, and to pesticides/herbicides in Finland.

Farm Workers. Increased risk was found in Washington State and British Columbia orchard workers, and in pesticide-exposed sugar plantation workers (nonsmokers, non-coffee drinkers) in Hawaii; for

herbicide/insecticide exposure (adjusted for smoking) in Michigan; and paraquat exposure in Taiwan. Decreased risk was found in French workers (smokers); and there was no association with pesticides in Quebec.

Other Occupational or Unstated. Increased risk was found related to insecticide exposure in Washington State (diagnosis before age 50); to occupations in pest control for black males in the NOMS study; to herbicide/insecticide exposure in Germany; in a French elderly cohort; to Germany wood preservatives in Germany; and to any occupational handling in Sweden. No association with herbicide/pesticide exposure was found in Pennsylvania, Australia, Quebec, Spain, and Italy.

Home Exposure. Increased risk was found for residents in a fumigated house in Washington State (diagnosed less than age 50), for home wood paneling more than 15 years in Germany. No association was found for home use, and self-reported use in another study in Washington State.

Environmental Exposure. An increase in mortality was found for living in a pesticide use area in California.

Pesticide Serum and Tissue Levels. The mean plasma level of DDE in Greenland Inuits (men and women) with Parkinson's disease was almost threefold higher than in controls. The mean lindane level in substantia nigra autopsy samples of Parkinson's patients was four-and-a-half times higher than in nonneurological controls. Dieldrin residues were significantly higher in postmortem brain samples from patients with Parkinson's compared to those with Alzheimer's disease, and nonneurological controls. Another study found that dieldrin was significantly decreased in a parkinsonian brain when analyzed by lipid weight.

Genetic Interactions.⁷⁰ Genetic susceptibility to Parkinson's may be mediated by pesticide metabolism and degradation enzymes in the cytochrome P450 system. A study in France found a threefold increase in risk in D6 CYP2D6 poor metabolizers exposed to pesticides that was not present in the unexposed control. In a Kansas study, those with pesticide exposure and at least one copy of the CYP2D6 29B⁺ allele had an 83% predicted probability of Parkinson's with dementia. An Australian study found that those with regular exposure to pesticides who were poor D6 CYP2D6 metabolizers had an eightfold increase in risk of Parkinson's, and carriers of the genetic variant a threefold increase. Polymorphism of the CYP2D6 gene is common in Caucasians, but very rare in Asians and was not found to be a significant factor in Parkinson's disease in a large study in China. Animal studies show that polymorphisms at position 54(M54L) and 192(Q192R) in paraoxonase (PON1) can affect metabolism and detoxification of pesticides. A study in Finland found no association between sporadic Parkinson's disease in humans and PON1 variation in these alleles.

Other Neurological Disease

Dementia. Most studies of pesticides as a risk factor for dementia report small, insignificant increases in risk or no association. Increased risk of Alzheimer's disease was found for exposure to pesticides in Canada and France, of mild cognitive dysfunction in the Netherlands, and of presenile dementia for self-reported use in the United States. Other studies in the United States did not report any association with pesticides.

Amyotrophic Lateral Sclerosis. An ongoing mortality study of Dow Chemical Company workers in Michigan Dow reported three deaths from Amyotrophic Lateral Sclerosis (ALS), all in workers whose only common exposure was to 2,4-D (1947–49, 1950–51, 1968–86). A nonsignificant increased risk was found for pesticide exposure in Italy. Other investigations are anecdotal case reports: from Brazil of two men exposed to aldrin, lindane, and heptachlor; from England of a death of a man exposed to chlordane and pyrethrins; and

from Italy of a conjugal cluster 30 months apart in which no association was found for pesticide levels in their artesian well.

vCruetzfeld-Jacob Disease. The only reports are two studies from England that found no association with PON1 alleles (paraoxonase).

Eye Disorders. A study in the United States found a significant 80% increase in risk of retinal degeneration related to cumulative days of fungicide use; a follow-up of 89 poisoning cases in France found two cases of visual problems along with other neurological sequelae; and a study of 79 workers in India exposed to fenthion found macular lesions in 15% and three cases of paracentral scotoma and peripheral field constriction. Other investigations are anecdotal case reports, including blindness related to methyl bromide in an agricultural applicator in California and in a suicidal ingestion of carbofuran in Tennessee.

Guillains-Barre Syndrome. There are no well-designed studies of pesticide exposure as a risk factor for Guillain-Barre, only sporadic reports.

Multiple System Atrophy. Increased risk was found for occupational pesticide exposure in the United States and Italy. A death record review in the United States implicated pesticides/toxins in 11% of cases. A prevalence study in France found no association with occupational pesticide exposure.

Progressive Supranuclear Palsy. No association with pesticides was found in a U.S. study. A report from Canada cites multiple insecticide exposure in two cases.

Vascular Dementia (Stroke). Increased risks related to occupational pesticide exposure were found in Canada.

Pesticide-Induced Delayed Neuropathy

Certain organophosphates are known to produce a delayed neuropathy 1–3 weeks after apparent recovery from acute poisoning, known as organophosphate-induced delayed neuropathy (OPIDN). It is characterized by a sensory-motor distal axonopathy and myelin degeneration, resulting in muscle weakness, ataxia, and paralysis. Exclusive sensory neuropathy is not seen in OPIDN, and in all reported cases, the sensory component, if present, is much milder than the motor component. The delayed neurotoxic action is not related to cholinesterase inhibition, but to the binding (phosphorylation) of a specific enzyme in the nervous tissue called neurotoxic-esterase, or neuropathy target esterase (NTE).⁷¹

OPIDN has been reported from exposure to Mipafox in a research chemist in 1953, in leptophos (Phosvel) manufacturing workers in 1977, and more recently from high exposures to methamidophos (Monitor), chlorpyrifos (Dursban, Lorsban), trichlorfon, and dichlorvos. Most reported cases are from suicidal or accidental ingestion of large doses. The hen brain inhibition bioassay is required by the EPA for screening new organophosphate insecticides for delayed neuropathic effects.

Reproductive Effects

Maternal and paternal pesticide exposure has been found to be a risk factor for infertility, sterility, spontaneous abortion, stillbirth, and birth defects.^{72–76} Several studies document a high percentage of women use pesticides in the home during pregnancy.

Data Sources

Pesticide-related data are available from the Collaborative Perinatal Project, a 1959–1965 cohort of about 56,000 pregnant women and their children at 12 medical centers; and from the Child Health and Development Study, a 1959–1967 cohort of 20,754 pregnancies in San Francisco Bay Area Kaiser members.

Fetal Loss

Spontaneous Abortion. Increased risk was found in wives of pesticide applicators in Minnesota; in wives of pesticide licensed farmers in Italy; in Canada related to exposure to thiocarbamates, glyphosate, and phenoxy herbicides; and in DBCP-exposed workers in Israel and in India. Maternal occupational exposure increased the risk in China (threatened), in Canada; in farm couples in India, in Columbia female flower workers and wives of male workers, in Filipino farmers using conventional versus less-pesticide-intensive methods, and in the toxic release incident in Bhopal, India.

Decreased risk was found in wives of New Zealand sprayers. No associations with pesticides were found in Germany, Italy, U.S. crop duster pilots, wives of DDT sprayers in Mexico, in a 17-year follow-up of wives of DBCP exposed in Israel, and with DDE blood levels in Florida.

Stillbirth

Increased risk was found in the United States for maternal and paternal home use, for maternal occupational exposure, in women exposed to pesticides and germicides in Canada, in Hispanics living near an arsenate pesticide factory in Texas, in Canadians living in a high pesticide use area, and in female farm workers in Canada and male farm workers in Spain.

No associations were found in Columbia flower workers, in wives of Minnesota pesticide applicators, for home pesticide use in California, and in long-term follow-up of women involved in the toxic release in Bhopal, India.

Birth Defects

Farmers. Increased risk for *cleft lip/palate* was found for agricultural chemical users in Iowa and Michigan; decreased risk was found for *cleft lip/palate* for paternal exposure in England/Wales; no association was found for *limb reduction defects* for farmers in New York state or for *neural tube defects* in male and female farmers exposed to mancozeb in Norway, or of any *major defect* in Filipino farmers using high pesticide input methods.

Farm Workers. Increased risks of *cleft lip/palate* was found in Finland for female farm workers exposed in the first trimester; of *limb reduction defects* in California if either or both parents were farm workers; of any *major defect* in female flower workers and wives of male workers in Columbia, and in female cotton field workers in India.

Pesticide Applicators. Increased risk of *cardiac defects* and any *major defect* was found for paternal occupation as a licensed applicator in Minnesota and of *central nervous system defects* for paternal occupation as glyphosate and phosphine applicators in Minnesota. No association for *cleft lip/palate* was found in New Zealand herbicide sprayers, for *limb reduction defects* in United States crop-dusters, and of any *major defect* in male malaria DDT sprayers in Mexico.

Other Occupational or Unstated. Increased risk was found for *cardiac defects* and *eye defects* in foresters in Canada; of *limb reduction defects* for maternal exposure in Washington State; of *neural tube defects* in China for maternal exposure in the first trimester (very high risk found, study done before folate supplementation instituted); for *cryptorchidism* (undescended testicles) for paternal occupational exposure in China, and in the Netherlands for paternal but not maternal exposure; of *hypospadias* for paternal exposure in Italy; and for any *major defect* in Spain for paternal paraquat exposure.

Decreased risk was found for *cardiac defects* in women exposed in the first trimester in Finland. No association was found with maternal exposure for septal defects, or hypoplastic left heart syndrome in Finland; with *eye defects* and parental benomyl exposure in a large multicenter study in Italy; with *hypospadias* parental exposure in Norway.

Home Use. Increased risk of *cleft lip/palate* was found in California for maternal periconceptual home use; of *cardiac defects* in California for periconceptual home use and maternal use of insect repellent; of *cardiac defects* in the Baltimore Washington Infant Study, including transposition of the great arteries for maternal exposure in the first trimester to rodenticides, herbicides, or any pesticide; of total anomalous venous return, and an attributable risk of 5.5% for ventricular septal defect; of *neural tube defects* in California if the mother was the user, which was borderline significant for commercial home application; of *limb reduction defects* in California for periconceptual home use, and in Australia for home use during the first trimester which increased further for more than one use. No association was found for maternal first trimester exposure and *Down syndrome* in Texas.

Environmental Exposure. Increased risk was found of *cleft lip/palate*, *kidney defects*, and *neural tube defects* for living in a high pesticide use area in Canada; of *limb reduction* and *neural tube defects* for maternal residence in high pesticide use areas in California; of potential benomyl-related *eye defects* (anophthalmia/microphthalmia) in rural areas in England.

No association with pesticide exposure was found for *neural tube defects* in a study on the United States–Mexican border, or for a cluster in California; or with any *major defect* for a toxic release of methylisocyanate from a pesticide factory in Bhopal, India.

Fertility⁷⁷

Sterility. Two pesticides, chlordecone (Kepone) and DBCP (dibromochloropropane), are well-documented causes of sterility in male factory workers. Kepone was banned in 1976 and DBCP in 1979. The cases in DBCP workers occurred without any related acute illness; in Kepone only in the severely poisoned. Studies of workers exposed to ethylene dibromide (EDB), a soil fumigant related to DBCP, found lowered sperm counts and impaired fertility. EDB replaced DBCP in 1979, but was banned in 1984, and most uses were replaced by methyl bromide.

Fecundability. Easily collected data that includes both partners and that can be done in any randomly selected population is “time to pregnancy.” A fecundability ratio is determined, which is a comparison of the number of months it takes for a couple to conceive when not using birth control in exposed versus unexposed couples. Pesticide-related effects have not shown a clear pattern as the results of recent studies show.

A significant decrease in fertility was found in the Netherlands related to pesticide exposure, but no dose-response was found; another study found lower fertility during spray season. Females exposed to pesticides in Canada had significantly lower fertility, and Danish female greenhouse sprayers a nonsignificant decrease. Nonsignificant lower fertility related to DDE serum levels was found in the Collaborative Perinatal Project⁷⁸ and in a study of former malaria sprayers in Italy.⁷⁹ No carbaryl-associated effects on fertility were found in U.S. factory workers. A significant increase in fecundability ratios (greater fertility) was found in male farmers and farm workers in Denmark, France, and Italy.

Biomonitoring

Males. High LH and FSH levels, an indication of testicular failure, were found in Chinese pesticide factory workers, in German workers with short-term exposure to pesticides, in Israeli workers 17 years after cessation of exposure to DBCP, and in lindane factory workers. No increase was found in Minnesota herbicide applicators. Decreased levels of testosterone were found in Chinese pesticide factory workers, Danish farmers, lindane factory workers, and black farmers in North Carolina exposed to DDT. No significant association with pesticide exposure was found in Minnesota herbicide applicators. The fungicide vinclozolin and the herbicide molinate act as antiandrogens in animal studies. No significant association

with pesticide exposure and fertility was found in male vinclozolin and molinate factory workers.

Semen. 2,4-D was found in 50% of seminal fluid samples in Canadian farmers. Detectable levels of hexachlorobenzene, lindane, DDT, and dieldrin were found in German men, with the highest levels in chemistry students. DDE, aldrin, endosulfan, and isomers of hexachlorocyclohexane (α -, β -, γ -, δ -) were detected in men in India, and DDE and ϵ -HCH in Poland. A study in France found no DDE in semen of fertile and subfertile men, and no difference in blood levels, but serum DDE was higher in the mothers of the subfertile men.⁸⁰

Sperm Counts. In Denmark, a report that a self-selected group of organic farmers attending a convention had higher sperm counts than traditional farmers created quite a stir. A well-designed study using a random sample of a larger number of farmers did not support the earlier findings. The mean sperm count in organic farmers was 10% higher than in traditional farmers, but the difference was not significant. A study of pesticide exposure in Danish farmers found 197 m/ml before pesticide exposure, decreasing 22% to 152 m/ml after exposure, but the difference was not significant. Lower counts were found in farmers in Argentina using 2,4-D or for any farm pesticide exposure. Except for well-documented studies in DBCP workers, the only pesticide-related study of sperm counts in the United States was in molinate factor workers where no association was found.⁸¹

Adipose Tissue (Fat). The highest reported level of DDT in mothers at delivery is 5,900 ppb in fat tissue of Kenyan women who also had high levels of β -HCH (30 ppb). Very high levels of DDE (4,510 ppb) were also found in tissue of Mexican women at delivery.

Ovarian Follicular Fluid. Trace amounts of chlordane, DDE, and hexachlorobenzene were found in follicular fluid from Canadian women undergoing in vitro fertilization (IVF); endosulfan and mirex in 50% or more of samples in another study, and hexachlorobenzene and lindane in the fluid of German women.

Amniotic Fluid. A study done in Florida at a time of heavy agricultural DDT use found 14 ppb in black babies and 6 ppb in whites. A recent study found low levels of DDE and α -hexachlorocyclohexane in California women in their second trimester of pregnancy.

Meconium. Meconium is a newborn baby’s intestinal contents—the first “bowel movement”—an accumulation of intestinal epithelial cells, mucus, and bile. Alkylphosphorylate metabolites of organophosphate pesticides were found in a recent New York study; DDE, DDT, dieldrin, and α - β - γ -HCH in an early study in Japan. A collaborative study in Australia and the Philippines found lindane, pentachlorophenol, chlordane, DDE, chlorpyrifos, and malathion in all samples, with levels much higher in the Filipino babies. Diazinon and parathion were found only in the Filipinos. A study done in Germany found DDE in 5% of samples collected in 1997.

Placenta. DDE was found in 1965 samples from women living in high agricultural production areas of California, and DDE and β -HCH in samples from Japanese women in the 1970s. Levels of DDT and lindane in stillborn babies were not different from live births in India. A study in Mexico found that pesticide exposure increased the prevalence of atypical placental villi.

Testes. In Greece, autopsies of suicide victims who died from ingesting pesticides found paraquat, fenthion, and methidathion in the testes.

Endocrine Disruptors

“The dose makes the poison,” attributed to the sixteenth-century Dutch alchemist Paracelsus, is the key concept in toxicology, in the

scientific basis of dose-response models used in determination of thresholds, and in regulation of allowable levels of exposure to toxic chemicals. The ability to detect increasingly lower levels of chemical contaminants in biological samples, and a rethinking of dose-response when the exposure is to the developing fetus, has had a profound impact on risk assessment. Challengers of a rigid dose-response model state that it is not relevant to the fetus during critical periods of development in the first days and weeks of pregnancy, and contend that small disturbances in hormonal function by xenobiotics, called “endocrine disruptors,” can lead to profound effects, which may not be manifested until adulthood.⁸²

Many pesticides can be considered potential endocrine disruptors based on animal findings in tests of the pituitary, adrenal, thyroid, testes, ovaries, reproductive outcome, and transgenerational effects, and *in vitro* screening in nonmammalian species. This includes chlorinated hydrocarbons, organophosphates, synthetic pyrethroids, triazine and carbamate herbicides, and fungicides.

Questions have been raised about the relevance of the findings in wildlife to human populations. Human studies have conflicting findings in the role of pesticides in conditions often attributed to endocrine disruptors, such as decreasing quantity and quality of sperm, increasing incidence of breast and prostate cancer, cryptorchidism and hypospadias, and other effects, as described above.⁸³ A recent review concludes that “At this time, the evidence supporting endocrine disruption in humans with background-level exposures is not strong.”⁸⁴

The EPA is developing protocols for screening and testing pesticides to determine if they are endocrine disruptors, and research is ongoing.

► REGULATION AND CONTROLS

Legislation

The Federal Insecticide Act of 1910, a labeling law to prevent adulteration, was repealed by the Federal Insecticide Fungicide and Rodenticide Act (FIFRA) of 1947. FIFRA was administered by the U.S. Department of Agriculture (USDA) until 1970, when control passed to the Environmental Protection Agency. Most pesticides now on the market were approved by the USDA in the 1940s through the early 1970s, without the chronic toxicity, health, and environmental fate data required by current law.

Pesticides must be registered with the EPA before they can be sold. Registration is contingent upon submission by the registrant (manufacturer) of scientific evidence that when used as directed, the pesticide will effectively control the indicated pest(s); that it will not injure humans, crops, livestock, wildlife, or the environment; and that it will not result in illegal residues in food and feed. About 25–30 new active pesticide ingredients are registered annually.

FIFRA amendments in 1972 required all pesticides to meet new health and safety standards for oncogenicity/carcinogenicity, chronic toxicity, reproductive toxicity, teratogenicity, gene mutation, chromosomal aberrations, DNA damage, and delayed neurotoxicity by 1975. Failure to meet the new standards resulted in 1988 FIFRA amendments, requiring the EPA to undertake a comprehensive reregistration review of the 1138 active-ingredient pesticides first registered before November, 1984. Registration Eligibility Decisions (REDs) summarize the reviews of these older chemicals. There were a large number of voluntary cancellations due to the review process, but a large percentage has not met the new rules.

In 1996, the Food Quality Protection Act (FQPA) amended both FIFRA and the Federal Food, Drug and Cosmetic Act (administered by the FDA) requiring a reassessment of all food tolerances (the maximum amount of pesticide residues allowed on food), and replacement of FIFRA’s cost-benefit analysis with a “reasonable certainty of no harm” standard, mandating three additional steps to determine the new health-based standard: (a) Take into account aggregate exposure from food, water, and home and garden uses; (b) Add an additional tenfold margin of safety (or higher if necessary) to protect infants and

children; (c) Consider cumulative risks from all pesticides which have a common mechanism of activity. Organophosphate insecticides, for example, have the same basic mechanism of toxicity and biological activity.⁸⁵ To date, 7000 of the 9721 tolerances requiring reassessment have been completed.⁸⁶

Human Studies. Intense controversy continues to surround the issue of the use of human beings in risk assessment of pesticides.⁸⁷ An initial study approved by the EPA was called the Children’s Environmental Exposure Research Study (Cheers). It offered \$970, a free camcorder, a bib, and a T-shirt to parents whose infants or babies were exposed to pesticides if the parents completed the two-year study. The requirements for participation were living in Duval County, Florida, having a baby under 3 months old or 9–12 months old, and “spraying pesticides inside your home routinely.” The study was being paid for in part by the American Chemistry Council that includes pesticide registrants. The EPA withdrew approval for the study, but is still reconsidering the issue of some form of human testing.

Worker Protection Standards

Chemical workers who manufacture and formulate pesticides are covered by the Occupational Safety and Health Act (OSHA) passed in 1970. Agricultural workers were specifically excluded from the law, including the Hazard Communication Standard (Right-to-Know) provisions.

The EPA issued Worker Protection Standards (WPS) under section 170 of FIFRA in 1992, with full implementation by October 1995. The EPA estimates that about four million workers on farms and in nurseries, greenhouses, and forestry are covered by the rules. The regulations require restricted entry intervals (REIs) for all pesticides: 48 hours for all toxicity category I products, which can be extended up to 72 hours for organophosphates applied outdoors in arid areas; 24 hours for toxicity category II products; and 12 hours for all other products, later amended to exempt cut-rose workers. The rules require posting of warning signs for certain applications, worker education and training, and providing pesticide-specific materials upon request. The WPS are based on acute toxicity only, and there are no rules that specifically address the exposures to pesticides that are known or suspect carcinogens and teratogens. The rules apply to adult workers, without any modifications or consideration of exposures to children and pregnant women.

Federal and State Administration and Enforcement

The EPA delegates administration and enforcement of FIFRA to the states through working agreements. In most states, enforcement authority is in departments of agriculture.

The pesticide label is the keystone of FIFRA enforcement, and any use inconsistent with the label is illegal. The label must contain the following: brand name, chemical name, percentage active ingredient(s) and inert ingredient(s); directions for use; pests that it is effective against; crops, animals, or sites to be treated; dosage, time, and method of application; restricted entry interval, preharvest interval; protective clothing and equipment required for application; first-aid and emergency treatment; name and address of the manufacturer; and toxicity category. The toxicity category and associated signal word (Table 33-2) must also be on the label.

Other Agencies

Other Federal agencies with responsibilities for enforcement of pesticide regulations include the Food and Drug Administration (FDA), the USDA, and the Federal Trade Commission (FTC). The EPA sets the maximum legal residues of pesticides (called tolerances) allowed to be on food at the time of retail sale, but does not enforce them. The FDA is responsible for enforcement of tolerances in fruits, vegetables, grains, feed, and fiber; and the USDA, for meat, poultry, and fish.

The FTC protects consumers against false and deceptive advertising claims by pesticide distributors and professional applicators—the FTC has brought only three actions in the past 10 years.

Banned, Suspended, and Severely Restricted Pesticides

Table 33-4 lists selected pesticides that have been banned, suspended, or severely restricted for use in the United States. Many pesticides that are banned or severely restricted in the United States, Canada, and Western Europe are widely used in developing countries. An Executive Order requires the United States to inform third-world countries if an exported pesticide is banned in the United States and to obtain official approval before it can be exported.

Temperature and Health

Edwin M. Kilbourne

► THERMOREGULATION

Humans are a homeothermic (warm-blooded) species. Although the temperature of the arms, legs, and superficial areas (*acral* body parts) may vary greatly, the body maintains a relatively constant deep body (core) temperature. Substantial deviations from normal core body temperatures cause adverse effects ranging from minor annoyance to life-threatening illness. Although far less affected by temperature changes than the core, acral body parts can be adversely affected by cold temperatures, particularly if the exposure is prolonged or repeated.¹

Body temperature is affected by *five fundamental physical processes*:

1. **Metabolism**—Heat is generated by the biochemical reactions of metabolism.
2. **Evaporation**—Heat is lost by evaporation of moisture from the skin and respiratory passages.
3. **Conduction**—Heat is transferred to or from matter with which the body is in contact.
4. **Convection**—Heat transfer by conduction is greatly facilitated when the body is immersed in a fluid medium (gas or liquid) because of the ability of substance to flow over body surfaces. Conduction in this context is called *convection*.
5. **Thermal radiation**—Heat may be gained or lost due to thermal radiation. The body radiates heat into cold surroundings or gains heat from objects that radiate infrared and other wavelengths of electromagnetic radiation (for example, the sun or a hot stove). The process is independent of the temperature of matter in contact with the body.¹

► ADVERSE EFFECTS OF HEAT

Heat Stress

Heat stress may result from alteration of any of the five physical processes involved in determining body temperature. For example, increased metabolic heat production caused by strenuous physical activity may stress the runner in a long-distance race or the soldier undertaking military maneuvers. A steel worker may experience heat stress because of the radiant heat emitted from a furnace at the workplace. At a hazardous waste site, a worker who must wear a heavy, impermeable suit may develop heat stress as the air in the suit becomes humid (decreasing evaporative cooling) and warm (limiting heat loss by conduction/convection).

¹Burns involve acute destruction of skin and other tissues. They are caused by a variety of noxious physical and chemical influences, including both extremely high and extremely low temperatures. Burns present a unique set of problems and issues and thus are not discussed further in this chapter.

People seek to relieve heat stress by altering one or more of the processes by which the body gains or loses heat. They may rest (lowering metabolic heat production), move to the shade (avoiding radiant solar heat), sit in front of a fan (increasing convective and evaporative heat loss), or swim (facilitating heat loss by conduction/convection through water).

The acute physiological response to heat stress includes perspiration and dilation of the peripheral blood vessels. Perspiration increases cutaneous moisture, allowing greater evaporative cooling. Peripheral vasodilation reroutes blood flow toward the extremities and body surfaces, thereby enhancing transmission of heat from the body's core to peripheral body parts, from which it can be more readily lost.^{2,3}

With continuing exposure to heat stress, a process of physiological adaptation takes place. Although maximal adaptation may take weeks, significant acclimatization occurs within a few days of the first exposure.^{4,5}

Indices of Heat Stress

In most circumstances, there are *four principal environmental determinants* of heat stress. They are ambient (dry-bulb) temperature, humidity, air speed, and thermal radiation. A number of heat indices have been developed to attempt to combine some or all of these separate factors into a single number indicating how hot “it feels” and, by implication, attempting to quantify the net pathophysiological significance of a given set of environmental conditions.

The original “effective temperature” (ET) index is read from a nomogram reflecting dry-bulb and wet-bulb temperatures, as well as air speed. The ET was derived empirically, based on subjects' reports or thermal sensations of subjects placed in a wide variety of conditions of temperature, humidity, and air movement. As originally formulated, ET attempted to quantify the dry-bulb temperature of still, saturated air that would produce the same subjective thermal effect as the conditions being evaluated.⁶ A revision of the ET, the corrected effective temperature (CET), was developed to take radiant heat into account and substitute globe thermometer temperature for dry-bulb temperature. (The globe thermometer is a dry-bulb thermometer with the bulb placed at the center of a 6-inch-diameter thin copper sphere, the outside of which is painted matte black.) Because of concern that the original ET was too sensitive to the effect of humidity at low temperatures and not sensitive enough to humidity at high temperatures, a reformulated version of ET has been published.^{7,8}

The wet-bulb globe temperature (WBGT) is a heat stress index calculated as a weighted average of wet-bulb, globe, and dry-bulb thermometer temperatures:

$$\text{Outdoors: } WBGT = 0.7 T_{wb} + 0.2 T_g + 0.1 T_{db}$$

$$\text{Indoors: } WBGT = 0.7 T_{wb} + 0.3 T_g$$

where T_{wb} is the temperature read by a naturally convected wet-bulb thermometer, T_g is the globe thermometer temperature, and T_{db} is the

dry-bulb temperature. Its formulae were chosen to yield values close to those of the ET for the same conditions.⁹

The WBGT has been used to assess the danger of heatstroke or heat exhaustion for persons exercising in hot environments. Curtailing certain types of activities when the WBGT is high decreases the incidence of serious hour-related illness among military recruits.¹⁰ Current standards and recommendations for limiting heat stress in the workplace are frequently expressed in terms of WBGT, although a person's degree of acclimatization, energy expenditure, and the amount of time spent performing the stressful task are factored in as well.¹¹

The "Botsball" or wet-globe thermometer (WGT) consists of a thermal probe within a black sphere 6 cm in diameter, the surface of which is covered with black cloth kept wet by water in a reservoir. The WGT is smaller and lighter than the equipment required to take WBGT readings and has a shorter stabilization time. These attributes facilitate its use to measure conditions in an employee's personal workspace. WGT readings approximate those of WBGT. Mathematical formulae for approximating the WBGT from the WGT have been proposed.^{12,13}

Other than in military and occupational contexts, the use of R.G. Steadman's scheme of apparent temperature (AT) is favored by meteorologists and climatologists in the United States, Canada, Australia, and other countries. In the United States, the dry-bulb temperature and humidity components are used alone during hot weather to generate an approximation of the AT referred to as the "heat index."

Like ET, WGT, and WBGT, AT functions as a measure of the heat stress associated with a given set of meteorological conditions (Fig. 34-1). Unlike the effective temperature, which was derived empirically, AT is the product of mathematical modeling, based on principles of physics and physiology. The AT for a given set of conditions of temperature, humidity, air speed, and radiant heat energy is equal to the dry-bulb temperature with the same predicted thermal impact on an adult walking in calm air of "moderate" humidity with surrounding objects at the same temperature as ambient air (no net heat gain or loss by radiation).¹⁴

For public health purposes, heat stress indices may be helpful in assessing the danger posed by particular weather conditions, but they are limited by underlying assumptions regarding metabolic heat production, clothing, body shape and size, and other factors. Moreover, most indices are also limited in that they yield instantaneous values that do not reflect the time course of a community's heat exposure, which may be critical to the occurrence (or not) of adverse health effects.

Heatstroke

The most serious illness caused by elevated temperature is heatstroke. Its hallmark is a core body temperature of 105°F (40.6°C) or greater. Temperature elevations as high as 110°F (43.3°C) or higher are not uncommon. Mental status is altered, and initial lethargy proceeds to confusion, stupor, and finally unconsciousness. Classically, sweating is said to be absent or diminished, but many victims of clear-cut heatstroke perspire profusely. The outcome is often fatal, even when patients are brought quickly to medical attention. Death-to-case ratios of 40% or more have been reported.^{15,16,17}

Heatstroke is a medical emergency requiring immediate steps to lower core body temperature. A patient can be cooled with an ice-water bath, ice massage, or specialized evaporative cooling procedures. Further treatment is supportive and directed toward potential complications of hyperthermia, including fluid and electrolyte abnormalities, rhabdomyolysis, and bleeding diathesis. Maximal recovery may occur quickly or may not occur for a period of days or weeks, and there may be permanent neurological residua.^{15,16}

Heat Exhaustion

Heat exhaustion is a milder illness than heatstroke, due primarily to the unbalanced or inadequate replacement of water and salts lost in perspiration. It typically occurs after several days of heat stress. Body temperature is normal-to-moderately elevated but rarely exceeds 102°F (38.9°C). The symptoms, primarily dizziness, weakness, and fatigue, are those of circulatory distress. Treatment is supportive and directed toward normalizing fluid and electrolyte balance.^{16,17}

Heat Syncope and Heat Cramps

Heat syncope and heat cramps occur principally in persons exercising in the heat. Heat syncope is a transient fall in blood pressure with an associated loss of consciousness. Consciousness typically returns promptly in the recumbent posture. The disorder is thought to arise from circulatory instability due to cutaneous vasodilation in response to heat stress. Prevention is accomplished by avoiding strenuous exercise in the heat, unless one is well trained and acclimatized.¹⁸

Heat cramps are muscle cramps, particularly in the legs, that occur during or shortly after exercise in a hot environment. They are thought to arise from transient fluid and electrolyte abnormalities. Heat cramps decrease in frequency with athletic training and acclimatization to hot weather. Increasing salt intake may be helpful.¹⁶

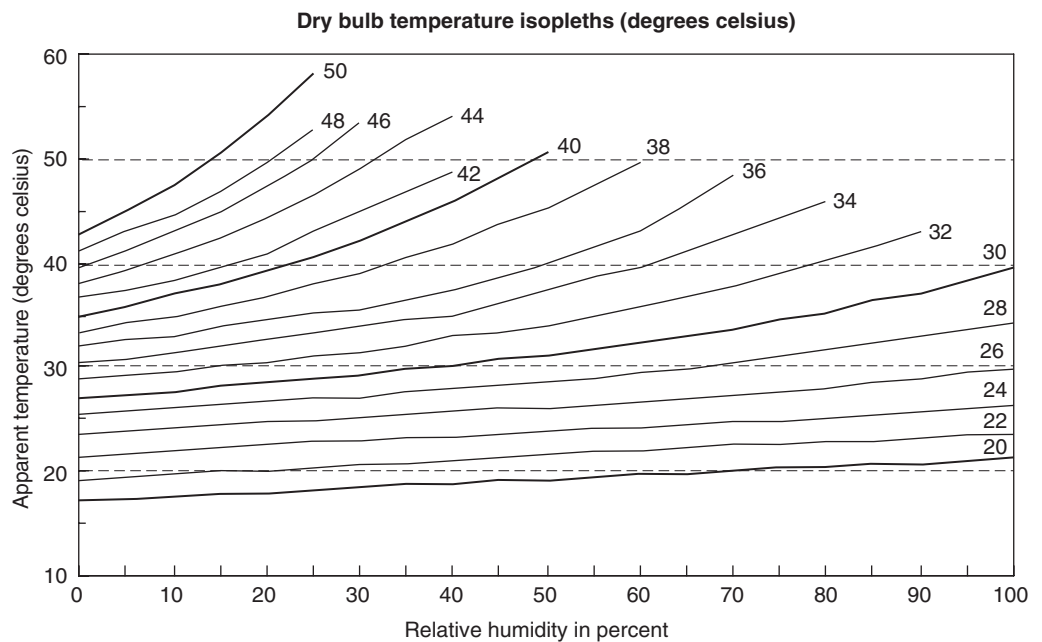

Figure 34-1. Nomogram for approximating Apparent Temperature. Based on data from Steadman RG. A universal scale of apparent temperature. *J Climate Appl Meteorol.* 1984;23:1674-87. Draw a vertical line upward from the relative humidity value (horizontal axis) to meet the dry-bulb temperature. The vertical axis value directly left of this point is the approximate apparent temperature.

Reproductive Effects

Among men, frequent or prolonged exposure to heat can result in elevated testicular temperatures, causing a substantial decrease in sperm count.¹⁹ Occupational exposure to heat has been associated with delayed conception.²⁰ Measures to enhance scrotal cooling have been shown to increase both the numbers and quality of spermatozoa.²¹

Data continue to accumulate suggesting that heat stress during pregnancy may cause neural tube defects.^{22–25} Current data associating this group of birth defects with exposure to environmental heat may not be sufficient to prove cause and effect. However, they are sufficiently strong to make it advisable that women who are pregnant or who may become pregnant avoid environments and physical activities that are likely to result in a substantial increase in core temperature.

► EPIDEMIOLOGY OF HEAT-RELATED ILLNESS

Heat Waves

Prolonged spells of unusually hot weather can cause dramatic increases in mortality, particularly in the urban areas of temperate regions. Although they are especially frequent in North America, a lethal summer heat wave killed thousands in Europe during the summer of 2003, underscoring the need for an international view of prevention. During the heat wave of 1980 in St. Louis, Missouri, some 300 more persons died than would have been expected on the basis of death rates observed before and after the heat wave.²⁶ More recently, in the summer of 1995, record-breaking heat resulted in the loss of more than 700 lives in Chicago, largely in the course of a single week.²⁷ In fact, more than 150 excess deaths occurred in a single day.²⁸

A surprisingly small proportion of heat wave–related mortality is identified as being caused by or precipitated by the heat. In general, recognized heat-related deaths comprise from none to less than two-thirds of the heat-wave mortality increase.²⁹

The connection of heat with many heat wave–related deaths is simply unrecognizable. Retrospective reviews of death certificates and clinical records have shown that increases in three categories largely account for the heat-related increase: These are deaths due to cardiovascular, cerebrovascular, and respiratory diseases.²⁹ As a practical matter, it may be difficult or impossible for a physician to distinguish the myocardial infarctions or strokes that would have occurred anyway from those occurring because of the heat.

Frequently, the overall health effects of the heat are most evident in the office of the medical examiner or coroner, where elevated

mortality due to the heat presents as an abrupt increase in the number of sudden unattended deaths. (Such cases are generally referred to the medical examiner or coroner.) In severe heat, the sheer volume of such cases may preclude conducting an in-depth investigation of each one. The absence of such data may further complicate the task of distinguishing those that are heat related. Finally, although efforts have been made to standardize postmortem diagnosis of heat-related cases, both the requirements for investigation and the interpretation of findings are at the discretion of individual medical examiners and are not standardized.

Nevertheless, the reported increases in numbers of deaths apparently due to cerebrovascular disease (largely stroke) and cardiovascular disease (principally ischemic heart disease) are biologically plausible. Some studies suggest that heat stress induces some degree of blood hypercoagulability.^{30,31} Thus, external heat may favor the development of thrombi and emboli and may cause an increase in fatal strokes and myocardial infarctions.

The increase in mortality during heat waves is paralleled by an increase in nonspecific measures of morbidity. During hot weather, the numbers of hospital admissions and emergency room visits increase.^{26,32}

Excess mortality due to heat waves occurs primarily in urban areas. Suburban and rural areas are at far less risk.^{26,32} The urban predominance of adverse health consequences of the heat may be explained, in part, by the phenomenon of the urban “heat island.”³³ The masses of stone, brick, concrete, asphalt, and cement that are typical of urban architecture absorb much of the sun’s radiant energy, functioning as heat reservoirs and reradiating heat during nights that would otherwise be cooler. In many urban areas, there are few trees to provide shading. In addition, tall buildings may effectively decrease wind velocity, decreasing in turn the cooling, convective, and evaporative effects of moving air. Other factors contributing to the severity of heat-related health effects in cities include the relative poverty of some urban areas.^{26,32} Poor people are less able to afford cooling devices such as air conditioners and the energy needed to run them.

Impact on the Elderly

The elderly are at particularly high risk of severe, heat-related health effects. Except for infancy and early childhood, the risk of death due to heat increases throughout life as a function of age (Fig. 34-2). In St. Louis and Kansas City, Missouri, during the 1980 heat wave, about 71% of heatstroke cases occurred in persons age 65 and over; despite the fact that this group constituted only about 15% of the population.²⁷ A similar predominance of elderly casualties during other heat waves has been noted.³⁴

Figure 34-2. U.S. heat-related deaths (ICD-9 Codes E900.0–E900.9) for the years 1979–1998, rates by age group indicated.

The predisposition to heat-related illness among the elderly may be explained, in part, by impaired physiological responses to heat stress. Vasodilation in response to heat requires increased cardiac output, but persons older than 65 are less likely to have the capacity to increase cardiac output and decrease systemic vascular resistance during hot weather.³⁵ Moreover, the body temperature at which sweating begins increases with increasing age.³⁶ The elderly are more likely to have underlying diseases or to be taking medications (major tranquilizers and anticholinergics) that have been reported to increase the risk of heatstroke.^{37,38,39,40} Finally, the elderly perceive differences in temperature less well than younger persons do. This attribute may render an older person less able to regulate his or her thermal environment.⁴¹

Other Factors Affecting Risk

Although their death rates due to heat are lower than those of the elderly, infants and young children are also at increased risk from the heat. Healthy babies kept in a hot area have been found to run temperatures as high as 103°F (39.4°C). Mild fever-causing illnesses of babies may lead to frank heatstroke by a heat stress.⁴² Sensitivity to heat is greatest in children less than 1 year old and decreases quickly up to the age of about 5–9 years (Fig. 34-2). The risk of both fatal and nonfatal heatstroke is increased in infants and young children.⁴³ Children with congenital abnormalities of the central nervous system and with diarrheal illness appear to be particularly vulnerable.^{42,43} Parents may contribute to risk by failing to give enough hypotonic fluid during the heat and dressing or covering the child too warmly.^{43,44} Temperatures may approach 140°F (60°C) in cars parked in sunlight in warm weather, and the great hazard of leaving infants and young children in parked cars has been emphasized repeatedly.^{45,46} From news media accounts alone, one study identified 171 heat-related fatalities during the years 1995–2002 among children in stationary motor vehicles.⁴⁷

Death rates due to heat in the United States are generally higher in males than in females. This trend is most evident among young adults and is much less evident at the extremes of age. The reasons for the apparent increased risk of males are not known, but differences between the sexes in patterns of thermal exposure (for example, in choice of occupation, recreational activities, and risk-taking behavior) may be maximal during young adult life and could be the causal factor.

During an urban heat wave, the rate of heatstroke is disproportionately high in areas of low socioeconomic status. The association in the United States of black race with relatively low socioeconomic status may well explain the disproportionately high heatstroke rates of blacks in the United States.^{27,32} No biologically based vulnerability of any particular race has been shown.

Chronic illnesses resulting in loss of the ability to care for oneself or in a bedfast or relatively immobile lifestyle are more frequent in heatstroke patients than control subjects. No specific chronic disease is known to be as effective a predictor of heatstroke as this more general characterization.^{27,37}

Socially isolated persons appear to be a high-risk group. In studies of the 1995 and 1999 heat waves in Chicago, factors such as living alone, not having access to transportation, or being confined to bed indicated an increased risk for the combined category of heatstroke death and death due to heat-related exacerbation of underlying cardiovascular disease.^{27,48}

Persons with a history of prior heatstroke maintained thermal homeostasis in a hot environment less well than comparable volunteers who have never suffered heatstroke.⁴⁹ Whether heatstroke causes damage to the body's ability to regulate its temperature or thermoregulatory abnormalities antedate the first heatstroke is not known.

Frequently referred to as a risk factor, the extent to which obesity contributes to heatstroke risk is unclear. Obese subjects exercising in a hot environment showed a greater increase in rectal temperature and heart rate than did lean subjects.^{50,51} Soldiers in the U.S. Army who died from exertional heatstroke during basic training in World War II were more likely to be obese than their peers.⁵² However, studies of heatstroke and fatal cardiovascular disease among the relatively sedentary, older persons principally at risk during urban summer heat

waves have failed to demonstrate high body mass index as a risk factor.^{27,37}

Neuroleptic (“major tranquilizing”) drugs have been strongly implicated in increasing risk from the heat in both animal and human studies.^{37,38,40,41,53} Neuroleptic drugs appear to impair thermoregulatory function in both directions, sensitizing to cold as well as to the heat.

Anticholinergics decreased the heat tolerance of human volunteers in laboratory tests. Persons treated with anticholinergics while exposed to heat had a decrease or cessation of sweating and a rise in rectal temperature.³⁹ Many commonly used prescription drugs (e.g., tricyclic antidepressants, antiparkinson agents) and nonprescription drugs (e.g., antihistamines, sleeping pills) have prominent anticholinergic effects, and in one study the use of such drugs was more common in heatstroke victims than in control subjects.³⁷

► PREVENTION OF HEAT-RELATED ILLNESS

In most parts of the United States, heat waves severe enough to threaten health do not occur every year. Several relatively mild summers may intervene between major heat waves. The erratic occurrence of heat waves hinders prevention planning. It is logistically difficult to provide adequate resources if needed, but not waste these resources if a heat wave does not materialize.

Programs to prevent heat-related illness should concentrate on measures the efficacy of which is supported by empirical data. Many heatstroke-prevention efforts for the community at large have been based on the distribution of electric fans to persons at risk. Nevertheless, systematic studies of urban heat waves failed to demonstrate any protective effect of electric fans.^{27,37} Indices of heat stress predict a diminished cooling effect of air movement as dry-bulb temperature increases.^{6,14} Physiologic experimentation confirms the inability of increasing air movement to increase heat tolerance at high temperatures.⁵¹ Fans thus appear unlikely to offer protection from heat under the conditions of very high ambient temperature at which heat-related health effects are most likely to occur. Accordingly, the distribution of free fans during heat waves as a public health measure should be abandoned.

Air conditioning, on the other hand, is the single most effective intervention, for prevention of heatstroke. In separate studies, the availability of home air conditioning was associated with a 70% decrease in fatality from the combined endpoint of either heatstroke or cardiovascular disease²⁷ and a 98% decrease in fatal heatstroke.³⁷ Moreover, both studies showed additional major reductions in risk (50% and 75%, respectively) from simply spending more time in air-conditioned places.^{27,37} Thus, such strategies as setting up air-conditioned heat-wave shelters and air conditioning the lobbies of apartment buildings of lower socioeconomic-status tenants may be effective in preventing heat wave-related illness and death. Even when shelters cannot be provided, elderly and other persons at high risk can be encouraged to spend a few hours each day at public air-conditioned places, such as movie theaters and shopping malls.

Heatstroke is an occupational risk for an estimated six million Americans who work in “hot” industries (e.g., foundries, glassworks, and mines). To prevent heat-related illness among the occupationally exposed, the U.S. National Institute for Occupational Safety and Health (NIOSH) recommends acclimatizing new workers and those returning from leave, arranging frequent rest periods in a cool environment, scheduling hot operations for the coolest part of the day, making drinking water readily available, conducting preemployment and periodic medical examinations, and instructing workers and supervisors about preventive measures and early recognition of heat-related illnesses.¹¹

► COLD WEATHER

Seasonal Trends in Mortality

Human mortality is highly seasonal. In the United States, the death rate is greatest in late winter (usually February) and lowest in late summer (August) (Fig. 34-3). A similar seasonal pattern of mortality

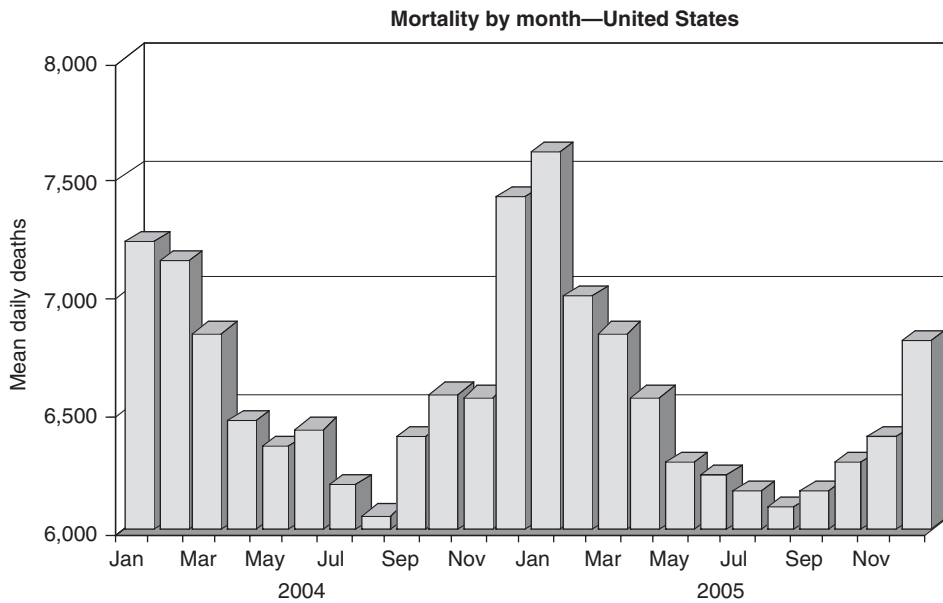

Figure 34-3. Mean deaths per day by month among U.S. residents during the years 2004 and 2005.

occurs in other countries in the temperate zones of both the Northern and Southern Hemispheres, although the mortality curves of the two hemispheres are 6 months out of phase.¹

The wintertime increase in the death rate is most marked in the elderly and becomes increasingly prominent with advancing age. Among persons aged 45 years and younger, however, the pattern is reversed; the death rate is lower in the winter and greater in the summer.⁵⁴

The extent of seasonal variation in mortality varies greatly by cause of death. The death rates for diseases of heart, cerebrovascular disease, pneumonia and influenza, and chronic obstructive pulmonary disease show substantial increases in the winter. In contrast, the occurrence of death due to malignant neoplasms remains virtually constant throughout the year.⁵⁴

Some of the seasonal winter increase in deaths due to major chronic diseases such as stroke and myocardial infarction may reflect seasonal changes in underlying risk factors for vascular diseases. For example, blood pressure in humans fluctuates seasonally and is higher in the winter.⁵⁵ Cold stress can enhance the coagulation of blood, possibly contributing to the winter excess of deaths due to stroke and ischemic heart disease.⁵⁶ In addition, many types of exercise are practiced seasonally, with sedentary periods tending to occur in winter.⁵⁷

The winter death increase cannot be attributed entirely to the direct effect of cold exposure. In the United States, the increase occurs even in states noted for their relatively mild winter temperatures (e.g., Florida and Arizona) at approximately the same magnitude as in colder states (e.g., Michigan and Montana).⁵⁴ Low winter humidity may contribute to the winter death excess, since it favors the transmission of certain infectious agents, notably influenza.⁵⁸ In addition, winter increases in deaths due to some types of unintentional injuries may reflect seasonal increases in certain behaviors. For example, deaths due to fire are more common in the winter, perhaps a result of the use of fireplaces and heating devices. Finally, the peaks and valleys in the U.S. death rate have not always come in mid-to-late winter and late summer, respectively, as they usually do now. In the early part of this century, the peak was usually in February or March, and the nadir was in June rather than August.⁵⁹ This change in seasonal pattern is further evidence that temperature is not the only determinant of seasonality in mortality.

Cold Stress and its Indices

The two most important adaptive physiological responses to the cold are vasoconstriction and shivering. Peripheral vasoconstriction causes a rerouting of some blood away from cutaneous and other

superficial vascular beds toward deeper tissues where the blood's heat is less easily lost. In addition, blood is rerouted from the superficial veins of the limbs to the *venae comitantes* of the major arteries. Such rerouting activates a "countercurrent" mechanism by which arterial blood warms venous blood before the venous blood returns to the core.

Conversely, venous blood cools arterial blood so that it gives up less heat when it reaches the periphery. The result is a fall in the temperature of superficial body parts in defense of core temperature.^{1,60}

Humidity and radiant heat energy are less important in the evaluation of cold environments than of hot. Thus the popular "wind chill" index of Siple expresses the intensity of cooling expected from a cold environment as a function only of ambient temperature and wind speed:

$$H = (10.45 + 10\sqrt{s - s}) (33 - t)$$

where H is the wind chill expressed in kcal/m²/h¹, s is the wind speed in m/sec, and t is the ambient temperature in degrees Celsius.⁶¹ The value of H permits comparison of the cooling effect of various temperature and wind speed combinations. The subjective thermal perception associated with any given value of H is influenced greatly by one's level of activity and the type and amount of clothing worn.

Often, the wind-chill effect is described in terms of a wind-chill equivalent temperature. This is the temperature that would produce the same intensity of cooling as the temperature-wind speed combination under consideration if the wind speed were some relatively low reference value. A wind-chill equivalent temperature can be calculated from a modification of the Siple formula:

$$t_{eq} = 33 - \frac{(10.45 + 10\sqrt{s - s})(33 - t)}{10.45 + 10\sqrt{s_{ref} - s_{ref}}}$$

where t_{eq} and t are the wind-chill equivalent and ambient temperatures in degrees Celsius, and s and s_{ref} the actual and reference wind speeds in m/sec. Wind-chill equivalent temperatures in degrees Celsius for a reference wind speed of 2 m/sec are shown in Fig. 34-4.

The wind-chill formula of Siple has been criticized as being too sensitive to changes in wind speed when wind speed is low, and not sensitive enough to changes in wind speed at higher velocities.⁶² The formula is clearly only an approximation since, for any temperature, the wind chill is maximal at winds of 25 m/sec (56 mph) and actually decreases as wind speed goes even higher, a physical impossibility.

Figure 34-4. Nomogram of wind chill. A line corresponding to the value of the wind speed and drawn directly upward from the horizontal axis will intersect the curve of the measured dry-bulb temperature at a height corresponding to the wind-chill equivalent temperature, which can be read from the vertical axis. The curves are based on the formula of Siple and Passel⁶¹ and are based on a comparison to wind chill in relatively "still" air moving with a speed of 2 m/sec.

► ILLNESSES CAUSED BY COLD

Hypothermia

Hypothermia refers to a core body temperature below 35°C (95°F). The condition may be purposefully induced (e.g., to decrease oxygen consumption during surgery). More notably, hypothermia also occurs unintentionally as a result of exposure to cold environmental conditions (so-called accidental hypothermia). Unintentional hypothermia is a problem of considerable public health importance.

As body temperature drops, consciousness becomes clouded, and the patient appears confused or disoriented. Intense vasoconstriction causes pallor of the skin. Shivering is maximal in the higher range of hypothermia core temperatures, but decreases markedly in intensity as body temperature falls further and hypothermia itself impairs thermoregulation. In severe hypothermia (body temperature below about 90°F or 30°C), consciousness is lost, respirations may become imperceptibly shallow, and the pulse may not be palpable.¹

At such low temperatures, the myocardium becomes irritable and ventricular fibrillation is common. The patient may appear dead even though he or she may yet be revived with proper treatment. Persons found apparently dead in circumstances suggesting the possibility of hypothermia should be treated for this condition until death can be confirmed. In particular, the potential for recovery of cold-water drowning victims should not be underestimated, since there have been reports of virtually complete recovery in patients who were without an effective heartbeat for periods as long as two hours.⁶³

Hypothermia occurs both as a direct consequence of overexposure to the cold (primary hypothermia) and as the apparent result of thermoregulatory failure due principally to other severe illness (e.g., sepsis, myocardial infarction, central nervous system damage, metabolic derangements). Cold exposure may also contribute to such secondary hypothermia. Primary hypothermia has a better prognosis than hypothermia occurring as a result of concomitant illness.⁶⁴ Death is also more likely in patients who present with a particularly low body temperature.⁶⁵

Treatment of hypothermia depends on its severity. Noninvasive, external rewarming is appropriate for mildly hypothermic patients who have a perfusing cardiac rhythm. Invasive rewarming procedures, such as body cavity lavage, may be required if hypothermia is severe.

However, rapid rewarming or sudden alterations in other metabolic variables may precipitate ventricular fibrillation. Cardiopulmonary bypass with extracorporeal rewarming of the blood is a definitive treatment and may be required in patients with severe hypothermia or in patients who have no effective cardiac function.^{66,67} All but very mild hypothermia cases require intensive supportive medical care.

Frostbite

Local tissue injury as a result of exposure to cold may be seen in hypothermia cases but often occurs independently from it. Frostbite involves actual freezing of tissue. It affects primarily acral body parts (i.e., distal extremities, ears, and nose) and can occur over a period of minutes to hours in severe cold. Severe frostbite may result in tissue necrosis requiring amputation. Frostbite injuries may become particularly frequent during a spell of unusually cold weather.⁶⁸

Nonfreezing Local Tissue Injury

Perniosis, also called chilblains, is characterized by tender and/or pruritic, erythematous, or violaceous papules occurring in the skin of acral body parts, particularly the hands. When severe, the lesions may blister or ulcerate. The condition is typically present only during the colder months of the year, and women are afflicted more frequently than are men.⁶⁹ The underlying pathophysiology may involve cold-induced ischemia of involved areas or a cold-mediated inflammatory reaction. Vasodilators (for example, nifedipine) may be useful both in treatment of the lesions and in prevention of recurrences.⁷⁰

A condition known as "cold water immersion injury" or "trench foot" (when it affects the lower extremity) results from continuous exposure of body parts (most frequently, the lower extremities) to wet and above-freezing cold conditions for a period of days to weeks. Local tissue injury occurs, possibly from reduced blood flow due to prolonged vasoconstriction. When affected extremities are warmed, they at first become swollen and numb. Later, a phase of painful hyperemia develops. Still later, muscle weakness and atrophy and fibrosis may occur, and there may be other long-lasting sequelae, including persistent pain, hypoesthesia, or increased sensitivity to the cold.⁷¹

Anyone with prolonged continuous exposure to cold water and/or cold wet clothing is at risk. The condition is prevented by fully rewarming and drying the body at frequent intervals.

► EPIDEMIOLOGY OF COLD INJURY

Hypothermia in the Elderly

The extent to which indoor cold causes clinically significant hypothermia has been increasingly appreciated in recent years. In particular, the special vulnerability of elderly persons to this condition has been recognized. After the first year or so of life, the rate of death due to effects of the cold increases steadily with advancing age (Fig. 34-5). In the United States, approximately 700–1000 deaths due to cold exposure occur each year. More than half of these cases occur in persons aged 60 years or older,⁷² although persons in this age group comprise less than 17% of the population.⁷³

The extent of hypothermia morbidity is difficult to measure; a nationwide study of hypothermia in New Zealand found an incidence of hypothermia hospital admissions that was 12 times the hypothermia death rate. However, hypothermia hospitalizations primarily involved infants, whereas hypothermia deaths occurred primarily among the elderly and among males 13–65 years old.⁷⁴

A wintertime survey conducted in Great Britain of 1020 persons age 65 and over revealed that relatively few (0.5%) persons surveyed had hypothermic morning deep-body temperatures (<35°C) and none had hypothermic evening temperatures. Nevertheless, a substantial number (10%) had near-hypothermic temperatures (35.5°C but >35°C).⁷⁵ In contrast, 3.6% of 467 patients more than 65 years old admitted to London hospitals in late winter and early spring were hypothermic.⁷⁶ The fact that hypothermia is relatively common among elderly persons admitted to hospitals, although virtually absent in the community, has been interpreted as showing that most elderly Britons with hypothermia are quickly hospitalized.

The apparent cold sensitivity of the elderly may be due to physiological factors. Collins and others found that a high proportion of persons age 65 and older failed to develop physiologically significant vasoconstriction in response to a controlled cold environment and that the proportion of such persons increased with the age of the cohort examined. These elderly subjects with abnormal vasoconstriction tended to have relatively low core temperatures.⁷⁷ The basal metabolic rate (BMR) declines substantially with age, requiring elderly people to battle cold stress from a relatively low level of basal thermogenesis.⁷⁸ Shivering, a mechanism by which metabolic thermogenesis can be increased, may be impaired in some older persons.⁷⁹ Voluntary muscular activity also releases heat, but the elderly are more prone than others to debilitating chronic illnesses that limit mobility. Metabolic heat produced through the oxidation of brown fat is less available to the elderly, in whom this type of adipose tissue is less abundant than in children and younger adults.⁸⁰

Elderly persons appear to perceive cold less well than younger persons and may voluntarily set thermostats to relatively low temperatures.⁸¹ In addition, the high cost of energy, together with the relative poverty of some elderly people, may discourage their setting thermostats high enough to maintain comfortable warmth.⁸²

Drugs Predisposing to Hypothermia

Ethanol ingestion is an important predisposing factor for hypothermia. The great majority of patients in many hypothermia case series are middle-aged alcoholic men.^{83,84} Ethanol produces vasodilation, interfering with the peripheral vasoconstriction that is an important physiological defense against the cold. Although ethanol-containing beverages are sometimes taken in cold surroundings for the subjective sense of warmth they produce, this practice is dangerous. Ethanol also predisposes to hypothermia by inhibiting hepatic gluconeogenesis, and thus producing hypoglycemia in carbohydrate-depleted persons (e.g., many chronic alcoholics). Ethanol-induced hypoglycemia has been clearly shown to produce hypothermia in healthy volunteers.⁸⁵

Treatment with the neuroleptic drugs (phenothiazines, butyrophenones, and thioxanthenes) also predisposes to hypothermia. Chlorpromazine, the prototype drug of this group, has been used to induce hypothermia pharmacologically.⁸⁶ Chlorpromazine suppresses shivering, probably by a central mechanism, and causes vasodilation. The hypothermic action of drugs of this class becomes more pronounced with decreasing ambient temperature.⁸⁷

Other Hypothermia Risk Factors

Infants under 1 year of age have a higher rate of death due to cold than do older children (Fig. 34-5). Neonates, especially premature or small-for-gestational-age babies, are at particularly high risk. Although the mechanisms for maintaining thermal homeostasis (vasoconstriction and thermogenesis by shivering) are present at birth, they function less effectively than in older children. Infants have a relatively large ratio of heat-losing surface to heat-generating volume, and the layer of insulating subcutaneous fat is relatively thin. Perhaps most importantly, a baby is unable to control his or her own environment. Babies are totally dependent on others to keep them warm, and if sufficient warmth is not provided, hypothermia results.

Hypothermia in infants can be a substantial public health problem in areas with severe winter weather. During December and January of the winters of 1961–1962 and 1962–1963, 110 hypothermic (T < 90°F, 32.2°C) babies were admitted to hospitals in Glasgow, Scotland. Mortality in this group was 46%.⁸⁸ Hypothermia, however, is not only a problem in cold climates. In tropical climates,

Figure 34-5. U.S. cold-related deaths (ICD-9 Codes E901.0–E901.9) for the years 1979–1998, rates by age group indicated.

hypothermia among babies and young children can also be a problem in winter. Children and infants suffering from protein-calorie malnutrition are particularly susceptible.⁸⁹

In older children and young adults, lethal hypothermia is relatively infrequent (Fig. 34-5). However, persons in this age group are still susceptible to an overwhelming cold stress. Unintentional immersion in very cold water can lead rapidly to hypothermia.⁹⁰ Cold and wet weather may be especially dangerous, because the insulating properties of clothing are markedly reduced by moisture.⁹¹

The rate of death due to cold is greater in males than in females in all age groups. Behavioral differences (for example, in choice of occupation and recreational activities) resulting in increased frequency of exposure to cold may account for the particularly great relative risk of males during the teenage years through late middle age but do not fully explain the apparent difference between the sexes in susceptibility.

Homelessness is an important hypothermia risk factor. Substantial proportions of hypothermia case series involve persons without a fixed address.^{92,93}

Epidemiology of Frostbite

Serious frostbite injury occurs predominantly among males and is less frequent among babies, young children, and the elderly than among other age groups. Alcohol intoxication plays a role in about half of each of several case series. Other factors frequently contributing to frostbite injury are psychiatric illness, vehicular failure or crash, and drug use. Hypothermia is frequently present. In one case series, 12% of frostbite patients had hypothermia (temperature less than 32°C).⁹⁴ Finnish conscripts were found to be at increased risk of frostbite if they did not wear scarves or headgear with earflaps or if they *did* wear supposedly protective ointments.⁹⁵

► PREVENTION OF COLD-RELATED ILLNESS

Hypothermia is best prevented by limiting the cold stress of susceptible populations. Thus, programs to help the elderly poor receive financial assistance for wintertime heating bills may be helpful. In some areas, governmental agencies and/or utility companies have been involved in establishing programs that provide either direct financial aid toward the payment of elderly people's energy bills or provisions for deferred payment.

Awareness of the problem of neonatal hypothermia by pediatricians and communication of this concern to new parents may help prevent hypothermia in infants. Children and young adults who are at low risk from the cold should nevertheless take appropriate precautions when venturing into a cold environment. Clothing should provide sufficient insulation, and care should be taken that it does not get wet. One should especially guard against immersion in cold water. To avoid frostbite in below-freezing temperatures, skin exposure should be minimized.

Ionizing Radiation

Arthur C. Upton

Since the discovery of the x-ray, in 1895, studies of the health effects of ionizing radiation have received continuing impetus from the expanding uses of radiation in medicine, science, and industry, as well as from the peaceful and military applications of atomic energy.¹ The extensive knowledge of the effects of ionizing radiation generated by these studies has prompted strategies for protection against radiation that have been influential in shaping measures for protection against other hazardous physical and chemical agents as well.

► PHYSICAL PROPERTIES OF IONIZING RADIATION

Ionizing radiations differ from other forms of radiant energy in being able to disrupt atoms and molecules on which they impinge, giving rise to ions and free radicals in the process. Ionizing radiations include (a) electromagnetic radiations of short wave length and high energy (e.g., x-rays and gamma rays) and (b) particulate radiations, which vary in mass and charge (e.g., electrons, protons, neutrons, alpha particles, and other atomic particles).

Ionizing radiation, impinging on a living cell, collides randomly with atoms and molecules in its path, giving rise to ions and free radicals and depositing enough localized energy to damage genes, chromosomes, or other vital macromolecules. The distribution of such events along the path of the radiation—that is, the *quality* or *linear energy transfer* (LET) of the radiation—varies with the energy and charge of the radiation, as well as the density of the absorbing medium.² Along the path of an alpha particle, for example, the collisions occur so close together that the radiation typically loses all of its energy in traversing only a few cells, whereas along the path of an x-ray the collisions are far enough apart so that the radiation may be able to traverse the entire body (Fig. 35-1).

Because the biological effects of ionizing radiation result from the deposition of energy in exposed cells, doses of ionizing radiation are customarily expressed in terms of energy deposition (Table 35-1). On traversing a given cell, a densely ionizing radiation (e.g., an alpha particle) is more likely than a sparsely ionizing radiation (e.g., an x-ray) to deposit enough energy in a critical site, such as a gene or chromosome, to injure the cell.³⁻⁶ Hence an additional dose unit (the *equivalent dose*) is used in radiation protection to enable different types of radiation to be normalized in terms of their relative biological effectiveness (RBE). The equivalent dose (expressed in sievert [Sv]) is the dose in gray (Gy) multiplied by an appropriate weighting factor to adjust for differences in RBE; that is, 1 Sv of alpha radiation is that dose (in gray) of alpha radiation that is equivalent in biological effectiveness to 1 Gy of gamma rays (Table 35-1).

The uptake, distribution, and retention of an internally deposited radionuclide vary, depending on the physical and chemical properties of

the element in question. Once deposited, the amount of radioactivity remaining in situ decreases with time as a result of both physical decay and biological removal. The physical half-lives of the different radionuclides vary, from less than a second in some to billions of years in others.^{2,3} Biological half-lives also vary, tending to be longer with radionuclides that localize in bone (e.g., radium, strontium, plutonium) than with those that are deposited predominantly in soft tissue (e.g., iodine, cesium, tritium).⁴

► SOURCES AND LEVELS OF IONIZING RADIATION IN THE ENVIRONMENT

Life has evolved in the continuous presence of natural background radiation. The major sources of natural background radiation to which the human population is exposed are (a) cosmic rays, which originate in outer space; (b) terrestrial radiations, which emanate from the thorium, uranium, radium, and other radioactive constituents of the earth's crust; (c) internal radiation, which is emitted by the potassium-40, carbon-14, radium, and other radionuclides normally present in living cells; and (d) radon and its daughter elements, which are inhaled in indoor air (Table 35-2). The dose from cosmic rays varies appreciably with altitude, being higher by a factor of 2 in the mountains than at sea level and being higher by orders of magnitude at jet aircraft altitudes.⁷ Likewise, the dose from internally deposited radium may be higher by a factor of 2 or more in geographic regions where the earth's crust is rich in this element.^{5,7} The dose to the bronchial epithelium from radon also may vary by an order of magnitude or more, depending on the concentration of radon in indoor air, and it typically exceeds by far the dose from all other sources combined.^{5,7} In cigarette smokers, moreover, portions of the bronchial epithelium may receive additionally as much as 0.2 Sv (20 rem) per year from the polonium that is normally present in cigarette smoke.⁷

In addition to natural background radiation, populations in the modern world are exposed to radiation from various artificial sources as well. The largest such source is the use of x-rays in medical diagnosis (Table 35-2). Lesser sources include (a) radioactive minerals in building materials, phosphate fertilizers, and crushed rock; (b) radiation-emitting components of TV sets, video display terminals, smoke detectors, and other consumer products; (c) radioactive fallout from nuclear weapons and nuclear accidents; and (d) radionuclides released in the production of nuclear power (Table 35-2).

Additional doses of radiation are received by workers in various occupations, depending on their particular work assignments and working conditions. The average annual effective dose received occupationally by monitored workers in the United States is lower than the dose from natural background radiation, and in any given year less

Type of radiation	Source	Range in tissue
ALPHA	²¹⁰ Po 5.3 MeV	 Range 0.037 mm
BETA	¹⁴ C 0.154 MeV maximum energy	 Maximum range 0.29 mm (typically less)
BETA	³² P 17.1 MeV maximum energy	 Maximum range 8 mm (typically less)
GAMMA	¹²⁵ I 0.035 MeV	 Average distance to collision 33 mm
GAMMA	⁶⁰ Co 1.33 MeV	 Average distance to collision 164 mm

Figure 35-1. Differences among various types of ionizing radiation in penetrating power in tissue.²

than 1% of such workers receive a dose that approaches the maximum permissible yearly limit of 50 mSv (5 rem).^{5,9}

Radiation accidents have been another source of exposure for workers and members of the public.¹⁰⁻¹² In spite of elaborate precautions, some 285 nuclear reactor accidents (excluding the Chernobyl accident) were reported in various countries between 1945 and 1987, resulting in the exposure of more than 1,350 persons and 33 fatalities.¹⁰ In the Chernobyl accident alone, enough radioactivity was released to require the evacuation of tens of thousands of people and farm animals from the surrounding area and to result in a collective committed effective dose to the Northern Hemisphere of 600,000 person-Sv (60,000,000 person-rem).^{4,11,12} The large amounts of radioactive iodine (>600 PBq) that were released in the accident¹⁰ have since been implicated in an increase in the incidence of thyroid cancer in

TABLE 35-1. QUANTITIES AND DOSE UNITS OF IONIZING RADIATION

Quantity Being Measured	Definition	Dose Unit*
Absorbed dose	Energy deposited in tissue	Gray (Gy)
Equivalent dose	Absorbed dose weighted for the relative biological effectiveness of the radiation	Sievert (Sv)
Effective dose	Equivalent dose weighted for the sensitivity of the exposed organ(s)	Sievert (Sv)
Collective effective dose	Effective dose applied to a population	Person-Sv
Committed effective dose	Cumulative effective dose to be received from a given intake of radioactivity	Sievert (Sv)
Radioactivity	One atomic disintegration per second	Becquerel (Bq)

*The units of measure listed are those of the International System, introduced in the 1970s to standardize usage throughout the world.³ They have largely supplanted the earlier units; namely the rad (1 rad = 100 ergs/g = 0.01 Gy); the rem (1 rem = 0.01 Sv); and the curie (1 Ci = 3.7×10^{10} disintegrations per second = 3.7×10^{10} Bq).

TABLE 35-2. AVERAGE AMOUNTS OF IONIZING RADIATION RECEIVED ANNUALLY FROM DIFFERENT SOURCES BY A MEMBER OF THE U.S. POPULATION

Source	Dose*		
	(mSv)	(mrem)	(%)
■ Natural Background			
Radon†	2.0	200	55
Cosmic	0.27	27	8
Terrestrial	0.28	28	8
Internal	0.39	39	11
Total natural	2.94	294	82
■ Artificial			
X-ray diagnosis	0.39	39	11
Consumer products	0.14	14	4
Occupational	0.10	10	3
Nuclear fuel cycle	<0.01	<1.0	<0.3
Nuclear fallout	<0.01	<1.0	<0.03
Miscellaneous‡	<0.01	<1.0	<0.03
Total artificial	0.63	63	18
Total natural and artificial	3.57	357	100

*Average effective dose to soft tissues, excluding bronchial epithelium.

†Average effective dose to bronchial epithelium alone.

Byelorussia and the Ukraine, as noted below. More numerous than reactor accidents, although less catastrophic, are accidents involving medical and industrial sources.¹² In 1981, for example, a cesium-131 radiotherapy source that was inadvertently dismantled by junk dealers severely contaminated parts of Goiania, Brazil, exposing more than 120 persons, 54 of whom required hospitalization and four of whom were injured fatally.¹²

► RADIATION EFFECTS

Types of Effects

In radiation protection, it is customary to distinguish between effects for which there are dose thresholds and effects for which there may be no dose thresholds. The former—so-called *nonstochastic* (or *deterministic*) effects—include various tissue reactions that are elicited only by doses large enough to kill many cells in the affected organs.¹³ The latter, by contrast—which include the mutagenic and carcinogenic effects of radiation—are viewed as *stochastic* (or *probabilistic*) phenomena of a type that may be produced by a subtle change within a single cell in an affected organ and which may therefore be expected to increase in frequency as linear-nonthreshold functions of the dose of radiation.^{3-6,8}

Effects on Genes and Chromosomes

Any molecule in the cell may be damaged by ionizing radiation, but damage to a single gene, unless properly repaired, may permanently alter or kill the cell. Such damage may be caused by the radiation energy that is deposited within an affected cell itself, or it may be caused by the effects of radiation on one or more of its neighboring cells (the so-called “bystander effect”).¹⁴ A dose that is large enough

to kill the average dividing cell (1–2 Sv) suffices to cause dozens of lesions in its DNA. Most such lesions tend to be reparable, depending on the effectiveness of the cell’s repair processes, but residual damage, expressed in the form of mutations, appears to increase as a linear-nonthreshold function of the dose in human somatic cells and the cells of other organisms. The frequency of such mutations approximates 10^{-5} – 10^{-6} per locus per Sv, depending on the genetic locus and conditions of irradiation.^{4,8}

Chromosomal aberrations also increase in frequency with the dose of ionizing radiation, approximating 0.1 aberration per cell per Sv in the low-to-intermediate dose range (Fig. 35-2). The dose-dependent increase in the frequency of such aberrations, which has been reported to be detectable in radiation workers and persons residing in areas of elevated natural background radiation levels, may be of use as a biological dosimeter in radiation accident victims.^{16,17}

The yields of mutations and chromosome aberrations produced by a given dose of low-LET radiation are lower at low-dose rates than at high dose rates; but the weight of evidence suggests that there may be no threshold in the dose-response relationship for these effects.^{5,8,18} Extensive studies of the children of the A-bomb survivors have been largely negative thus far, but the findings are not incompatible statistically with the results of experiments on laboratory animals, in which heritable mutagenic effects of radiation have been well documented.^{5,8} On the basis of the available data, it is estimated that a dose in excess of 1.0 Sv would be required to double the frequency of heritable mutations in the human species, and that less than 1% of all genetically related human diseases is attributable to natural background radiation (Table 35-3).

Cytotoxic Effects

As noted early in this century by Bergonie and Tribondeau, cells generally vary in radiosensitivity in proportion to their rate of proliferation and inversely in relation to their degree of differentiation. Cells of only few types (e.g., lymphocytes and oocytes) are radiosensitive in a nonproliferative state. The percentage of clonogenic human cells retaining the ability to proliferate decreases exponentially with increasing dose, acute exposure to 1–2 Sv typically sufficing to reduce the surviving population by 50%. Successive exposures tend to be less than fully additive in their cytotoxicity if they are sufficiently separated in time, owing to repair of radiation damage during the interim.^{4,6,8}

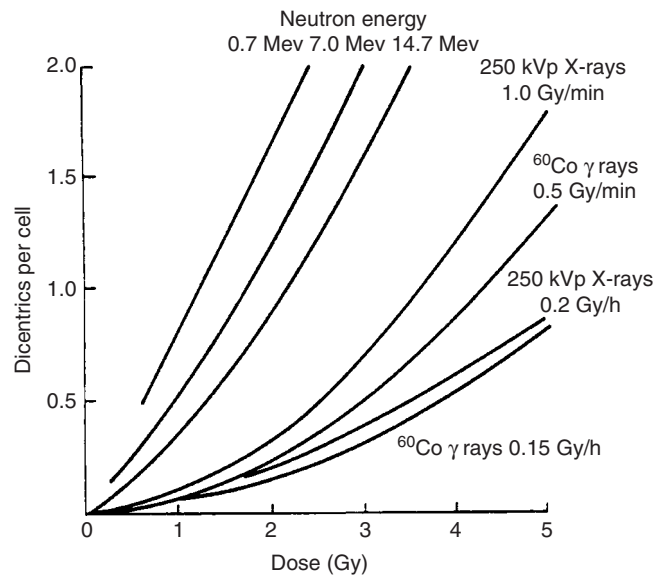

Figure 35-2. Frequency of dicentric chromosome aberrations in human lymphocytes in relation to dose, dose rate, and quality of irradiation in vitro. (Source: Modified from Lloyd DC, Purrott RJ. Chromosome aberration analysis in radiological protection dosimetry. Radiat Protect Dosim. 1981;1:19–28.¹⁵)

Through cytotoxic effects on dividing cells, intensive irradiation can give rise to a wide variety of acute and chronic tissue reactions, depending on the tissue or organ irradiated, the dose, and the conditions of exposure.⁴ In such reactions—exemplified by erythema of the skin, depression of the blood count, impairment of fertility, and cataract of the lens—interference with normal cell replacement in the exposed area leads to hypoplasia, functional disturbances, and atrophy of the affected part. If enough stem cells remain viable to repopulate the tissue in question, regeneration may ensue within days or weeks; however, a second wave of degenerative changes may occur months or years later, as a result of residual damage and gradually progressive radiation-induced

TABLE 35-3. ESTIMATES OF THE RISKS OF GENETIC DISORDERS IN CHILDREN THAT ARE ATTRIBUTABLE TO IRRADIATION OF THEIR PARENTS

Disease Class	Natural Incidence per Million Liveborn Children	Risk per Sv per Million Liveborn Children	Risk from Natural Background Irradiation per Million Liveborn Children*	
			(No.)	(%)
Autosomal dominant and X-linked diseases	16,500	~750–1500	22–45	~0.2
Autosomal recessive diseases	7500	~0	<1	<1
Chromosomal diseases	4000	†	†	†
Chronic multifactorial diseases	650,000‡	~250–1200	8–36	~0.004
Congenital abnormalities	60,000	~2000§	60§	0.1
Total	738,000	~4000	~90–140	~0.02

*Based on an assumed dose rate of 1 mSv per year and a genetic doubling dose of 1 Gy.

†Risk of chromosomal diseases is assumed to be subsumed under the risk of autosomal dominant and X-linked diseases and, in part, under the risk of congenital abnormalities.

‡Frequency in the general population.

(Based on data from NAS, 2006 and Sankaranarayanan, 2001.¹⁹)

fibrosis of the exposed connective tissue and vasculature.^{4,20} Depending on their anatomical location and severity, such changes can cause a dose-dependent decrease in the long-term survival of the affected individuals.^{21,22}

► THE ACUTE RADIATION SYNDROME

Intensive irradiation of the hemopoietic system, gastrointestinal tract, lungs, or brain can cause the *acute radiation syndrome*. This syndrome may take one of several forms, depending on the size and anatomical distribution of the dose (Table 35-4). In each of the forms, anorexia, nausea, and vomiting typically occur within minutes or hours after irradiation, to be followed by a symptom-free interval that lasts until the onset of the main phase of the illness.

Carcinogenic Effects

Cancers of various types have been observed to increase in frequency with the dose of ionizing radiation in atomic bomb survivors, radiotherapy patients, early radiologists, radium dial painters, uranium miners, and other irradiated human populations.^{4,5,23} Such growths have not appeared until years or decades after irradiation, and none has exhibited features identifying it as having been produced specifically by radiation, as opposed to some other cause. The causal connection between such cancers and previous irradiation can, therefore, be inferred only from appropriate epidemiological analysis of the dose-incidence relationship.^{5,6,8}

The most extensive dose-response data available thus far have come from the study of atomic bomb survivors, in whom the overall incidence of cancer has increased roughly in proportion with the radiation dose (Fig. 35-3). The magnitude of the dose-dependent increase varies, however, from one type of cancer to another, and not all types of cancer appear to have been affected. The most extensive data available to date concerning dose-response relationships for individual types of cancer pertain to leukemia, cancer of the female breast, and cancer of the thyroid gland.

Leukemia. The frequencies of all major types of leukemia, except chronic lymphocytic leukemia, have been observed to increase with dose after exposure of the whole body or a major part of the hemopoietic system. In A-bomb survivors and other irradiated populations, the increases have appeared within 2–5 years after exposure; have been dose-dependent, averaging approximately 1–3 cases per 10,000 persons per year per Sv to the bone marrow over the first 25 years after irradiation; and have persisted for 15 years or longer, depending on the type of leukemia, age at irradiation, and other variables.^{5,8} A comparable excess has been reported in radiation workers, based on combined analyses of different occupational cohorts.^{5,24,25} While the data do not suffice to define the shape of the dose-incidence relationship precisely, they appear to be most consistent with a linear-quadratic function.^{5,6}

Leukemia has also been observed to be increased in frequency in children who were x-irradiated prenatally through the abdominal radiographic examination of their mothers, the increase approximating 25 cases per 10,000 per Sv per year during the first 10 years of life.^{5,8,25} Although no such increase was evident in prenatally exposed A-bomb survivors, the difference is not statistically significant in view of the limited numbers of such survivors.²⁵ Irradiation of maternal or

Figure 35-3. Dose-response relationship for the relative risk of solid cancer, all types combined, in atomic bomb survivors, 1958–1994. The dashed curves represent ± 1 standard error for the smoothed curve. The unity baseline corresponds to the zero-dose value for survivors within 3 km of the bombs, and the horizontal dotted line represents the alternative zero-dose baseline when the more distal survivors are also included. The inset shows the same information for the fuller dose range. (Source: Modified from Pierce DA, Preston DL. Radiation-related cancer risks at low doses among atomic bomb survivors. *Radiat Res.* 2000;154:178–86.²³)

paternal germ cells also has been postulated to account for excesses of leukemia that have been observed in children subsequently conceived by some exposed individuals, but the weight of evidence argues against this hypothesis.²⁵

Breast Cancer. The incidence of breast cancer has appeared to increase in proportion to the radiation dose in women surviving A-bomb irradiation, women given radiotherapy to the breast for acute postpartum mastitis, women fluoroscoped repeatedly in the treatment of pulmonary tuberculosis with artificial pneumothorax, and women employed as radium dial painters.^{4,5,26} In all four groups, the excess did not become evident until at least 5–10 years after irradiation, depending on age at the time of exposure, and it has persisted for the duration of follow-up. The excess, averaged over all ages, has also been of similar magnitude in each group, in spite of marked differences among the groups in the rapidity with which the total doses of radiation were received, implying that successive small doses were highly additive in their cumulative carcinogenic effects.^{4,5,26}

Susceptibility decreases markedly with increasing age at the time of irradiation, little excess being detectable in women exposed beyond the age of 40.^{27,28} Following irradiation in childhood, moreover, the resulting cancers are similar in age distribution to those occurring in the general population, implying that expression of the carcinogenic effects of radiation on the breast depends on the hormonal stimulation associated with sexual maturation.^{27,28} In those A-bomb survivors who were the first to develop tumors, the excess was disproportionately large, suggesting that such women may have represented a genetically susceptible subgroup.²⁸

Thyroid Gland. Dose-dependent excesses of thyroid cancer have been observed in A-bomb survivors, patients treated with x-rays for various benign conditions in childhood, Marshall Islanders and others exposed during childhood to radioactive fallout from nuclear weapons tests, and children exposed to radionuclides from the Chernobyl accident.^{4,5} The cancers have consisted mainly of papillary carcinomas and

have typically been preceded by a latent period of 10 years or longer, after which their frequency has remained elevated for the duration of follow-up. Children appear to be several times more susceptible to the induction of such tumors than adults, and females several times more susceptible than males.^{4,5} The dose-incidence relationship after therapeutic x-irradiation of the neck in infancy has been observed to be consistent with a linear-nonthreshold function, corresponding to approximately four additional cancers per 10,000 persons per Sv per year, with an excess evident at doses as low as 65 mSv.^{4,5,8} No excess has been detectable in persons who have received as much as 0.5 Gy to the thyroid from iodine-131 administered for diagnostic purposes, however, which implies that the radiation emitted by this radionuclide is appreciably less carcinogenic to the thyroid than external x- or gamma radiation, possibly because of spatial and temporal differences in the distribution of the radiation within the gland.^{4,5}

Assessment of the Risks from Low-Level Exposure. Although existing evidence does not suffice to define precisely the dose-incidence relationship for the carcinogenic effects of low-level radiation or to exclude the possibility that a threshold for such effects may exist in the millisievert dose range, the available epidemiologic and experimental data argue against the likelihood of such a threshold, in spite of evidence that cells have some capacity to adapt to low-level radiation.^{4–6,8} Attempts to estimate the risks of radiation-induced cancers from low doses have, therefore, generally been based on the assumption that the overall incidence of cancer varies as a linear-nonthreshold function of the dose. Extrapolations based on the linear-nonthreshold model have yielded risk estimates for cancers of different organs (Table 35-5). These estimates imply that less than 3% of all cancers in the general population are attributable to natural background radiation, although a larger percentage—perhaps up to 10%—of lung cancers may be attributable to inhalation of indoor radon.^{4,5,8,30}

The extent to which a cancer arising in a previously irradiated individual can be attributed to the radiation that he or she may have received cannot be determined with certainty; however, it may be assumed to increase with the radiation dose in question, all other

things being equal.^{31,32} On the basis of this assumption, one may arrive at a crude estimate of the probability of causation, given sufficient knowledge of the dose, when the dose was received, and the extent to which other causal factors also may have been involved.^{31,32}

► EFFECTS OF PRENATAL IRRADIATION

Apart from the relatively high susceptibility of the unborn child to the carcinogenic effects of ionizing radiation, noted above, the embryo is also highly susceptible to the teratogenic effects of radiation. Thus, although the latter are generally considered to be nonstochastic in nature, exposure to as little as 0.25 Sv during critical stages of organogenesis has sufficed to cause malformations of many types in laboratory animals,^{33,34} and similar developmental disturbances have been reported to follow intensive prenatal irradiation in humans.^{4,5,8,34} Noteworthy examples of the latter include a dose-dependent increase in the frequency of severe mental retardation and dose-dependent decreases in IQ and school performance scores in A-bomb survivors who were irradiated between the 8th and 15th weeks (and to a lesser extent the 16th and 25th weeks) after conception.^{4,5,8,34} Furthermore, unlike mutagenic and carcinogenic effects, which are expressed in only a small percentage of exposed individuals, some disturbance of growth and development may be projected to affect all who are exposed at a vulnerable stage to a dose that exceeds the relevant threshold. Thus, while only a small percentage of the individuals who were exposed prenatally to atomic bomb radiation at a critical stage in brain development (i.e., 8–26 weeks after conception) exhibited severe mental retardation, a larger percentage exhibited less marked decrements in intelligence and school performance, implying that there was a dose-dependent downward shift in the distribution of intelligence levels within the entire cohort.^{8,12}

► ADAPTIVE RESPONSES AND HORMESIS

A brief exposure to a small, “conditioning” dose of x-rays or gamma rays has been observed experimentally to elicit an adaptive response that enhances growth and survival, augments the immune response,

and increases resistance to the cytotoxic, genetic, and carcinogenic effects of a subsequent, larger “test” dose of radiation.^{4,6,8,12,36,37} The adaptive response to radiation resembles in many respects adaptive responses elicited by other toxicants,³⁷ and it undoubtedly accounts in part for the decrease in the biological effectiveness of X-rays and gamma-rays that generally occurs as the dose rate is reduced. These features of the adaptive response have prompted some observers to postulate that the dose-response relationships for the genetic and carcinogenic effects of ionizing radiation is biphasic or “hormetic” in nature; that is, that it increases with the dose at moderate-to-high levels of exposure but decreases with the dose at low levels of exposure.^{36,38} This hypothesis, far reaching in its implications for radiation protection, remains to be validated, however, and the weight of existing evidence argues against it.^{6,8,18,39,40}

► RADIATION PROTECTION

With the abandonment of the threshold dose-response hypothesis for the mutagenic and carcinogenic effects of radiation, the goal of minimizing the risks of such effects has become preeminent in radiation protection. In pursuit of this goal, the following guidelines have been recommended for any activity involving exposure to ionizing radiation: (a) *justification*, that is, the activity should not be considered justifiable unless it produces a sufficient benefit to those who are exposed, or to society at large, to offset any harm it may cause; (b) *optimization*, that is, the dose and/or likelihood of exposure should be kept as low as is reasonably achievable (ALARA), all relevant economic and social factors considered; and (c) *dose limits*, that is, the likelihood of exposure and the resulting dose to any individual should be subject to control by operating limits.³

The dose limits that have been recommended (Table 35-6) are intended to restrict exposures sufficiently to completely prevent nonstochastic effects in any organ of the body, even in the most sensitive members of the population.³ Although the limits are not expected to protect completely against the mutagenic and carcinogenic effects of radiation, since there may be no thresholds for such effects, the limits are judged to be low enough to prevent the risks of mutagenic and carcinogenic effects from reaching levels that are socially unacceptable.^{3,41}

Implicit in the above guidelines are requirements that any facility dealing with ionizing radiation (a) be properly designed; (b) be carefully planned and its operating procedures be overseen, including dose calibration; (c) have in place a well-conceived radiation protection program; (d) ensure that its workers are adequately trained and supervised; and (e) maintain a well-developed and well-rehearsed emergency preparedness plan, to be able to respond promptly and effectively in the event of a malfunction, spill, or other type of radiation accident.^{3,41}

Since the doses received from medical radiographic examinations and from indoor radon constitute the most important controllable sources of exposure to ionizing radiation for members of the general public, measures to limit these exposures are also called for.^{3,41} Other potential sources of exposure against which protection is warranted are those posed by the millions of cubic feet of radioactive and mixed wastes (mine and mill tailings, spent nuclear fuel, waste from the decommissioning of nuclear power plants, dismantled industrial and medical radiation sources, radioactive pharmaceuticals and reagents, heavy metals, polyaromatic hydrocarbons, and other contaminants), which tax increasingly severely the existing storage capacities at numerous waste sites.^{42,43}

► SUMMARY

The health effects of ionizing radiation are widely diverse, ranging from rapidly fatal injuries to cancers, birth defects, and hereditary disorders months or decades later. The nature, frequency, and severity

TABLE 35-6. RECOMMENDED LIMITS OF EXPOSURE TO IONIZING RADIATION FOR RADIATION WORKERS AND MEMBERS OF THE PUBLIC*

Type of Exposure	Maximum Permissible Dose (mSv)
A. Occupational Exposures	
1. For protection against stochastic effects	
a. Annual effective dose	50
b. Cumulative effective dose	Age × 10
2. For protection against nonstochastic effects in individual organs	
a. Lens of the eye (annual effective dose)	150
b. All other organs (annual effective dose)	500
3. Planned special exposures (effective dose) [†]	100
4. Emergency exposure	— [‡]
B. Public Exposures	
1. Continuous or frequent exposure (effective dose per year)	1
2. Infrequent exposure (effective dose per year)	5
3. Remedial action recommended if:	
a. Annual effective dose would exceed	5
b. Effective dose from radon would exceed	0.007 jhm ⁻¹
C. Education and Training Exposures[§]	
1. Annual effective dose	1
2. Annual equivalent dose to lens of the eye, skin, extremities	50
D. Exposure of the Embryo and Fetus	
1. Total equivalent dose	5
2. Equivalent dose in any one month	0.5

*Including natural background radiation exclusive of that from internally deposited radionuclides.

[†]Sum of internal and external exposures, excluding medical irradiation.

[‡]Effective dose in any one planned event; or cumulative effective dose in planned special exposures should not exceed 100 mSv (10 rem) over a working lifetime.

[§]Short-term exposure to more than 100 mSv (10 rem) is justified only in lifesaving emergency situations.

of the effects depend on the quality of the radiation in question, as well as on the dose and conditions of exposure. For most effects, radiosensitivity varies with the rate of proliferation and inversely with the degree of differentiation of the exposed cells; as a result, the embryo and growing child are especially vulnerable to radiation injury. Although many types of effects require relatively high levels of exposure, the genotoxic and carcinogenic effects of ionizing radiation appear to increase in frequency as linear-nonthreshold functions of the dose. To minimize the risks of the latter, therefore, exposures to ionizing radiation need to be limited accordingly.

Nonionizing Radiation

Arthur L. Frank

The term *nonionizing radiation* refers to several forms of electromagnetic radiation of wavelengths longer than those of ionizing radiation. As wavelength lengthens, the energy value of electromagnetic radiation decreases, and all nonionizing forms of radiation have less energy than cosmic, gamma, and x-radiation. In order of increasing wavelength, nonionizing radiation includes ultraviolet (UV) radiation, visible light, infrared radiation, microwave radiation, and radiofrequency radiation. The latter two are often treated as a single category. The energy, frequency, and wavelength range for electromagnetic forces are shown in Table 36-1. All forms of electromagnetic radiation have the same velocity of 3×10^{10} cm/s in a vacuum.

Radiation is emitted continuously from the sun over a wide range from 290 nm in the ultraviolet range to more than 2000 nm in the infrared range with a maximum intensity at about 480 nm in the visible range. The radiation from the sun is modified as it passes through the earth's atmosphere. Ozone, which is found in the upper atmosphere, absorbs the highest energy ultraviolet radiation. Infrared radiation is absorbed by water vapor, and other wavelengths are altered by passage through smoke, dust, and gas molecules.

All objects above absolute zero temperature emit radiation, much of it as infrared radiation. At low temperatures, only long wavelength radiation is emitted, but as the temperature of the objects increases, shorter wavelength radiation is emitted. Heated metal gives off a red glow; if heating continues, the metal becomes "white hot" as energy throughout the whole visible spectrum is given off. Heated gases may give off wavelengths in the ultraviolet, visible, or infrared regions. Ultraviolet radiation is given off with the use of extremely high-temperature welding equipment such as carbon or electric arcs.

The biological effect of radiation exposure depends on the type and duration of exposure and on the amount of absorption by the organism. The carcinogenic and other effects of ionizing radiation are discussed in Chapter 36.

► ULTRAVIOLET RADIATION

The sun is the major source of ultraviolet radiation although there are artificial sources such as electric arc lights, welding arcs, plasma jets, and special ultraviolet bulbs. The amount of ultraviolet radiation reaching the earth from the sun varies with season, time of day, latitude, altitude, and specific atmospheric conditions. Intensity is greatest at midday and is greater in summer than in winter. In a summer month, about as much ultraviolet radiation reaches the earth's surface as in the entire period from autumn to spring equinoxes. Total ultraviolet exposure is greater on a cloudy day due to reflection, and snow reflects about 75% of ultraviolet radiation. Therefore, sunburn may be more severe on a cloudy than a clear day and may be especially severe in those spending a great deal of time on snow. Window glass and light clothing efficiently filter out ultraviolet radiation.

There is a wide range of potential occupational exposures^{1,2} to ultraviolet radiation in both outdoor work and industrial settings (Table 36-2).

Biological Effects

The organs primarily affected by ultraviolet radiation are the skin and eyes since it has little ability to penetrate. Ultraviolet radiation is strongly absorbed by nucleic acids and proteins, and the effects in humans are largely chemical rather than thermal. Mutations resulting from ultraviolet exposure occur in organisms such as plants and flies but not in humans, again because of low penetration.

Short-term effects on humans include acute changes in the skin. There are four types of changes: (a) darkening of pigment, (b) erythema (sunburn), (c) increase in pigmentation (tanning), and (d) changes in cell growth. Ultraviolet radiation does not penetrate subcutaneous tissue. The corneum, or outermost layer of skin, which is about 0.03 mm thick, absorbs the shortest wavelength ultraviolet radiation. The longer the wavelength, the deeper the radiation penetrates; the longest ultraviolet radiation passes through the corneum and corium into the Malpighian layer. The darkening of preformed pigment occurs immediately and is particularly noted at wavelengths between 300 and 400 nm. The erythema (sunburn) does not begin for at least one-half hour, and there are several peaks within the ultraviolet spectrum with variable times of maximum effect, ranging from 12 hours for radiation at 54 nm to 48 hours for radiation at 297 nm. Darker skin has protective effect, and estimates for darkest skin shades suggest a two- to tenfold threshold value for erythema production. Subsequent exposure reduces the threshold value for erythema production. The increase in pigmentation (tanning) results from a migration of melanin pigment into more superficial skin cells and also from an increased production of melanin pigment. Ultraviolet radiation works as a catalyst to oxidize tyrosine to dihydroxyphenol 1-alanine, which is a precursor of melanin. Changes in skin cell growth follow exposure to ultraviolet radiation. There occurs a cessation of cell growth, followed 24 hours later by an increase in cell division. At this time there is intracellular and intercellular edema that thickens the skin. Eventually there is shedding of cells by scaling. Severe reactions can be seen with blistering, desquamation, and even ulceration of the skin.

Ultraviolet radiation also causes acute effects on tissue of the eye. Exposure can lead to keratitis, inflammation of the cornea, and conjunctivitis. The keratitis may develop after a latency of several hours and returns to normal in a few days. Since the cornea possesses a large number of nerve endings, even small amounts of inflammation can be painful. The effect in the eye is independent of skin color, and there appears to be no development of protection of the eye with repeated exposures.

Long-term effects of ultraviolet exposure include an increased rate of aging of skin with degeneration of skin tissue and a decrease

TABLE 36-1. ENERGY, FREQUENCY, AND WAVELENGTH RANGE FOR ELECTROMAGNETIC FORCES

Type of Radiation	Energy Range	Frequency Range	Wavelength Range
Ionizing (includes cosmic, gamma, and x-ray)	>12.4 eV	>3000 THz	<100 nm
Ultraviolet	6.2–3.1 eV	1500–750 THz	200–400 nm
Visible	3.1–1.8 eV	750–429 THz	400–700 nm
Violet			400–424
Blue			424–491
Green			491–575
Yellow			575–585
Orange			585–647
Red			647–700
Infrared	1.8 eV–1.2 meV	429 THz–300 GHz	700 nm–1 mm
Microwave	1.2 meV–1.2 µeV	300 GHz–300 MHz	1 mm–1 m
Radio frequency	1.2 µeV–1.2 neV	300 MHz–300 KHz	1 m–km

in elasticity. Late effects of ultraviolet radiation on the eye include the development of cataracts. The most serious chronic effect of ultraviolet exposure is skin cancer.

More than 90% of skin cancers occur on parts of the body exposed to sunlight. Approximately 40% of all cancers in the United States are skin cancers, and in general they are the most common malignancy in light-skinned populations. Rates for skin cancer vary from less than 2 cases per 100,000 in dark-skinned populations to more than 100 per 100,000 in South African whites and Australians.³ The incidence of skin cancer on a worldwide bases correlates with decreasing latitude. Great excesses of skin cancer occur among persons with outdoor occupations such as agricultural, forestry, and marine activity. Most skin cancers in humans are epithelial cell origin, most commonly noted as basal cell carcinomas followed in frequency by squamous cell carcinomas followed in frequency by melanomas.

Some individuals, for example, those with xeroderma pigmentosum, have particular sensitivity to ultraviolet radiation and are at increased risk for developing disease on exposure. Photosensitivity reactions occur after exposure to a variety of chemicals and drugs, including dyes, phenothiazine, sulfonamide, and sulfonylurea.

Ultraviolet radiation has an important role in the prevention of rickets. Vitamin D is produced by the action of ultraviolet radiation on 7-dehydrocholesterol or related steroidal compounds.

Protection

Protection measures against ultraviolet radiation include administrative controls, equipment design, and personal protection. Administrative actions include educating and instructing of individuals who will be exposed, posting of notices, limiting access in the workplace,

and regulating exposure time. Equipment design includes placement of ultraviolet glass shields. Personal protection includes the use of shields, goggles, and appropriate clothing. Polyvinyl chloride can be used for gloves, and the use of barrier creams is also possible. Exposure during recreation, such as winter sports and sunbathing, including use of tanning beds, should be done in moderation, especially by fair-skinned persons.

Recommended Values for Protection against Ultraviolet Radiation. Based on regulations adopted from the American Conference of Governmental and Industrial Hygienists in 1976, the federal limits in the United States are as follows:

1. For the near ultraviolet spectral region (320–400 nm), total irradiance incident upon the unprotected skin or eye should not exceed 1 mW/cm² for periods greater than 10³ seconds (approximately 16 minutes), and for exposure times less than 10³ seconds, should not exceed 1 J/cm².
2. For the actinic ultraviolet spectral region (200–315 nm), radiant exposure incident upon the unprotected skin or eye should not exceed the values given in Table 36-3 within an 8-hour period.

TABLE 36-3. THRESHOLD LIMIT VALUES (TLV) FOR ULTRAVIOLET RADIATION

Wavelength (nm)	TLV (mJ/cm ²)	Relative Spectral Effectiveness (S _λ)
200	100.0	0.03
210	40.0	0.075
220	25.0	0.12
230	16.0	0.19
240	10.0	0.30
250	7.0	0.43
254	6.0	0.5
260	4.6	0.65
270	3.0	1.0
280	3.4	0.88
290	4.7	0.64
300	10.0	0.30
305	50.0	0.06
310	200.0	0.015
315	1000.0	0.003

TABLE 36-2. OCCUPATIONAL EXPOSURE TO ULTRAVIOLET RADIATION

Food irradiators	Vitamin D makers
Foundry workers	Welders

- To determine the effective irradiance of a broadband source weighted against the peak of the spectral effectiveness curve (270 nm), the following weighting formula should be used:

$$E_{\text{eff}} = \sum E_{\lambda} S_{\lambda} \Delta_{\lambda}$$

where

E_{eff} = effective irradiance relative an E_x

E_{λ} = monochromatic source at 270 nm spectral irradiance in $W/cm^2/nm$

S_{λ} = relative spectral effectiveness (unitless)

Δ_{λ} = band width in nanometers

- Permissible exposure time in seconds for exposure to actinic ultraviolet radiation incident upon the unprotected skin or eye may be computed by dividing 0.003 J/cm by E_{ch} in W/cm^2 . The exposure time may also be determined using Table 36-4, which provides exposure times corresponding to effective irradiances in $\mu W/cm^2$.

► VISIBLE LIGHT

Visible light ^{4,5} is radiation with a wavelength between 400 and 700 nm. The sun is the major source of visible light, but it can also be produced by heating tungsten or other filaments and by electrical discharge in a gas such as mercury or neon. Any ultraviolet radiation given off is largely absorbed by the glass enclosing the bulb.

The abnormal biological effects of visible radiation are generally not serious. A flash of light will bleach visual pigments, causing “spots” in the visual field. Intense visible light, such as one may experience by staring directly into the sun for extended periods, may cause coagulation of the retina, and the scrotoma that results may be permanent. Snow blindness results from overexposure to sunlight and is characterized by conjunctivitis and keratitis accompanied by photophobia. Use of appropriate lenses will protect against the above effects.

Of potentially greater seriousness are injuries caused by lasers. Laser stands for *light amplification of stimulated emission of radiation*. Lasers are used in industry, communications, surveying, construction, medicine, and electronics. There are many types of laser apparatus, but all are characterized by their ability to produce an intense, monochromatic, coherent beam in which all waves are parallel and all are in phase. There are three types of lasers: (a) continuous, (b) pulsed, and (c) Q-switched, which are pulsed, but the beam is turned on and off at a rapid rate to produce a beam with higher peak power of shorter duration than the pulsed variety.

TABLE 36-4. THRESHOLD LIMIT VALUES FOR ULTRAVIOLET RADIATION

<i>Duration of Exposure per Day</i>	<i>Effective Irradiance, E_{off}</i>
8 h	0.1
4 h	0.2
2 h	0.4
1 h	0.8
30 min	1.7
15 min	3.3
10 min	5.0
5 min	10.0
1 min	50.0
30 s	100.0
10 s	300.0
1 s	3000.0
0.5 s	6000.0
0.1 s	30,000.0

Because the laser is a light beam, it follows all the laws of optics and can be manipulated like other light beams. When focused on a spot, a laser can produce enormous heat for drilling and related purposes.

Burns may occur with exposure to lasers, either to the skin or to the eye, if the laser beam hits the retina. This can cause blindness. Lasers also emit ultraviolet radiation, which can cause corneal damage, and infrared radiation, which can cause opacification of the lens.

Threshold values have been proposed for a wide variety of laser equipment.

► ILLUMINATION

Units for Expressing Amount of Light

The amount of visible radiation (light) emitted by a luminous object, such as an electrical light bulb, is measured in terms of candle power, based on a standard international candle. The amount of illumination that falls on a surface from a light source is expressed in terms of foot-candles. One foot-candle of illumination is intensity of illumination at any point on a surface 1 foot away from a light source of 1 candle power. The illumination falling on a surface varies inversely as the square of the distance from the light source. The total amount of light that falls on 1 square foot of surface, all points of which are 1 foot from a light source of 1 standard candle, is called 1 lumen, lumen being the term used to measure light flux. The brightness of the light source or of an object reflecting light is usually expressed in terms of foot-lamberts or candles per square inch. One foot-lambert is equivalent to 1 lumen emitted per square foot of the light source. One candle per square inch is the candle power emitted per square inch of light source and is equivalent to 452 foot-lamberts.

General Principles of Illumination

Intensity of Illumination. Sufficient illumination is essential for visual acuity, maximum speed of seeing, prevention of eye fatigue and eye strain, and thus for efficient work and prevention of accidents. Definite proof that poor illumination leads to permanent eye injury is lacking, but the character of the illumination may affect psychological reactions. Most authorities agree that high levels of illumination, except under such unusual circumstances as direct viewing of the sun, do not produce harmful effects on the eye. The human eye is adapted for vision outdoors where foot-candle levels may range from 1000 in the shade to 10,000 in the sun.

Standards of illumination usually are set in terms of the amount of illumination that falls on the work area. Since vision depends on the light reaching the eye, however, the important consideration is not the amount of illumination on the desk or workbench but the amount of light reflected to the eye. For example, if there are 50 foot-candles of illumination falling on a white object, which reflects about 80% of the visible light, then 40 foot-candles of illumination are reflected toward the eye. If the same amount of light falls on a dark object, which reflects 20% of the light, only 10 foot-candles of illumination are reflected to the eye. Hence it is necessary to specify different standards of illumination for different circumstances, depending on the amount of light reflected from each work area.

Authorities differ on the amount of illumination essential for vision. Visual acuity and speed of vision increase markedly with an increase in illumination up to about 10 foot-candles, and then increase more slowly up to about 20 foot-candles. Hence 15–20 foot-candles can be accepted as a bare minimum level of illumination for vision under the most optimum conditions. When the reflection factor is reduced, as in work on dark colors or when the contrast in color between the object and its background is reduced, higher levels of illumination are necessary for good visual acuity and speed of vision. Higher levels are required also for continuous and fine eye work. Persons with poor vision or eye defects require more illumination than those with normal eyesight. Generally it is recommended that when the contrast in color and brightness between the object and the immediate

background is good and when the object being viewed is the size of normal print, the lighting for continuous eye work should supply a minimum of 30 foot-candles on the object. Where poor contrast exists or the size of the object is small, the minimum illumination requirement should be set at 50 foot-candles. Higher levels are necessary under certain conditions. In 1965, the American National Standards Institute (ANSI), in cooperation with the Illuminating Engineering Society, published an American Standard Practice for Industrial Lighting, including a list of the current recommended much higher levels of illumination, but the 1965 standards were reconfirmed in 1970 by the American National Standards Institute and adopted by the United States Department of Labor as the standards to be used under the 1971 Occupational Safety and Health Act.

Brightness and Glare. The amount of light reaching the eye from a light source or by reflection from an object is commonly designated as the brightness of the source or object and is usually expressed in foot-lamberts. Although the eye can adapt to very high levels of brightness, such as daylight outdoors, it cannot tolerate great contrasts in brightness between the central field of vision and the surrounding area. Such contrasts interfere with vision and may produce an uncomfortable sensation. In viewing an object against its surroundings, the visual acuity is greatest when the surrounding area has the same brightness as the central field of vision. The brightness of this central field should never be less than that of the surroundings.

Brightness contrasts are produced also when bright light sources are in the field of view. If the eye is adapted to a high level of illumination and the contrast is not great, a bright light in the field of vision does not produce discomfort. The degree of the glare sensation depends on the distance of the eye from the light source, the brightness of the light source in relation to that of the object on which the eye is focused. Excessive reflection from shiny surfaces, so-called reflected glare, produces an uncomfortable sensation and may completely obliterate the outline of an object. The effect of glare on vision increases sharply in older age groups; bare light bulbs should never be permitted in the field of vision.

Differences in Illumination. Great differences in illumination between one work space and another or between a work area and a hallway are dangerous if people are required to move from one space to the other. When passing from a brightly lighted area to one with a low level of illumination, the visual acuity is markedly decreased until dark adaptation has occurred. Although some adaptation occurs fairly rapidly, it requires at least one-half hour for adequate readjustment of vision to dim light. The greater the light adaptation, the slower the dark adaptation that follows. During the readjustment period, the ability of the eye to see clearly is so reduced that the danger of accident is increased. Adaptation requires only a few minutes when passing from a dimly lighted space to one at a high level of illumination.

Color of Light and Surroundings and Surface Finish

A contrast in color between the object and its immediate background is important; the more definite the color contrast, the greater the visual acuity and speed of vision. The value of color contrast is due partly to the dissimilarity in color and partly to differences in the amount of light reflected by the different colors. Recognition of an object becomes most difficult when a black object is viewed against a black background. Here, differences in texture and shadows are necessary for vision. Higher levels of illumination are required where the color contrast is reduced. The color and finish of the walls, ceiling, furniture, and machinery are of great importance in illumination because the amount of light reflected is determined chiefly by the color.

Recommendations: Artificial and Natural Lighting

Artificial Illumination. It is evident from the above discussion that a basic amount of general illumination must be supplied to all areas of

a room to prevent great contrasts in brightness. Local or supplemental lighting, in addition to general lighting, is necessary when very high levels of illumination are required, when illumination is needed in specific areas not accessible to general lighting, where the light must come from a particular angle, where hand readjustments are needed, where shadows are required for the prevention of reflected glare, and in various other circumstances. Supplementary lighting sources should be arranged so that other persons in the vicinity are not exposed to excessively bright spots of light.

Lighting fixtures fall into four types:

1. Totally indirect units give diffuse illumination with no shadows or glare, but they are uneconomical and accumulate dirt. Good reflection from the ceiling is necessary, but excessive brightness of the ceiling must be avoided.
2. Direct units are economical but cause shadows, produce glare, and give spot rather than diffuse illumination. They are used chiefly with high ceilings or for local lighting.
3. Semi-indirect units are satisfactory when equipped with diffusers, when ceiling reflection is adequate, and when they are properly placed to avoid too much brightness in the field view.
4. Large units have a lower candle power per square inch; for example, long tubular fluorescent lights give less concentrated lighting than round tungsten-filament bulbs, which have a higher brightness per unit area (Table 36-5). Large units with moderate brightness also may cause discomfort if placed directly in the field of view.

Natural Illumination. Daylight, if properly arranged, may be a very effective source of good illumination in a room. Much more difficulty is encountered in designing for daylighting than for artificial lighting, however. The amount of daylight reaching a room varies with the location and orientation of the building, with the presence of surrounding buildings, and with the time of day, season, weather, and degree of atmospheric pollution. Furthermore, while artificial lighting can be evenly spaced throughout a room and directed as desired, daylight is available only from certain areas, and its distribution is more difficult to control. Because of these variable factors, only a few general recommendations for providing daylight illumination can be given.

Windows facing south give maximum heat in cold climates but considerable glare; those facing north are advised for buildings in warm climates. The glass area should be at least 20% of the floor area of the room. The tops of the windows should be as near the ceiling as possible, since the higher the windows, the more effectively the light

TABLE 36-5. BRIGHTNESS OF NATURAL AND ARTIFICIAL LIGHT SOURCES

<i>Light Source</i>	<i>Foot-Lamberts</i>	<i>Candles per Square Inch</i>
Sun as observed at earth's surface	450,000,000	1,000,000.0
Full moon, clear sky	1500	3.3
1000 W type H-6 mercury lamp	104,000,000	230,000.0
400 W type H-1 mercury lamp	443,000	980
Brightest spot on bulb of:		
500 W tungsten-filament lamp	131,000	290.0
100 W tungsten-filament lamp	58,800	130.0
40 W tungsten-filament lamp	24,800	55.0
30 W fluorescent, 1-inch tube (white)	2400	5.3
40 W fluorescent, 1½ inch tube (white)	1750	3.9
100 W fluorescent, 2⅛ inch tube (white)	2180	4.8

reaches the opposite side of the room. An increase in the height of a window produces a much greater increase in illumination than a proportional increase in width. Windows on two sides of the room are desirable, but where windows are only on one side of a room, the glass area should extend the full length of the room if possible. It is recommended that windows should not be in the field of view for normal working conditions. The size and position of monitors and skylights also must be related to the size of the building. Since direct sunlight often produces excessive brightness, it is necessary to provide some means of sunlight control, such as venetian blinds, shades, louvers, outside projectors, and glass block.

A complete discussion of recommended practices for day-lighting in schools, factories, offices, and homes has been published by the Committee on Daylighting of the Illuminating Engineering Society.

There has been an increase in research activities related to lighting in the past several years. Lighting patterns have been looked at in nursing home settings⁶ (where they seemed to make little difference), to the effects on food intake patterns^{7,8} (where lighting does seem to make a difference). Lighting seems to have a potential beneficial effect in some hospital settings, such as neonatal intensive care units,^{9–11} or nursing stations.¹² There is also increased interest in the issue of how light may effect circadian rhythms.¹³ With increasing long-distance travel, this may become an increasingly important area of useful research.

TABLE 36-6. OCCUPATIONAL EXPOSURE TO INFRARED RADIATION

Bakers	Foundry workers
Blacksmith	Glass workers
Chemists	Solderers
Cooks	Steel mill workers
Electricians	Welders

► INFRARED RADIATION

Infrared radiation, of longer wavelength than visible light, ranges in wavelength from 700 nm to 1 mm. All objects above absolute zero radiate some infrared radiation. Objects of higher temperature radiate to objects of lower temperature; the sensation of a hot stove results from this. Infrared radiation is the most important part of the spectrum for the production of heat.

Infrared radiation causes dilation of the capillary bed of the skin and if strong enough can cause a burn. Infrared radiation can cause damage to the eye and is a cause of cataract development among glassblowers and others. Occupational exposures to infrared radiation are listed in Table 36-6.

Extremely Low Frequency Electromagnetic Fields

Louis Slesin

Extremely low frequency (ELF) electromagnetic fields (EMFs) are in the 0–300 Hz frequency range. Transmission and distribution power lines, which operate at 60 Hz in the United States and at 50 Hz in most other countries—together with electric appliances—are the most common sources of ELF EMF exposures. The strength of the magnetic field, measured in microtesla (μT) or milligauss (mG), is a function of the electric *current* flowing in the power line: the greater the current, the higher the magnetic field (note that $1 \mu\text{T} = 10 \text{ mG}$). The electric field is proportional to the voltage of the line and is measured in volts per meter (V/m). The intensities of the electric and magnetic fields decrease as one moves away from the source.

Because the current flowing in a power line changes over time, so does the associated magnetic field. The only reliable way to estimate the magnetic field is to use a gaussmeter.¹ Both single- and three-axis meters are available. The three-axis units automatically calculate the vector sum of the field in all directions.

A large-scale survey of ELF EMF exposures in the United States in the mid-1990s estimated that more than half of the American population is exposed to an average magnetic field of less than 1 mG, while approximately 6% are exposed to a 24-hour average of more than 3 mG, and approximately 0.5% or one million Americans are exposed to more than 10 mG.² The largest exposures occurred in the workplace and the lowest were in bed at home.

Electric appliances can have a very high magnetic field very close to the units, but the fields decrease even more rapidly with distance than for power lines. In general, the greater the current draw, the higher the fields. Appliances that can entail the highest exposures are microwave ovens and hair dryers, as well as some types of electric blankets.

The potential health effects of exposure to ELF EMFs remain controversial. On the one hand, there is now a consensus among epidemiologists that children exposed to ambient magnetic fields of 3–4 mG show an increased incidence of leukemia. Yet, on the other hand, there is still no accepted mechanism to explain how ELF EMFs can induce or promote cancer and only inconsistent support for a cancer link from laboratory and animal studies.

In 2001, a committee assembled by the International Agency for Research on Cancer (IARC) classified ELF magnetic fields as a Group 2B carcinogen—that is, they are “possibly carcinogenic to humans.”³ Three years earlier, another expert group advised the U.S. National Institute of Environmental Health Sciences (NIEHS) that it too considered ELF magnetic fields to be possible human carcinogens.⁴ In each case, the driving force for the designation was the possible risk of childhood leukemia.

The following year, 2002, at the end of an 8-year project at a cost of more than \$7 million, the California Department of Health Services issued a report,¹ which concluded that EMFs are likely linked to the development of not only childhood leukemia, but also of adult brain cancer, amyotrophic lateral sclerosis (ALS), and miscarriages.

Epidemiological Studies

Nancy Wetheimer and Ed Leeper first pointed to a link between high-current electrical facilities and childhood cancer in 1979.⁶ Over the next 20 years, a host of follow-up studies were carried out, most of which, but not all, showed an increased risk of childhood leukemia among those exposed to milligauss-level magnetic fields.

More recently, two independent meta-analyses,⁷ with data from the best of these epidemiological studies, have found that the risk of a child developing leukemia doubles following exposure to magnetic fields above 3–4 mG.

Associations have also been reported among those living near power lines. For instance, in June 2005, the Childhood Cancer Research Group in the United Kingdom found a 70% increase in leukemia among children living within 200 meters of a power line. The team concluded like many others in the past: “We have no satisfactory explanation for our results in terms of causation by magnetic fields, and the findings are not supported by convincing laboratory data or any accepted biological mechanism.”⁸

The lack of support from laboratory and animal experiments clearly weakens the association but may be due to our still primitive understanding of what aspect of EMF exposure is responsible for the increased cancer risk. Most experimental studies have used a pure sinusoidal EMF at 50–60 Hz, rather than real-world fields that include more complex waveforms. For instance, short-lived electromagnetic transients with high peak-power have long been cited as being more biologically active than simple sine waves, but unfortunately, very little research has been done to investigate the potential effects of complex fields.

As Kenneth Olden, the director of the NIEHS, reported to the U.S. Congress in 1999 at the end of a 6-year federal research program known as EMF RAPID: “The human data are in the ‘right’ species, are tied to ‘real life’ exposures and show some consistency that is difficult to ignore.”⁹

Studies of EMF-exposed workers show less consistency than the childhood residential studies, but they too show a pattern of excess leukemia, as well as brain cancer. Meta-analyses sponsored by the U.S. electric utility industry point to small, but statistically significant, associations for both types of cancer.¹⁰ Here again, the difficulties associated with identifying the appropriate exposure parameters have frustrated attempts at reaching firm conclusions.

Most occupational studies have focused on worker exposure to magnetic fields, but Anthony Miller observed much higher risk estimates when he took into account exposures to electric fields. For instance, in a study of electric utility workers, Miller reported “significant elevations” in the risk of leukemia for relatively high exposures to both magnetic *and* electric fields.¹¹ In a later analysis, Paul Villeneuve and Miller found that workers who had worked for at least 20 years and had considerable exposure to electric fields above a threshold of 10–20 V/m had an increased risk of leukemia which was 8–12 times the expected rate.¹² Unfortunately, there have not been any follow-up studies to see whether other workers have experienced similar, elevated risks of leukemia and whether the risks are dependent on exposures above a certain threshold.

The importance of an exposure threshold got a big boost when a *prospective* study by De-Kun Li of Kaiser Permanente in Oakland, California, showed that women who were exposed to 16 mG or more on a typical day had up to a sixfold increased risk of spontaneous miscarriage.¹³ Prior to this, EMF-miscarriage studies had found mixed results. Li’s result also awaits replication and confirmation.

The lack of a clear resolution is common for a number of possible ELF EMF health risks. The case for ALS is quite strong,¹⁴ while that for Alzheimer’s is more mixed.¹⁵ For female breast cancer, it is still hard to reach any firm conclusion: Some occupational studies show an association,¹⁶ while others do not.¹⁷ For residential exposures, all the recent efforts have shown no elevated risk,¹⁸ but this may be at least partially due to the fact that exposures at home were quite low. There is a stronger association for *male* breast cancer and EMF exposures.¹⁹

Biophysical Bases for the Epidemiological Links

The lack of a mechanism of interaction continues to undermine the acceptance of the EMF–cancer link. Nevertheless, two lines of laboratory research offer support for the epidemiological findings. The first stems from experiments carried out at the University of Washington, Seattle, where Henry Lai and N. P. Singh have shown

that power-frequency magnetic fields can induce single- and double-strand breaks in the DNA of rats.²⁰ A number of others have also found this genotoxic effect: Sweden’s Britt-Marie Svendsten²¹ did so using mice, and Austria’s Hugo Rüdiger²² with *in vitro* studies.

Even though the quantum energy at 50/60 Hz is far below that needed to break a chemical bond, there may be alternative explanations based on epigenetic changes. Meanwhile, researchers are trying to extend the work in the hope that it throws some light on the nature of the interaction. For instance, Rüdiger found the strongest effect on DNA with an intermittent EMF exposure (field on for 5 minutes, followed by 10 minutes with the field off) and at a relatively low intensity—350 mG (35 μ T). Lai and Singh argue that free radicals are the key to understanding the EMF–DNA interaction: they have shown that free radical scavengers can block DNA strand breaks.²³ They have won support from an Italian group that has also linked the breaks to the formation of free radicals.²⁴

A second possible mechanism centers on melatonin, a natural hormone and powerful antioxidant produced by the pineal gland at night. Visible light has long been known to stop the flow of melatonin from the pineal; EMFs can have a similar, albeit weaker, effect. In 1987, Richard Stevens proposed that electric power, by both increasing light-at-night and EMF exposures, could be responsible for the increased incidence of breast cancer in industrially advanced societies.²⁵

While laboratory studies exposing humans and animals to pure sinusoidal 50/60 Hz magnetic fields have yielded mixed results, surveys of people exposed to EMFs on the job²⁶ and at home²⁷—that is, in real-world environments—have been much more consistent in showing suppression of melatonin.

Jim Burch of Colorado State University has helped elucidate some of the complexities of the EMF–melatonin interaction. He has found that electric utility workers exposed to circularly- or elliptically-polarized fields have lower melatonin levels, but he did not see a similar reduction among those exposed to linearly-polarized EMFs.²⁸

EMFs can not only inhibit the production of melatonin by the pineal, they can also block its oncostatic action. In the 1980s, David Blask found that melatonin can inhibit the growth of MCF-7 breast cancer cells.²⁹ Then about 10 years later, Robert Liburdy showed that a very weak (1.2 μ T or 12 mG) 60 Hz field can counteract the antiproliferation action of the melatonin on breast cancer cells.³⁰ Four other labs have succeeded in repeating Liburdy’s experiment. A Japanese group, the fifth to document this effect, went on to show how a low-intensity magnetic field can disrupt a cell’s signaling system.³¹

In a series of animal exposure studies, a team led by Wolfgang Löscher of Germany’s Hannover Medical School has shown that a 50 Hz magnetic field can promote breast cancer in rats initiated by the carcinogen 7,12-dimethylbenz[a]anthracene (DMBA).³² An effort by the U.S. National Toxicology Program failed to replicate this finding,³³ but subsequent experiments by Löscher explained the apparent discrepancy. He identified a genetic component to the effect: two substrains of the rats can respond differently to the tumor-promoting effects of the magnetic fields.³⁴

▶ RADIO FREQUENCY AND MICROWAVE RADIATION

Radiofrequency and microwave (RF/MW) radiation covers the 3 kHz–300 GHz frequency band of the electromagnetic spectrum. The most common sources of public exposure to RF/MW radiation are mobile phones and their associated towers (see following sections). Television and radio stations use more powerful signals to broadcast their programs. Other high-power sources include radars and satellite uplinks. (Satellite dishes are passive: they only collect microwave signals much like a magnifying glass can focus the sun’s rays.) The military is a major user of RF/MW radiation for communications, radar, and electronic warfare. A multitude of industrial applications make use of the radiation’s heating properties—for instance RF heaters and sealers are used to make products as diverse as loose-leaf plastic

binders to car seats; other applications include laminating wood veneers. Microwaves are also used in hyperthermia for the treatment of cancer.

The ambient intensity of the radiation is measured in milliwatts per square centimeter (mW/cm^2) or watts per square meter (W/m^2) ($1 \text{ mW}/\text{cm}^2 = 10 \text{ W}/\text{m}^2$). Specific absorption rates (SARs) are used to quantify energy delivered to tissues and are measured in watts per kilogram (W/Kg).

RF/MW meters are more expensive than those that can measure 50/60 Hz fields. SARs are difficult to estimate and must be converted to intensity limits for enforcement. For adult humans, an average whole-body SAR of $4 \text{ W}/\text{Kg}$ is approximately equivalent to a power density of $10 \text{ mW}/\text{cm}^2$ at 30–300 MHz.

Epidemiological Studies

There are far fewer high-quality epidemiological studies of RF/MW-exposed populations than there are power frequencies. Stanislaw Szmiigielski of the Center for Radiobiology and Radiation Safety in Warsaw is the only researcher to ever run a major epidemiological study of military personnel occupationally exposed to RF/MW radiation. Overall, he found that exposed soldiers had twice the expected rate of cancer, a statistically significant finding. For leukemia and lymphoma, the incidence was six times that of the controls, with even higher rates for younger (20–50-year-old) servicemen.³⁵

In the United States, an early effort³⁶ to investigate those exposed to radar in the military was marred by the selection of controls—some of these had been exposed to radar radiation. A later study³⁷ of navy personnel found a suggestion of a leukemia risk, but this study also suffered from poor exposure assessment.

Problems with estimating exposures have similarly set back epidemiological studies of possible risks associated with radio and TV broadcast radiation. Nevertheless, studies in a number of different countries have implicated various different types of broadcast radiation with leukemia, especially among the young. In Australia, Bruce Hocking, an occupational physician, found higher rates of leukemia among children living near a TV tower in Sydney.³⁸ Helen Dolk saw a similar pattern in the United Kingdom among adults near TV and FM transmitters outside of Birmingham,³⁹ but her follow-up study of those living near other transmitter sites in England was ambiguous.⁴⁰ A team from South Korea identified a significantly higher mortality rate from leukemia among young adults (under 30 years of age) living in the vicinity of AM broadcast towers.⁴¹ A higher than expected incidence of childhood leukemia has also been found near the high-power shortwave transmitters operated by the Vatican radio outside Rome. Convincingly, there was a significant decline in cancer risk with increasing distance from the Vatican antennas.⁴² In an earlier study, Sam Milham had reported higher rates of leukemia and lymphoma among amateur radio operators⁴³ but the nature of their electromagnetic exposures (as well as other possible toxic substances) is not clear.

The focus of RF/MW epidemiology has now turned to mobile phones and to a lesser extent to their associated towers (see below). This is also the case for in vitro and animal studies.

► MOBILE PHONES AND TOWERS

The most important public health issue related to nonionizing electromagnetic radiation is the widespread use of mobile (cellular) phones. More than two billion people around the world are now regular users of these hand-held devices. Whether or not there are any deleterious effects of long-term exposure to microwave radiation remains an open question.

The International Agency for Research on Cancer (IARC) is coordinating the Interphone Project,⁴⁴ in which epidemiologists from 13 countries (the United States is not among them) are investigating possible mobile phone cancer risks. Each country is running its own case-control study. The combined data—projections point to a total

of more than 5100 cases of benign and malignant brain tumors, as well as more than 1100 cases of acoustic neuromas and more than 100 cases of malignant parotid gland tumors—will then be analyzed together. The results are due by 2008.

A number of participating teams have already published their findings—these include Denmark,⁴⁵ Germany,^{45A} and Sweden.⁴⁶ More significantly, five northern European countries have pooled their data and seen a statistically significant 39% increase in gliomas on the side of the head the phone was used among those who had used cell phones for at least ten years.⁴⁷ A similar ipsilateral, long-term risk has been seen for acoustic neuroma, a benign tumor of the acoustic nerve by the Swedish group⁴⁸ and in a five-country meta-analysis.⁴⁹

A second team of Swedish researchers, led by Lennart Hardell and Kjell Hansson Mild, has also seen a risk of acoustic neuromas, as well as certain types of brain tumors.⁵⁰ In addition, they found indications that there are also health risks associated with the use of cordless phones. These same researchers have reported a higher brain tumor risk among those using phones in rural areas, compared to those using them in urban environments.⁵¹

These potential risks should become somewhat clear when the complete Interphone results become available. Nevertheless, there are reasons to suspect that even then considerable uncertainty will remain. First, only a relatively small number of people participating in the Interphone study will have used mobile phones for more than 10 years, an important limitation given that some cancers have a latency of 15–20 years. In addition, epidemiologists have a hard time estimating exposures to mobile phone radiation. This is further complicated by changes in technology—for instance, the transition from analog to digital as well as the variety of possible signal types, such as CDMA (code division multiple access) and TDMA (time division multiple access).

While much of the concern over mobile phones has been focused on cancer and acoustic neuromas, a number of other effects have also been reported. These include:

- *DNA Breaks:* Lai and Singh, who have shown that ELF EMFs can cause DNA breaks, had previously found a similar effect at RF/MW frequencies.⁵² These findings touched off a major controversy with clear implications for the safety of mobile phones. As a result, Motorola commissioned a series of studies in Joe Roti Roti's lab at Washington University in St. Louis. He failed to see any RF/MW-induced DNA breaks.⁵³ More recently, however, others have found that mobile phone signals, at relatively low intensities, can damage DNA both in live animals⁵⁴ and in cell cultures.⁵⁵ Here again, there is a lot of contradictory results and the nature of this genotoxic effect remains uncertain.
- *Increasing the Permeability of the Blood-Brain Barrier (BBB):* This microwave effect also remains unresolved. The issue is as controversial today as it was when first reported 30 years ago by Allan Frey.⁵⁶ Leif Salford and Bertil Persson of Sweden's University of Lund are the latest to point to changes in the BBB following low-level microwave exposure.⁵⁷ More recently they have observed cellular damage in the brains of exposed rats after only a 2-hour exposure to very-low intensity mobile phone radiation.⁵⁸ They attribute the neuronal damage to changes in the BBB. Pierre Aubineau of France's University of Bordeaux has also observed BBB leakage in rat brains.⁵⁹
- *Changes in Brain Activity and Sleep Patterns:* A Swiss group led by Alexander Borbély and Peter Achermann at the University of Zurich has shown that a single 30-minute peak exposure to a $1 \text{ W}/\text{Kg}$ (in the head) microwave signal simulating that from a GSM mobile phone had an immediate effect on the brain's electrical activity which lasted through most of the night's sleep.⁶⁰ This group has found that "pulse modulation is crucial for RF EMF-induced alterations in brain physiology."

- *Activation of Stress Proteins:* Dariusz Leszczynski of Finland's Radiation and Nuclear Safety Authority has found that nonthermal mobile phone signals can cause changes in the expression of heat-shock proteins. Leszczynski has suggested that these effects, "when occurring repeatedly over a long period of time, might become a health hazard because of the possible accumulation of brain tissue damage."⁶¹
- *Changes in Reaction Times:* A number of research teams have seen improvements in cognitive functions and reaction times in psychological tests—by small but significant amounts—following exposure to mobile phone radiation.^{62,63} There are inconsistencies among these reports, and their relevance to human health remains unclear.

In light of the uncertain health impacts associated with the use of mobile phones, a number of expert panels have recommended a precautionary approach to their use by children. The first of these was a U.K. group headed by Sir William Stewart, which, in its report issued in 2000, discouraged widespread use by children "because of their developing nervous system, the greater absorption of energy in the tissue of the head and longer lifetime of exposure."⁶⁴ In a follow-up report issued in 2004, Stewart reaffirmed this recommendation.⁶⁵ Similarly, a French panel has also advised that parents limit the use of mobile phones by children.⁶⁶

Numerous devices are being marketed to reduce radiation exposures from hand-held phones. Practically all are useless. Hands-free sets are the single exception: they allow you to move the phone away from your head and your eyes.

Although unrelated to radiation exposure, it is worth pointing out that the use of a mobile phone while driving a motor vehicle substantially increases—by a factor of four, according to one estimate⁶⁷—the risk of an accident. The use of a hands-free set has been shown to do little to improve the reaction time for applying brakes.^{68,69}

Mobile phone towers entail much lower exposures than the phones—on the order of 1000-times less—but on the other hand, the towers are transmitting all the time. Such low exposures make epidemiological studies very difficult to carry out. Nevertheless, in 2003, the U.K. government funded a study of leukemia and other cancers among children living near these towers—the first effort of its kind.

One provocation study, carried out in The Netherlands, has found, to the surprise of many observers, that a RF/MW radiation of only 1 V/m has an impact on the "well-being" of those exposed.⁷⁰ But an attempt to repeat this finding failed.^{70A} Claims of electrosensitivity among certain populations remain controversial and unresolved.

► EMF AND RF/MW EXPOSURE LIMITS

The United States has no federally enforceable standards to govern ambient exposures to any type of ELF EMFs or RF/MW radiation. Two, sometimes competing, groups set voluntary exposure limits: the International Commission on Non-Ionizing Radiation Protection, better known as ICNIRP,⁷¹ and the International Committee on Electromagnetic Safety (ICES), a group working under the aegis of the Institute of Electrical and Electronics Engineers (IEEE), based in Piscataway, New Jersey.

There are two federal limits for specific products: one governing mobile phones and the other microwave ovens. The Federal Communications Commission (FCC) has adopted the IEEE exposure limit for hand-held mobile phones: an SAR of 1.6 W/Kg averaged over 1 g of tissue. This is stricter than the ICNIRP limit of 2.0 W/Kg averaged over 10 g of tissue. The averaging volume may seem of little consequence, but in fact going from 1 g to 10 g results in a two-to-threefold increase in allowable exposures. In 2005, the IEEE relaxed its mobile phone limit to match the ICNIRP standard, except that the IEEE exempts the pinna while ICNIRP does not.^{71A} The FCC has not yet indicated whether it might adopt the weaker standard.

More than 30 years ago, the Food and Drug Administration adopted an emission standard of 1 mW/cm² at 5 cm from the door of a new microwave oven and 5 mW/cm² once it leaves the store.

Both the ICNIRP and the IEEE guidelines are based only on acute hazards and do not address possible long-term risks, such as cancer. At ELF frequencies, the standards seek to protect against shocks and burns, while for RF/MW radiation, they are designed to protect against thermal hazards. Both groups have discounted the well-documented childhood leukemia risk at power frequencies.

The ICNIRP standard specifies a general public limit of 1 G (1000 mG) and 5 kV/m for power frequency magnetic and electric fields, respectively. For workers, the limits are 5 G and 10 kV/m. The IEEE limits are more lenient: approximately 9 G and 5 kV/m for the public and 27 G and 20 kV/m for those in "controlled" environments, respectively (these latter limits are essentially equivalent to occupational standards).⁷²

Given the enormous gulf between the general public limit of 1–9 G and the apparent threshold of 3–4 mG for a leukemia risk among children, there have been calls for a precautionary approach to reduce exposures to ELF EMFs⁷³ similar to those for mobile phones and children. Others, for instance those at the World Health Organization, have opposed such proposals, arguing that they would undermine the scientific basis of exposure standards.⁷⁴

In the United States, precautionary policies are framed in terms of "prudent avoidance," a term first applied to EMF health risks by a team at Carnegie Mellon University in the late 1980s in a report prepared by the Congressional Office of Technology Assessment (OTA—now disbanded).⁷⁵ Prudent avoidance, like other precautionary policies, may be defined in various ways. The OTA proposed that ELF EMF exposures may be reduced by rerouting power lines and redesigning electrical systems and appliances when these actions entail "modest costs." Prudent avoidance is a low-cost variation of the ALARA (as low as reasonably achievable) strategy devised to limit exposures to ionizing radiation.

At RF/MW frequencies, the ICNIRP⁷⁶ and IEEE^{71A} standards are similar. They are both frequency dependent, based on the assumption that the threshold for ill effects is 4 W/Kg (averaged over a 6-minute interval). Each then applies a safety factor of 10 to determine the occupational or controlled exposure limits. These are thus based on an SAR of 0.4 W/Kg. For exposures of the general public, each then adds another safety factor of 5 for a resulting SAR of 0.08 W/Kg. When converted to ambient exposure limits, the two sets of guidelines are frequency dependent to take into account the changes in energy absorption. When plotted as a function of frequency, the limits have a well shape. At their most restrictive frequencies (10–400 MHz for ICNIRP and 100–400 MHz for IEEE) these SARs translate to 1 mW/cm² for workers and 200 μW/cm² for the general public.

Above 400 MHz, the ICNIRP public exposure limit rises to 1 mW/cm² at 2 GHz (to 5 mW/cm² for workers). The IEEE is less strict above 400 MHz, rising to 10 mW/cm² at 15 GHz for the uncontrolled and at 2 GHz for controlled exposures. For frequencies below approximately 100 MHz, limits for contact currents are specified.

The guidelines also include looser limits for partial body exposures. ICNIRP and the IEEE allow a 25-fold (for the head and trunk) and a 20-fold increase, respectively. These less strict limits do not apply to the eyes or the testes, however. (The mobile phone exposure limits of 1.6 W/Kg [IEEE] and 2.0 W/Kg [ICNIRP] are derived by multiplying the 0.08 W/Kg guideline by 20 or 25, respectively.)

Some national governments, notably those of Italy and Switzerland, have adopted precautionary limits for both ELF EMFs and for RF radiation. In addition, China and Russia have their own sets of limits that are significantly stricter than those of ICNIRP and the IEEE. In 2000, for instance, Switzerland adopted a 10 mG (1 μT) exposure standard for magnetic fields from new power lines, substations, and electric railway lines in places where people spend time—a level that is 100 times stricter than the ICNIRP guidelines. For RF/MW radiation from mobile phone towers, the Swiss have an

ambient limit of $4.2 \mu\text{W}/\text{cm}^2$ (4 V/m), which is 100–150-times stricter than ICNIRP and the IEEE. Italy's standard for mobile phone towers is $10 \mu\text{W}/\text{cm}^2$ (6 V/m).

Individual countries cannot easily set strict standards for mobile phones because they would be seen as barriers to trade. Nevertheless, TCO Development, an arm of the Swedish white-collar union, is advocating an SAR limit of 0.8 W/Kg averaged over 10 g of tissue for mobile phones, with an additional specification on the communications efficiency.⁷⁷ Using a similar strategy promoting a precautionary limit that is technologically feasible—TCO prompted an industry-wide reduction of operator exposures from video display terminals (VDTs). Today, essentially all large manufacturers market TCO-compliant displays, and concerns over radiation emissions have faded away. While this is good news for data entry workers and the huge number of other computer users, it has left unresolved the question as to whether or not EMFs from cathode ray tubes can lead to miscarriages and other adverse pregnancy outcomes.⁷⁸

► FUTURE RESEARCH

Health research on ELF EMFs and RF/MW radiation has come to a standstill in the United States. The only organizations doing any work are EPRI, the research arm of the electric utility industry, and the U.S. Air Force. Both organizations have clear conflicts of interest. EPRI is spending most of its budget trying to show that childhood leukemia is attributable to contact currents rather than the magnetic fields from their members' power lines. The Air Force is developing crowd control weapons, for example "active denial technology"—one of a growing number of "nonlethal weapons." Active denial uses millimeter waves (~100 GHz) to cause heat-induced pain to disperse crowds. Air Force researchers argue that skin heating does not cause any long-term ill effects.⁷⁹ The Air Force has played a leading role in the development of the IEEE safety standards, but few have raised objections to its simultaneous promotion of weapons and exposure limits.

The U.S. National Toxicology Program has proposed to undertake a major series of RF/MW-animal studies. At this writing, the studies are due to begin in the near future, possibly by late 2007. The situation in Europe is very different with both the EC and individual countries sponsoring their own sets of health studies.

Effects of the Physical Environment: Noise as a Health Hazard

Aage R. Moller

Noise is hazardous to health mainly because it can damage the ear, but it may also influence other bodily functions. A temporary or permanent decrease in hearing acuity, such as that from noise exposure (noise induced hearing loss, NIHL), may impair speech communication. Noise can also mask speech and warning signals and thus poses a risk to safety and to the general health of workers.

The most apparent and best-known health risk from noise is damage to hearing, so this will be addressed first. The other effects of noise are dealt with later in the chapter.

► EFFECT OF NOISE ON HEARING

In this chapter, we use the word *noise* to describe sound that may be damaging to hearing, because this word has traditionally had negative connotations and thus will be identified more readily with health hazards. The potential of noise to damage hearing, however, is entirely related to its physical properties. The amount of NIHL that is acquired is related to the intensity and durations of the noise exposure and the character of the noise (spectrum and time pattern). The character of the noise—whether it is continuous or transient and its spectrum—also plays a role and different types of noise pose different degrees of risk to hearing, even though the overall intensity of the noises is the same; impulsive sounds such as that from gunshots generally pose a greater risk than continuous noise.

Low-frequency sounds are considered to be less damaging than high-frequency sounds of the same physical intensity. Therefore, when noise intensity is measured with a sound-level meter for predicting its effect on hearing, a frequency weighting is used. The commonly used weighting (A-weighting) gives energy at low frequencies less weight than energy at high frequencies. The importance of the temporal pattern of noise is more difficult to represent in standard measurement of noise level.

Since it is the physical characteristics of the sound that determines its potential for causing hearing loss, the origin of the sound has no influence upon the degree of risk it presents for hearing damage, and sounds to which people are exposed during recreational activities pose as great a risk to hearing as noise that is associated with work activities such as in industry. Activities where people are exposed to gunshot noise in particular pose a high risk of inducing NIHL.

There is great variation in an individual person's susceptibility to noise-induced hearing loss (NIHL) and, therefore, only the

average probability for acquiring a hearing loss can be predicted on the basis of knowledge about the physical characteristics of noise and the duration of exposure to noise.

Temporary Threshold Shift and Permanent Threshold Shift

The first effect noticed when an ear is exposed to sounds above a certain intensity and for a certain time is a reduction in the ear's sensitivity (elevated hearing threshold). This reduction in hearing is greatest immediately after the exposure and decreases gradually after the exposure has ended. If the noise has not been too loud or the exposure too long, hearing will gradually return to its original level. This kind of hearing loss is known as *temporary threshold shift* (TTS) (Fig. 37-1). TTS may be experienced after single exposures to high-intensity sounds such as from explosions and from gunfire. If the noise is more intense than a certain value and/or the exposure time longer than a certain time, the resulting hearing threshold never returns to its original value and a *permanent threshold shift* (PTS) has occurred. PTS is the stable threshold shift that is experienced after recovery from TTS (Fig. 37-1). PTS dominate in people who have been exposed to such noise for many years, and the TTS component after the end of the exposure is small. Individual variation in NIHL for the same noise exposure is considerable and the curves in Figure 37-1 represent the *average* course of hearing loss.

While TTS probably results from temporary impairment of the function of the sensory cells in the cochlea (which is a part of the inner ear), PTS has been associated with irreversible damage to these cells. However, research has shown that the cause of NIHL (TTS and PTS) is more complex than just morphological changes in hair cells.¹ It is thus interesting that prior exposure to sounds of moderate levels can decrease the TTS caused by exposure to more intense noise at a later time.^{2,3} It has also been shown that exposure to noise causes morphological changes in the auditory nervous system (cochlear nucleus).⁴ Whether these changes in the nervous system are caused by a direct effect of overstimulation or by the deprivation of input caused by the injury to cochlear hair cells is not clear, but the changes in the nervous system most likely contribute to the symptoms of NIHL. Animal studies have disclosed that activation of a particular neural circuit in the brainstem (the olivocochlear bundle) may protect the ear from noise-induced hearing loss.⁵ While the damage to the cochlear hair cells can be seen when the cells are examined histologically under high-power magnification, these other

Figure 37-1. Schematic diagram illustrating how noise can affect hearing. The graph shows the hearing loss (threshold shift) at 4000 Hz a certain time (horizontal axis) after noise exposure. Noise with intensity below a certain value is expected to give rise to a temporary threshold shift (90 dB, 7 days curve), while a louder noise (100 dB, 7 days) results in a permanent threshold shift. A very intense noise (120 dB, 7 days) gives rise to a considerable permanent shift in threshold.²⁷ (Modified from Miller J. *Effects of noise on people.* J Acoust Soc Am. 1974;56:3.)

changes caused by noise exposure are more difficult to evaluate quantitatively.

The basilar membrane of the cochlea, along which the sensory cells are located, is a complex and intricate organ that performs spectral analysis of sounds so that specific groups of sensory cells become activated in accordance with the spectrum of a sound. There are two types of sensory cells (hair cells) in the cochlea, inner and outer hair cells. Although they are similar in appearance, they have totally different functions. The inner hair cells convert sounds into a neural code in the individual fibers of the auditory nerve, but the outer hair cells' function is mechanical; they act as "motors" that amplify the motion of the basilar membrane and thereby increase the sensitivity of the ear. Destruction of outer hair cells from noise exposure is more extensive than destruction of inner hair cells.⁶ Destruction of outer hair cells reduces the sensitivity of the ear because the "cochlear amplifiers" have been destroyed also impairing the automatic gain control of the cochlea, resulting in an abnormal perception of loudness (recruitment of loudness). Damage to hair cells cannot be reversed.¹

► NATURE OF NOISE-INDUCED HEARING LOSS

Hearing loss from noise exposure is normally greatest in the frequency range around 4 kHz. When the exposure time to noise is increased, or the level of the noise is increased (100 dB versus 90 dB), the magnitude of the hearing loss increases and the frequency range of the hearing loss widens. Most of the hearing loss that is expected after 40 years of noise exposure is already acquired during the first 10 years of the exposure (Fig. 37-2).

Measurement of Hearing

Hearing loss is measured in decibels (dB)^a relative to a normative average hearing threshold obtained based on the hearing thresholds of young people who have had no known exposure to noise. Slightly different standards for "normal" hearing are used in different parts of the world. The difference between the hearing threshold of an individual and the "standard" hearing threshold is known as the "hearing threshold level" (HTL) and is measured in decibels. When the hearing level is plotted on the vertical axis as a function of the frequency tested, a graph results that is known as an audiogram. (Usually, the hearing thresholds are determined only in the frequency range of 125–8,000 Hz [8 kHz], despite the fact that a young person with normal hearing can hear sounds in the frequency range of about 18 Hz–20 kHz.)

Hearing loss caused by exposure to pure tones, or to noise the energy of which is limited to a narrow range of frequencies, is largest in a frequency range that is approximately one-half octave above that at which the tone or noise has its highest energy. The reason is that nonlinearities of the cochlea cause a shift of the maximal deflection of the basilar membrane toward the base of the cochlea when the intensity is increased.¹

The hearing loss shown in Figure 37-2 is typical for individuals who have been exposed to noise in various manufacturing industries

^adB is an abbreviation of decibel and is a logarithmic measure, used here as a measure of sound pressure. 1 dB is one-tenth of a logarithmic unit (a ratio of 1:10). The reason for using a logarithmic measure of sound pressure to measure hearing thresholds is that the subjective sensation of sound intensity is approximately related to the logarithm of the sound pressure.

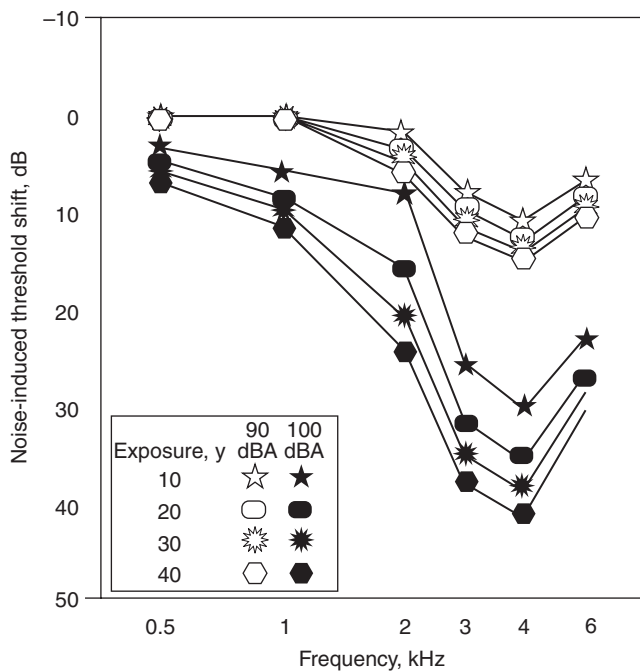

Figure 37-2. Median estimated noise-induced permanent threshold shift plotted as a function of frequency for two exposure levels (assuming 8-hour daily exposure) and four durations of exposure.

where the noise tends to be of a broad spectrum and continuous in nature. The reason that the hearing loss is greatest around 4 kHz is that the ear canal acts as a resonator that amplifies sounds in the frequency range of 3 kHz, and the half octave shift makes the greatest hearing loss to occur around 4 kHz (the exact frequency of the largest hearing loss in an individual person depends on the length of the ear canal which varies among individuals).¹

Individual Variation in Noise Susceptibility

The susceptibility to NIHL varies among individuals and different people who are exposed to exactly the same noise for exactly the same period of time may suffer different degrees of hearing loss. Some people can tolerate high-intensity noise for a lifetime and not suffer any noticeable degree of hearing loss while other people may acquire a substantial hearing loss from exposure to much less intense noise (Fig 37-3). Notice that the *average* hearing loss as a result of exposure to continuous noise with a sound intensity of 90 dB(A) for 20 years in the study depicted in Fig 37.2 is less than 5 dB at 4,000 Hz, but that many people in this study experienced 30- to 40-dB hearing loss.

The *noise emission level* combines the two characteristics of noise—duration and intensity—which are assumed to be of the greatest importance in defining its potential for harm. The noise emission level $E = L + 10 \log(T)$, where L represents the sound level (measured with A-weighting) that is exceeded during 2% of the exposure time, T , in months. For example, exposure to 85-dB noise during 20 years of work corresponds to $85 + 10 \log(20 * 12) = 85 + 10 \log 240 = 85 + 24 = 109$. For continuous noise, L deviates only slightly from the A-weighted sound intensity, but for noise that contains transient or intermittent noises (i.e., noises that vary considerably in intensity) the difference between these two values is great.

Susceptibility to noise exposure varies among individuals and attempts have been made to estimate an individual's susceptibility to PTS by the degree of TTS evidenced on exposure to a test sound that is not loud enough to cause permanent hearing loss, but the results have been discouraging. It appears that there is only a weak correlation

Figure 37-3. Individual age-corrected hearing levels, at 4 kHz as a function of the total amount of noise exposure (emission level), for 581 individuals. Each square represents an individual person, and the solid lines are the mean values of the threshold.

between susceptibility to PTS and the degree of TTS in any individual person. The only way to determine an individual's susceptibility to noise-induced hearing loss is to test, at frequent intervals, the hearing of those who were exposed to loud noise.

Studies in animals have pointed toward some factors that may predispose to noise-induced hearing loss. For example, studies in rats showed that rats that were genetically predisposed to high blood pressure acquired a higher degree of hearing loss from noise exposure than normal rats when both groups were exposed to noise for their entire lifetimes.⁷ Although these findings have not been duplicated in humans, the results of some studies in humans support a relationship between high blood pressure and hearing loss from noise exposure.⁸ Alterations in cochlear blood flow may also affect susceptibility to noise-induced hearing loss.⁹ Research along these lines has provided important knowledge but has not resulted in the development of efficient ways to assess an individual's susceptibility to noise-induced hearing loss or to effectively decrease a person's susceptibility to noise-induced hearing loss.

Since NIHL usually first affects the hearing threshold at frequencies around 4 kHz thus above the range that is essential for perception of speech, NIHL often goes unnoticed until it becomes severe. Common hearing tests can easily reveal hearing loss before it affects the ability to understand speech. A beginning hearing loss may indicate that the person in question is particularly susceptible to noise-induced hearing loss. It is, therefore, important to do frequent hearing tests in workers who are exposed to noise. This testing is part of modern hearing conservation programs. In addition, to obtain pure tone audiograms, it is important to determine a person's ability to understand speech because there are great individual variations in the relationship between the tone audiogram and the ability to understand speech.¹ However, determination of speech discrimination is not standardized and the outcome depends on whether the tests are done in quiet or with a background of noise.¹⁰ Also, other effects of noise exposure on people with noise-induced hearing loss may include ringing in the ears (tinnitus)¹¹ and headaches.

► NOISE STANDARDS

To reduce the risk of noise-induced hearing loss, recommendations of acceptable noise levels have been established and appear in the form of "noise standards." Different countries have adopted different

standards, and the ways in which the standards are enforced also differ. All presently accepted standards use a single value that is a combination of noise level and the duration of the exposure to calculate the risk of noise-induced permanent hearing loss. Some of these standards include correction factors regarding the nature of the sound (for instance, impulsive versus continuous sounds). Some standards take normal age-related hearing loss (presbycusis) into account while others do not.

Present Noise Standards

In the United States, legislation that covers noise includes the Federal Aviation Act of 1958, the 1969 Amendment of the Walsh-Healy Public Contracts Act, the Occupational Safety and Health Act of 1970, the Noise Control Act of 1972, and the Mine Safety and Health Act of 1978. These acts require certain agencies to regulate noise. In Europe, legislation in various countries regarding the limitations on industrial noise has largely been guided by recommendations made by the International Organization for Standardization (ISO).¹²

The maximal noise level and duration accepted in most industrial countries is either 85 or 90-dB(A),^b for 8 hours a day, 5 days a week. In Europe the 85-dB(A) level is more common. In the United States 90 dB(A) is the accepted level stated by the Occupational Safety and Health Administration (OSHA), although certain measures have to be taken if workers are exposed to noise levels above 85 dB(A). The National Institute for Occupational Safety and Health (NIOSH) has recently issued a recommendation that has 85 dB(A) as the limit of accepted exposure level.¹³

Noise Level and Exposure Time

Noise standards are based on exposure for 8 hours per day. If the exposure time is shorter, a higher level of noise can be tolerated. To estimate how much higher level of noise can be tolerated when the duration of the exposure to noise is less than 8 hours per day, a conversion factor is used. Europe has used a 3-dB “doubling factor” for a long time while the United States has used a 5-dB doubling factor.

Research indicates that a doubling factor of 5 dB may be adequate for relatively low noise levels, but that a smaller doubling factor (3 dB, i.e., equal energy) more correctly reflects the hazards presented by noise of a high level. NIOSH also now recommend a 3-dB doubling factor for calculation of the time-weighted average exposure to noise.¹³

A 3-dB doubling factor implies that a reduction of the exposure time by a factor of 2 (e.g., from 8 to 4 hours), can allow a 3-dB higher sound level to be accepted. Thus 88 dB(A) for 4 hours is assumed to have the same effect on hearing as 85 dB(A) for 8 hours. If the exposure time to noise is 2 hours per day, a 6-dB higher sound level is assumed to be acceptable, and so on. This way of calculating an acceptable noise level reflects “the equal energy principle,” which assumes that it is the total energy of the noise that determines the risk for permanent hearing loss.

In the United States, standards have been tightened by stating that no worker should be exposed to continuous noise above 115 dB(A) or impulsive noise above 140 dB(A), independent of the duration of exposure. This action sets a ceiling for acceptable combination of noise intensity and exposure time.

Because the level of noise exposure usually varies during a work day, noise exposure is often described by its *equivalent level* (L_{Eq}), which is defined as the level of noise that has the same *average* energy as the noise that is measured during a work day. The equivalent level is measured by summing the total noise energy to which a person is exposed and dividing it by the duration of exposure. The calculation of this equivalent level assumes that the equal energy principle discussed above is valid.

^bThe (A) after dB indicates that the noise spectrum has been weighted to place less emphasis on low frequencies than on high frequencies. This is done because low-frequency sounds generally possess less risk for causing hearing loss than do high-frequency sounds.

The fact that the present noise standards are based on a simplified measure of noise, namely the A-weighted measure dB(A), adds to the uncertainty in predicting the risk of acquiring a hearing loss that may result from exposure to a certain noise.

► MEASUREMENT OF NOISE

Sound level meters are available in many different forms, from simple devices consisting of basic components such as a microphone, amplifier with circuits that allow integration of the output of the amplifier and display of a single value. Noise level meters are now standardized by the International Electrotechnical Commission (IEC) (IEC 61672:1999), the International Organization for Standardization (ISO), and the American Standards Institute (ANSI) S1.4-1971 (R1976) or S1.4-1983 (R 2001) with Amd.S1.4A-1985, S1.43-1997 (R2002) (Type 0 is used in laboratories, Type 1 is used for precision measurements in the field, and Type 2 is used for general-purpose measurements). (Standards are available from www.ansi.org).

Most sound level meters have at least one spectral weighting, namely A-weighting. The most sophisticated devices that have many options regarding weighting functions, spectral filtering (1/3- and 1-octave wide), and integration times and provide readings of Leq.

Measurements of sound levels are usually made at a location where people work, but the sound level at the entrance of the ear canal of a person in that location will be different because the head and the outer ear amplify sounds within frequencies between 2 and 5 kHz by as much as 10–15 dB.¹ If the noise contains much energy in that frequency range, the sound that actually reaches the ear may be as much as 10–15 dB higher than the actual reading on a sound-level meter placed in the person’s location when the person is not present.

The noise level is often different at different locations and when a person walks around, the exposure varies and it becomes difficult to estimate the average exposure. *Noise dosimeters* have been developed to improve the accuracy of determination of the average noise exposure. These devices, worn by the person, function in a similar way as radiation monitors. They register the sound level near the ear or, sometimes, at other locations on the body and integrate the energy over an entire working day.

Impulsive Noise. Noise-level meters in earlier times were designed to integrate sound over about 100 millisecond (ms) in order to provide a reading that was in accordance with the perceived loudness of sounds. This integration time is appropriate for the purpose to assess the subjective intensity (or annoyance) of sound but that integration time is not appropriate for assessing what risk noise poses to hearing because the ear (cochlea) has a much shorter integration time than the brain, and injury from noise exposure occurs in the cochlea. The more sophisticated sound-level meters (so-called impulse sound-level meters)¹⁴ have integration time that is appropriate for measurement of impulsive sounds.

What Degree of Hearing Loss Is Acceptable?

Because the great individual variation in susceptibility to noise-induced hearing loss makes it impossible to predict what hearing loss an individual will acquire when exposed to a certain noise, noise standards at best merely predict the percentage of people in a population with normal hearing who will acquire less than a certain specified (acceptable) hearing loss when exposed to noise no louder than a certain value.^{15,16} The presently applied standards allow that a certain (small) percentage of a normal-hearing population will acquire a permanent hearing loss (threshold elevation) that is greater than a certain value.

In the beginning of the era in which efforts were made to reduce (or prevent) noise-induced hearing loss, the “acceptable hearing loss” was defined as the level of hearing loss at which an individual begins to experience difficulty in understanding everyday speech in a quiet environment. This definition was based on the American Academy of Ophthalmology and Otolaryngology (AAOO) guidelines for evaluation

of hearing impairment (revised in 1979 by AAO, from 1959 and 1973),¹⁴ which state that the ability to understand normal everyday speech at a distance of about 1.5 m (5 ft) does not noticeably deteriorate as long as the hearing loss does not exceed an average value of 25 dB at frequencies 500 Hz, 1 kHz, and 2 kHz, and that hearing loss was regarded as a just-noticeable handicap for which a worker in the United States was entitled to receive worker's compensation for loss of earning power. These recommendations have not been updated by the American Academy of Otolaryngology (AAO) but the American Medical Association (AMA)¹⁷ has recently provided its own guidelines. However, these guidelines follow the AAO 1979 guidelines.

It is puzzling that this degree of hearing loss given in the AAO (1979) recommendation to describe the hearing level at and above which disability occurs was later designated as acceptable. The estimated percentage of individuals who acquire hearing loss in excess of such hearing loss (Table 37-1) depends on the noise exposure.

It has been argued that these guidelines should be modified to include hearing loss at 3,000Hz.¹⁷ The AMA Guidelines include 3,000 Hz and if the average hearing loss at 500, 1,000, 2,000, and 3,000 Hz is equal or less than 25 dB, no impairment rating is assigned.

These values are based on studies of workers in the weaving industry, and research indicates that the number of people with noise-induced hearing losses may be higher in other industries. The difference between 85 and 90 dB(A) daily average exposure is, however, that the risk of hearing impairment doubles, regardless of which data are used as a basis.

The NIOSH 1998 Criteria Document¹³ (a revision of the 1972 criteria document) states that "an increase of 15 dB in the hearing threshold level (HTL) at 500, 1000, 2000, 3000, 4000, or 6000 Hz in either ear as determined by two consecutive audiometric tests" is a criterion for significant threshold shift. Using a criterion of the equivalent of 8-hour exposure to 85 dB-A-weighted noise, it is estimated that 8% of exposed individuals will acquire more hearing loss over a 40-year work period, while exposure to 90 dB(A) noise will result in an average of 29% excess risk.

Effect of Age-Related Hearing Loss. Hearing loss from causes other than noise interacts with noise-induced hearing loss in a complex way. For instance, the "normal" progressive hearing loss that occurs with age (presbycusis) is not directly additive to hearing loss from noise. The 1998 NIOSH criterion¹³ no longer recommend age correction to take into account presbycusis. If one would attempt to determine the hearing loss from noise alone by subtracting the hearing loss from aging, a paradoxical result will in many cases become evident, namely, that the noise-induced hearing loss will *decrease* with age and with the duration of the exposure to noise. The reasons for the

**Percentage with hearing loss greater than 25 dB at 500, 1000, and 2000 Hz after subtracting the percentage who would normally incur such impairment in an unexposed population.

paradoxical findings are that subtracting presbycusis from the total hearing loss to get the PTS assumes that these two factors add in a linear way, which they do not. Presbycusis also varies very much from individual to individual, which adds to the uncertainty in predictions of an individual person's hearing loss. In the recent NIOSH recommendation, age-related hearing loss is not added to the allowed hearing loss.¹³

Models of Noise-Induced Hearing Loss. Elaborate models of noise-induced hearing loss have been used for prediction of hearing loss from noise exposure, mainly for medicolegal purposes but some models have also been used to predict previous exposure on the basis of hearing loss.¹⁸ While such models may provide valid predictive values of the *average* hearing loss or average noise exposure, the large individual variation makes the accuracy of such predictions low when used for individual people. It is, therefore, questionable to use such models for prediction of the hearing loss that an individual will acquire, or for predicting what noise exposure a person has had on the basis of his or her hearing loss, which has been done for medicolegal purposes.

► PREVENTION OF NOISE-INDUCED HEARING LOSS

It has been advocated that noise standards be modified to reduce the number of people who acquire a hearing loss that can be regarded as a social handicap. The maximal tolerable noise level for an 8-hour exposure is around 75 dB(A) if significant noise-induced hearing loss is to be eliminated.¹⁹ The main obstacles in adopting a lower noise level are economic: the cost of having all workplaces comply with such regulations has been considered prohibitive. However, a much less expensive alternative,²⁰ having all *new* equipment comply with regulations, has not been considered.

It is not the noise level that machinery emits that is important, but rather the noise level to which workers are exposed. Therefore, moving people to less noisy locations can reduce the exposure levels, which means that changes in operating machinery can, in fact, lead to reduction in the risk of noise-induced hearing loss.

Personal Protection

Two types of personal protection are in common use: earmuffs, which are attached to a helmet or worn on a headband, and earplugs. Earmuffs can be removed more easily than earplugs and are therefore better suited for intermittent use as in situations when people are walking in and out of noisy areas (such as airports). On the other hand, earplugs are more practical for people who spend long periods of time in noisy environments. The sound attenuation of different types of earplugs and earmuffs depends on the type of device and how well it fits the individual person. When measured in the laboratory, earplugs are found to attenuate sound more than earmuffs:

Insert ear protectors provide approximately 20 dB attenuation at 125 and 250 Hz, 20–25 dB for frequencies from 500–2000 Hz, and approximately 40 dB at 4000 and 8000 Hz. Some types of earplugs provide 4–5 dB more. Ear muffs provide less attenuation; 10–15 dB for 125 and 250 Hz, 20–25 dB at 500 Hz and 35–40 dB for 1000–8000 Hz.

Studies of hearing loss from noise exposure in workers who were exposed to high-intensity noise (shipyard) showed that those who wore earplugs had better protection than those who wore earmuffs.²¹ The gain that is achieved in practice from wearing ear protection may be less than anticipated. The efficacy of ear protectors depends not only on their sound attenuation determined in the laboratory but also on compliance with the use of ear protectors, which is difficult to control and poorly documented. The beneficial effect is much reduced if the protective devices are not worn all the time.²¹ Wearing ear protectors for long periods may be inconvenient especially in hot environments, and ear protectors impair speech communication, which makes it more difficult for people to hear alarm signals or other acoustic signs of danger.

For ethical reasons, it is not possible to do studies making use of a controlled situation where participants who wear ear protectors are randomized with control participants who do not wear ear protectors. Nilsson and Lindgren's study in which the hearing loss in groups of people wearing ear protectors was compared with the hearing loss in people not wearing ear protectors²² found that people who did not wear ear protectors were almost twice as likely to acquire a hearing threshold shift of 15 dB or more than those who used earmuffs. Other studies showed similar results.²³ Earmuffs are easier to remove and may not always be worn when indicated.²² When the efficacy of ear protectors was studied in shipyards, in combination with intense continuous noise and superimposed impulsive noise, thus presenting an extreme hazard to hearing,²² those who were exposed to low-intensity noise suffered more hearing loss than did those in the high-intensity noise group. This surprising result is likely due to workers' different habits of wearing ear protectors: many more workers exposed to high-intensity noise rather than low-intensity noise wore ear protectors.²²

Active noise cancellation can reduce the sound that reaches the ear. Such devices amplify sounds and apply the sound through an earphone after being reversed. The amplification is set so that the sound from the microphone cancels out the sound that reaches the inside of the headset.

► HEARING CONSERVATION PROGRAMS

Hearing conservation programs are based on understanding of the effect of noise on the ear, measurement of noise levels in the workplace and personal measurements (using dosimeters), and measurement of hearing (audiometry). Knowledge about noise standards and promotion of noise reduction at the source and promotion of personal protections (ear protectors) are also important factors in reducing the risk of acquiring NIHL. Regulations on noise-induced hearing loss by OSHA²⁴ state that hearing conservation programs must be designed so that people who are exposed to noise levels of 85 dB(A) (8-hour weighted average) or more can be identified and that measures must be taken to reduce the noise. If these measures do not result in a reduction of the noise level to 90 dB(A) or lower, workers must participate in a hearing conservation program, and employers must make personal hearing protection devices (ear protectors) available to such workers and perform hearing tests at specified intervals during employment. If a hearing loss of 10 dB average over frequencies 2, 3, and 4 kHz is detected, then the person must be referred for further evaluation and action must be taken to avoid further deterioration of hearing. The progress of hearing deterioration can usually be halted by moving the person to a less noisy environment, thus preventing the progress of the hearing loss before it becomes a social handicap.

► EFFECTS OF NOISE ON OTHER BODILY FUNCTIONS

The effects of noise on bodily functions other than hearing are poorly understood. It has been reported that noise exposure can cause an increase in blood pressure and changes in other important bodily functions such as change (usually increases) in the secretion of pituitary hormones.

Some retrospective studies (i.e., Jonsson and Hansson)²⁵ of the effects of exposure to noise on the blood pressures of industrial workers found that workers who were exposed to industrial noise had higher systolic and diastolic blood pressures, while other studies (i.e., Sanden and Axelsson)²⁶ found no relationship between noise-induced hearing loss and blood pressure in shipyard workers. However, there is evidence that individuals with a predisposition for circulatory diseases acquire more PTS when exposed to noise than people in general. The observed correlation between PTS and elevated blood pressure may thus be the result of a higher susceptibility of people with hypertension. Studies in rats have shown that animals with a hereditary predisposition for hypertension developed considerably greater degrees of hearing loss from exposure to noise than did rats without this hereditary predisposition to high blood pressure.⁸

If the results of these experiments in spontaneously hypertensive rats⁸ can be applied to humans, then the results of the study of hypertension reported by Jonsson and Hansson²⁵ may have to be reevaluated. By using hearing loss as the criterion for degree of noise exposure, they may inadvertently have selected workers who were predisposed to hearing loss because of their hypertension and not vice versa, as was intended.

► EFFECTS OF SOUNDS ABOVE AND BELOW THE AUDIBLE FREQUENCY RANGE (ULTRASOUND AND INFRASOUND)

Sounds that are not audible to humans because their frequencies are above or below our audible frequency range are known as ultrasound and infrasound, respectively. There is no evidence to indicate that exposure to sounds that are not audible can damage the ear, and there is little evidence that such sounds could have other untoward effects.

Ultrasounds are rapidly attenuated when transmitted in air and, therefore, decrease rapidly in intensity with distance from the source. Although very high intensities of ultrasound can kill furred animals such as mice, rats, and guinea pigs because of the buildup of heat by sound absorption in the fur, such an effect could not occur in humans because bare skin cannot absorb enough energy to cause damage.

Exposure to low-frequency sounds (infrasound) of high intensity has been reported to cause various diffuse symptoms such as headache, nausea, and fatigue. The results of some experiments indicate that infrasounds may give rise to a *decrease* in blood pressure, possibly mediated through stimulation of the vestibular part of the inner ear.

Ergonomics and Work-Related Musculoskeletal Disorders

W. Monroe Keyserling • Thomas J. Armstrong

Ergonomics is the study of humans at work in order to understand the complex relationships among people, machines, job demands, and work methods in order to minimize gaps between task demands and human capacities in activities of work and daily living.¹ All human activities, regardless of their nature, place both physical and mental demands on the worker. As long as these demands are kept within reasonable limits, performance will be satisfactory and health will be maintained. However, if stresses are excessive, undesirable outcomes may occur in the form of errors, accidents, injuries, and/or a decrement in health.

Occupational ergonomics is a discipline concerned with evaluating stresses that occur in the work environment and the ability of people to cope with these stresses. Its goal is to design facilities (e.g., factories and offices), furniture, equipment, tools, and job demands to be compatible with human dimensions, capabilities, and expectations. Ergonomics is a multidisciplinary science with four major areas of specialization:

Cognitive Ergonomics (sometimes called engineering psychology) is concerned with the information-processing requirements of work. Major applications include designing displays (e.g., gauges, warning buzzers, signs, instructions), controls (e.g., knobs, buttons, joysticks, steering wheels), and software to enhance human performance while minimizing the likelihood of error.²⁻³

Anthropometry is concerned with the measurement and statistical characterization of body size in the context of workplace and task dimensions. Anthropometric data provide important information to the designers of clothing, furniture, machines, tools, and workstations.⁴⁻⁶

Work Physiology is concerned with the responses of the cardiovascular system, pulmonary system, and skeletal muscles to the metabolic demands of work. This discipline is concerned with the prevention of whole body and/or localized fatigue that results from a mismatch between job demands and worker capacities.⁷

Biomechanics is concerned with the transfer of forces through the musculoskeletal system and the corresponding deformation of tissues.⁸ Many mechanical stresses can cause *overt* injuries (e.g., a concussion when a worker is struck in the head by a dropped object). In most cases, overt injury hazards are readily recognized and can be controlled through safety engineering techniques such as machine guarding and personal protective equipment.⁹ Other stresses are more subtle and can cause chronic or cumulative injuries and disorders. These stresses may be external (e.g., a vibrating tool that causes white finger syndrome) or internal (e.g., tension in a tendon when the attached muscle contracts).

This chapter is concerned primarily with physical work activities and prevention of work-related musculoskeletal disorders (WRMSDs). Typical examples of WRMSDs include:

- A poultry worker develops numbness and tingling in the hand and fingers due to the repetitive hand motions associated with dismembering chickens.
- A farm worker experiences pain in the lower back attributed to the awkward stooping posture required to harvest vegetables.
- A nurse's aide suffers a back strain when transferring a patient from a hospital bed to a wheelchair.

It is important to note that the health problems described above typically are not the result of an accident. (*An accident* is defined as an unanticipated, sudden, and discrete event that results in an undesired outcome such as property damage, injury or death.⁹) Instead, they can be generally classified as overexertion or overuse disorders and syndromes caused by performing work tasks that are regular and predictable requirements of the job.

Anthropometry, work physiology, and biomechanics are the ergonomic disciplines which are most relevant to the development of programs for ameliorating overexertion injuries and chronic musculoskeletal disorders. The following sections present some of the tools used for measuring and analyzing physical work requirements so that they can be compared to recommended human capacity as shown in Fig. 38-1. It will consider not only the ability to merely perform a given task, but also the ability to perform it repeatedly and safely, day in and day out, over the course of many years. Readers who desire additional information pertaining to cognitive ergonomics are directed to the References section for a short list of general survey texts.²⁻³

► ANTHROPOMETRY

Anthropometry is concerned with measuring the size of the human body and using this information to design facilities, equipment, tools, and personal protective equipment (e.g., gloves, respirators, etc.) to accommodate the physical dimensions of the user. As illustrated in Fig. 38-2, most anthropometric design problems are nontrivial due to the large variation in body dimensions within the working population. In this example, a designer must specify the height of an overhead conveyor used to transport parts between two areas of a plant. If the conveyor is too high, short workers would not be able to load or unload parts without elevating the shoulder to an extended reach posture. On the other hand, if the conveyor is too low, tall workers could sustain head injuries from collisions with hung parts.

Figure 38-1. Ergonomics entails analysis of jobs so that job demands can be compared with worker capacities and job/task design enhancements.¹³

Suppose that the designer's primary goal is to avoid head injuries to tall workers. To accomplish this, she decides to provide sufficient overhead clearance to accommodate 95 percent of the U.S. male population by positioning the conveyor so that the lowest point of the hung parts is 190.5 cm (75 in) above the floor. (Note: This dimension is computed using nude stature data for a 95th percentile male from Table 38-1 and adding 2.5 cm [1 in] as an adjustment for shoes.)^{5,10} With this design, a short worker (a 5th percentile female is illustrated) can reach the parts only by raising the shoulder into an elevated, awkward position which may cause fatigue and/or

Figure 38-2. For safety reasons, an overhead conveyor should be higher than the stature of a tall worker (95th percentile male illustrated). This can create a difficult reach for a short worker (5th percentile female illustrated).

musculoskeletal injury in the shoulder region.¹¹ In this situation, there is no simple solution that will simultaneously satisfy the needs of persons who are very tall or very short.

The characterization of body size must consider the large variations in dimensions from person to person and from population to population. Consequently, statistical methods are used to analyze body dimensions, and the results are typically reported as means and standard deviations for various body segments.¹² Extensive tables of these statistics are available in reference texts.^{4-6,10,12} Table 38-1 and Fig. 38-3 present a summary of useful body dimensions for anthropometric applications.

In the following sections, several examples are presented which illustrate how awkward postures can contribute to the onset of fatigue and musculoskeletal and nerve disorders. Body posture is frequently determined by the physical dimensions of a workstation and the location and orientation of equipment and tools. Anthropometric methods can be used during the design of workstations in order to avoid situations which require the use of awkward working postures.

► FATIGUE

Repeated or sustained exertions are associated with a constellation of performance impairments and symptoms collectively referred to as fatigue. Fatigue is typically characterized as "whole body" or "localized." Whole body fatigue is associated with activities where the work load is distributed concurrently over many parts of the body (e.g., legs, torso, and arms), causing high rates of energy expenditure, such as when walking briskly, shoveling snow, or stacking containers. Localized fatigue is associated with tasks in which one segment of the body performs repeated or sustained work, for example, forearm fatigue when using a hand tool, shoulder fatigue associated with overhead work, or back fatigue resulting from sustained trunk flexion.

Fatigue not only affects how workers feel; it also affects their ability to manipulate parts and tools precisely, and may increase their risk of an accident. Symptoms of localized fatigue include localized discomfort, a sense of tiredness, reduced strength, reduced motor control, and tremor.¹⁴ In addition, there are circulatory, biochemical, and electrical changes within the muscle tissue.

Localized fatigue entails physiological and biomechanical processes.^{14,15} Muscle contraction results in consumption of substrates and accumulation of byproducts. At low-level exertions, blood flow increases and these concentrations are maintained at work levels. At high-exertion levels, increased muscle pressure and deformation of the vascular bed impede circulation, and concentrations of substrates and metabolites become excessive. In addition to increased muscle pressure, there also is deformation of connective tissues that causes pain and may be a precursor to chronic soft tissue injuries.

Localized fatigue can develop over periods as short as several seconds or as long as several hours. Similarly, recovery occurs within periods of seconds, minutes, or hours and should be complete after a night of rest, or in extreme cases, after a few days. Altering the work activity will generally provide prompt relief of fatigue symptoms. For example, a seated operator usually gets relief from stretching, changing seat position, standing up, or from a night of rest. If altering the work activity or posture does not provide prompt relief, if symptoms persist from one day to the next, or if the symptoms interfere with activities of work or daily living, then the affected person should be referred to a health-care provider for evaluation. Chronic localized fatigue may be a harbinger of more clinically significant muscle, tendon, and nerve disorders.¹⁶⁻²⁰

Localized fatigue may also have an impact on work performance because fatigue may limit the endurance time prior to the onset of objectionable discomfort during a sustained exertion. Numerous laboratory studies have shown that endurance time increases as the intensity (forcefulness of the exertion) decreases. At an exertion level of 100% of a muscle's maximum strength, the endurance time is only a few seconds before exhaustion occurs. Reducing the exertion level to 50% maximum strength extends the endurance time to approximately

Stature from Wagner D, Birt JA, Snyder MD, Duncanson JP, eds. *Human Factors Design Guide for Acquisition of Commercial Off-the-Shelf Subsystems, Non-Developmental Items, and Developmental Systems*. Document number PB96-191267INZ. Atlantic City International Airport, NJ: Federal Aviation Administration Technical Center; 1996 and link lengths from Drillis R, Contini R. *Body Segment Parameters*. Report No. 1166-03 (Office of Vocational Rehabilitation, Dept. of HEW). New York: NYU School of Engineering and Science; 1966.

1 minute.^{15,19,21-22} These studies led investigators to conclude that exertions below 15% maximum strength could be sustained indefinitely without fatigue. This conclusion was also supported by studies showing that intramuscular blood flow is unimpeded in exertions below 15% maximum strength.^{15,23} It is not desirable for workers to exert themselves to the point of exhaustion used in laboratory experiments (i.e., task termination), as objectionable levels of discomfort are experienced well before this endpoint.^{21,24-25}

Significant fatigue occurs within parts of muscles for even the lowest levels of exertion; it is recommended that work activities be designed so that workers can rest or alter their work activities.¹⁶⁻²⁸

Figure 38-3. Link lengths of body segments expressed as a proportion of stature. (Adapted from Drillis R, Contini R. *Body Segment Parameters*. Report No. 1166-03 [Office of Vocational Rehabilitation, Dept. of HEW.] New York: NYU School of Engineering and Science; 1966.)

Bystrom and Fransson-Hall²⁹ concluded that intermittent hand exertions (5 seconds of static work at 10–40% maximum strength alternating with rest periods of 3–7.5 seconds) with mean contraction intensity greater than 17% maximum strength were unacceptable, while continuous exertions greater than 10% maximum strength were also unacceptable. These results, based on strength, electromyography, blood potassium and lactate concentrations, muscle blood flow, heart rate, and perceived strain during the exertions and up to 24 hours following the exertions, provide guidance for design of work activities. They also demonstrate how fatigue is a complex process involving multiple physiological and biomechanical mechanisms, which are dependent on the intensity and temporal qualities of exertion.

Fatigue can be assessed through the intensity, location, and consistency of discomfort.²⁴⁻²⁶ Advantages of using discomfort for assessing fatigue are (a) it is relevant to how workers feel, (b) it provides information about many tissues and parts of the body, and (c) it requires minimum equipment. Disadvantages are (a) it requires worker cooperation, (b) it can be hard to separate the symptoms of work-related fatigue from other causes, and (c) it is necessary to study multiple workers to control intra- and intersubject variability.

In its simplest form, assessment of effort or discomfort entails asking workers how they feel; however, it is important to ask the question in a way that does not suggest they should be experiencing discomfort or pain. It also is important to ask the question so that the actual areas of discomfort can be identified. Several scales and procedures have been suggested and used for this purpose. The Borg scale of perceived exertion showed a high correlation with heart rate among subjects running on a treadmill.³⁰ As illustrated in Fig. 38-4a, the Borg scale uses ordinal numbers with verbal anchors. It can be argued that perceived exertion data should be treated as ordinal data and analyzed using nonparametric statistics, but many investigators utilize parametric analyses. Borg characterized these scales as categorical with analog properties.³⁰

An alternative to the Borg scale is a body map and visual analog scale, shown in Figs. 38-4b and c. Visual analog scales are lines with verbal anchor points at various locations.^{26,31} The subjects place a check at the location on the line that corresponds to the level of their perceived discomfort or effort at a specific body location. Studies by Harms-Ringdahl et al.²⁶ found that subject ratings of elbow pain using the 10-point Borg scale and a visual analog scale agreed favorably; Ulin et al.³¹ reported similar findings for subjects using powered hand tools. The scale shown in Fig. 38-4c was used to rate back discomfort during

Figure 38-4. (A) Ten-point Borg perceived exertion scale, (B) body map used to identify areas of localized discomfort, and (C) visual analog discomfort scale.

sustained trunk flexion.³² A mark placed at a distance of 20% of the scale length measured from the left anchor point corresponded to “distracting discomfort” (the point where a worker would choose to take a momentary rest pause if permitted by job demands) for an average subject. A mark placed at a distance of 50% of the scale length corresponded to the maximum level of discomfort considered to be acceptable for routine work activities. As a practical matter, the visual analog scale may be the easiest to use in work settings where subjects do not have time to read and contemplate all of the verbal anchor points.

Another technique for evaluating localized fatigue in muscles involves the use of electromyography, or EMG. EMG uses electrodes, preamplifiers, amplifiers, rectifiers, frequency analyzers, and recorders to measure electrical responses of muscles to work.^{14,33} EMG measurements are considered by some to be more objective than discomfort surveys. However, it is difficult to obtain reliable EMG measurements on some subjects and in certain work environments; and the intra- and intersubject variability of those measurements may be quite high. EMG responses are most useful after the affected muscles have been identified using discomfort surveys or other methods. Use of EMG is beyond the scope of this discussion.

To summarize, localized fatigue is characterized as discomfort and/or performance decrement caused by repeated or sustained exertions. The development of and recovery from localized fatigue can occur in seconds, minutes, or hours. Failure to control localized fatigue through the proper design of work equipment and/or the effective management of work activities may lead to more-severe, long-lasting pain or recognized medical conditions. Workers who experience persistent symptoms should be referred to a qualified health-care provider.

► CHRONIC WORK-RELATED MUSCULOSKELETAL DISORDERS

Musculoskeletal disorders are a leading cause of worker impairment, lost work, and compensation. There is strong evidence that both personal and work-related factors are important in the pathogenesis of these disorders.^{17,20,34,35} The World Health Organization uses the term “work related” to characterize disorders that involve both personal and work-related factors, and distinguishes them from occupational

diseases where the entire cause is attributed to work exposures.³⁴ Frequently-cited personal factors associated with chronic musculoskeletal disorders include history of certain injuries or illnesses, age, vitamin deficiencies, gender, and obesity. Work factors include: repeated or sustained exertions, high forces, certain postures, mechanical contact stresses, low temperature, and vibration. Personal factors are important and should be considered during clinical assessments of patients and controlled in studies of the causes and amelioration of WRMSDs.

Other terms, such as cumulative trauma disorders, repetitive strain injuries, and overexertion injuries and overuse syndromes, are sometimes used in place of the term Work-Related Musculoskeletal Disorders (WRMSDs).^{17,35} These terms are not intended to be used in place of specific diagnoses such as tendinitis, epicondylitis, bursitis, fibromyalgia, or carpal tunnel syndrome for the upper extremity; or sciatica, spondylosis, or osteoarthritis for the lower back. WRMSDs refer to a group of disorders that have work activities as a common factor. Some important characteristic of WRMSDs include the following:

1. Their pathogenesis involves both mechanical and physiological processes
2. Weeks, months, and years may be required for them to develop
3. Weeks, months, and years may be required for recovery, and in extreme cases, recovery may never be complete
4. Their symptoms are often nonspecific, poorly localized, and episodic
5. They often go unreported

Mechanical processes refer to the deformation and, in some cases, damage caused by exertions and movements of the body. Physiological processes refer to pain, metabolic repair, and adaptive responses that result from deformation of tissue.

The symptoms of WRMSDs set them apart from acute injuries such as lacerations or fractures where there is a conspicuous event and a conspicuous effect that can be observed by a health-care provider, supervisor, or coworker. Work factors associated with WRMSDs are often overlooked, and the symptoms may not be observable by a third party. Workers themselves may not recognize an association between what they do at work and how they feel. This may explain why WRMSDs are often not reported. Even when workers do suspect an association with their job, they may be reluctant to report their condition to an employer for fear of losing their job. These factors contribute to the great reporting differences of WRMSDs that sometimes occur between one site and another.

WRMSDs are observed frequently in the upper extremity and the lower back, as discussed in the following sections.

► WORK-RELATED MUSCULOSKELETAL DISORDERS OF THE UPPER EXTREMITY

Morbidity

One of the earliest references to these disorders is that of Bernardino Ramazzini³⁶ who in 1713 attributed “diseases reaped by certain workers” to “violent and irregular motions and unnatural postures.” Gray³⁷ in 1893 described “washerwomen’s sprain,” which is commonly referred to as “de Quervain’s” disease, or tendinitis of the extrinsic abductor and extensor muscles of the thumb near the radial styloid process.³⁸

Reports of insurance claims due to tendinitis were recorded in the early twentieth century. For example, in 1927 Zollinger³⁹ reviewed Swiss insurance records and reported 929 cases of crepitant tenosynovitis attributed to repeated strain. The work-relatedness and compensability of musculoskeletal disorders have been surrounded with controversy starting with the implementation of workers’ compensation laws in the early part of this century. Conn reported that the State of Ohio amended its state workers’ compensation rules in 1931 to include musculoskeletal disorders following 12 years of debate in the state legislature.⁴⁰

The controversy centers on how causation is divided between personal and work-related factors. WRMSDs are now compensable in most states of the United States; however, the rules and reporting behavior may vary considerably from one state to another. In most cases, workers must initiate a claim against their employer to receive compensation. This often results in an adversarial relationship, which may inhibit some workers from taking action. While workers' compensation claims provide valuable documentation of the severity of WRMSDs, only in a few cases have investigators been able to develop meaningful generalizations from compensation data.^{41,42}

The reporting of WRMSDs increased substantially at the end of the twentieth century in the United States, reaching a peak of 41.1 lost time cases per 10,000 workers in 1994 and then decreasing to 23.8 cases in 2001 according to the Bureau of Labor Statistics.⁴³ Due to changes in guidelines for reporting work-related illnesses and injuries implemented in 2004,⁴⁴ new data for musculoskeletal disorders cannot be directly compared to the rates reported above.

In summary, the overall prevalence, incidence, and severity of various WRMSDs of the upper extremity in the United States are difficult to determine. The data that are available suggest that while there is significant underreporting, these disorders are a major cause of impairment and work disability.

Individual and Work-Related Risk Factors

Commonly-cited individual risk factors include age, female gender, acute trauma, rheumatoid arthritis, diabetes mellitus, hormonal factors, wrist size or shape, and vitamin deficiency.^{20,35} These factors should be evaluated as possible causes in each reported case; however, the sensitivity and specificity of these factors is not sufficient for use as a screening test at the time of employment to identify workers at risk. Even if such tests were available, affirmative action regulations would require employers to show that workplace modifications to accommodate "at-risk" workers are unfeasible before they could be denied employment. Attempts to use individual risk factors for worker selection or screening should be regarded as experimental and must include appropriate safeguards for risks and rights. It may be advisable to monitor workers with recognized personal risk factors and to counsel these individuals in regard to the potential risks of certain types of work.

Work-related factors include repeated and sustained exertions, forceful exertions, certain postures, mechanical contact stress, vibration, low temperatures, and work organization.^{17,20,35,45} It has been shown that the prevalence of WRMSDs increases with exposure to certain risk factors; however, it is not known at what level the risk becomes significantly elevated for a single factor or combination of work factors. While it is not yet possible to state specific design standards for equipment and work procedures; it is possible to identify some of the most conspicuous risk factors, to identify possible work-related causes when new cases are reported, and to modify jobs in order to accommodate affected workers and prevent future cases.

Control of Upper Extremity WRMSDs

The process for controlling WRMSDs includes (a) surveillance of worker health, (b) treatment and follow-up of new cases, (c) inspections and analyses of workplaces and jobs for possible risk factors, (d) proactive design of new jobs, (e) corporate support, including strong management commitment, (f) education of company personnel and health-care providers, and (g) worker involvement. Detailed information on ergonomics program management is beyond the scope of this chapter; however, several useful publications are listed in the References section.⁴⁶⁻⁴⁹ Employers and workers are referred to their respective trade organizations, unions, and workers' compensation carriers for guidance on implementation of a control program.

Surveillance of Worker Health

Surveillance includes (a) to the extent possible, identifying and evaluating all musculoskeletal disorders for possible work relatedness, (b) periodically reviewing available medical records for musculoskeletal disorders, and (c) proactive surveys of the workplace for risk

factors at the time of program implementation or following a substantive change in work equipment or procedures. While analysis of available injury and illness data is recommended, it is often difficult to identify areas or processes with statistically elevated risks because of the small numbers of workers.^{50,51} In addition, at least several months are generally required for the effects of a given job, method, or tool change to stabilize. Unfortunately, most work populations are not stable enough to rigorously evaluate all possible factors. There is turnover in the work force, due to work and nonwork causes, changes in production schedules, plant shut downs, etc. For this reason it is recommended that all cases be identified and investigated.

Surveillance may also be supplemented with worker surveys and medical examinations. Surveys provide information about overall discomfort or morbidity patterns; however, most survey instruments do not yet have sufficient sensitivity or specificity to be used for case screening or medical diagnosis.^{52,53}

Job Analysis

The number of jobs at a given work site may vary from only a few to several thousand, and there may not be sufficient resources to examine them all in detail. The level of detail required for analyzing jobs depends on the purpose of the analysis. In some cases, it will be better to obtain a little information about a lot of jobs rather than a lot of information about a few jobs. A walk-through inspection of the production facility may be sufficient to confirm that the production process has not changed since a previous study or to find out about the types of equipment, materials, and methods used. In some cases, these walk-through inspections may be supplemented with critiques of representative jobs.⁵³ If high levels of exposure to risk factors are found, it may be desirable to perform more-detailed analyses to quantify those stresses, understand their causes, and design interventions.^{45,50}

Job analysis is divided into four steps: (a) documentation of the job, (b) analysis of stresses, (c) design of interventions, and (d) evaluation of intervention effectiveness. Documentation is the collection of the information necessary to identify and quantify risk factors for WRMSDs. Documentation is based on traditional industrial engineering work methods analysis and entails collection of data for a systematic evaluation of the job.^{54,55} The following items are determined during job documentation:

- *Objective:* why the job is performed
- *Standards:* production quantity and quality expectations
- *Staffing:* the number of workers performing the job
- *Method:* the steps required to perform each task
- *Workstation layout:* blueprints or a sketch of the workplace with dimensions that can be used to determine reach distances
- *Materials:* parts and substances used in the production process
- *Tools:* devices used to accomplish the work
- *Environment:* conditions at and near the workstation

Analysis of Work Factors

The ergonomic assessment of work factors entails characterization of stresses that may contribute to WRMSDs. Stresses can be identified, ranked, and rated from observations by the analyst.⁵⁶⁻⁵⁸ Jobs may be analyzed from direct workplace observations and measurements, or from videotapes. An advantage of videotapes is that they may be played repeatedly and/or slowed down. A disadvantage is that it may be hard to see the entire job in a videotape. Worker ratings also may be used to supplement observations; however, care should be exercised not to ask workers leading questions.⁵⁹ Quantitative physical measurements, such as the cycle time, weights of tools, and locations of work objects, should also be taken. In some cases, these can be supplemented with physiological and biomechanical measurements such as muscle activity and joint position.^{50,50-62} The best method of assessing work stresses depends on the purpose of the analysis and available resources.

Figure 38-5. Workstation for packing notebooks. Bundles of notebooks weighing 25N move from right to left to the worker who puts two bundles into each case.

Repeated and Sustained Exertions

The number of exertions per hour or shift can be estimated from the work standard and methods analysis. Assessments of repeated exertions should take into consideration the frequency and speed of exertions as well as the recovery time between exertions. An exertion is defined as a movement or action to gain control of or to work on an object (e.g., picking up a part, placing a part into a machine, twisting a screw once with a screw driver, pressing a control to activate a machine, etc.). Figure 38-5 shows a workstation for packing notebooks

into cases. Table 38-2 provides a time line of the steps required to perform this job. The job entails a series of reaches and grasps to obtain and erect the case (a corrugated carton) and to transfer notebooks. Each step that involves an exertion is identified by the letter “E.” This job requires 12 exertions during a work cycle with a duration of 13.7 seconds (a rate of 0.88 exertions/s). It is also possible to calculate the time spent working (exertions) versus the total cycle time. The ratio of the work time to the total time is called the duty cycle. For the notebook job, this is computed as 70% (9.6 sec/13.7 sec) for the left hand and 66% (9.0 sec/13.7 sec) for the right hand.

An observational scale for rating repeated exertions is presented in Fig. 38-6.⁵⁸ The verbal anchor points consider the frequency of motion, recovery time, and the speed of motion. This repetition scale has been adopted by ACGIH Worldwide as a measure of Hand Activity Level (HAL) and is used as a basis of a Threshold Limit Value (TLV) for hand-intensive work described later in this chapter.⁶³

Forceful Exertions

Forceful exertions can be identified by inspecting the work methods for steps that involve resisting gravity, surface finishing operations (e.g., grinding, polishing, or trimming), or tool reaction forces (using a manual or powered tool to tighten a screw or nut). On most jobs, exerted forces are not constant throughout the work cycle; there are usually distinct periods of exertion and periods of recovery, and the magnitude of exertions vary from step to step. Returning to the notebook-packing job (Fig. 38-5), each step was inspected for exertion of force (identified by the letter “E”). The magnitude of the force was estimated based on task attributes. Force estimates can be expressed in conventional force units or normalized on a scale of 0–100% or 0–10.

TABLE 38-2. THE STEPS AND START TIMES FOR EACH STEP OF THE NOTEBOOK-PACKING JOB. STEPS ARE LISTED ON THE SAME TIME LINE FOR THE LEFT AND RIGHT HANDS. MAJOR ACTIONS INCLUDE (A) GETTING AND ERECTING CASES (CORRUGATED CARTONS), (B) LOADING BUNDLES OF NOTEBOOKS INTO THE CASE, (C) CLOSING THE CASE, AND (D) PUSHING IT INTO A TAPING MACHINE. EACH DISCERNABLE EXERTION IS IDENTIFIED WITH THE LETTER “E.”

Time	Left Hand		Right Hand	
	Step	Ex	Step	Ex
0.00	Reach for flat case

Hand repetition–hand activity level**Hand force (average/peak)****Contact stress (average/peak)****Posture (average/peak)**

Figure 38-6. Form for recording observational ratings of physical job stresses. (Adapted from Latko W. *Development and evaluation of an observational method for quantifying exposure to hand activity and other physical stressors in manual work*. Ph.D. Dissertation, Dept. of Industrial and Operations Engineering, Ann Arbor, MI: The University of Michigan; 1997.)

For example, it was estimated that the pinch force required to “get and erect the cases” was 5N based on size and weight of the carton and how it was handled. Normalized for a female with 50N pinch strength, 5N corresponds to 10% on a 0–100% scale or to 1 on a 0–10 scale. The force to move a bundle of notebooks to the case (“Pinch/ move notebooks to case”) was 25N per hand, corresponding to normalized values of 50% or 5. Considering all of the steps required to perform this job, the peak force is associated with the “Pinch/move notebooks to case” step. As shown later in this chapter, the ACGIH TLV⁶³ considers peak force when evaluating a job.

Forces can be determined from biomechanical calculations, estimated from knowledge of task attributes and observations, estimated using worker ratings or measured using instrumental methods. Fig. 38-6 shows a 10-point visual analog scale for estimating peak and average hand force.⁵⁸ Assessments of force requirements should take the following factors into consideration:

- The magnitude of weight, resistance, and reaction forces
- The effects of friction
- Balance (well-balanced tools require lower exertions than poorly balanced tools)
- Posture (pinch grips require higher exertions than power grips)
- Pace
- Gloves

Jobs that require workers to get, hold, or use heavy objects will require more force than jobs that require workers to get, hold, or use light objects in the same way. Ratings should be adjusted upward if objects or glove surfaces are slippery or if objects are poorly balanced or supported with the ends of the fingers. Ratings also should be increased for rapid movements or if stiff or bulky gloves are used.

Forceful exertions can be averaged across the entire length of the work cycle, but they must be weighted for time durations. As pointed out before, most people cannot sustain an average force exertion

greater than 10–20% of maximum strength without excessive fatigue. For example, consider a job in which a worker gets parts one at a time and installs them onto a passing unit on an assembly line. The hand force required to reach for the part is negligible, the force required to transfer the part is 20% of maximum muscle strength, and the force required to install the part is 60% of maximum strength. The average force across all tasks (including nonexertion tasks and recovery time) is 10% of maximum strength. Using a 10-point scale for rating force, this job would be given average and peak ratings of 1 and 6, respectively.

Force can also be assessed using electromyography and direct measurements. Jonsson has proposed a method in which the normalized EMG measurements (0–100% of maximum) are presented as a cumulative frequency histogram, called an amplitude probability distribution.^{60,61} Armstrong et al.⁶⁴ utilized force gauges under keyboards to measure forces exerted during typing.

Posture Stresses

Stressful postures can be identified by inspecting work elements for steps that involve repeated or sustained maximum reaches: elevation of the elbows, reaching behind the torso, full elbow flexion, full forearm rotation, ulnar/radial wrist deviation, wrist flexion, full wrist extension, or a pinch grip. Posture analysis may be performed by directly observing the job or from videotapes that are played back in slow motion. The analysis should examine each joint, for example, neck, shoulder, elbow, wrist, and hand (see Fig. 38-6). Posture stress ratings increase as deviations from neutral position, duration, and frequency increase. Posture, like force, varies from the beginning to the end of the work cycle. Consequently, the maximum and average values should be considered in the analysis. Postures can also be assessed with computers using goniometers attached to the joint of interest.⁶²

Localized Mechanical Stresses

Localized contact stresses can be calculated as the force acting on the body, divided by the area of contact. Consequently, the average contact stress will be higher if the weight of the arm is distributed over a padded surface than if it is rested on the sharp edge of a work surface. Stresses may not be uniformly distributed due to the irregular shapes of the workstation and tools, as well as the bones. Stresses can be identified by inspecting work methods for steps that involve contact of the body with external objects. Average and peak stresses should be considered in the analysis. Contact forces can be rated based on observations (see Fig. 38-6), however, there may be significant variation from one rater to the next.

Low Temperature

Exposure to low temperature affects how workers hold and use tools, peripheral circulation, and neurological symptoms of existing nerve disorders. Adverse effects may occur when the skin temperature falls below 20°C. Exposure to low temperatures can be identified by inspecting work methods for steps that result in exposure to cold air, tools, and/or materials. Rankings may be based on temperature, but should be adjusted for thermal conductivity and protective equipment. Ratings also should be adjusted for clothing, as fingers' skin temperature is affected by the body's core temperature.

Vibration

Vibration refers to the cyclical displacement of an object and has properties of frequency and amplitude. Available evidence suggests that vibration exerts a direct action on soft tissue and that it affects the way workers hold and use work objects.^{16,65} Vibration is often reported as a velocity or an acceleration. Acceleration is often reported because accelerometers are widely used to measure vibration.⁶⁵ Instrumental measurements are beyond the scope of this discussion, but vibration exposure can be identified by inspecting work methods for steps that involve the use of stationary or hand-held power tools, impact tools, or controls connected to vibrating equipment. In the

absence of proper instrumentation, ratings may be based on the duration and amplitude of contact with vibrating objects. For example, a grinding or buffing job would probably be rated higher in terms of vibration stress than an assembly job that requires periodic use of a powered wrench.

Worker input

Assessment of ergonomic stresses may be supplemented by worker interviews. Interviews should be carefully designed to avoid suggesting to workers how they should feel. Also, it is important that all workers be asked the same questions. One way of doing this is through the use of surveys in which workers rate discomfort or perceived exertion. An example of a survey in which a visual analog scale was used to assess the weights used in an automobile trim shop is shown in Fig. 38-7.⁵⁹ These data show a significant increase in ratings toward "too heavy" as the tool mass increases above 2 kg. It cannot be said that workers will not develop a WRMSD if they use tools less than 2 kg, but in the absence of better data, worker ratings may be used as a design or selection benchmark. Designing lifting tasks to match acceptable levels of perceived exertion has been reported to reduce the risk of overexertion disorders of the back.⁶⁶ While this has not been shown for upper limb disorders, it is a tenable hypothesis.

Exposure Limits for Jobs with Upper Extremity Exertions

A number of tools or procedures have been proposed that can be used to quantify the risk factors described above so that they can be compared with worker capacities or recommended exposure limits. A discussion of all of the tools is beyond the scope of this chapter. Please refer to the reference list for additional information on tools and job analysis methods.^{46,58,63,67–72}

ACGIH TLV for Monotask Handwork

ACGIH Worldwide defines itself as a "scientific organization"—"not a standards setting body." The ACGIH maintains committees of qualified experts who review peer-reviewed literature and develop guidelines known as Threshold Limit Values—TLVs. TLVs are intended to help health professionals make decisions about safe levels of worker exposure. Information regarding the TLVs can be found in the ACGIH TLV guide and their documentation.⁶³

The TLVs for HAL apply to monotask hand work that is performed for four or more hours per shift. It considers HAL and peak finger force (Fp) Hand described above. "Monotask" means that the worker repeats a similar set of motions or exertions for 4 or more hours. At the present time, the TLV does not consider work durations beyond 8 hours, awkward posture, mechanical contact stress, vibration, and/or psychosocial stresses; these are left to professional

Figure 38-7. Ratings of 33 tools by 22 workers show that tools in excess of 2 Kg were considered "Too Heavy" in an automobile trim shop. (Source: From Reference 59, Armstrong TJ, Punnett L, Ketner P. Subjective worker assessments of hand tools used in automobile assembly. 1989;50:639–45. Reproduced with permission of American Industrial Hygiene Association Journal. <http://www.ahj.org>.)

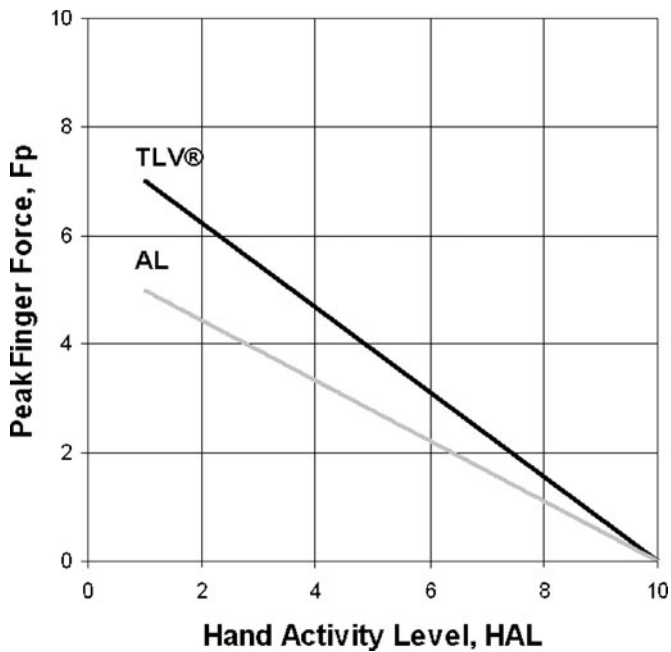

Figure 38-8. ACGIH TLV for hand activity level provides guidance for determining acceptable peak finger force (Fp) levels for a given hand activity level (HAL). (Adapted from American Conference of Governmental Industrial Hygienists [ACGIH]. 2005 TLVs and BEIs. Cincinnati: ACGIH Worldwide; 2005.)

judgment. TLV users are cautioned that some transient discomfort is a normal part of all physical activity (see the discussion of fatigue) and may not be prevented by the TLV. Also, there are many nonoccupational exposures that may contribute to the development of MSDs.

The TLV is shown graphically in Fig. 38-8. Peak finger force (Fp) is plotted on the vertical axis and HAL is plotted on the horizontal axis using scales ranging between 0 and 10. The TLV is depicted as a line that goes from a peak finger force of 7 for an HAL value of 1 to a peak finger force of zero for an HAL value of 10. There is also an action limit (AL) that goes from a peak finger force of 5 for an HAL value of 1 to zero for an HAL value of 10.

Work with HAL levels less than 1.0 is not considered repetitive work and the TLV does not apply. Exposures to combinations of HAL and Fp should not exceed the TLV. When this occurs, job modifications are indicated to reduce HAL and/or Fp. These modifications should be based on the results of job analysis methods described above. Exposures that exceed the AL should trigger a control program that includes surveillance of workers for MSDs, education of managers, supervisors, and workers, early reporting of symptoms, and appropriate health care of workers who have developed MSDs.

The TLV can be applied using observations and ratings as described above. If additional information and certainty are desired, it also can be applied from a work methods analysis like the one shown for the notebook-packing job in Table 38-2. The ACGIH provides a table for estimating HAL based on exertion frequency and duty cycle. (See Table 38-3.) In the notebook-packing job, the frequency of exertions was estimated as 0.88/sec and the duty cycle as 70%. Using Table 38-3, the HAL can be estimated as 5. The peak finger force during notebook packing was estimated as 5. In Fig. 38-8, the maximum acceptable hand force for an HAL of 5 is 3.8. Clearly, the TLV is exceeded and engineering enhancements should be implemented to reduce peak finger force and/or HAL.

Intervention and Evaluation of Control Methods

Jobs ranked high in terms of ergonomic stresses should be redesigned to minimize those stresses. Possible strategies may focus on the redesign or modification of methods, tools, workstations, and production processes. Worker training may help workers to select and use tools properly or to properly adjust their workstation, but in many cases ergonomic stresses result from the work requirements and cannot be reduced through training.

As has been previously stated, there are not yet specification standards for acceptable levels of ergonomic stress. Therefore, it is necessary to evaluate interventions to ascertain their effectiveness. Evaluation may be accomplished through reanalysis of the job, measures of localized discomfort or exertion, and ongoing surveillance of health data. These procedures have been described above.

► OCCUPATIONAL LOW BACK PAIN

Low back pain is a nonspecific condition that refers to perceptions of acute or chronic pain and discomfort in or near the lumbosacral spine that can be caused by inflammatory, degenerative, neoplastic, gynecologic, traumatic, metabolic, and other types of disorders.⁷³ A large number of disease conditions have been associated with low back pain, including sciatica, lumbago, spondylosis, osteoarthritis, and degenerative disc disease.⁷⁴ However, most episodes of work-related back pain cannot be associated with a specific lesion. Therefore, in most epidemiologic studies of occupational low back pain, the specific cause is not identified. Typically, all categories are grouped together as an idiopathic condition with similar reported symptoms.⁷⁵

There is no objective measurement of back pain, it can only be assessed using subjective self-reports such as pain/discomfort diagrams and visual-analog scales. In some cases, back pain may affect activities of daily living and/or result in occupational disability (lost work time or work restrictions). However, disability is a complex process that is affected by a variety of occupational, socioeconomic, and personal factors (e.g., physical job demands, psychosocial climate, compensation systems and insurance benefits, personality, etc.). As a result, there is a poor correlation between back pain and disability.^{73,76}

TABLE 38-3. HAL CAN BE ESTIMATED FROM EXERTION FREQUENCY (EXERTIONS PER SECOND) OR PERIOD (CYCLE DURATION IN SECONDS) AND WORK DUTY CYCLE TIME*

Frequency	Period	Duty Cycle

†Values extrapolated by author—not from ACGIH.

Because the causes of back pain are so poorly understood, it is difficult to specify a treatment plan. In most episodes, people with back pain are able to continue working and cope with the problem without seeking medical treatment. Most disabling cases are temporary and typically resolve themselves within a few weeks using only conservative treatment such as reduced physical activity and OTC pain medication. More invasive interventions such as surgery should not be considered during the first three months unless indicated by a specific diagnosis.⁷⁷

Low back pain is one of the most common and costliest health problems in industrialized societies. Studies in the United States and Scandinavia have shown that 60–80% of adults experience at least one episode of back pain during their adult working life (ages 18–65).^{78,79} Other studies have found the one-month prevalence rate to be approximately 35% and the one-year prevalence rate to be approximately 50%.^{80,81} (It is important to note that most episodes reported in these prevalence studies did not result in occupational disability.) It is estimated that over 2% of U.S. workers file injury claims for back pain each year.^{80,82,83} When workers' compensation indemnity payments and other indirect costs are added to medical expenditures, the total cost of occupational low back pain in the United States is estimated to be \$50–\$100 billion per year.⁸⁰

Occupational risk factors associated with the development of back pain include the following:

- *Forceful exertions during manual materials handling*, such as lifting, pushing, and/or pulling of heavy loads^{20,84–93}
- *Awkward trunk postures*, such as flexion, lateral bending, axial twisting, and/or prolonged sitting^{20,88–91,93,94–96}
- *Whole body vibration*, usually transmitted through a vibrating seat or platform^{20,89,90,97,98}
- *Repetitive or prolonged exposure* to any of the above risk factors^{75,88,89,92,99}
- *Work-related psychological or psychosocial stress*^{80,100,101}
- *Slips and falls*^{87,102}

Note: For the first five risk factors listed above, workers are typically exposed on a continuing or ongoing basis, and it may be difficult to associate a back complaint with a specific incident or accident. Back pain complaints associated with slips and falls are different in the sense that the complaint can almost always be associated with a specific event.

Truck drivers experience elevated rates of back pain when compared to other occupational groups.^{91,99} Many truck drivers load and unload their own rigs; this activity often requires heavy lifting combined with awkward posture (e.g., trunk flexion when bending down to grasp an object on the floor of the trailer). Truck drivers also spend a considerable portion of their workday in a sustained seated posture and may be exposed to high levels of whole body vibration if the vehicle and seat suspension systems do not adequately isolate the driver from roadway bumps and shocks. Finally, slips and falls are common in the truck driving population due to the need to regularly ingress and egress tractors and trailers, working and walking outdoors on slippery surfaces in inclement weather, and maneuvering hand trucks on ramps and other irregular surfaces, sometimes with impeded vision (due to the size of packages that can partially block the visual field).¹⁰²

Other high-risk occupations include nurses and nurses aides, garbage collectors, warehouse workers, and mechanics.^{103,104} All of these occupations require heavy lifting and associated materials handling tasks.

Lifting and Back Pain

Because of the hazards associated with manual lifting, the National Institute for Occupational Safety and Health (NIOSH) developed guidelines for evaluating lifting tasks in 1981.⁸⁵ These guidelines were updated in 1993 in a monograph titled *Applications Manual for the Revised NIOSH Lifting Equation*.¹⁰⁵ This document discusses risk factors associated with lifting and describes procedures for analyzing and designing manual tasks to keep biomechanical, physiological, and psychophysical loads within acceptable limits.

To use the NIOSH lifting guidelines, it is necessary to measure the following eight task variables:

1. Load Weight (L)—measured in kilograms.
2. Horizontal Location (H)—the distance from the midpoint of a line connecting the ankles to a point on the floor directly below the load center as shown in Fig. 38-9. This distance is measured in centimeters at the origin and destination of the lift.
3. Vertical Location (V)—the location of the hands at the origin of the lift, measured vertically from the floor or working surface in centimeters. See Fig. 38-9.
4. Vertical Travel Distance (D)—the vertical displacement of the object (origin to destination) over the course of the lift, measured in centimeters.
5. Asymmetry Angle (A)—angular displacement of the load from the front of the body (the midsagittal plane) at the origin and destination of the lift, measured in degrees as shown in Fig. 38-10.
6. Lifting Frequency (F)—the average number of lifts per minute.
7. Duration of lifting activities—measured in hours.
8. Coupling Classification (C)—quality of the hand to object coupling (i.e., gripping surface), classified as good, fair, or poor.

These variables are substituted into the NIOSH Lifting Equation to compute the Recommended Weight Limit (RWL):

$$RWL = 23 \text{ kg} \times HM \times VM \times DM \times AM \times FM \times CM \quad (39-1)$$

where:

HM is the *horizontal multiplier* computed as $(25/H)$, where H is the horizontal location (defined above). Table 38-4 presents values of HM for various horizontal locations. If H is ever less than 25 cm (10 in), the

multiplier is set to a value of 1.0. If H exceeds 63 cm (25 in), HM is set to zero since this is greater than the reach capability of some workers.

VM is the *vertical multiplier* computed as $[1 - (.003 \times |V - 75|)]$, where V is the vertical location (defined above). Values of VM for various vertical locations are presented in Table 38-5. VM is set to zero if the vertical location is higher than 175 cm since this exceeds the vertical reach capability of some workers.

DM is the *distance multiplier* computed as $[\.82 + (4.5/D)]$ where D is the vertical travel distance (defined above). DM cannot exceed a value of 1.0 even if the actual vertical travel distance is less than 25 cm. Table 38-6 presents values of DM for selected travel distances.

AM is the *asymmetric multiplier* computed as $(1 - 0.032 \times A)$, where A is the angle of asymmetry (defined above). Values of AM for selected asymmetry angles are presented in Table 38-7.

FM is the *frequency multiplier* from Table 38-8. The purpose of the frequency multiplier is to adjust for fatigue that results from frequent and/or prolonged lifting. Note that it is necessary to consider both the *frequency* and *duration* of lifting activities in order to use Table 38-8. It is also necessary to consider the vertical location since low lifts involve lowering and raising the weight of the trunk and the head. This requires additional energy and may contribute to fatigue. (Note: NIOSH has not yet determined multipliers for jobs where the duration of lifting activities exceeds 8 hours.)

CM is the *coupling multiplier*. A “good” coupling ($CM = 1.0$) exists if the object is equipped with handles or hand-hole cutouts of sufficient size and clearance to accommodate a large hand. For loose objects without handles, a “good” coupling exists if the shape of the object allows the fingers to be comfortably wrapped around the object. A “fair” coupling ($CM = 0.95$) exists if the object has no handles or hand-holes, but the size, shape, and rigidity are such that the worker can

TABLE 38-5. VALUES OF THE VERTICAL MULTIPLIER (VM) FOR VARIOUS VERTICAL LOCATIONS (V)*

comfortably clamp the fingers under the object (such as when lifting a corrugated case from the floor). "Poor" coupling (CM = 0.90) exists whenever the object is difficult to grasp (e.g., slippery surfaces, sharp edges, nonrigid shape, etc.). Large objects that require a hand separation distance of more than 40 cm are considered to have a poor coupling.

Once all the multipliers have been determined, use Equation 39-1 to compute the Recommended Weight Limit for the lifting task. To estimate the relative level of stress associated with a lifting task,

NIOSH defines the Lifting Index (LI) as the ratio of the Load Weight (L) to the computed Recommended Weight Limit:

$$LI = L/RWL \tag{39-2}$$

The LI can be used to compare the relative hazard of two or more jobs, or to prioritize lifting jobs for ergonomic interventions. There is limited epidemiological evidence that the rate of back injury increases as the LI increases from 1.0 to 2.0.⁹² NIOSH suggests that jobs should be designed to achieve an LI of 1.0 or less. For additional information on using the NIOSH Lifting Equation, including numerous detailed examples, refer to the *Applications Manual for the Revised NIOSH Lifting Equation*.¹⁰⁵

The most effective way for reducing injuries and disorders associated with manual lifting is to implement engineering controls (i.e., changes in equipment, workstation layout, work methods, etc.) that reduce exposure to one or more of the risk factors discussed above. Possible approaches are briefly outlined below:

1. Reduce the weight of lifted items. For example, is it possible to put fewer parts in a tote pan or to reduce the size and weight of bags containing granular or powdered materials?
2. If the weight of the load cannot be reduced, provide mechanical assistance (e.g., hoist or articulating arm) to reduce the forces exerted by workers.
3. Eliminate low reaches by delivering objects to the worker at knee height or above. Provide an adjustable-height lift table to allow the worker to pick up objects without excessive trunk flexion.
4. Reduce horizontal reach distances by eliminating or relocating barriers that prevent a worker from getting as close to the object as safely as possible prior to starting the lift. Forward reaches should require no trunk flexion.
5. Reduce carrying distances by changing the workstation layout or by installing mechanized equipment (e.g., conveyors). Eliminate twisting by changing the layout or changing the task sequence.

If engineering controls do not reduce the LI to less than 1.0, administrative controls should be considered. A rotation scheme that allows workers to alternate between jobs with heavy lifting requirements and jobs with insignificant lifting requirements reduces cumulative exposure to lifting stresses. Although NIOSH does not endorse the use of worker selection tests, a limited number of studies have indicated that strength testing and/or aerobic capacity testing may be used to identify workers who can perform work activities with moderate to high lifting without significantly increasing their risk of work-related injury.¹⁰⁶⁻¹⁰⁷ Employee selection testing, however, is a

TABLE 38-8. VALUES OF THE FREQUENCY MULTIPLIER (FM) FOR VARIOUS LIFTING FREQUENCIES (F)*

nontrivial process that requires extensive analysis of job demands and validation of all screening criteria.

Another type of administrative control claimed to be beneficial in preventing back injuries is the back belt, a personal protective device worn by persons who perform manual materials-handling tasks. Studies of the effectiveness of back belts have been limited. Laboratory research has indicated that back belts may be effective in reducing biomechanical risk factors during lifting.¹⁰⁸ However, based on a small number of epidemiological studies, NIOSH concluded that there is insufficient evidence to support the claim that back belts prevent injuries to healthy workers.¹⁰⁹⁻¹¹⁰ A study of airline baggage handlers found that worker compliance in wearing back belts is poor, with 58% of subjects discontinuing use after 8 months. Furthermore, workers who discontinued wearing belts had higher injury experience than a control group who never wore belts.¹¹¹

Awkward Posture and Back Pain

Awkward trunk posture during work can be caused by poor workstation layout. The neutral position of the trunk occurs when it is in a vertical upright position with no axial twisting. Trunk flexion (forward bending in the sagittal plane) can usually be attributed to one of two causes: (a) reaching down to grasp an object that is lower than knuckle height (the level of the hands when standing upright with the arms hanging vertically), or (b) reaching forward to grasp an object that is too far in front of the body. Lateral bending (in the frontal plane) and axial twisting are usually associated with reaching for objects that are located either to the side of or behind a worker's body. Laboratory and field studies have shown that these nonneutral postures are associated with local muscle fatigue and excessive rates of back pain.^{85,95-97,112,113} Nonneutral postures can prove particularly challenging for persons with preexisting and chronic back pain; and workplace accommodations to reduce postural demands are essential to successful placement.³² Workstations should be designed to avoid trunk postures that deviate more than 30° from the neutral, upright position, and highly dynamic trunk motions should be avoided.

Because working posture is a function of an individual's anthropometry, a workstation layout that is good for one person may not be

appropriate for workers who are considerably larger or smaller. For this reason, adjustability should be incorporated into the workstation wherever possible.

Seated Work and Back Pain

Due to the rapid growth of service and information industries and technological advances in manufacturing methods, an increasing number of workers are spending a major fraction of their workday in a seated posture.¹¹⁴ Sitting provides many ergonomic benefits, such as a reduction in the amount of body weight borne by the tissues of the feet and lower extremities, a reduction in whole-body energy expenditure due to decreased muscle activity, and stabilization of the body for tasks that require precise manual dexterity. The primary disadvantage of sitting is increased stress on the spine.⁸

Clinical and epidemiological studies have shown that prolonged sitting is associated with increased rates of lower back pain.^{94,115} A possible explanation is that when a person moves from a standing to a sitting posture, the pelvis rotates backward, flattening the normal lordotic curve of the lower spine.^{116,117} This flattening has the following effects: compression on the anterior portion of the disc, tension on the exterior portion of the disc, increased intradiscal pressure, tension on the apophyseal joint ligaments, and tension on the erector spinae muscles.^{118,119} These stresses affect the supply of nutrients to the disc and surrounding tissue and may be related to the development of back disorders.

Spinal stresses associated with sitting are affected by the design of the chair. An important design consideration is the angle between the backrest and the seatpan. As this angle is increased, pelvic rotation and lumbar flattening is reduced.¹¹⁷ This can be accomplished by tilting the seatpan slightly below the horizontal or by rotating the backrest in a rearward direction from the vertical. Jobs which require the worker to lean forward while sitting (e.g., sewing, many bench assembly tasks, microscope work, etc.) should have forward-slanting seatpans. A study of full-time sewing-machine operators found that comfort was enhanced and fatigue reduced by tilting the seatpan to slant forward at an angle 15° below the horizontal.¹²⁰ Furthermore, laboratory experiments have demonstrated that intradiscal pressures can be reduced up to 50% by increasing the included angle between

the seatpan and backrest from 90° to 110°. Adding a lumbar support to the backrest also reduces intradiscal pressure.¹²¹

The height and shape of the seatpan are also important considerations in chair design. If the seat is too high, the worker's feet dangle causing pressure on the underside of the thigh. This can interfere with circulation and cause swelling in the feet and lower legs. If the seat is too low, the thighs do not make good contact with the seatpan and an excessive amount of body weight will be borne by the ischial tuberosities and surrounding tissue. This may cause considerable discomfort, particularly if sitting on an unpadded seat or if sitting for a prolonged period. To accommodate the range of body sizes found in the working population, it is suggested that seat height be adjustable from 38 cm to 53 cm, measured from the floor to the front of the seatpan.¹²¹ This adjustment should be easy to perform and not require any special tools. Ease of adjustment is particularly important if the chair is used by more than one person (e.g., where the same workstation is used by both day-shift and night-shift workers). Where feasible, the workstation and job demands should be designed to avoid prolonged seated postures.¹²² For example, the job can include occasional tasks that must be performed away from the primary workstation. This allows the worker to periodically stand up and walk during the shift.

When selecting or designing a work seat, it is important to match the characteristics of the chair to the requirements of the job. For example, workers who must periodically reach behind or to the side of the body typically prefer seatpans that swivel, while workers who perform precision assembly tasks prefer seatpans which are stable.¹²³

► MANAGEMENT ISSUES

As discussed above, stresses that result in musculoskeletal disorders of the upper limb and low back can frequently be controlled through redesign of equipment, tools, and/or work methods. While these interventions may reduce the incidence and severity of WRMSDs, it is unrealistic to prevent all disorders. They are multifactorial in nature and their causation is not yet understood well enough to achieve zero risk. In addition, there will continue to be some cases due to individual factors. It is necessary to provide accommodations for people who experience these impairments so that they do not become long-term disability cases. The details of such a program are beyond the scope of this chapter, but are described elsewhere.⁴⁶⁻⁴⁹ It suffices to say that the worker, supervisor, engineer, and health-care provider must work together as a team to determine what the worker can do, and to find or modify jobs to accommodate any limitations.

Control of WRMSDs involves health professionals, supervisors, engineers, and workers. Thus, an ergonomics program is best managed by a team of persons from each of these areas. The team should meet regularly to review health data, new and old cases, set goals, recommend allocation of resources to control ergonomic stresses, and review the progress of ergonomic interventions.

► SUMMARY

Many worker health and safety problems can be attributed to failure to anticipate the capacity and behavior of the entire work population. Fatigue, accidents, and back and upper limb disorders are all too common examples of these problems. Ergonomics is the application of epidemiology, anthropometry, biomechanics, physiology, psychology, and engineering to the evaluation and design of work for preventing injury and illness while maximizing productivity. Ergonomics is not yet an exact science, therefore, all interventions should include appropriate evaluations to ascertain their effectiveness.

Industrial Hygiene

Robert F. Herrick

► BACKGROUND

Within the scope of public health practice, industrial hygiene is the health profession devoted to the recognition, evaluation, and control of hazards in the working environment. These include chemical hazards, physical hazards, biological hazards, and ergonomic factors that cause or contribute to injury, disease, impaired function, or discomfort. Throughout the world, the profession that addresses these hazards is known as occupational hygiene; however, the United States has not yet adopted this newer, more accurate term. In this chapter, the term industrial hygiene is used as the equivalent of occupational hygiene.

Industrial hygiene principles have evolved over many years with accelerated development since the Industrial Revolution. Industrial hygiene is a young profession, which traces its name to Hygeia, the goddess of health and prevention, daughter of Aesculapius, god of medicine in Greek mythology. The modern history of industrial hygiene starts with the organization of manufacturing processes into industrial sectors. This history was chronicled by Theodore Hatch, who summarized the “Major Accomplishments in Occupational Health in the Past Fifty Years” on the 50th anniversary of the Division of Occupational Health of the U.S. Public Health Service in 1964. Hatch noted that, prior to World War I (about 1914), the United States was a rural, agricultural society, where the industrial processes were few and conducted by manual labor. The only plastic available was celluloid, petroleum refining dumped most of the product to waste, and Henry Ford had just introduced the radical concept of a \$5 daily wage. This was the industrial world that Alice Hamilton discovered when she began to trace the health problems she found among immigrant families back to the husbands’ workplaces.

In the 50 years that Hatch reviewed, industrial hygiene had emerged as one of the core disciplines in public health. In 1964, he attributed the progress that had been made in improving workplace conditions to the application of the principle of “epidemiologic assessment of occupational health hazards.” Progress in the identification of these hazards resulted from “. . . the joining of skills from the health sciences and medicine on the one hand, and from the physical sciences and engineering on the other, with the two groups cemented together by biostatistics and epidemiology.”¹

This approach taken by the pioneers in industrial hygiene resulted in remarkable progress. Not only did they identify important questions, they had the vision to develop interdisciplinary approaches to solve them. This vision places industrial hygiene in the larger field of public health. The industrial hygienist’s work in the recognition, evaluation, and control of hazardous exposures in the work environment is a practice of primary prevention, and the identity of industrial hygienists as public health practitioners is clear. Prevention is the key to a safe and healthful workplace, and industrial hygiene is a practice of primary prevention.

The steps that are involved in the prevention of occupational and environmental diseases are hazard recognition, hazard evaluation, and hazard control/intervention.

Hazard Recognition

The human health hazard resulting from an occupational exposure is determined by both the toxicity of an agent or factor and the extent or magnitude of human exposure. Successful industrial hygiene practice has been defined to include a step that is in some ways preliminary to hazard recognition: the anticipation of hazardous exposures and conditions before they actually occur. Toxicological testing in animals produces information that is an important component of hazard anticipation and early recognition. In combination with human health data that may be generated through environmental/occupational medicine and surveillance programs, or through epidemiological studies, this information provides the basis for a strategy of hazard anticipation and recognition. For established workplace conditions, surveillance of both exposure and disease provides clues and hypotheses for further evaluation.

Hazard Evaluation

Hazard evaluation is a type of risk assessment, developed from the information gained in the hazard recognition and identification process and the characteristics of the (exposed) population at risk. The series of steps in reaching a conclusion about the degree of hazard associated with a particular exposure or work condition is known as hazard evaluation. Hazard evaluations are essential to determine the need for control measures to minimize exposures and to identify clues to the etiology of an adverse health condition observed in a worker or group of workers.

Hazard Control/Intervention

Primary prevention involves identification and evaluation of environmental hazards that are factors or cofactors in disease production, followed by application of methods to reduce or eliminate human exposures. This is the classical public health approach. Principles and methods for controlling occupational hazards include a range of techniques from substitution or elimination of hazardous materials and processes, to engineering and administrative exposure controls, to exposure reduction using personal protective equipment at the level of individual workers.

Recognition of Occupational and Environmental Hazards

Principles of Hazard Recognition

Hazard recognition involves a systematic review of a worker’s occupational environment to identify exposures and potential exposures. This review should include information on the materials used and produced, the characteristics of the workplace including the equipment used, and the nature of each worker’s interaction with the sources of workplace hazards. Specific information is obtained on the

raw materials used in a process, materials produced or stored, and the by-products formed during the production process. Sources of this information are described in the following section. Hazard recognition also includes gathering information on the types of equipment used in the workplace, the cycle of operation and/or frequency of exposure, and the operational methods and work practices used. Information such as this is available from industrial hygiene reference sources.² A workplace review for the purpose of hazard recognition also includes identification of health and safety controls in place, including use of personal protective equipment.

The Occupational Safety and Health Administration (OSHA) Hazard Communication Standard provides a valuable information resource for hazard identification and evaluation. This standard requires employers to: (a) develop a written hazard communication program, (b) maintain a list of all hazardous chemicals in the workplace, (c) make available to workers Material Safety Data Sheets (MSDSs) for each hazardous chemical, (d) place labels on containers as to the chemical identity and precautions in handling, and (e) provide workers with education and training in the handling of hazardous chemicals.

Classification of Hazards

For purposes of hazard control and disease prevention, contaminants are classified largely on the basis of their physical and chemical characteristics, as these characteristics determine the route of exposure. Workers may be exposed to contaminants by inhalation, by absorption through the skin, by ingestion, or by injection, as in the case of accidental puncture wounds. Inhalation and skin absorption are the primary routes of exposure for most materials in the occupational environment. In cases where poor hygiene practices such as consumption of food and beverages in contaminated work areas are allowed, ingestion may be an important source of exposure. Environmental agents can be classified as either physical hazards or health hazards.

Physical Hazards. In its hazard communication standard, OSHA classifies materials such as explosives, flammable or combustible liquids, oxidizers, compressed gases, organic peroxides, pyrophoric materials, unstable (reactive) chemicals, or water-reactive chemicals as physical hazards. Other exposures in the workplace such as excessive noise, ionizing and nonionizing radiation, and temperature extremes are other examples of physical hazards.

There is a rapidly growing recognition that ergonomic factors are important causes of injury in the workplace. Repetitive motions, conducted in awkward positions, result in a variety of chronic trauma disorders, including carpal tunnel syndrome.

Health Hazards. Chemical and biological materials capable of producing adverse acute or chronic health effects are defined as health hazards. Exposures to chemical mists, vapors, gases, or airborne particles (dusts and fumes) occur through inhalation, ingestion, or by absorption through the skin. OSHA classifies hazardous chemicals as carcinogens, toxic or highly toxic agents, reproductive toxins, irritants, corrosives, sensitizers, hepatotoxins, nephrotoxins, agents that act on the hematopoietic system, and agents that damage the lungs, skin, eyes, or mucous membranes. Biological hazards include exposures to infectious or immunologically active agents such as molds, fungi, and bacteria.

Types of Airborne Contaminants

Aerosols. Liquid droplets or solid particles in a size range that allows them to remain dispersed in air for a prolonged period of time are known as aerosols. Aerosols are also known as airborne particulate matter. The hazard associated with airborne particulate matter is determined by three factors: (a) the biological activity of the material, (b) concentration of the airborne material, and (c) airborne particle size. Particle size is an important determinant of hazard, because it strongly influences the site of deposition within the respiratory system. Many occupational diseases, including silicosis and asbestosis,

are associated with material deposited in specific regions of the respiratory tract. Criteria³ have been developed to define critical size-fractions most closely associated with various health effects and are defined as follows:

- **Inhalable fraction:** This is the fraction of airborne particulate matter that can present a hazard when deposited any place within the respiratory tract. Most particles of diameter less than 100 μm are considered inhalable.
- **Thoracic fraction:** Those particles that are hazardous when deposited anywhere within the lung airways and the gas-exchange region. Particles in this size range are generally less than 25 μm in diameter.
- **Respirable fraction:** Those particles that are a hazard when deposited in the gas-exchange region of the lungs. These particles are less than 10 μm in diameter.

Gases and Vapors. In general, materials are considered gases if they are predominantly in the gaseous state at temperatures and pressures normally found in ambient or occupational environments. Vapors are the gaseous form of substances normally present in the solid or liquid state at room temperature and pressure. Liquids undergo phase transformation to the vapor state by the process of evaporation and mix with the surrounding atmosphere. In the workplace environment, organic solvents volatilize to form vapors at normal temperatures and pressures. In many industrial applications, solvents are heated, which results in increased vaporization and elevated airborne solvent concentrations.

Measures of Airborne Concentration

A number of terms and units are used to describe airborne concentrations and exposures to contaminants. The form of the contaminant and the sampling and analytical method used to measure the airborne concentration dictate the choice of terms that are used. The following terms are used to describe airborne concentrations and exposure:

- Ppm (ppb): parts of vapor or gases per million (or billion) parts of contaminated air by volume at room temperature and pressure.
- Mppcf: millions of particles of a particulate per cubic foot of air.
- Mg/m^3 ($\mu\text{g}/\text{m}^3$): milligrams (or micrograms) of a substance per cubic meter of air.
- Vapor %: parts of vapor or gas per 100 parts of contaminated air by volume at room temperature and pressure.
- Fibers/cc: a measure of the numbers of fibers longer than 5 μm in length per cubic centimeter of air. This measure is used for asbestos and other fibers.

Sources of Hazard Information

Toxicological Reviews. There are many sources of information on hazardous properties of materials found in the workplace environment. These reviews and evaluations are prepared by private organizations as well as government agencies in the United States and internationally. The U.S. National Institute for Occupational Safety and Health (NIOSH) prepares several sets of criteria and recommendations for limiting exposure to occupational hazards. These are not legally enforceable themselves, but NIOSH recommendations are transmitted to OSHA, where they can be used in promulgating legal standards. The Agency for Toxic Substances and Disease Registries (ATSDR) of the U.S. Department of Health and Human Services develops toxicological profiles for compounds commonly found at hazardous waste sites. The National Institute of Environmental Health Sciences (NIEHS) of the U.S. Department of Health and Human Services prepares an Annual Report on Carcinogens, which reviews and evaluates information on evidence of carcinogenicity. The report provides a listing of chemicals classified on the basis of the strength of the evidence of carcinogenic risk. The American

Conference of Governmental Industrial Hygienists (ACGIH) prepares a listing of Threshold Limit Values (TLVs) and Biological Exposure Indices (BEIs), which are updated annually. Several international organizations review scientific information for purposes of evaluating risks resulting from human exposure to chemicals. The International Agency for Research on Cancer (IARC) prepares critical reviews of information on evidence of carcinogenicity for chemicals. The International Programme on Chemical Safety (IPCS) is a joint venture of the United Nations Environment Program, the International Labor Organization, and the World Health Organization. This program develops Environmental Health Criteria Documents, which are summaries and evaluations of the information on toxic effects of specific chemicals and groups of chemicals.

A number of information sources are now available on CD-ROM and the World Wide Web. For example, the OSHA Standards, Letters of Interpretation, Environmental Protection Agency (EPA) Standards, and Hazardous Substances Databanks from the National Library of Medicine, Medline, TOXLINE, etc. can all be accessed directly from a personal computer. The use of Internet-based resources is one of the industrial hygienist's greatest information and communication assets. The following list is a sample of some of the readily available information on the World Wide Web. It is not an exhaustive list, and due to the dynamic nature of internet-based resources, general search tools (such as Google) should be used to locate the most current information sources on any subject. The OSHA "Safety/Health Topics" webpage contains a wide variety of information on hundreds of topics to provide users relevant reference materials including standards, directives, training materials, etc. The site also covers timely topics such as molds, ergonomics, and anthrax. On the OSHA eTools webpage there are a wide range of downloadable "Expert Advisors" and "eTools" for example, expert advisors available on topics such as: asbestos, confined space, fire safety, hazard awareness, lead in construction, respiratory protection, and lockout/tagout. The National Library of Medicine (<http://www.nlm.nih.gov/>) includes links to Medline (a large database of peer-reviewed publications in medicine and toxicology); Hazardous Substances Databank (HSDB), (including ~4500 detailed reviews); Integrated Risk Information System (IRIS) (including Cancer Slope Factors, and a variety of other information); Toxicology Database of Peer Reviewed Toxicology Publications (TOXLINE); Developmental and Reproductive Toxicology Data (DART); Chemical Carcinogenesis Research Information System (CCRIS); Toxic Release Inventory (TRI) of chemicals released by companies into the environment, by name, location etc.). Other information sources include INCHEM from the World Health Organization (WHO) in conjunction with the International Labour Organization (ILO) and the United Nations (UN). This database includes Chemical Safety Data with references (www.inchem.org); and INTOX Toxicological information (www.intox.org). Additional information is found at Work Safe (Australia) (www.worksafe.gov.au); the Canadian Center for Occupational Safety and Health (CCOSH) (www.ccohs.ca); and North Carolina Occupational Safety and Health Education and Research Center (OEM Web Resource <http://occhealthnews.net/index2.htm>).

Resource Hotlines. A number of emergency response services are in operation, some of which are primarily intended to provide information on environmental aspects of chemical hazards. These services are good sources of information on the toxicity and risk of exposure to a wide range of chemicals, regardless of whether exposure takes place in an environmental or an occupational setting. NIOSH operates a toll-free technical service to provide information on workplace hazards. The service is staffed by technical information specialists who can provide information on NIOSH activities, recommendations and services, or any aspect of occupational safety and health. The number is not a hotline for medical emergencies, but is a source of information and referrals on occupational hazards. The NIOSH toll-free number is 800-35-NIOSH (800-356-4674).

CHEMTREC is a 24-hour hotline to the Chemical Transportation Emergency Center operated by the Chemical Manufacturers Association (800-262-8200). CHEMTREC assists in the identification of

unknown chemicals and provides advice on proper emergency response methods and procedures. It does not provide emergency treatment information other than basic first aid, however. CHEMTREC also facilitates contact with chemical manufacturers when further information is required.

The National Pesticides Telecommunications Network Hotline is jointly operated through Oregon State University and the U.S. Environmental Protection Agency (800-858-7378). The hotline provides information on pesticide-related health effects on approximately 600 active ingredients contained in over 50,000 products manufactured in the United States since 1947. It is also a source of information on pesticide product formulations, basic safety practices, health and environmental effects, and cleanup and disposal procedures.

Several hotline and information lines are available for response to information requests on toxic materials and environmental issues. The Toxic Substances Control Act (TSCA) Assistance Information Service (TAIS) provides information and publications about toxic substances, including lead and asbestos (202-554-1404). The EPA also operates a National Response Center, which is a source of information on oil discharges and releases of hazardous substances (800-424-8802). In addition, each of the 10 U.S. EPA Regional Offices has a hotline telephone number.

► EVALUATION OF HAZARDS

The series of steps followed to assess the hazard associated with a particular exposure or work condition is known as hazard evaluation. Hazard evaluations are essential to determine the need for control measures to minimize exposures. They are also conducted in search of clues to the etiology of an adverse health condition observed in a worker or group of workers. Hazard evaluation is founded upon the information gained in the hazard recognition and identification process just described and requires knowledge and information on:

1. Workplace activities and processes, and potential exposures to contaminants
2. Properties of contaminants and potential routes of human exposure
3. The actual magnitude and frequency of worker exposures to a contaminant. In the absence of quantitative exposure information, estimates of the potential for human exposure are often useful for hazard evaluation
4. Potential adverse health effects resulting from an exposure and the approximate level of exposure at which adverse effects occur

While the techniques for evaluation are tailored to each type of hazard, the principles of evaluation can be generalized. Exposure is evaluated in its role as an underlying cause of disease, so in these investigations, exposure may be regarded the measure of contact with the potential causal agent(s).

Measurements of Environmental Contaminants

Over the range of types of exposures (gases and vapors, aerosols, and biological and physical agents), there are two general classes of measurement techniques. One class is termed the extractive methods, in which the contaminants of interest are removed from the environment for laboratory analysis. With these methods, a sampling device is used to collect the contaminants, usually from air in the vicinity of the worker's breathing zone. This sort of measurement of exposure is termed a personal sample, as it attempts to characterize the composition of the environment at the point the worker contacts it by inhalation. Because of the importance of inhalation exposures, most measurement methods assess airborne contaminants. However, methods to measure contamination of surfaces, as well as the exposure of the skin, are available. These methods are described later in this section. A large number of sampling and analytical methods are available for measurement of personal exposures. Both NIOSH and OSHA

develop and publish methods, and these are considered to be standard for workplace exposure measurements.^{4,5} Direct measurements of contaminants in the atmosphere comprise the second general class of techniques. These approaches are described as monitoring methods, and they have been developed from instrumental methods first used in the laboratory. Examples of these monitoring methods are devices that perform automated chemical analysis or make measurements based upon chromatographic or spectrophotometric approaches. These monitoring methods can measure continuously and report results immediately, which allows the examination of the pattern of exposure as it changes over time. This can be a substantial improvement over the information provided by extractive sampling methods, which accumulate material over the time of sampling and give a result that is time integrated over that period.

Dermal and Surface Contamination

As methods for hazard evaluation have progressed, it has become apparent that inhalation is only one of the significant routes of exposure. Contamination on the skin, as well as on surfaces, may be sources of dermal exposure in the workplace. One approach to measuring this exposure is the placement of cloth patches on the outside of workers' clothing, or by providing workers with thin cotton inspectors' gloves, which are worn while they perform tasks where dermal exposure is of interest. A similar method has been used in which the patches are placed under the workers' clothing to measure the quantity of a contaminant that penetrates the protective clothing. Analysis of the patches or glove material then provides an estimate of the exposure. This approach has also been used to evaluate the performance of protective gloves by wearing the cotton glove under the protective glove. Another technique used to estimate dermal exposure of the hands is to rinse the hands, or both the inside surface of the protective gloves and the hands, after a worker has performed the task of interest. The volume of rinse solution is collected and analyzed for the contaminant. A dermal exposure sampling strategy that removes the outermost layer of skin (the stratum corneum) has been used in studies of workers exposed to metals, acrylates, and jet fuel. This approach is intended to measure the contaminant that is absorbed through the skin, rather than the amount that is deposited on the skin surface.⁶

The measurement of surface contamination in a working environment can provide another, less direct indication of dermal exposure. Techniques for wipe sampling have been developed to measure surface contamination. These methods have been widely used in industries where exposure may result from resuspension of settled aerosols. For example, surface sampling for lead has been extensively done in industries such as foundries and lead smelters. In cases where the exposure of interest is nonvolatile, such as most metals, and organic chemicals such as polychlorinated biphenyls (PCBs), surface contamination is a useful measure of the likelihood of exposure from skin absorption or ingestion resulting from eating or smoking with contaminated hands. There is a standardized surface wiping method specified by OSHA that describes techniques for collecting samples from contaminated surfaces.⁵

Measurements in Biological Media

Comprehensive hazard evaluation includes the assessment of exposure by several routes. In addition to pulmonary absorption, materials may be cleared from the respiratory tract and swallowed, resulting in uptake from the gastrointestinal tract. Many industrial materials can also be absorbed directly through the skin. Measurement of contaminants in biological media reflects the contributions from these multiple routes of exposure, as well as the variability in absorption, distribution, and metabolism among exposed individuals. Progress in biological monitoring has been driven by the uncertainties in the relationship between measurement of contamination in the workplace environment, such as those made with conventional industrial hygiene air sampling methods, and the actual quantity of a toxic material that may be present in the body.

The measurement made in biological media may be for a particular chemical itself or its metabolites. Another type of measurement

used to evaluate workplace exposure is reversible biological change, which is characteristically induced by chemical exposure. These measurements can be made in blood, urine, exhaled breath, or other media. Biological monitoring methods are usually used to complement measurements of inhalation exposures, as they provide information on the total exposure from all sources (nonoccupational and workplace) and by all routes (i.e., skin and gastrointestinal absorption). The medium that is selected for sampling can be chosen to suit a particular purpose, as materials such as organic solvents may be eliminated by several pathways. There are reference values for measurements made in biological media. The ACGIH has prepared these values, known as BEIs, with documentation for their measurement and interpretation of results, for approximately 45 chemicals.³

Interpreting Exposure Measurement Information

Exposure measurements are usually compared with a legal or recommended exposure limit. There are several sources of exposure limits, as discussed earlier. While the exposure limit values vary between sources, virtually all these limits are specific to the airborne concentration of a single chemical, and the vast majority set a level that is not to be exceeded as a time-integrated average over an 8- to 10-hour work shift. While this data lends itself to determining compliance with a limit, measurements of levels below a limit should not be considered conclusive for purposes of hazard evaluation. None of the exposure limit values, including the OSHA Permissible Exposure Limits (PELs), which are legally enforceable, are intended to be used as fine lines to distinguish between safe and dangerous working conditions. When interpreting the results of exposure measurements, an environment should not be considered to be free from risk when exposure levels are below the limit value. In the case of individual workers in the environment, reported symptoms should not be considered non-work related only because measured exposure levels are below a limit. The extent of individual variability in response to workplace exposure is not well known, and a conservative approach to the interpretation of exposure is appropriate. The ACGIH has thoroughly described the factors that must be considered in interpreting exposure information, including simultaneous exposure to mixtures of toxic agents, variability in the composition and levels of exposure over time, exposure by multiple routes, and unusual working conditions.³

Mixed Exposures

Most exposures in the working environment are comprised of mixtures of potentially hazardous materials. In general, very little is known about the combined effects of exposure to multiple agents. The combined effects of some materials that act upon the same organ system are recognized in the ACGIH TLVs for Mixtures. A common example is an atmosphere containing a mixture of solvents. While each solvent may have neurotoxic effects, it may be that no single chemical exceeds its recommended exposure limit. The hazard should be evaluated in consideration of the additive effect of the exposure. The TLVs provide guidelines for assessing the effect of exposure when the components of a mixture have similar toxicological properties.

Exposure Variability

The variability in exposure can be broken down into components. The characteristics of a contaminant in the environment are described by its composition and intensity. The composition, that is, the chemical makeup, and the distribution of particle sizes changes through time. The intensity of exposure, expressed as its concentration (such as parts of benzene vapor per million parts of air, or number of asbestos fibers per cubic centimeter of air) may also change through time, resulting in a highly variable exposure over a workday. Exposure variability is also introduced by the characteristics of the individuals in the exposure environment. Even for jobs at fixed workstations, where workers perform similar tasks, there can be substantial exposure differences between individuals because of personal work practices.

When interpreting exposure information for hazard evaluation, these sources of exposure variability must be considered. For example,

consider two workplaces where benzene exposure is of concern. In one workplace, there is a steady concentration of 1 ppm, so the exposure of a worker spending a full shift in this area would be measured as 1 ppm as an 8-hour time-weighted average exposure. A worker in the second workplace could be in an environment in which the level of exposure to benzene varies widely from periods of no detectable exposure to very high but short-term peaks of exposure. For example, if this second worker experienced a single, high, peak exposure level of 48 ppm of the solvent, for only 10 minutes a day, then spent the remainder of the shift in an unexposed area, this worker's 8-hour time-weighted average exposure would also be 1 ppm. Classifying these two workers as equally exposed could result in an erroneous conclusion in hazard evaluation. When exposure varies widely over time, the time course of exposure must be considered in order to develop an appropriate hazard-control strategy. Industrial hygiene sampling methods can be used to measure the high, short-term exposure and identify the work activities that cause it, as well as to measure exposure integrated over the time of sampling.

Exposure by Multiple Routes

While inhalation is an important route of exposure for many occupational hazards, skin exposure may also be a significant route of entry for industrial chemicals. Most exposure guidelines and limits include notations indicating cases in which skin contact may be a significant route of exposure. In the case of the ACGIH-TLVs, this notation appears for approximately 10% of the chemicals listed. Unlike measurements of airborne contaminants, the interpretation of information obtained by measuring dermal contact is complicated by the absence of guidelines or reference values. Measurement of skin contact does not necessarily provide a direct indication of the quantity of a chemical that may be absorbed, as the relationship between the material found on the skin and the absorbed amount depends on several factors. The physical and chemical properties of the material, the anatomical area of contact, the duration of contact, and the individual characteristics of the exposed individual can all influence the relationship between the amount of material on the skin and the amount that may be dermally absorbed. The importance of dermal exposure should not be underestimated; however, as in some occupational settings, materials such as pesticides have been shown to enter the body primarily by dermal absorption. In these cases, measurements in biological media can be very helpful in hazard evaluation, as they can integrate the contribution of exposures from a number of routes.

Unusual Working Conditions

Any interpretation of exposure information should recognize that there is uncertainty associated with both the measurement of exposure, as well as the limit value to which it is compared. Information on exposure should be interpreted in view of the overall conditions in the working environment. For example, exposure measurements are generally made with the expectation that the individuals are in the working environment for the "normal" 8-hour day, and 40-hour work week. Many jobs operate on a schedule that varies from this. The potential effect of extended duration on occupational exposure is rarely recognized in exposure limits, however. Of the over 600 materials for which there are OSHA PELs, only the lead standard specifies that the maximum daily allowable exposure level be adjusted down in proportion to the time by which the length of the daily exposure exceeds 8 hours. For purposes of hazard evaluation and decisions about the need for exposure controls, however, duration of exposure should be considered for any exposure situation.

► CONTROL OF HAZARDS

Principles and Limitations of Controls

Recalling the public health basis of industrial hygiene practice, exposure control is a means of primary prevention. The elimination or reduction of hazards to the extent feasible is the primary means of

prevention for occupational disease and injury. The strategy for effective hazard control is an ordered hierarchy. The three elements of this effective ordered hierarchy of control solutions are:

1. First, prevent or contain hazardous workplace emissions at their source
2. Next, remove the emissions from the pathway between the source and the worker
3. Last, control the exposure of the worker with barriers between the worker and the hazardous work environment⁷

This strategy mandates the use of environmental controls as the primary means of exposure prevention. These controls may take several forms and are frequently used in combinations as part of an overall prevention strategy. Specific control methods include substitution of materials with less hazardous substances, modification of the working environment to contain the source of the hazard, isolation of the worker from the hazardous environment, removal of the hazardous substance by ventilation, modification of work practices to reduce exposure, and use of personal protective equipment to reduce exposure. It should be noted that the use of protective equipment, including respirators, is intentionally mentioned last. Personal protective equipment should be considered the least preferable means of hazard control, implemented only when other means of control are not feasible or effective.

Material Substitution

The practice of reducing risk in the workplace by the removal of a toxic material and its replacement with a less toxic substitute is well established. Elimination or reduction of extremely toxic materials, such as asbestos as an insulating material, or benzene in solvents, adhesives, and gasoline, illustrates the principle of substitution. These examples also illustrate the risk of replacing one hazard with another. As more information is discovered about their toxicity, some of the materials used to replace asbestos as an insulating material, such as artificial mineral fibers and fibrous glass, are suspected of having effects similar to asbestos. The replacement of benzene with another chemical, such as hexane, with similar solvent properties may reduce the risk of exposure to a carcinogen, but increase the hazard of exposure to a neurotoxin. Substitution is an important method of primary prevention of workplace exposures, but it should be practiced with a recognition of the effect the replacement material may have on the work environment. The result of substitution should not be the replacement of one hazard with another.

Process Modification

The application of engineering control technology to modify the design of industrial processes is a very effective method of intervention to reduce exposures. Spray painting is an example of a process in which technology has changed, substantially reducing solvent exposures by using airless atomization systems instead of compressed air spray guns. Many common industrial processes, such as material handling procedures, can be redesigned to minimize the release of contaminants. Exposure control should be included as a central design element at the design stage of a new industrial process or in the modification of existing operations. The anticipation and control of potential hazards at the design stage is more efficient than redesign of existing systems.

Isolation

By considering exposure to be the result of personal contact with a source of contamination, we can easily see the effectiveness of isolation to interrupt the pathway between the source of a hazard and the worker. This approach can be implemented in two ways: by enclosure to isolate a source from the working environment or by isolating the workers from a contaminated environment. Both approaches may be part of a comprehensive exposure-control strategy; however, containment of the source is generally preferable. The glove box used in

handling infectious materials is a common example of containment for hazard control. This approach is particularly well suited to control individual point sources of contaminants, or physical hazards such as noise. By preventing the release of a hazardous agent into the work environment, exposure is controlled at the source.

Isolation of the workers from the contaminated environment may be preferable, and more feasible, in cases where contaminants are released from multiple sources dispersed through the work environment. While this approach does not prevent the release of the hazard into the environment, it is possible to protect workers through isolation. The use of clean air-supplied control rooms in chemical production facilities is an example of isolation of workers from general environmental contamination.

Ventilation

Ventilation is a very common method of workplace hazard control. There are two general types of ventilation: dilution ventilation (also known as general or comfort ventilation) and local exhaust ventilation. There is some amount of dilution ventilation in any indoor space, even if it is only the natural infiltration of outside air. Most workplaces require additional ventilation, known as local exhaust, to capture contaminants at or near their source and remove them from the work environment. Although they are frequently used together, the two types of system are very different in design and performance.

Dilution Ventilation. Dilution (also known as general) ventilation is the replacement of contaminated air with fresh air. In its most simple form, general ventilation is provided by the natural entry of outdoor air through windows, doors, and other openings. Most indoor workplaces require some means of providing mechanical air movement to supplement the natural airflow. Mechanical roof ventilators or wall fans are common in buildings used as workplaces. The human occupants of office buildings may be the primary source of indoor pollution in cases where there are no industrial processes. General building air provided by a heating, ventilation, and air conditioning (HVAC) system may be the only means of controlling the carbon dioxide, water vapor, particulate material, and biological aerosols that are the result of human occupancy. Ventilation guidelines for general dilution are provided by the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) to specify minimum ventilation rates and indoor air quality that provide an acceptable work environment; however, these guidelines are based more on perceptions of comfort by building occupants than on prevention of adverse health effects.

Dilution ventilation is generally not sufficient to provide effective control in workplaces where there are sources of contamination in addition to human occupancy. This is clearly the case where major industrial processes are conducted, but it can also be true where the contaminant sources are limited to office equipment such as photocopy machines. The volume of air needed to dilute contaminants to acceptable levels is usually large, requiring large and expensive air handling systems to move the air, as well as to heat and cool it. These systems may reduce the amount of contaminant present in the work environment, but they do not control its release. Local exhaust systems, described in the following section, are generally preferable for a variety of reasons.

Local Exhaust Ventilation. Local exhaust systems differ fundamentally from dilution systems. Rather than allowing contaminants to escape, then reducing their concentration by dilution with clean air, local exhaust ventilation systems capture air contaminants at the source and prevent their dispersion in the environment. By interrupting the pathway between the source of the contaminant and the worker, these local systems control emissions and prevent exposures. These systems typically include a hood, which may partially enclose the source and facilitate the entry of contaminated air into the exhaust system. The force to move air into the system is provided by a fan, connected to the hood with duct work. Many systems also include an air cleaning device, such as a filter, to remove contaminants

before the air is released to the environment. The design and testing of local exhaust systems is a specialized aspect of industrial hygiene, and the ACGIH's manual⁸ and text by Burgess² should be consulted as sources of further information.

Personal Protective Equipment

Personal protective devices are at the lowest level of the hierarchy of exposure control methods. These devices are intended to provide a barrier between workers and contaminated environments. They include equipment to protect the eyes (safety glasses, goggles, and face shields); the skin (gloves, aprons, and full body suits made of impervious materials); and the respiratory tract (a wide variety of respiratory protective devices). The selection and use of these devices is largely driven by the particular application, and there is a large number of choices available to protect against chemical, physical, and biological hazards.⁹

The specification and use of respiratory protective devices is more complex than is the case for other personal protective equipment. This is due to the legal requirements, as well as the importance of matching the choice of respiratory protection with both the hazard and the individual respirator user. OSHA has a specific regulation for respirator use (Code of Federal Regulations, 29 CFR 1910.134). In addition, some OSHA standards for specific air contaminants such as asbestos and lead include requirements for respiratory protection programs.

Respiratory protective devices may be classified into two general types. Respirators that operate by removing contaminants from air by filtration, adsorption, or chemical reaction are known as air-purifying respirators. Respirators that supply air from a source other than the surrounding environment (such as from a cylinder of compressed air) are known as atmosphere-supplying respirators. Both types of respirators are tested and certified for use by NIOSH.

NIOSH has developed a full respirator decision logic, which is a recommended procedure to guide to the selection and use of respirator protection. The correct choice of a respirator requires consideration of the particular contaminants that may be present and the concentrations at which they will be found in the working environment. OSHA has an internet-based eTool that guides users through the respirator selection process at <http://www.osha.gov/SLTC/etools/respiratory/index.html>, and NIOSH has updated its respirator decision guidelines as of 2005.¹⁰ The ability of an individual worker to wear the respirator in a manner that will provide adequate protection must also be determined as part of a respirator selection and use program. Individual workers vary widely in the degree of protection that a respirator will provide in actual use in the working environment, and the decision logic includes requirements for comprehensive respiratory protection programs with respirator fit testing to ensure that each respirator performs effectively for the individual user.

Education and Training

Worker education and training are essential components of effective programs of primary prevention and exposure control. Any of the control strategies just described function best when workers understand the physical and chemical hazards associated with their work, as well as methods for controlling these hazards. In the OSHA substance-specific regulations (for asbestos, lead, arsenic, cotton dust, etc.), worker education and training are required, although these regulations often lack detailed training specifications. Training requirements also are contained in several OSHA process-specific standards such as the respiratory protection standard, the blood-borne pathogens standard, and the standard concerning process safety management for highly hazardous materials. In addition, the OSHA Hazard Communication Standard, which was promulgated in 1985, establishes generic training requirements for hazardous substances. The OSHA Hazard Communication Standard requires chemical manufacturers and importers to provide hazard information to users of their products. Information must be provided in the form of MSDSs and product labels. The standard requires that employees be provided with information and training on hazardous chemicals in the workplace. Training must include

information concerning requirements of the OSHA standard, identification of hazardous materials in the work area, information on the company's written hazard communication standard, methods for detecting presence or release of hazardous chemicals in the work area, specific hazards of chemicals in the workplace, measures to protect workers from exposure to hazardous chemicals, and details concerning the employer's hazard-labeling system for chemicals in the workplace. Although the sort of training required by the hazard communication standard is not legally required for all occupational hazards, it contains the elements of a model program that can be adapted to a variety of workplace situations where hazard control is needed.

Surveillance and Health Screening in Occupational Health

Gregory R. Wagner • Lawrence J. Fine

► INTRODUCTION

This chapter will discuss surveillance and health screening in occupational health and the common principles that guide program performance.

► SURVEILLANCE IN OCCUPATIONAL HEALTH

Surveillance in occupational health, as in other public health endeavors, involves the systematic and ongoing collection, evaluation, interpretation, and reporting out of health-relevant information for purposes of prevention. Surveillance can help establish the extent of a problem, track trends, identify new problems or causes, help set priorities for preventive interventions, and provide the means to evaluate the adequacy of the interventions. Surveillance programs can focus on an enterprise, an industry, or on the general population.

At the national level, surveillance data can be used to identify high-risk industries. One of the few sources of national data is collected by the Bureau of Labor Statistics (BLS) in the Department of Labor, which surveys a representative sample of private sector employers with more than 11 employees each year.¹ The number of occupational illnesses and injuries is collected from each surveyed employer. This system is periodically revised to improve the classification of occupational diseases and to collect more information about the etiology of diseases and injuries.

The most effective workplace surveillance systems have both health and hazard or exposure components. While hazard surveillance may be less common than health surveillance, it is vital. Hazard surveillance provides the opportunity to identify and intervene on hazardous exposures before an injury or disorder develops. Both health hazard surveillance efforts are often characterized by their speed and practicality. Indications of abnormality generally need confirmation or further validation.

Health Surveillance

Health surveillance within an enterprise often involves analysis of the information gathered in baseline or pre-placement examinations and periodic screening testing. In addition, administrative records such as health insurance data, work absence records, workers' compensation claims, or worksite "incident reports" may provide insight into the health of the workforce. Records from poison control centers and from emergency room visits have been used for population-based occupational injury surveillance as well. Population-based workforce data can be analyzed for rates of disease or injury, so areas of unusual

occurrence within an enterprise, a community, or a country can be identified and investigated. Some conditions such as silicosis are so characteristically occupational that all cases should be investigated. These are known as sentinel events.²

Hazard Surveillance

Hazard surveillance (systematic monitoring of the workplace for hazardous exposures) is an important part of occupational surveillance activities. The identification of potentially harmful levels of exposure to hazardous substances or conditions before work-related diseases or injuries have developed or are recognized provides the opportunity for prevention through workplace redesign and implementation of engineering or administrative controls to reduce risk.

Hazard surveillance information can be collected by worker interview, walk-through inspections, or environmental sampling. As a result of hazard surveillance and other health surveillance information, jobs can be prioritized for more intensive evaluation to identify hazardous exposures. The purpose of the more complete evaluation is to precisely assess the nature of the exposures and to evaluate possible methods to reduce exposures. Sometimes, exposures identified by hazard surveillance will be so clearly hazardous and ways to reduce the level of exposure will be so obvious that more sophisticated evaluation will be unnecessary.

In most contemporary U.S. workplaces, when hazardous exposures involve only small groups of workers, serious work-related health problems are infrequent. It is particularly difficult to detect increased occurrence of common diseases that may be caused by occupational and nonexposure factors (alone or in combination) based on health surveillance alone. In contrast, with hazard surveillance data, hazards may be readily identified regardless of the number of exposed workers. The ability of a hazard surveillance system to identify hazardous exposures depends on the overall accuracy of methods used to identify the nature and the intensity of the exposures.

► TYPES AND PURPOSES OF WORKPLACE HEALTH EXAMINATIONS

Pre-placement Examinations

After an offer of employment is made, but before or soon after work is initiated, workers may undergo selective or comprehensive health examinations. Ethically and legally, these examinations may not be used to exclude the worker from employment but may be used to guide proper placement for the worker, identify educational and training needs, assist in the selection of personal protective equipment,

and identify necessary work-station design or other kinds of accommodations needed for workers with disabilities. These examinations are more likely to take place when known hazardous exposures are anticipated, and some are mandated by legal health standards. For example, each coal miner is mandated by the Mine Safety and Health Act (MSHA) to have a chest radiograph prior to starting underground coal mine work. Pre-placement examinations provide an opportunity for education concerning work hazards and an orientation to occupational health services.

Medical Screening

Medical screening examinations attempt to identify health effects from work exposures at an earlier stage than they would ordinarily be detected by the worker without the examination. In general, after a positive screening test is confirmed, available, acceptable interventions must be able either to reverse the detected abnormality or to reduce the severity of the outcome. Screening is intended to benefit the screened individuals. Screening programs may also indirectly benefit other similarly exposed workers if the detection of work-related health effects trigger an investigation of the workplace and efforts to reduce hazardous exposures or change unsafe working conditions. If large groups are tested periodically, the resulting data can be analyzed to identify group trends as part of a surveillance program as described above. Screening examinations may include administration of questionnaires, physical examinations, and clinical tests such as tests of pulmonary or liver function. Screening examination should be voluntary and are intended to benefit the individual worker who is screened. Therefore, the screening tests used in these one-time or periodic examinations should be evaluated to ensure that the tests are effective for screening objectives and pose minimal risk.

Biological Monitoring

Biological monitoring involves the measurement of workplace agents or their metabolites in biological specimens, usually blood or urine, for the purpose of monitoring the level of exposure and absorption. It is a common adjunct to medical monitoring or screening. This approach to exposure assessment is particularly useful when dermal absorption is possible. Biological monitoring should not be used to replace careful assessment of exposure conditions by other effective methods such as environmental air measurements.

Susceptibility Screening

Another type of screening, where ethical issues are particularly important, is the attempted identification of individuals who may be more susceptible to workplace toxins from individual characteristics such as genetic or phenotypic factors common in the general population. There is currently no regulatory mandate to perform any such testing, and the performance of examinations for genetic or other susceptibility factors raises significant legal issues. Few validated tests are currently available, and the predictive value of proposed tests is limited. Employers continue to have a legal and ethical responsibility to maintain a workplace free of recognized hazards for the entire workforce, not just the least susceptible.

General Health Appraisal

Some employers offer limited or comprehensive health examinations at work as a component of an overall effort to promote employee health. These examinations may include structured questionnaires (investigating diet, exercise, tobacco use, etc.) and medical testing (e.g., blood pressure, cholesterol, BMI calculation) to appraise risk and assist in general health promotion counseling. Although general health appraisal examinations have traditionally been separate from examinations focused on occupational risk factors, there is growing interest in exploring the value of integrating programs for protection of the workforce from occupational hazards with efforts at individual health promotion.³

Coke oven emissions
Ethylene oxide
Noise
Lead

Legally Mandated Medical Examinations

Some OSHA and MSHA standards mandate medical examinations as part of a comprehensive approach to prevention. For example, people exposed to asbestos or cotton dust in general industry must be offered periodic pulmonary examinations; lead-exposed workers must undergo periodic blood lead analyses; and workers exposed to excessive noise must be offered periodic audiometry. Examinations either focus on the primary “target organ” of the toxin, as with asbestos, or involve biological monitoring as with lead. Table 40-1 lists selected substances from among approximately 30 OSHA standards requiring medical screening or surveillance. Generally, examinations are required if a worker is exposed above a specific level of exposure, which is often one-half of the 8-hour permissible exposure limit (PEL).⁴ For example, OSHA requires baseline and annual audiometry testing in employees exposed to noise at an average of 85 dBA or above for a typical 40-hour work week. NIOSH recommends health examinations for a broader list of agents than those covered by OSHA or MSHA standards.

► ETHICAL ISSUES IN HEALTH EXAMINATIONS IN THE WORKPLACE

The relationship between the health-care provider and the examinee in occupational settings is different from the traditional physician-patient relationship. In the traditional physician-patient relationship, the health-care provider serves only the interests of the patient and the health-care provider’s only loyalty is to the patient. When the employer hires or contracts for the occupational health-care provider, the provider may have difficulty resolving conflicts of interest between the employer and the employee-patient. This conflict is one of the most important ethical concerns of occupational health.⁵ Ethical codes have been developed by professional organizations such as the American College of Occupational and Environmental Medicine (ACOEM) and the International Commission on Occupational Health (ICOH).^{6,7} Rothstein has proposed a Bill of Rights of Examinees.⁵ ICOH codes explicitly deal with many of the issues related to screening and surveillance activities, and the ACOEM has a position on medical surveillance in the workplace.⁸ All of these codes recognize the need to maintain the confidential nature of most medical-screening information.

Legal responsibilities to maintain medical information confidentially is reinforced by the Americans with Disabilities Act (ADA)⁹ and mandated by the Health Insurance Portability and Accountability Act (HIPAA).¹⁰ All medical information must be collected confidentially and stored in separate, secure medical files. Under ADA, management may be informed of workers’ restrictions that limit their ability to perform the job duties. In addition to ADA and HIPAA, other federal and state laws or regulations such as the Occupational Safety and Health Act, Department of Transportation examinations for interstate truck drivers, or state laws on human immunodeficiency virus (HIV), or drug testing deal with the issue of medical confidentiality. While the OSHA

TABLE 40-2. CRITICAL INFORMATION CONCERNING MEDICAL EXAMINATIONS IN THE WORKPLACE

The purpose and nature of the examination and any risks
 Who is employing the health-care provider
 Policies and practices to protect the confidentiality of the collected data
 Who will be provided with the results of the examination
 How the information will be used, including what actions will be taken to further evaluate possible hazardous workplace exposures
 How the worker will be notified of individual and group test results
 How the worker may have access to his or her health records
 How medical follow-up may be obtained if the test results are positive

Data from Rothstein MA. Legal and ethical aspects of medical screening. *Occup Med.* 1996;11(1)31–9.

mandates various pre-placement and periodic medical examinations that employers must offer employees, the employees have the right to refuse to participate in these OSHA-mandated examinations unless participation is specified in an employee-employer contract. Maintaining the confidentiality of medical data is not only important from legal and ethical perspectives but is critical in facilitating the employee's participation in the program.

One of the best methods to address the ethical issues in workplace examinations and to ensure a high level of voluntary participation in a workplace screening program is to carefully educate workers about the program. Rothstein has suggested a number of issues that should be addressed in any education effort⁵ (Table 40-2).

► OTHER PROGRAM DESIGN ISSUES

The value of preventive examinations at work depends on a number of program planning and design elements.¹¹ The purpose (or purposes) of any program should be clear both to those performing examinations and to the intended beneficiaries. As a rule, programs for screening and surveillance respond to the presence of hazardous exposures in the workplace and focus on workers most likely to be exposed. Examinations should be selected to identify early evidence of significant health effects that might result from these exposures. Tests of reasonable sensitivity, specificity, and predictive value must be available, and a process for confirmation of abnormal tests and medical follow-up incorporated into the program. Most questionnaires and some of the medical tests that are commonly included in occupational screening programs have not been extensively evaluated for their ability to detect those with and without adverse effects. An efficient medical screening program should detect most individuals with subclinical adverse health effects (high sensitivity) while not mislabeling any truly healthy individuals (high specificity). Tests must be free of any significant risk for the screened subjects, since the main use of the test is to identify subclinical disease or diseases before an employee would normally seek health care. Tests must also be acceptable to the screened population.

OSHA or MSHA standards or NIOSH recommendations can help guide program development. International organizations such as the International Labor Organization (ILO) and World Health Organization (WHO) have developed materials that are useful in designing occupational health surveillance programs.^{12,13} Table 40-3 summarizes design elements for workplace health examinations.

An individual is responsible for oversight of the program and should be identified. Trained and qualified technical and professional staff should be performing all components of the examinations. Adequate maintenance and calibration of equipment is necessary to obtain valid test results that can be compared with one another over time to track health status in individuals and groups. Individually identifiable health information must be stored in a way that meets legal and ethical obligations to protect confidentiality.

TABLE 40-3. COMPONENTS OF A MEDICAL SURVEILLANCE PROGRAM

Exposure assessment and identification of most likely adverse health effects
 Selection of medical tests based on evaluation of test characteristics
 Identification of employees to be tested and testing frequency
 Training of testing staff
 Analysis and interpretation of individual and group test results
 Actions based on test results
 Verification of test results
 Notification of employees and the employer while protecting confidentiality
 Additional tests or treatment and steps to reduce an individual's exposure
 Exposure evaluation and reeducation of hazardous exposures
 Maintenance of records
 Evaluation for adequate quality control and revise based on the program performance

Selection of tests and test frequency can be a challenge. Professional organizations may provide guidelines to assist in equipment selection and test performance,¹⁴ and comprehensive health regulations or guidelines in some instances specify test standards and frequency. When programs are being designed *de novo* and are not in response to a legal mandate, tests should be performed frequently enough to identify problems that may arise between test cycles sufficiently early to intervene effectively and should also take into consideration the likelihood that not every worker will participate in each test cycle. Interpretation of changes in test results in any individual over time must take into consideration expected fluctuations in testing in individuals or populations as well as variability related to equipment, technician performance, etc. Test selection and frequency is often resource dependent.

The adequacy of some surveillance programs attempting to track trends or determine the success of interventions depend on reasonable levels of participation of the workforce. If a program provides workers with the type of information listed in Table 40-2, a high level of participation is more likely. Privacy and confidentiality must be assured. Consent to any testing must be provided, and all programs must be free of any hint of coercion. Individuals who participate in programs for medical screening and surveillance should be given their own individual test results and counseling should be available to provide answers to any resultant questions and advice on any follow-up that might be appropriate. Participants should also have access to the results of analyses of group data and be informed of any actions taken in response to problems identified.

► DATA ANALYSIS

Effective health screening and surveillance programs depend on data analysis, although this analysis does not need to be sophisticated. In some instances, confirmation of any occurrence of an abnormal potentially occupational condition such as tuberculosis in a health-care setting should immediately stimulate further evaluation and response. In other settings, calculation of rates and analysis of trends is needed to target work areas requiring intervention. Screening and surveillance can identify problems but do not prevent them. The analysis of the data and the response to findings are critical steps for reducing the burden of disease and injury in individuals and groups.

One of the features of an effective surveillance program is the use of a standard coding system for recording health outcomes. Standardized coding permits more homogeneous disease categories comparable across an industry or among industries with common exposures. For example, the ILO disseminates a standardized method for classification of chest x-rays for the presence of pneumoconiosis¹⁵ and the

WHO disseminates an International Classification of Diseases, facilitating common coding of medical records.¹⁶

Surveillance systems generally have to be as cost effective as possible to be widely used. The principal advantage of using existing data sources such as workers' compensation records is low cost. Supplementing an existing surveillance system with an additional component such as symptom questionnaires should be considered when observations of the workplace suggest that there are potentially hazardous common exposures, but the existing surveillance data suggests that there are no problems.

The apparent absence of problems will commonly occur for two reasons: the exposures are not high enough to cause any health complaints or underreporting. Underreporting of problems is likely to be more common where there are obstacles or disincentives to the reporting of a possible disorder to supervisors or health professionals. For example, if an organization gives awards to departments without lost time injuries or work-related disorders, either supervisors or coworkers may discourage reporting. More active collection of surveillance data is indicated when there is simply no existing health surveillance information to determine if a problem exists but substantial exposures are common. For example, in many sectors of the economy, OSHA logs are not required.

Symptom questionnaires are used frequently for workforce surveillance and may be administered by a number of methods. The analysis of questionnaire data requires some training. Generally, the case definition must be defined prior to analysis. The purpose of these definitions is to improve the uniformity or consistency of the data collected, thereby improving the quality of the surveillance data. The goal is to ensure that cases have a common set of characteristics. Symptom questionnaires are generally not used to establish a clinical diagnosis unless supplemented by other more definitive health examinations.

The analysis of health surveillance data is conceptually similar to the analysis of epidemiological research data.¹⁷ In the analysis of surveillance and epidemiological data, issues of misclassification and random or systematic errors in assessing either exposures or health outcomes should be considered. Errors due to misclassification are likely to be more common with surveillance data compared to epidemiological research data. When the goal of the analysis is to determine if a specific group of workers or jobs is associated with an elevated risk, use of an internal comparison reference group from the same organization rather than some external comparison is useful since the identification of cases within an organization and their reporting are likely to be similar. While random and systematic errors in surveillance data limit the conclusions that can be drawn, these limitations are less important, since the goals of the surveillance analyses are the identification of a possible problem than in hypothesis-testing epidemiological research. Changes in requirements for case reporting may occur over time in surveillance systems, making longitudinal analyses difficult.

Frequently in the analysis of surveillance data, the variation in risk between jobs, departments, or industries is so large that real differences in risk can be characterized by simple statistical analyses and are unlikely to be explained principally by errors in the classification of disease, confounding factors, or random errors. Nevertheless, surveillance data should always be interpreted cautiously, given its limitations. The goal of the analysis of surveillance data is to trigger further investigation if a problem is detected, not to definitively establish its presence or absence.

The magnitude of the occupational injury or disease problem can be estimated at the national, state, or enterprise level. Local surveillance systems are typically based on one or more of the following data sources: (a) OSHA 200 log, an important source of data for the BLS surveillance system;¹⁸ (b) in-plant medical records or logs; or (c) workers' compensation records. Analytic methods such as capture-recapture methods using different data sources to examine the same outcome in the same population can be helpful in improving the validity of estimates of the magnitude of disease occurrence.¹⁹

Analyses of surveillance data for the purpose of determining the magnitude of a problem may suggest a possible cause for the problem.

Since resources for evaluating exposures and implementing possible prevention strategies are commonly limited, surveillance data identifying the magnitude of the problem should be used to guide resource allocation for further investigation and preventive activities.

The goal of many surveillance systems is to track trends in the number of workers exposed to occupational hazards, or the number of workers with injuries, disorders, and diseases over time. A major use of trend data is to qualitatively evaluate the effectiveness of prevention activities. However, an important limitation of surveillance data is that changes in the rate of disorders may be due to changing levels of exposure or changes in reporting of disorders independent of their level of occurrence. Despite the limitations of surveillance data systems, the opportunity they provide for evaluation of preventive efforts is often unique because large-scale research evaluations of intervention programs are difficult and costly to undertake.

► CONCLUSIONS

Occupational health surveillance can contribute to improved prevention of occupational disease and injury. Health examinations at work are the "inputs" for programs aimed at early identification of adverse effects to reduce disease in individuals and for programs of surveillance designed to identify new hazards, track trends, and evaluate the adequacy of interventions for groups of workers. Hazard surveillance is another significant element in comprehensive occupational disease and injury prevention efforts. The development and conduct of any successful program that includes health examinations must address critically important ethical issues including those of worker autonomy and confidentiality. The results of health examinations and hazard information, thoughtfully analyzed, can help target preventive interventions. Surveillance systems can contribute to prevention but do not, in themselves, prevent disease or injury. This is done through the recognition and control of hazardous exposures at work.

Workers with Disabilities

Nancy R. Mudrick • Robert J. Weber • Margaret A. Turk

► FRAMEWORK FOR DEFINING DISABILITY

The term disability is defined in various ways. In some contexts it is defined in terms of health conditions; in other contexts it is defined in terms of functional limitations; and in still other settings it is defined in terms of activity and role limitations. These varying definitions of disability have in some cases been codified into law, into standardized data collection instruments, and into the practice framework of professionals and organizations that serve people with disabilities. One consequence of the different ways in which disability is defined is that before the characteristics and needs of people with disabilities can be discussed, the parameters of the disability definition being used must be addressed. Whatever the specific components of the definition, there does appear to be some consensus that a person with a disability is someone who experiences limitations in function as a consequence of a permanent physical or mental impairment or a chronic health or mental health condition in interaction with the person's environment. The health condition or impairment may be one that is visible, or it may be invisible. Onset may occur at any age or it may be present at birth. Finally, the severity of disability may vary, even among people with the same condition or impairment, such that some individuals may find it difficult to participate in many life activities, while others experience the effects of disability in a single area.

Among the many definitions of disability used by professionals, government programs, service agencies, and individuals with disabilities, there are three that are most dominant. The first definition involves the extent of limitation in the Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADL). The second construct for defining disability is based upon a model developed by Saad Nagi that defines disability in terms of the interaction of environment, functional limitation, and impairment.^{1,2} The third definition is embodied in the International Classification of Functioning, Disability, and Health (known as ICF) of the World Health Organization (WHO). A fourth measure, used in epidemiological contexts, does not define disability, but it tries to account for the severity of disability by measuring what is referred to as “disability adjusted life years” (DALY).

ADL and IADL

The ADL scale measures disability in terms of limitations in the Activities of Daily Living. This scale was developed by Katz and coworkers in the 1950s, and has been used extensively by researchers studying the elderly.³ The ADL scale asks about the need for assistance in the activities of eating, bathing, dressing, transfer, and toileting. A related measure, developed by Lawton and Brody in 1969, is the IADL scale.³ The items in this scale ask about the need for assistance in such activities as everyday household chores, managing finances, shopping, and getting around outside one's home. The scales are now used to define levels of disability among all adults.^{4,5} Both the

ADL and IADL approaches measure disability by examining tasks or activities that are limited or prevented by an impairment or health condition. The items do not directly address work, although people with ADL and IADL limitations report low rates (approximately 25%) of employment.⁵

Functional Limitation Model

Saad Nagi's work has served as the basis for a model with three components: impairment, functional limitation, and disability.¹ Impairment is defined as the chronic or permanent anatomical or physiological problem (i.e., health conditions) that results from injury or illness. Functional limitations are the restrictions or functional incapacities that result from an impairment. Functional limitations include the inability to climb stairs or lift objects weighing more than 20 pounds. Finally, disability is defined as the consequence of functional limitation in terms of the activities of normal or expected roles. Although people have many different roles in their lives, it is the work role that has been most often used to assess whether impairments and functional limitations are disabling. Someone whose employment is affected by functional limitations is often labeled disabled. More recent elaboration of the model has included consideration of the impact of environment on role performance and quality of life.² One implication of this model is that the determination of disability rests on the particular activities required by different roles—as well on the presence or absence of environmental barriers that support or impede role (work) performance. In this framework, it is possible for two people with the same impairments and functional limitations to be rated differently in terms of disability.

ICF

The ICF is part of the “family” of international classifications developed by the WHO that are intended to provide codes that can be applied internationally to describe health conditions and compare prevalence of morbidity, mortality, and health outcomes.⁶ The ICF is intended to complement the WHO International Classification of Diseases-10 (ICD), which focuses on diseases and disorders that are often used to classify death, by offering a classification system that describes health conditions and related health outcomes as a means of describing population health.⁷

The ICF is a substantially revised and modified version of the first disability-related classification system issued by the World Health Organization in 1980, called the International Classification of Impairments, Disabilities, and Handicaps (ICIDH).⁸ The ICIDH used a framework consisting of four main categories: disease, impairment, disability, and handicap. Disease was not really defined in the ICIDH, but was implicitly based upon the definitions contained in the ICD. While the ICIDH was similar to the Nagi model because it separated the medical condition from its functional and social consequences, it was not as well accepted. Part of the reason was the lack of conceptual

clarity in the different classifications and categories and the use of the term “handicap.”^{9,2}

The World Health Organization’s new ICF is a “biopsychosocial model” (p. 9) of disability that is a synthesis of the two previously dominant disability models, the medical model and the social model.⁷ It is structured with two major parts, each with two components. Part 1 is titled *Functioning and Disability*, and within it the two components are (a) Body functions and structure and (b) Activities and participation. Part 2 is called *Contextual Factors*, and within it the components are (c) Environmental factors and (d) Personal factors. Within each of the components are domains, and within the domains are the categories that are the units of classification. Without detailing how the exact classification code is implemented, the overall conceptual model is illustrated in Fig. 41-1.

What is significant about the ICF is its utilization of information about the body function and structure along with information about the individual’s activities, participation, and environmental circumstances to arrive at a coded description of health outcome. This may have limited utility in determining interventions for a specific individual; however, it has the potential to provide a global description of the prevalence of disability in a population that takes into account not only medical condition, but societal barriers and individual expectations for social participation. Since the ICF is in the early stages of implementation, it is too early to evaluate its utility, utilization, or impact in the United States and internationally.

Disability Adjusted Life Years (DALYs)

As part of the Global Burden of Disease study, the World Health Organization, in collaboration with the World Bank, supported the development of a measure that provides a quantitative estimate of the burden of disease and disability across populations in different nations. The measure, *disability adjusted life years*, or DALY, is a single number calculated for an individual based upon a formula that considers the impact of a health condition on life expectancy, the age of the individual, and a measure of the quality of life for someone with that condition or disability. When aggregated, disability adjusted life years for a nation or population represent the gap between the population’s health and a hypothetical ideal.

The DALY measure has generated considerable controversy, and there are a number of critiques of its underlying assumptions and calculation methodology.¹⁰ DALYs calculations are built upon an estimate of the negative impact upon quality of life of various diseases and chronic conditions by a panel of experts, mostly without disabilities, a fact defended by the DALYs’ developer because the goal is to indicate social valuations, not individual valuations which may be affected by a person’s ability to adjust over time.¹¹ DALYs weight the impact of conditions by age; young children and older persons receive smaller weights for a condition than working-age persons. In their summary of the ethical issues raised by the DALYs,

Gold, Stevenson, and Fryback point out that if DALYs are used to determine health intervention investments, the computational structure gives lower priority to those with preexisting disability or illness, who are young or elderly, and whose poor health may be related to low social class.¹⁰ Thus, while DALYs are viewed as a way of determining an appropriate allocation of resources for health care and rehabilitation, the assumptions built into the measure must be understood. Also, the DALYs methodology ties life with a disability to lower quality of life, at odds with the other disability definitions that treat disability as a characteristic with rights to equal access in the built and social environments.

Disability Defined for Workers

The most common definition of disability in the research literature on employment is that of *work disability*. Work disability is present when an individual reports that a mental or physical condition “limits the kind or amount of work, or prevents work” (understood to be paid work). This work disability definition comes out of the Nagi functional limitation model, and has been used to identify people with disabilities in surveys since 1966.¹² It also is implicit in the definition of disability utilized by the Social Security Administration to determine eligibility for income support. As a result of its wide usage, many of the statistics on the prevalence of disability in the United States are actually reports of work disability.

While the work disability construct has been useful because it focuses on role performance, not medical condition, it is increasingly inadequate as the demand for information about the labor market experience of people with disabilities increases. This is because disability is only recorded if employment is limited or prevented by a chronic condition or impairment. If an assistive device or a workplace accommodation enables someone to work without limits in the kind or amount of work, then no disability may be deemed present. This may be an appropriate outcome—the presence of a disability is not noteworthy because it is not a relevant fact about the skills and value of the worker. However, it prevents a full estimation of the number of working Americans with chronic health or other conditions that constitute disabilities. A second problem with the work disability construct is that it may not sufficiently distinguish work from occupation. Asked whether they are limited in the kind or amount of work they can do, do respondents answer with reference to their usual occupation or kind of work, or do they view this as asking about limitations to any kind of work, even work they would not consider doing if there were no disability? The work disability construct may be vulnerable to the attitudes, aspirations, life experiences, and opportunities of the respondents.

► DEMOGRAPHIC CHARACTERISTICS

In recognition of the problems posed by the *work disability* construct, the U.S. Census Bureau has introduced some additional indicators of disability, both in the decennial census and the more frequent Current Population Survey. These indicators ask whether the respondent experiences a disability in broad physiological categories (sensory, physical, or mental) and whether the individual’s condition results in limitation in self-care, going outside the home, and/or employment. The prevalence of disability based upon these several indicators is displayed in Table 41-1. Table 41-1 indicates that the percentage with any disability is higher than the percent of persons who report that disability results in employment disability. Overall, nearly 12% of the U.S. population aged 16–64 report employment disability, with a small difference between men and women (the percentage is slightly higher for men). The presence of any disability varies by race and ethnicity (Table 41-1), with higher prevalence rates among African-Americans, Latinos, and American Indians and Alaskan Natives. The differences in disability prevalence are larger across race than between the genders. The prevalence for whites is 16.8%, while it ranges from 24% to 27% for the other race/ethnic groups. Disability is

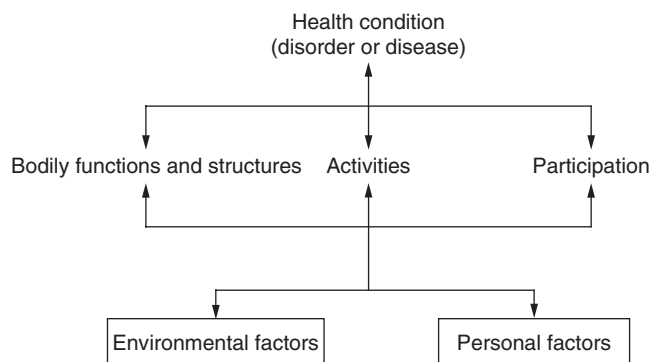

Figure 41-1. Disability model of the International Classification of Functioning. (Source: World Health Organization, *ICF: Introduction*, p. 18.)

TABLE 41-1. PERCENTAGE OF THE POPULATION AGE 16–64 WITH DISABILITY BY GENDER, RACE, AND HISPANIC ORIGIN: 2000*

	% With Disability	Number with any Disability
TOTAL POPULATION	18.6	33,153,211
Men		17,139,019

associated with a substantially higher prevalence of poverty compared to persons without disability, across all age groups. For working-age persons (16–64 years), the poverty rate difference is 9.6% for those without disability compared to 18.8% for persons with disability.¹³ Work disability prevalence increases with age and decreases with increasing years of education. Among those 16–24 years, 4.1% report work disability (2.8% severe work disability); among those 45–54 years, 13.0% report work disability (9.4% severe); and among those 55–69 years, 21.6% report work disability (15.6% severe for ages 55–64 and 8.4% severe for ages 65–69).¹⁴

Differences in the prevalence of work disability by demographic characteristic illustrate that work disability is associated with other social, economic, and environmental factors. Age is a factor because health may decline with age, and because older persons have had more years in which to experience an impairment or health problem. While those with higher levels of education may work in occupations that pose fewer risks to health, it is also the case that the occupations associated with higher levels of education are less physical so that impairments may have only a modest impact on the ability to continue working. Racial difference in the prevalence of disability may reflect racial differences in education and occupation. With respect to poverty status, disability affects earnings and income; however, for a variety of social and economic reasons associated with low income, people with low incomes also experience impairments and health problems that have a disabling impact to a greater degree than persons at higher levels of income.

Table 41-2 displays the most prevalent conditions reported by people age 18–69 who also report work limitation. Musculoskeletal conditions, especially involving the back, are the most common; heart disease and arthritis and related joint disorders also are prevalent. Most of the conditions listed in Table 41-2 are conditions with onset in midlife or later. Some of the conditions are the consequence of disease, while others are the result of injury, on or off the job. For many of the conditions there may have been a period of acute illness; however, it is not the case that all people with disabilities are sick. Finally, it is possible for people to experience more than one disabling condition.¹³ An additional risk faced by people with a disability is the onset of a secondary condition that is a consequence of or related to the primary condition.¹⁵

► EMPLOYMENT AND DISABILITY

The labor force participation rates of people with disabilities are substantially lower than the labor force participation rates of people without disabilities. Of those who are employed, a large proportion work part-time. Data from the 2004 Current Population Survey find that 28.7% of men and 23.7% of women ages 16–64 with a work disability are in the labor force. This contrasts with a labor force participation rate for men and women without disabilities of 87.1% and 74.2%, respectively.¹⁶ Among persons with disabilities who are employed, 13.3% work full-time; 62.1% of employed persons without disabilities work full-time. The unemployment rate for people with a work disability is also higher than for other labor force participants. Across both men and women aged 16–64 with a work disability, the unemployment rate was 15.2% in 2004, compared to 5.8% for men and women without a work disability.¹⁶ Another national survey of people with disabilities, conducted by Louis Harris and Associates for the National Organization on Disability, found that 63% of their respondents with disabilities said they preferred to be working; however, only 28% actually had a job or were self-employed.¹⁷

When people with disabilities are asked what they believe are the most significant barriers to employment, they name factors that include the limitations imposed by their impairments, the absence of transportation and accommodations, labor market discrimination, and the concern that employment might cause them to lose their disability

TABLE 41-2. MOST PREVALENT CONDITIONS CAUSING WORK LIMITATION, 1992

Main Cause of Limitation	Number of People (1,000s)	% of People with Work Limitation
All conditions	19,023	100.0
Orthopedic impairments, deformities, and disorders of the spine or back	2181	11.5
Heart disease	2071	10.9
Arthritis and allied disorders	1818	9.6
Orthopedic impairments, deformities, and disorders of other extremities	1775	9.3
Intervertebral disc disorders	1479	7.8
Asthma and other respiratory diseases	1072	5.6
Diseases of the nervous system	1029	5.4
Mental disorders, excluding learning disability and mental retardation	925	4.9
Speech, hearing, and visual impairments (including disorders of the eye)	743	3.8
Diabetes	624	3.3
Cancer	529	2.8

and health benefits.¹⁸ Among those who are employed, nearly one-half feel their jobs do not utilize the full extent of their talents or abilities.¹⁸ About 22% of people with disabilities also report that they have encountered job discrimination, mostly in the form of being refused a job interview, refused a job, or denied a workplace accommodation due to disability.¹⁷

Economists also have measured wage differences between people with and without disabilities to assess what portion of the wage differential is due to productivity differences associated with limitations, and what portion can be attributed to wage discrimination.^{19,20} Baldwin and Johnson find larger discriminatory wage differentials among men whose impairments are subject to greater prejudice compared to those with impairments associated with less prejudice.²⁰ Most of the impairments classified in the less prejudiced group are invisible impairments, such as back or spine problems and heart trouble, while those in the more prejudiced group tend to be visible impairments, such as paralysis or missing legs, feet, arms, hands, or fingers. Also included in the group that is subject to more prejudice, are persons with mental illness, alcohol or drug problems, and cancer. Although wage discrimination has been observed, Johnson and Baldwin conclude that employment discrimination is the more significant problem for workers with disabilities.²⁰

► POLICIES FOR WORKERS WITH DISABILITIES

Policies for workers with disabilities can be placed in one of three categories: (a) policies to protect employment by prohibiting employment discrimination, (b) policies to enable employment through rehabilitation and training, and (c) policies to replace income for workers no longer able to work. While these policies are implemented at the federal, state, community, and firm level, only the federal policies in these areas will be described in the following sections.

Nondiscrimination

The principal source of protection from discrimination in employment on the basis of disability is through Title I of the 1990 Americans with Disabilities Act (ADA), which applies to employers of 15 or more employees. The enforcement structure relies on the Equal Employment Opportunity Commission (EEOC) and the methodology developed to enforce the 1964 Civil Rights Act. The ADA defines persons protected from disability-based employment discrimination as (a) people with a mental or physical impairment that substantially limits a major life activity, (b) persons with a record of such impairment, and (c) those who are perceived to have such an impairment. Title I protects a “qualified person with a disability,” who is someone who can perform, with or without “reasonable accommodation,” the “essential functions” of the job. An employer who can show that a requested accommodation would cause the firm undue hardship will not be required to hire the individual and make the accommodation. Undue hardship is judged in terms of the expense of the accommodation in the context of size of the firm, the extent of change required, and the potential hazard posed to self or other people. These provisions of the ADA require that employers articulate the essential functions of their jobs, take action to ensure that the job application process does not improperly screen out people with disabilities, and have a means through which they can respond to requests for reasonable accommodation.

Between July, 1992, when the ADA went into effect, and September 30, 2004, there were 204,997 complaints of discrimination filed with the EEOC under Title I of the ADA.²¹ Data from the EEOC through September 2003 indicate that of the complaints filed, 31.5% were about discharge, 17.8% involved failure to provide reasonable accommodation, 8.7% involved terms and conditions of employment, and 7.8% charged harassment. Altogether, 90% of the complaints were about issues that arise from current employment (e.g., promotion, discipline, wages, demotion). Only 6% of all complaints charged failure to hire.²² This pattern of complaints reflects the large percentage

of people with disabilities who experience the onset of disability in midlife, many of whom are employed at the onset of disability.¹⁹ For employers, this means that some people who already work for them will become people with disabilities on whose behalf they must comply with the requirements of the ADA.

Rehabilitation and Training

Rehabilitation services were first authorized under federal and state law to enable veterans with disabilities to obtain and maintain employment. The system of services has been expanded to include all persons with disabilities with the aim of assisting first-time employment for persons with disabilities, as well as the maintenance of employment for workers post disability onset. Some rehabilitation services are financed by private insurance, under an individual’s health insurance or through workers’ compensation, but many rehabilitation services are financed by public funds at the state and federal level.

Until July 2000, the Rehabilitation Act was the main vehicle for specifying federal policy and expenditures for rehabilitation services. Various titles under this act supported programs to provide job counseling, retraining, and the provision of prosthetic and assistive devices with much of the service activity delivered through a network of state agencies. The Workforce Investment Act of 1998 (PL 105-220) consolidated most of the federal employment and training programs into a single statute, with much of the prior Rehabilitation Act incorporated into Title IV. The Workforce Investment Act (WIA) requires states to establish One-Stop service delivery systems to provide employment assistance to all workers, including those with disabilities. State vocational rehabilitation agencies are to be an integral part of the services available through the One-Stop centers, ideally with on-site vocational rehabilitation staff. Assessments of the new structure, which serves workers with disabilities in a manner integrated with other workers seeking employment assistance, indicate that the One-Stops have yet to be fully accessible, with staff sufficiently familiar with disability issues. Moreover, performance measures for One-Stops appear to create a disincentive to serve people for whom obtaining or maintaining employment may be difficult.^{23,24} The services of the One-Stop centers are not well known by people with disabilities. Less than 50% of those surveyed by the National Council on Disability/Harris Poll had heard of the One-Stops, and of those, 26% had ever used the services.¹⁷ For those who used special equipment or assistive devices, nearly 50% reported learning about them through their doctors.¹⁷

Income Support

The main source of replacement income for workers whose disabilities prevent continued employment is Social Security Disability Insurance (DI). Coverage for DI is earned at the same time that workers earn coverage for the social security retirement benefit, with part of the social security payroll tax (FICA) directed to the DI Trust Fund. To be eligible, a worker must have contributed to Social Security for 20 of the past 40 quarters (essentially 5 of the past 10 years) and have a condition meeting the medical criteria that prevents “substantial gainful activity.” The disability need not be the result of a work injury or work related. Because it defines disability as the inability to engage in substantial gainful activity (measured as earnings in excess of \$900 per month in 2007, \$1500 if statutorily blind), and includes a 5-month waiting period before the start of benefits, DI essentially requires complete labor force withdrawal to establish eligibility. The DI benefit amount is based on a formula that is a variant of the one used to calculate monthly social security retirement benefits. After 2 years as a DI beneficiary, health insurance coverage under Medicare is available.

Less than 0.5% of DI beneficiaries on the program at a point in time ever leave DI for employment.²⁵ The Social Security Administration has several policy provisions within DI and other service initiatives to try to increase the rates of reemployment. One initiative involves placing a “Navigator” at the One-Stop centers to help people with disabilities access needed services, training, or other information

to facilitate employment. Another initiative is a new structure for financing rehabilitation services, called the “Ticket to Work,” that reached full implementation by the Social Security Administration in 2005. The Ticket to Work Program and Work Incentives Improvement Act of 1999 involves a voucher for rehabilitation services (i.e., ticket), sent to the DI beneficiary. That individual uses the ticket to contract for services with a traditional state vocational rehabilitation agency or one of a number of other organizations registered with the Social Security Administration as an employment network. In contrast to the past, the service providers are paid based on outcome, with partial payment early and full payment occurring after the client has been employed for 60 months. It is too soon to judge whether this alternative structure to financing rehabilitation facilitates rehabilitation and the return to work. Early evaluation results indicate beneficiaries are slow to utilize the tickets and some of the providers are considering withdrawing because they cannot cover their costs.²⁵

Workers with work-related disabilities usually receive workers’ compensation. Workers’ compensation programs are state laws that require employers to carry insurance to compensate workers for injuries or illness obtained on the job. In some states, employers purchase workers’ compensation insurance from private insurance carriers or self-insure. In other states, employers must purchase the insurance through a state-run insurance fund. The intent of workers’ compensation is to replace lost earning capacity. People with a permanent impairment may receive a lump sum or a monthly payment in perpetuity; otherwise workers are paid a portion of their wage for the period they are out of work recovering from the injury or illness. Workers’ compensation also pays the medical expenses associated with the treatment of the work-related condition.

A small proportion of workers with disabilities also receives income support from the Supplemental Security Income Program (SSI), an income-tested public assistance program for low-income persons with disabilities. Many SSI recipients have no work history or have work attachment insufficient to meet DI eligibility, or earnings so low they are dually eligible for DI and SSI. The SSI program is administered by the Social Security Administration and financed out of general revenues (some states add a supplemental amount). SSI recipients are eligible for health-care coverage under the public assistance Medicaid program.

► ROLE OF CLINICIANS

Clinicians play an integral role in the diagnostic, rehabilitation, and return-to-work plan of workers with disabilities. Rehabilitation is a dynamic process, which is most effective when provided through a comprehensive transdisciplinary team approach. Rehabilitation deals not only with physical restoration, but recognizes the importance of psychosocial health and support. The disability evaluation process requires medical evaluation in preparation for hiring, the development and direction of a rehabilitation and return-to-work plan, and the determination of impairment or disability. Of significant importance is recognition that a worker with a disability is not ill or in poor health, but rather can participate in ongoing health maintenance and prevention of further disabilities and secondary conditions.

Acute and Chronic Medical Care

Acute medical management of worker injuries offers the clinician a range of challenges with distinct differences from those posed by chronic management. However, the attitudes, knowledge, and skills required of the practitioner in each area have broad overlap. The process of decision-making and support of worker needs should vary principally in respect to the weight assigned to input elements in each circumstance. The most obvious feature of acute management is the possibility of the abrupt onset of a catastrophic problem which forces an emergency course of treatment. In that circumstance the physician

provides triage, diagnosis, and treatment, directing care until stability is restored. This process should ideally lead to the transition into rehabilitation where worker involvement and empowerment become key elements.

The physician’s role in the acute management of problems with a less dramatic presentation, such as back injury or repetitive use disorders, is established through the dynamic interaction among worker, physician, employer, and the compensation system. The clinician should be attuned to address the worker’s interests as he individually, or through referral and transfer, moves through the responsibility for triage, diagnosis, treatment, and rehabilitation. Where the worker has knowledge of medical issues, she can influence the clinician’s role even more significantly. A knowledge of similar work site problems and workers’ experiences increases the likelihood that the worker will utilize the health-care system more effectively, a de facto self-selection of the physician role by the worker.

Acute and chronic management of occupational problems share the need for specific knowledge of signs, symptoms, etiology, treatment, rehabilitation, and prognosis of problems encountered in the workplace. While acute management may favor a greater proficiency in some diagnostic and intervention procedure skills, it is in the realm of attitude that clinicians most differ in the spectrum of acute to chronic care. In the chronic phase, maintenance, adjustment, support and accommodation, and prevention of secondary conditions are more prominent than direct intervention. Worker values, rather than medical pathways, determine the proper course. The physician serves to facilitate and to advise, not to effect change, and to intervene only when new factors emerge.

Rehabilitation

Rehabilitation programs are termed comprehensive when they function in an integrated manner to address the full spectrum of medical, functional, and psychosocial needs of the client throughout the time of need. They are transdisciplinary when they are organized across traditional disciplinary boundaries for services. Core members of comprehensive teams include a rehabilitation physician and nurse, physical, occupational, and vocational specialists, a psychologist, and a social worker. The team develops rehabilitation goals through formal team conferences that meet regularly to update goals, to discover and address evolving issues, and to devise means to leverage the team via transdisciplinary synergy. The team approach offers benefits through the initiative and knowledge resulting from wide participation, and from the efficiency of extending patient learning, reinforcement of skills, endurance, and confidence building throughout the full day through the close integration of the nursing unit with all services in the total plan.

The rehabilitation process can be separated into two broad conceptual categories. The first is composed of those cases in which the anticipated rehabilitation outcome is the ability to resume life and work roles with little or no accommodation. The second involves cases for which significant accommodation and perhaps residual impairment is likely. In each instance, rehabilitation proceeds through three general phases: establishment of goals, worker focused programming, and transition to the workforce.

Rehabilitation goal setting requires the translation of the medical prognosis into a function-based worker profile, the identification of resources, and the integration of worker options and preferences into practical outcome targets. Defining goals also separates expectations into broad programmatic categories, and promotes a rationale and consistency when selecting among options related to service intensity, intervention risks, and accommodations. Goal setting requires an understanding of both the personal and material resources available for rehabilitation.

The worker-focused phase is the process usually identified as medical rehabilitation—the transdisciplinary delivery of medical, physical, psychosocial, and vocational services to maximize the physical and psychological function of the worker in the context of the established goals. Here specific skill acquisition, adjustment and the determination of specific vocational targets, and accommodation requirements are emphasized.

The transition phase is relatively straightforward where function is well restored. Work site assessment is helpful in ensuring that worker preparation is appropriate or where return to work can be facilitated by minor or temporary accommodations or a phased return. Transition is often a longer process where major accommodation is required. Frequently a gradual shift occurs from a medically directed team management approach to a vocationally directed one. Here skill assessment and training for the worker, resource acquisition, job site analysis, and negotiation for job site accommodation and its funding take center stage.

Psychological Care

Psychological variables have an effect on the rehabilitation process and outcome, and can modify the expression of disability or determine the impact on function. In particular, cognitive impairment and functional limitation as a result of brain injury or mental retardation can determine initiation of or return to work capability. Issues of role or performance change can be difficult for the worker with the disability, the family or other support system, and the employer. Psychological evaluation of cognitive functioning involves standard intelligence and achievement tests, and batteries or individualized approaches for neuropsychological testing. The evaluation provides information regarding cognitive performance of executive functions, relative strengths and weaknesses, possible direction for cognitive related services, and useful strategies for cognitive compensation.

A worker with a disability may require psychological support during the acute medical phase and through the rehabilitation process. A psychological assessment is a combination of standardized testing and interview information that determines attributes (e.g., personality, intellectual, and cognitive factors) that may influence the rehabilitation process and outcome, and that identifies the presence or magnitude of certain other psychological factors (e.g., depression, anxiety, anger, disinhibition, denial) that may have an impact on return to work. Following a medical event, such psychological forces begin to play an increasingly important role in overall level of disability. Coincidental and independent sources of distress from family, employer, or vocational settings can be incorporated into the sense of impairment. The impact of the patient's altered social behavior on families can be substantial. Psychological intervention can be direct counseling, skill building in coping and adjustment strategies, and training in social skills. Families and other support systems should be a part of this process to better understand the psychological status of the patient, reinforce appropriate behaviors or coping strategies, and maintain personal psychological health to continue what may be a prolonged course of impairment and disability.

► ASSESSING THE ABILITY TO WORK AND ACCOMMODATIONS TO ENABLE WORK

Determination of work capability requires evaluation of the worker as well as the workplace. The physician becomes involved with issues of work disability in the context of medical evaluations of workers in preparation for hire, for the development and direction of a return-to-work plan, or for the determination of impairment or disability. A workplace assessment involves job description and on-site evaluation.

In the recent past, a number of employers have engaged in selection screening to identify a healthier workforce with the use of medical criteria in the selection and maintenance of a workforce. This involves worker fitness evaluations (e.g., current health, ability to perform job functions, required modifications) and risk evaluations (e.g., prediction of increased risk for illness or injury based on health history, work history, or behavioral patterns). In most instances, few data exist to support such determinations.^{26,27}

The disability evaluation process may require a clinician to assume one or more of three different roles that are potentially in conflict. The physician may act as an advocate and counselor to the patient, a source of information for the agencies that determine

benefits, and adjudicator and certifier of impairment or disability.²⁸ As advocate and counselor, the physician can advise the patient of disease or injury-specific issues related to initiation of or return to work. In this role, the physician can outline the process of rehabilitation and discuss possible accommodations. The physician also may provide information about the advantages and potential pitfalls of the various compensation and rehabilitation programs and make referrals to appropriate services.

For those patients who have applied for benefits, the physician will likely be asked to provide medical records and documentation of impairment. During the phases of reporting on initial, interim, and maximal medical improvement (MMI, the achievement of maximal benefit from intervention with stabilization of impairment), the physician is asked to complete return-to-work status reports, including a date of MMI.

Evaluation of the patient's impairment places the physician in the role of certifier. Impairments can be expressed in terms of functional loss of a unit or to a whole person. The impairment rating system most commonly employed for musculoskeletal impairments is the American Medical Association (AMA) Guides to the Evaluation of Permanent Impairment.^{29,30} The AMA Guides are anatomically based (description and quantifiable physical examination measurements) and diagnosis related (history plus objective diagnostic findings). However, there are concerns related to validity and reliability,^{31,32} inference of functional limitation from anatomically based impairment scales or findings,²⁹ and the issue of pain as it relates to impairment.³³ In cases involving a dispute between claimant and insurer concerning MMI determination or impairment rating, a physician examiner unfamiliar with the case can review the case records, examine the patient, and render a second opinion, referred to as an Independent Medical Examination (IME).

A number of standardized assessment tools are available to assist the physician in determining physical performance expectations for a disabled worker. A Functional Capacity Evaluation (FCE) is a comprehensive assessment of an individual's strength, flexibility, endurance, and job-specific functional abilities. This is perhaps the most valid predictor of appropriate restrictions to activities throughout the rehabilitation course and at the MMI. When no specific job is available, a more generic Functional Capacity Assessment (FCA) can provide more global information to assist in job placement. A Job Description is a formal listing of the essential job functions, and provides the basis of specific performance requirements. A Job Site Evaluation (JSE) determines optimal ergonomic design and validates performance requirements of the job. A JSE in conjunction with a FCE may be useful in determining work restrictions, need for accommodation, and employer/employee willingness to comply.

There is a wide range of possible workplace modifications. Many modifications made for the worker with disabilities also may benefit other workers or even customers. Architectural barriers can be modified with ramps, railings, more easily opened doors, modified bathroom fixtures, and space to accommodate wheelchair turning radius, to name a few. Work site adjustments, like ergonomic seating, placement of equipment for ease of use or reach, telephone headsets, use of switches, or lift assist devices, can allow improved productivity. Print adjustment (larger size, Braille, raised lettering) and improved lighting will assist persons with vision impairment, and also an aging population. Amplification systems, telephone devices for the deaf (TTD), and the use of vibration or lighting to alert individuals to surrounding activities are among the accommodations helpful to hearing-impaired workers. Schedules to assist with cognitive and physical performance (e.g., focused tasks, routine breaks, schedule) and to allow for needed health activities (e.g., intermittent catheterization for healthy urinary management, allowance for position change) must also be considered. The Job Accommodation Network (JAN), a federally-financed consultation service, provides specific advice and information about various methods of accommodation.³⁴ Independent Living Centers, regional ADA information centers, and many of the organizations that focus on a specific condition (e.g., National Spinal Cord Injury Association) also provide advice regarding workplace accommodation.

► PREVENTION AND WELLNESS

With disability ranking among the nation's largest public health problems, prevention is pertinent. Primary prevention of unintentional injuries, occupationally related injuries or exposures, and other medically or health-related etiologies of disabilities are a part of the national agenda. However, primary prevention of other health issues or secondary conditions of persons with disabilities should be acknowledged. This requires use of traditional public health prevention strategies and the clinician's index of suspicion regarding possible secondary conditions. Secondary prevention is aimed at early recognition of disability or disability-producing activities, with reduction of risk factors for work disabilities and improvement in the quality of life. Appropriate modification of the workplace for a worker with a disability who has initiated or returned to work also is a secondary prevention strategy. Tertiary prevention is centered on the rehabilitation aspects of a return to-work-plan.

Despite the medical complications and implications of disabling conditions, workers with disabilities are not ill or in poor health. There has been a paradigm shift from illness and disease to health and wellness. It is important to recognize health promotion for the worker with a disability, in spite of the disabling condition.

► CONCLUSION

Workers with disabilities make an important contribution to the support of their families and to the economy as a whole. While the care, services, and policies for workers with disabilities in the past often worked to push these individuals out of the labor force, there is now a stronger focus on facilitating continued employment. This focus is reinforced by the ADA, which prohibits discrimination and requires workplace accommodation, and by the increasingly wide acceptance of the functional/environmental model to define disability and disability policy. Challenges remain to achieve fuller inclusion in the workforce of workers with disabilities. Key issues include the need to increase insurance coverage for accommodations and assistive devices crucial to the maintenance of function, and reduce the inaccessibility and inadequacy of transportation systems so that workers with disabilities can reach the workplace. There also is a continuing need to educate employers, co-workers, and other professionals about the positive qualities of the lives and abilities of people with disabilities.

Environmental Justice: From Global to Local

Howard Frumkin • Enrique Cifuentes • Mariana I. Gonzalez

► INTRODUCTION

Environmental health, in its broadest sense, connotes places that are free of exposures that threaten human health and that promote healthy, wholesome lives. Such places may be defined on a very small scale—a home, a workplace, or a neighborhood—or on a much larger scale—a river system, a metropolitan area, or the entire earth.

Healthy environments are not equally distributed across populations. Within the United States, the term “environmental racism” emerged in the 1980s, reflecting evidence of disparities across racial groups (and ethnic and income groups as well) in exposures to environmental toxins.^{1,2} Indeed, there is increasing recognition that members of ethnic and racial minorities, whether in the workplace or in community settings, sustain disproportionate risk from chemical, physical, biological, and psychological hazards. These disparities, in turn, are related to health disparities, which have been defined as differences in health—or likely determinants of health—that are systematically associated with different levels of underlying social advantage or position in a social hierarchy. Braveman et al.³ explain that social advantage or position is reflected by economic resources, occupation, education, racial/ethnic group, gender, sexual orientation, and other characteristics associated with greater resources, influence, prestige, and social inclusion.

“Environmental justice” is a complementary term. While it explicitly refers to fair and equitable access to healthy environments, it also evokes broader underlying themes important in public health: access to information, community-based participatory decision-making, and social justice.⁴ Environmental justice is global in scope. The underlying notion is that economic and social disadvantages carry an increased risk of harm related to environmental exposures, a pattern that emerges both within nations and across national boundaries.

The concept of environmental justice—or distributive and procedural justice with respect to environmental goods—has a long history,⁵ rooted in the teachings of major religions and the practices of ancient societies.^{6–8}

In recent years, environmental justice has been recognized as a subset of human rights. In the early 1970s, the United Nations Conference on the Human Environment declared that “Man has the fundamental right to freedom, equality and adequate conditions of life, in an environment of a quality that permits a life of dignity and well-being”.⁹ Twenty years later, the UN Draft Principles on Human Rights and the Environment began with these three statements:

1. Human rights, an ecologically sound environment, sustainable development and peace are interdependent and indivisible.

2. All persons have the right to a secure, healthy and ecologically sound environment. This right and other human rights, including civil, cultural, economic, political and social rights, are universal, interdependent and indivisible.
3. All persons shall be free from any form of discrimination in regard to actions and decisions that affect the environment.

DDHRE, UN 1994

Within the United States, environmental justice concerns have focused on ethnic and racial minorities, including African-American, Hispanic, and Native American communities, and on poor and immigrant communities.¹⁰ A robust literature, including empirical data, policy analysis and commentary, and government reports, is now available (see the Further Reading section). On a global scale, environmental justice concerns have focused on indigenous peoples, communities, regions, and even entire nations in poor regions of the world. The environmental justice literature at the global scale is more sparse, consisting of a small number of journal articles, grey literature, and internet documents.

In several respects, environmental justice issues in wealthy and poor countries are comparable. In both settings, environmental justice issues arise both in the workplace and in the ambient environment. And in both wealthy and poor countries, affected populations live and work in patterns that distinguish them from the general population and from each other. They are likely to be composed of ethnic minorities. They tend to have less education, lower income, poorer housing, worse health status, and less access to services such as health care and legal support, compared with majority groups.

The spatial scale of environmental justice is different in wealthy and poor countries. In wealthy countries, landmark environmental justice struggles have typically arisen in disadvantaged local communities, such as Warren County, North Carolina, Anniston, Alabama, or Calcasieu Parish, Louisiana. Such local struggles certainly occur in poor countries, but environmental justice also occurs on the national scale, when entire nations become favored destinations for hazardous waste or hazardous industries.

► ENVIRONMENTAL HEALTH DISPARITIES: MECHANISMS

One or more of several mechanisms may contribute to the increased risk that underlies environmental justice concerns. These include excessive exposures, greater susceptibility, inadequate technical resources, and inadequate implementation of public health policies. These mechanisms operate in both the workplace and the general environment.

Excessive Exposures

In wealthy countries, certain populations work in relatively more dangerous industries and/or jobs than others. Classic examples include the Gauley Bridge, West Virginia, mining disaster of 1935, in which hundreds of minority workers succumbed to acute silicosis after working at unprotected tunnel-drilling jobs;¹¹ the steel industry of the mid-twentieth century, in which black workers were far more likely than white workers to be assigned to the most dangerous “topside” jobs on coke ovens, with attendant carcinogenic exposures;^{12,13} and the agricultural sector, in which predominantly minority workers sustain excessive exposures to pesticides and other hazards.^{14,15}

Excessive exposures can also be seen in the workplaces of poor countries.¹⁶ In part, this reflects the central economic role of agriculture and primary extractive industries—often dangerous and polluting activities—in poor countries. In part, it reflects unique environmental conditions, such as tropical weather, which increases the risk of heat stress among workers. Challenges also arise from work practices, such as work weeks that greatly exceed 40 hours and the use of imported, obsolete production machinery. Perhaps most significantly, industry in developing countries has weaker legal and technical resources, so hazardous exposures tend to be less controlled and therefore more intense. Exposures may reach levels not seen in developed nations for many decades. This pattern has been documented across the developing world, in Africa,^{17,18} China¹⁹ and other parts of Asia,^{20–23} and Latin America and the Caribbean,^{24,25} for hazards ranging from asbestos²⁶ to musculoskeletal hazards,²⁷ from shiftwork²⁸ to job insecurity.²⁹ Particular concerns exist for susceptible working populations such as women,^{30,31} children,^{32–35} and workers in the informal sector.³⁶

Moving beyond workplaces to the general environment, at-risk communities in both wealthy and poor countries also confront excessive hazardous exposures. In the United States, minority neighborhoods are more likely than white neighborhoods to be located near environmental hazards such as polluting factories and hazardous waste sites.^{37,38} A considerable body of work in recent years, much of it in the form of correlational studies, small area case studies, and ecological studies using Geographic Information Systems (GIS) or similar techniques, has demonstrated this pattern^{1,2,39–41} with respect to a range of exposures, including air pollutants;^{39,42} hazardous waste sites,^{1,43,44} water pollution (Calderon, 1993); and lead, mostly from substandard housing^{45,46} but also from road traffic.⁴⁷ Some environmental disparities are not toxicologic in nature; examples include squalid neighborhoods,⁴⁸ scarcity of healthy food alternatives in retail stores,^{49,50} and inadequate public transit.^{51,52}

In poor countries, environmental conditions can be far worse, and hazardous exposures far more widespread. Levels of urban air pollutants in many cities are well above those in the dirtiest North American and European cities.⁵³ The resulting risk of respiratory and cardiovascular disease is especially severe for vulnerable populations such as children.⁵⁴ Indoor air pollution is also a persistent problem in both urban and rural areas, due to the use of biomass fuels, coal, and other dirty-burning fuels in inefficient stoves or open hearths.^{55,56} Many poor nations lack potable drinking water, and the management of stormwater and sewage are hampered by scarce resources, informal settlements, and other factors.⁵⁷ As a result, water supplies commonly carry microbiological and chemical contaminants.^{58,59} This contributes to the staggering burden of diarrheal disease in poor countries; in what has been called a “silent emergency,” a child in a poor nation dies every 15 seconds of a water-borne disease, the equivalent of 20 jumbo jets crashing every day.⁶⁰ An additional burden is naturally occurring contaminants such as arsenic, which has caused a public health emergency in Bangladesh.⁶¹

Deficient solid waste management practices in poor countries compound problems with water, causing exposures to gastrointestinal and respiratory disease risks.^{62,63} Hazardous wastes are often mismanaged,⁶⁴ a problem that is compounded by the export of hazardous wastes from wealthy to poor countries.^{65–67} As urbanization proceeds rapidly in poor countries, all these environmental health problems, together with inadequate housing, transport, health-care

services, and other infrastructure, create enormous challenges in urban environmental health.^{68,69} Country-level case studies have explored the interrelationships and impacts of these problems.^{70,71}

Greater Susceptibility

Independent of excessive hazardous exposures, members of minority and poor communities may be especially susceptible to the effects of hazardous exposures. One or more of several mechanisms may operate: increased baseline risk of certain diseases to which occupational and environmental exposures further contribute; increased probability of other exposures that may combine with workplace or environmental exposures to harm health; increased genetic susceptibility; and increased general susceptibility to disease through stress, poverty, and decreased social supports.

Increased baseline risk of certain diseases: Many common illnesses are multifactorial in etiology. While occupational and environmental exposures may contribute to illness, so may a range of genetic, social, environmental, and lifestyle factors. If members of minority groups, poor people, and/or people in poor nations carry an increased baseline risk for some of these illnesses, then workplace and environmental exposures could pose special hazards for these groups. For example, in the United States, lung cancer incidence is approximately 50% higher in black men than in white men.⁷² The black excess is not fully explained by differences in smoking; although the prevalence of smoking is higher among black men than among white men, blacks initiate smoking at a later age and smoke fewer cigarettes than do whites. Based on this increased risk, blacks may be especially susceptible to the effects of further exposures to lung carcinogens in the workplace or general environment. Similarly, asthma prevalence and mortality differ by race and ethnicity; the prevalence is 122 per 1000 in blacks and 104 per 1000 in whites, and asthma mortality is approximately three times higher in blacks than in whites.⁷³ The racial and ethnic disparities may imply that minority populations are especially susceptible to the effects of any of the hundreds of environmental agents known to cause or aggravate asthma.⁷⁴ Other examples are relevant on a global scale. People in poor nations may suffer from anemia because of nutritional deficiencies; accordingly, they are more susceptible to the effects of lead, which interferes with heme synthesis. Asian populations have a high prevalence of hepatitis B antigenemia, which may increase susceptibility to hepatotoxins. Endemic parasitic disease in some poor nations reduces work capacity and immune competence, and increases susceptibility to a range of diseases.⁷⁵

Increased probability of other exposures that may combine with workplace or environmental exposures to harm health: Members of poor communities may be excessively exposed to risk factors that aggravate the effects of workplace or environmental exposures. Examples include exposures in the home environment, behavioral factors such as alcohol consumption, and cultural practices. Poor people and members of minority groups are at risk of living in substandard housing.^{76,77} Depending on circumstances, this housing may entail exposures to biomass fuel smoke, lead dust, secondary tobacco smoke, and antigens such as cockroaches and dust mites, compounded by inadequate ventilation.⁷⁸ Such home exposures could aggravate the effects of workplace and ambient environmental exposures to respiratory hazards. Behavioral factors such as alcohol abuse vary to some extent by ethnicity,^{79–81} and heavy drinking can increase the risk of injuries and compound the potential toxicity of liver toxins. Finally, cultural practices may entail hazardous exposures; examples include lead-containing cosmetics such as kohl and surma,^{82,83} and traditional medications that contain mercury.⁸⁴

Increased genetic susceptibility: It has long been recognized that several single-gene disorders vary in frequency among different racial and ethnic groups. Among blacks, disorders that are relatively prevalent include glucose-6-phosphate dehydrogenase (G6PD) deficiency, hemoglobinopathies (HbS and HbC), and alpha and beta thalassemias.⁸⁵ Moreover, differences in the ability to metabolize certain drugs, related to polymorphisms of one or more

gene loci, have been associated with specific racial and ethnic backgrounds. One example is debrisoquin hydroxylase (also known as CYP2D6), a cytochrome P450 enzyme that catalyzes the oxidation of more than 30 drugs. Compared to whites, blacks and Asians have fewer abnormalities of this enzyme.⁸⁶ Such abnormalities may either increase or decrease risk, depending upon the metabolic fate of a particular chemical. Increasingly, with growing success at mapping the human genome, individual genes have been associated with specific racial or ethnic groups, and with specific diseases. Cancer risk is a special area of interest with respect to genetic polymorphisms. Some genes that alter cancer risk have been reported to vary by race. For example, mutations of the CYP1A1 gene, which is involved with the metabolism of polycyclic aromatic hydrocarbons, are thought to increase the risk of lung cancer among smokers; this abnormality is more common among blacks than whites.^{87–89}

While genetic differences in disease susceptibility are increasingly recognized, their practical significance in occupational and environmental health remains limited. In the first place, few genetic factors have been clearly demonstrated to increase the risk of specific occupational diseases. Workers with G6PD deficiency are susceptible to hemolytic crises following exposure to oxidants such as naphthalene and trinitrotoluene,⁹⁰ but this event is unusual. Perhaps more importantly, job applicants have been excluded from certain jobs because of purported genetic risks, a practice that has been recognized as racial or ethnic discrimination.^{91–93} Hence, although genetic bases for susceptibility are being increasingly recognized, an emphasis on primary prevention—decreasing exposures to levels that are safe for all persons—remains the preferred approach.

Increased general susceptibility to disease through stress, poverty, and decreased social supports: Both in the United States and on a global scale, poor communities suffer poor baseline health due to poor nutrition, highly prevalent infectious diseases, poor access to immunization and other health-care services, stress, and other factors, as reflected in high infant mortality rates, low life expectancy, and other health indicators.⁹⁴ Poverty, and the income inequality that accompanies it, are bad for health.^{95,96} As a result, these populations may be less resilient following a wide range of hazards, including infectious, chemical, physical, and radiologic exposures.

Inadequate Technical Resources

Poor nations face severe shortages of trained personnel essential to environmental and occupational health practice. Adequately trained industrial hygienists, safety professionals, and environmental engineers who would be able to recognize, assess, and control hazards, are in short supply. So are epidemiologists with skills in surveillance, who would be able to monitor disease and injury trends and identify problem areas. Health-care providers such as occupational physicians and nurses are scarce, preventing adequate diagnosis and treatment of environmental and occupational illnesses. In addition to these human resources, equipment such as environmental measurement devices, analytical laboratories, and even vehicles to permit travel to field locations are often unavailable. These shortages of technical resources pose an obstacle to effective environmental and occupational health practice.

Inadequate Implementation of Public Health Policies

In both wealthy and poor countries, poor people and members of minority communities are less able to rely on protective public health actions. For example, research in the 1980s documented a pattern of selective enforcement of environmental laws across the United States, with less stringent enforcement in minority communities.⁹⁷ Minority workers are more likely to be employed in small and/or marginal firms, firms that are less likely to implement workplace safeguards because of scarcity of resources and know-how. And in poor nations, public health policies—epidemiologic and hazard surveillance, provision of information, regulatory enforcement, and private sector voluntary actions—are less consistently applied.

► THE GLOBAL CONTEXT

At the global level, environmental justice is a subset of global environmental affairs, which in turn reflect demographic changes, trends in resource use, and practices in manufacturing, transportation, energy, and other sectors. Population growth in most of the world's poor countries, population shifts from rural to urban areas with the resulting growth of large cities, economic liberalization with rapid growth in the manufacturing and service sectors (in at least some countries), and depletion of key resources, all play a role in defining the environmental conditions that affect health.⁹⁸ Several processes are illustrative: the growth of multinational companies, the development of free trade zones, and the promulgation of multilateral free trade agreements.

Multinational Companies

Multinational companies have increased in size, wealth, and international reach over recent decades. Half of the 100 largest economies around the globe are not countries but rather multinational corporations (MNCs). The 500 largest MNCs now account for 70% of world trade, 30% of all manufacturing exports, and 80% of technical and management services.⁹⁹

Many MNCs have the resources and expertise to implement environmental and occupational safety and health practices in their facilities worldwide. Indeed, in many instances the MNC facilities in poor countries are leading local examples of sound practice.¹⁰⁰ However, MNCs have also taken advantage of lax regulations to avoid standards of practice that prevail in rich countries. Examples include petrochemical industry operations in Ecuador¹⁰¹ and Nigeria,^{102,103} mining operations in Indonesia,^{104,105} and assembly plants in northern Mexico¹⁰⁶ (see case studies in this chapter). Moreover, there is typically a set of domestic firms associated with MNCs, supplying components, packaging, and other inputs, and these firms may not implement optimal environmental and workplace practices.

Free Trade Agreements

Multilateral free trade agreements (FTA) evolved throughout the world after World War II. To the extent that these agreements promote economic development in poor countries, they improve living standards and environmental performance. And to the extent that these agreements incorporate related social issues such as working conditions and environmental protection, they may motivate governments and private firms to protect environmental and occupational health. On the other hand, trade agreements that omit environmental and workplace standards may permit and even aggravate health risks that accompany development.^{107,108} Several major trade agreements are illustrative.

The *World Trade Organization* (WTO) succeeded the General Agreement on Tariffs and Trade (GATT), a system that originated in 1948 as an effort to liberalize and normalize world trade. With the creation of the WTO, the scope of this system expanded from trade in goods to include trade in services and intellectual property as well. Both GATT and the WTO have been generally silent on issues of worker safety, environmental health, and justice, restricting their domain to problems that bear directly on trade.¹⁰⁹

The process of *European economic integration*, in contrast, has extended well beyond trade issues to incorporate a wide range of social considerations, including occupational safety and health. Since the 1957 creation of the European Economic Community (now the European Union, or EU), foundational documents such as the Single European Act, the Social Charter, and the Framework Directive have established the intent to include environmental and workplace issues in the European trade regime. On the environmental side, a series of multiyear Action Programmes began in 1972, setting the stage for over 200 pieces of environmental legislation addressing such issues as waste management, water pollution, and air pollution. The EU has also integrated environmental considerations into laws and policies in other sectors such as agriculture, energy, transport, and tourism.

The Sixth Action Programme for the Environment, adopted in July 2002, identified four priority areas, of which one is environmental health (the others are climate change, nature and biodiversity, and the management of natural resources and waste). In this context, important environmental health initiatives such as the Precautionary Principle and a regulatory system known as REACH (Registration, Evaluation and Authorization of Chemicals) have arisen.^{110–112}

On the workplace side, action on occupational health dates from the 1952 formation of the European Coal and Steel Community. Since then, an extensive organizational infrastructure has arisen, including a Health and Safety Directorate within the European Commission, a multipartite Advisory Committee on Safety, Hygiene and Health Protection at Work (ACSH), and two agencies that conduct research and provide information and technical assistance, the European Foundation for the Improvement of Living and Working Conditions, based in Dublin, and the European Agency for Health and Safety at Work, based in Bilbao. Together these entities have worked with national counterparts on capacity building (such as national exchanges of workplace inspectors), policy development, and technical innovation. The 2002 EU document on occupational health, “Adapting to change in work and society” (available at http://europa.eu.int/comm/employment_social/health_safety/index_en.htm), introduced several new elements, including an enhanced emphasis on psychosocial aspects of work, a consolidated approach to risk prevention combining legislation, social dialogue and partnerships, best practices, corporate social responsibility, and economic incentives, and an explicit statement of the value of occupational health policy in economic competitiveness.

Several challenges persist in the European approach to environmental and occupational health—reconciling national sovereignty with coordinated progress, monitoring compliance with Community directives, reconciling differences between more and less progressive countries, integrating the countries of the former Soviet Union, and sharing scarce technical expertise and resources. However, Europe provides the world’s most advanced example of linking environmental and occupational health with free trade.

The *North American Free Trade Agreement* (NAFTA), ratified by the United States, Mexico, and Canada in 1992 and entered into force in 1994 for implementation over the next decade, was designed to abolish most trade restrictions among the three countries, addressing labor rights and environmental protection, through its “side agreements” (NAFTA, 1994). NAFTA is intermediate between the WTO and the EU in terms of its inclusion of labor issues.

The process that led to NAFTA differed from the European experience in several ways. NAFTA had a shorter history and was negotiated rapidly. There was limited interest in incorporating social and environmental issues into the process. Labor unions and their allies, especially in the United States and Canada, vigorously opposed NAFTA and campaigned more to block the treaty altogether than for specific labor-friendly provisions. Some environmental groups, in contrast, participated in negotiations, perhaps accounting for the relatively greater emphasis on environmental practices. Moreover, all three governments were reluctant to relinquish any sovereignty over their respective labor and environmental laws.

Accordingly, the focus in NAFTA is on dispute resolution, some information exchange, and promoting each country’s compliance with its own labor and environmental laws, rather than on joint research, training, standard-setting, technology development, and related initiatives. Neither the main trade agreement nor the side agreements express a shared commitment to upgrading or harmonizing environmental and occupational health laws or practices.

Given these limitations, while NAFTA’s contribution to advancing environmental and occupational health in North America has yet to be fully evaluated, it is likely to be limited.^{113–120} Assessing the impact of NAFTA is complex, since environmental and occupational health reflects many other forces—economic, technological, and political—in addition to NAFTA itself.¹²¹ In some sectors, there is evidence of deepening environmental health problems. For example, along the United States–Mexico border, the volume of freight transport has increased air pollution, and rapid growth has aggravated water

pollution and water scarcity. In other sectors, such as fisheries, evidence suggests little impact of NAFTA. There is little evidence that economic growth following the adoption of NAFTA has led to major investments in environmental services or infrastructure, or major improvements in environmental indicators. However, the prediction of pollution havens also did not materialize to the extent predicted, with possible exceptions in specific industry sectors such as denim.¹²²

On the labor side, the effect of NAFTA on workplace safety and health is also complex. Few data are available that would permit tracking workplace conditions and health outcomes, and associating any observed trends with NAFTA. Several cases have been brought under the NAFTA grievance procedure, alleging serious health and safety hazards in Mexican facilities and failure of the Mexican government to enforce applicable laws. Even when these cases are found in favor of the complainants, advocates maintain that the solutions are ineffective, amounting only to calls for consultation.¹²³

Free Trade Zones and Maquiladoras

Many governments have established special zones to promote global economic activity, typically located near seaports, airports, and/or national borders.¹²⁴ From their origin in the early 1970s to the 1990s, about 200 free trade zones (FTZ) had been established with an employment of approximately 4 million people. In the next 10 years, especially with the rise of China as a global manufacturing and export powerhouse, FTZs proliferated. By 2003, FTZs employed approximately 42 million people, about 30 million of these in China.¹²⁵ Free trade zones may offer any or all of several benefits to manufacturing and trading firms, including tax relief, low or absent customs duties, reduced export controls, land, water, energy, and infrastructure subsidies, a plentiful and tightly controlled labor force supply with low wages and weak institutions, and limited enforcement of labor and environmental laws.^{99,126} The economic activity in FTZs is typically labor-intensive, centering on manufacturing, although service work is also increasingly common. The workforces are often predominantly female. Workers may face physical hazards such as repetitive motions, awkward work positions, and noise, with risks of musculoskeletal disorders and hearing loss, chemical exposures, and stresses such as highly regimented work routines and dangerously high production quotas.

Maquiladoras are assembly plants south of the United States–Mexico border which typically import components from the United States and other countries, complete assembly and other value-added processes, and re-export the products. The maquiladoras produce a wide variety of products, including electrical and electronic equipment, automobile parts, toys, clothing, and others (see case studies below). Health and environmental studies in maquiladoras are scarce, but do suggest a high burden of musculoskeletal disorders, stress, and other health burdens.

The Export of Hazards and the Race to the Bottom

Scholars, public health practitioners, and labor advocates have for some years recognized that increasing international trade may threaten worker health and safety. In the 1980s, considerable attention was devoted to the “export of hazard.”^{127–131} Concern grew out of observations of double standards;¹³² critics anticipated that industries from developed nations would relocate plants in developing nations due to lower labor costs, more lax regulatory environments, and in some cases proximity to raw materials and/or markets.¹³³ In doing so they would fail to follow the same workplace and environmental safeguards that were required in their countries of origin, creating “pollution havens” and exposing people in developing nations to relatively greater risks. Case studies of such products as pesticides^{134–137} and hazardous wastes,^{138–140} and high-profile disasters such as the Bhopal explosion,^{141–145} fed concern that developing nations faced serious risks from rapid industrialization. Interestingly, these concerns recapitulated longstanding disparities within developed nations. For example, the migration of industry from northern to southern states—that is, from wealthier to poorer regions—in the United States during the nineteenth and early twentieth centuries may have demonstrated a similar pattern.^{146,147}

The same process was also postulated as a threat to environmental and occupational health in industrial nations. North American labor unions forcefully argued this point during the NAFTA debates in the early 1990s.^{148–152} Local and national governments, they maintained, would hesitate to enforce regulations for fear of driving plants from their jurisdictions to lower-wage areas and losing needed jobs—a phenomenon known as “regulatory chill.” Workers and communities, perceiving the same dilemma, would refrain from pressing for safer workplaces and lower emissions. And firms in developed nations, increasingly facing international competitors and seeking the lowest possible costs, would play one location against another. Standards of practice would descend in developed nations toward those of developing nations, exactly as predicted by the factor price equalization theorem that is central to the economics of free trade. This “race to the bottom” would threaten environmental and occupational health in both developed and developing nations.

An opposing set of arguments, based on economic theory and empirical data, suggested a more optimistic prognosis: that free trade would spur economic development, which would in turn lead to improved environmental performance. Moreover, liberalization of trade and investment would lead to the spread of greener technologies, especially as higher consumer expectations for “green” products and processes would emerge in an open, competitive market. Finally, increasing foreign direct investment was predicted to make funds available for upgrading industrial facilities.^{119,153–156} Further research will help clarify when, and in what circumstances, trade liberalization advances environmental and occupational health.

► GLOBAL SOLUTIONS

Several strategies may combine to advance environmental and occupational health in poor nations, in the process rectifying disparities that exist on a global scale. Some of these are policy initiatives, to which environmental and occupational health professionals can contribute as advisors and advocates. Others, such as training and research, fall within the traditional domain of public health practice.

Policy Initiatives

Policy initiatives include those that are official and legally binding, such as regulatory standards promulgated by governments, and those that are voluntary. Official standards may be developed in the context of trade agreements, but as noted above, with the exception of the European Union, this linkage is rare and controversial. More typically, standards are promulgated by national government agencies with jurisdiction over labor and environment.

Two sources of standards are available to the governments of developing nations for this purpose. First, many adopt specific exposure standards used in industrialized nations, especially those of the United States, Germany, Japan, Russia, and the Nordic countries. Of note, such standards are only as effective as their enforcement mechanisms, and enforcement often lags well behind promulgation. Second, developing nations may model their policies on relevant international norms, such as the Conventions of the International Labor Office,¹⁵⁷ or on treaties such as the Montreal Protocol on Substances that Deplete the Ozone Layer,¹⁵⁸ the Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal¹⁵⁹ or the Stockholm Convention on Persistent Organic Pollutants.¹⁶⁰ In general, such norms are legally binding when ratified by member nations. In some cases, such as the Montreal Protocol, global environmental diplomacy has been highly effective in reducing a hazard. However, such efforts are often compromised by the failure of important nations to ratify them and by limited compliance by nations that do ratify them, limiting their impact.

Voluntary standards for environmental and occupational health are also available. A principal example is the International Organization Standardization (ISO), which has promulgated internationally recognized standards on quality management (ISO 9000) and environmental management (ISO 14000). The ISO considered promulgating a

standard for occupational health and safety management systems in the mid-1990s, but this proposal was set aside in late 1996 due to strong opposition from businesses, labor organizations, and some governments.

Other voluntary standards or Codes of Practice have been promulgated by international agencies. For example, the Organization on Economic Co-operation and Development has published *Guiding Principles for Chemical Accident Prevention, Preparedness and Response* (www2.oecd.org/guidingprinciples/index.asp), the United Nations Environment Programme has promulgated a *Code of Ethics on the International Trade in Chemicals* (www.chem.unep.ch/ethics/english/CODEEN.html), the ILO has promulgated numerous Codes of Practice on workplace health and safety (www.ilo.org/public/english/protction/safework/cops/english/index.htm), and the International Programme on Chemical Safety (IPCS, a joint program of the ILO, UNEP, and WHO) has published *Health and Safety Guides* for nearly 100 chemicals (www.inchem.org/pages/hsg.html) and *International Chemical Safety Cards*, including handling recommendations, for over 700 chemicals (www.inchem.org/pages/icsc.html). The recommendations in these documents are readily available to authorities and practitioners in developing nations, and are often based on a careful review of evidence available at the time they are prepared. They may be of special utility to multinational firms that wish to establish a standard of practice in each of their operating locations. However, the resources to implement them may be out of reach, especially to smaller firms and governments in developing nations.

Some voluntary standards have been issued by industry groups. For example, the International Chamber of Commerce developed the 16-point “Business Charter for Sustainable Development” which was endorsed during its 1991 Rotterdam conference.¹⁶¹ The American Chemistry Council (formerly the Chemical Manufacturers Association) introduced its Responsible Care Program in 1988 to improve the industry’s safety and environmental performance (www.responsiblecare-us.com/about.asp). Segments of some industries, such as coffee and chocolate production, have adopted “fair trade” practices that include both occupational health and environmental safeguards.¹⁶² The principles are widely available and may be used by environmental and occupational health professionals in developing nations as useful benchmarks.

Voluntary standards and codes have also been issued by nongovernmental organizations. Although these lack official status, they may be effective in the context of public education, consumer campaigns, stockholder campaigns, and similar efforts. One example is the Ceres Principles (formerly the Valdez principles, growing out of the response to the Exxon Valdez disaster) (www.ceres.org/coalitionandcompanies/principles.php). These principles were promulgated in 1989 by the Coalition for Environmentally Responsible Economics (Ceres), a national network of banks, investment funds, brokers, environmental organizations, and other public interest groups working to advance environmental stewardship. They aim to promote environmentally sustainable operation by companies, and include commitments to protection of the biosphere, sustainable use of natural resources, reduction and safe disposal of waste, energy conservation, and environmental restoration. There is an explicit commitment to risk reduction—striving to “minimize the environmental, health, and safety risks to our employees and the communities in which we operate through safe technologies, facilities, and operating procedures, and by being prepared for emergencies”—and to providing safe products and services. And there are procedural commitments, such as to informing the public and conducting audits. Advocates promote the implementation of Ceres principles by working through stockholders and by encouraging socially responsible investment. Other nongovernmental organizations have issued standards that include environmental performance and safe working conditions, and have organized consumer campaigns to promote compliance with these standards through market pressure. Particular attention has been directed at the apparel, carpet, and toy industries. Examples include standards issued by the Clean Clothes Campaign (www.cleanclothes.org/codes/index.htm), the Fairtrade Labelling Organizations International (FLO, at www.fairtrade.net), and Co-op America (www.coopamerica.org/).

A final kind of policy relates to investment patterns. Lending institutions, such as the World Bank, and private lenders can link investment in industrial development to the implementation of sound workplace and environmental policies. Increasingly, major projects are contingent on environmental impact statements and proper provisions for environmental safeguards.

Initiatives by Public Health Professionals

Within the realm of public health work, professionals can promote environment and health in developing nations in several ways. These include training, technical assistance, collaborative research, and advocacy.

Training is an essential activity for occupational health professionals, given the shortages of expertise in industrial hygiene, environmental and safety engineering, occupational and environmental medicine and nursing, and related fields. Approaches to training include formal academic study in institutions in industrialized nations, short courses, and distance learning through newsletters and electronic means. One notable example is the extensive training efforts of the Finnish Institute of Occupational Health, through its ILO/FINNIDA African Safety and Health Project and its ILO/FINNIDA Asian-Pacific Regional Programme on Occupational Safety and Health. Regional newsletters (www.ttl.fi/AfricanNewsletter and www.ttl.fi/Asian-PacificNewsletter for Africa and Asia, respectively) published by the Institute are distributed to thousands of readers in developing nations of Africa and Asia, covering such topics as information retrieval, small-scale enterprises, and specific industries. In the United States, the Fogarty International Center of the National Institutes of Health introduced an international training program in environmental and occupational health in 1995.¹⁶³ This program brings trainees from developing nations to U.S. institutions for intensive study. Through large-scale efforts such as these, and through more limited training initiatives, needed expertise in occupational safety and health can be transferred to developing countries.

Technical assistance is another important area of effort for public health professionals. Joint investigations of outbreaks, consultancies on environmental and occupational health problems, and direct technology transfer can all advance the protection of workers in developing countries. Technical assistance may occur through private firms, through professional associations, through nongovernmental organizations, through multilateral organizations such as the International Labor Organization, and/or through government efforts. One example is the work of the Maquiladora Health and Safety Network (www.mhssn.org), which assists labor organizations and employers in the United States–Mexico border and in Asia to recognize and remediate workplace hazards.

Collaborative research is a third important activity for environmental and occupational health professionals. Would-be researchers in developing nations face daunting challenges: university salaries below subsistence levels, requiring outside employment; lack of infrastructure needs such as libraries, computers, analytical testing capability, and laboratory equipment; lack of domestic sources of research funding; lack of research mentors and collaborators; and the need to address diverse content areas rather than build in-depth specialization. Despite these challenges, there remain important research needs in developing nations.^{164–168} One goal of such research, as anywhere in the world, is the *discovery* of unknown exposure-response associations and disease mechanisms. Just as important, however, is the traditional public health research function of *documentation*. Many workplace and environmental hazards are well understood, and their effects easily predicted. However, it may require in-country data demonstrating that a hazard is taking a toll on local workers and communities to stimulate government to take action to control the hazard.

Finally, environmental and occupational health professionals in developing nations, with the strong support of colleagues in developed nations, need to engage in *advocacy*. In countries where expertise is rare, professionals rarely have the luxury of remaining only practitioners, or researchers, or teachers, or policy makers; they must play all these roles. Steps must be taken to identify and correct

workplace hazards, and working people must be cared for when injured or ill. Relevant data must be assembled, through primary or secondary research. Students must be taught to perform these functions. However, for lasting changes to be made, practical experience, data, and moral conviction must be laid before “those who need to know,” including government officials, company officials, and worker representatives, and systematic approaches to protecting public health must be implemented.

► U.S. SOLUTIONS

Solutions to domestic environmental justice concerns are in some cases parallel to those used globally, but in other cases reflect the unique social and political circumstances of the United States. A landmark event was the promulgation, in 1994, of a Presidential Executive Order, “Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations” (www.fs.fed.us/land/envjust.html). This Order required each Federal agency to “make achieving environmental justice part of its mission by identifying and addressing, as appropriate, disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations. . . .” Among its provisions, it established an Interagency Working Group on Environmental Justice, required each federal agency to develop an agency strategy to advance environmental justice, and mandated the inclusion of “diverse populations” in environmental health research. Perhaps the most active agency in advancing environmental justice has been the Environmental Protection Agency (EPA). EPA established an Office of Environmental Justice in 1992, established environmental justice authorities and activities throughout the agency, and formed an advisory committee, the National Environmental Justice Advisory Committee, that has become an important national forum for discussion and debate, including grassroots voices. EPA also makes environmental justice grants and operates an environmental justice internship program. These activities are described on the agency’s environmental justice web site (www.epa.gov/compliance/environmentaljustice/index.html).

Grassroots efforts in environmental justice have played a major role in advancing these issues in the United States. A large number of local groups, often formed around specific concerns such as a hazardous waste site or a polluting industrial facility, have arisen. These groups have coalesced at periodic National People of Color Environmental Leadership Summits (<http://www.ejrc.cau.edu/EJSUMMITwelcome.html>) and in national networks such as the National Black Environmental Justice Network (<http://www.nbejn.org/>) and the Indigenous Environmental Network (<http://www.ienearth.org/>). In addition, academic units such as the Environmental Justice Resource Center at Clark Atlanta University (www.ejrc.cau.edu) and the Deep South Center for Environmental Justice at Xavier University in New Orleans (relocated to Dillard University following Hurricane Katrina; see www.dscej.com/) have supported these community groups through unique academic-community partnerships.

An important means of partnership between researchers and communities has been community-based participatory research.^{169–176} Through this technique, researchers and community members together identify the need for research, define the most important research questions, agree on methods to be used, and pursue the research collaboratively. Ideally, this approach helps target environmental health research toward scientific questions important both to communities and to scientists, and results in a more responsive, relevant body of scientific knowledge.

Litigation has been used extensively by communities in an effort to seek redress of alleged environmental justice offenses.^{177–180} Plaintiffs have used a number of legal tools, including environmental laws, civil rights laws (especially Title VI of the Civil Rights Act of 1964), common law property claims, and constitutional challenges. Defendants have included both polluters and government agencies that

permitted siting or operation of emitting facilities. Interestingly, litigation practices in the United States have increasingly been applied globally, especially in developing nations, as illustrated in the case study on Texaco in Ecuador.^{181,182}

A final important strategy in environmental justice is building diversity in environmental health and related professions. An example is the Minority Youth Environmental Training Institute, a project of the National Hispanic Environmental Council (<http://www.nheec.org/>). This program targets Hispanic teenagers for a 10-day intensive training experience, during which they learn various aspects of environmental sciences, meet role models, and are encouraged to consider careers in environmental sciences, including environmental health. At the university level, the Association of Academic Environmental Health Programs (www.aehap.org) has joined the Environmental Justice and Health Union (www.ejhu.org) to encourage minority-serving institutions to offer accredited environmental health training. At the graduate level, the Agency for Toxic Substances and Disease Registry, working with the Minority Health Professions Foundation (www.minorityhealth.org), has funded fellows and residents to conduct research designed to fill identified data gaps on the health effects of toxic chemicals. Efforts such as these, across the entire spectrum of academic training, should help increase diversity in the environmental and occupational health professions, and thereby help advance environmental justice.

► DISCUSSION

This chapter has addressed environmental justice both in the United States and on a global scale. The concept of environmental justice has evolved differently on the two scales, but there is a consistency between the two. Both domestically and internationally, disadvantaged populations—as defined by race, ethnicity, socioeconomic status, and/or other attributes—tend to sustain disproportionate exposures to hazards, both in the workplace and in the ambient environment. Relative to the general population, these vulnerable populations bring fewer resources to bear in addressing the hazards they face—less biological reserve with which to withstand and recover, fewer technical resources, less political power, and less access to legal remedies. As a result, these vulnerable populations suffer adverse health consequences following exposures. The disparities that give rise to these circumstances are collectively known as environmental injustice. While environmental injustice may occur without intent, firms and governments have at times taken actions that create, exploit, and/or aggravate disparities (Kamuzora 2006). Across the globe, there is increasing recognition of the moral and practical dimensions of environmental injustice, and of the need to address these issues.^{183,184}

Public health has a long history of focusing attention on vulnerable populations, to target efforts at disease prevention and health promotion.¹⁸⁵ In recent years, this focus has become a central strategy in environmental and occupational health, both in the United States and across the globe—a trend that has the potential to transform the environmental movement.¹⁸⁶ From surveillance to technical assistance, from research to training, as public health professionals link with affected communities and workers, governments and non-governmental organizations, and private firms, they will be increasingly able to remediate disparities and improve health for all people.

► CASE STUDIES

The five case studies selected for this chapter were drawn from a limited number of reports, often unpublished, and are based on the DPSEEA framework (Driving force-Pressure-State-Exposure-Effect-Action).¹⁸⁷ The case studies relate to agriculture, mining, the *maquiladora* industry, and the petroleum industry, whose effects are especially marked in rural areas and in areas inhabited by indigenous, minority, and other marginalized populations. The case studies are drawn from both North and South America.

The first two case studies focus on farm workers in the Valle de San Quintín, in the Mexican state of Baja California, and in the Yakima Valley of Washington state. Agricultural work is one of the most dangerous occupations. In the case of San Quintín, the majority of migrant and seasonal farm workers come from the poorest communities of Oaxaca. While working in San Quintín, they are housed in crowded conditions in substandard structures, often without access to potable water, sewage, and other environmental and health services. Agricultural workers in the United States are predominantly Hispanic, with about 77% from Mexico.¹⁸⁸ The Yakima Valley is illustrative. The majority of farm workers there come from the *purépecha* region of Michoacán. With no access to labor unions or other mechanisms of social insurance, they have enjoyed few protections on the job.

The third case study describes small-scale mining in Ecuador. Artisanal mining is an activity steeped in poverty. These mines are generally located in geographically isolated communities, with little or no governmental regulation. Mine shafts often originate inside or next to workers' homes. Entire families may be involved, with children starting work in the mines before finishing primary school. Children who do not work with their families may be hired directly by mine owners. Still other children may start by doing *jancheo* work (gathering mineral rocks from stockpiles and dumps), either on their own or together with their mothers, as a way of contributing to the family income.

The fourth case study refers to workers in the maquiladora industry along Mexico's north border. As described in the text, environmental challenges in this region, on both sides of the border, are well documented. Within the maquiladora plants, workers face numerous hazards as well.

The final case study focuses on indigenous communities in the Amazonas region, affected by petroleum exploitation. Between 1971 and 1992, Texaco discharged an estimated 15 million gallons of crude petroleum and 20 billion gallons of toxic waste into pristine rainforest.¹⁸⁹ The resulting environmental damage has been compared to the 1989 Exxon Valdez disaster in Alaska.

Together these case studies illustrate the diversity of affected populations and economic sectors, common features such as the social disadvantages and resulting vulnerability these populations suffer, and the diversity of responses they and their advocates have mounted.

► SAN QUINTÍN FARMWORKERS, BAJA CALIFORNIA NORTE, MEXICO

The Valley of San Quintín, located south of the municipality of Ensenada in Baja California Norte, is known for its production of fruits and vegetables for export. This production depends on the labor of migrant workers, many of whom arrive as part of a seasonal cycle that brings workers from Mexico's west coast (especially from the Mixtec area of the Valley of Oaxaca).^{190,191} Every year, from March to July, thousands of workers arrive in the valley to tend the fields on properties that belong to 39 families. Workers are paid the equivalent of only five to seven dollars a day and do not receive even the minimal work benefits required under the law. Most workers are unaware of legal rights such as holiday pay, social security, and disability, and even if they do learn about them, they often cannot or do not access them.

Pressures that play a role include relative geographic isolation, the lack of planning policies, an annual population growth rate of 11.9%, tensions among different ethnic groups, the growing use of modern technology in agricultural activities, the introduction of other economic activities (for the most part aquaculture and tourism in the lakeside district), problems of land ownership, and the depletion of aquifers. These have resulted in rapid, unplanned growth of human settlements and deficient infrastructure for basic services such as drinking water and sewage treatment systems.

Living conditions and services are marginal. Of the field workers, 66.7% workers live in camp barracks and 33.3% live in informal communities known as *colonias*. Over 80% of housing is constructed

from improvised, nondurable materials, and there are few piped water sources for many homes, almost no sewage service, and only limited electrical service. Available piped water often fails to meet standards of human consumption, and is contaminated with fecal coliform bacteria and components of agricultural chemicals such as ammonia and phosphorous. In addition to health effects, this water flows downstream and eventually to the ocean, raising concerns about environmental pollution.¹⁹¹

Additional environmental pressures arise from production practices. Pesticide use is common, and many lead to ecosystem contamination. Plastic sheeting is used to protect the growing fruit and vegetables, but it fragments and is often improperly disposed of. The plastic waste interferes with the movement of moisture and nutrients in surface soil and with the recharge of the aquifers. Water with high concentrations of salt is used to irrigate crops, causing deterioration of the land, while treated and untreated wastewater often mix and recirculate in the fields. Other contributing factors are the domestic combustion of gas and biomass with resulting emissions of particles, carbon monoxide (CO), and volatile organic compounds, the emissions of dioxins, furans, mercury, and other pollutants from the burning of refuse, and a lack of waste disposal services and appropriate sites for the disposal of solid waste.

The migrant workers' assignments differ according to gender, age, and ethnicity.¹⁹² Mature men perform the heaviest field activities, including fumigating, irrigating, and working as stewards, *camperos*, and drivers. Women and children pick the fruits and vegetables. Mestizo women from the state of Sinaloa are generally hired for the packing process.¹⁹²

Prevalent health problems among the farmworkers include acute respiratory infections, acute and chronic diarrhea, and tuberculosis. The incidence of pesticide toxicity is unknown, and possible long-term sequelae such as cancer have not been well characterized in this population.

Several actions have resulted from these problems. Members of the migrant population, led by women and with the support of organizations of residents from the colonies, have sought improved services including water, electricity, transportation, medical care, and education.¹⁹³ In the 1990s, day nurseries, primary schools, and chapels were set up in some of the camps. Local nongovernmental organizations also successfully requested establishment of a rural Clinic-Hospital by Mexico's Instituto Mexicano del Seguro Social (IMSS), located in Delegación Vicente Guerrero. More recently, local groups, the Mexican federal government, and the home states of the migrants collaborated in a "Vete Sano Regresa Sano" (Leave Healthy, Return Healthy) public health initiative, in order to provide health protection for the migrants. More information on this initiative can be found at www.bajacalifornia.gob.mx/informe/1er_informe/part_social.htm.

► THE YAKIMA VALLEY, WASHINGTON STATE

The state of Washington is known for its agricultural products, including apples, cherries, asparagus, pears, berries, and hops. Much of this output, valued at more than a half billion dollars annually, comes from the Yakima Valley in the central part of the state. However, the plight of farm workers in the Yakima Valley stands in sharp contrast with the prosperity they help generate.^{194–197} Many of these workers are Mexican migrants, who arrive for the spring, summer, and fall seasons and depart during the winter months seeking employment elsewhere in the United States. This workforce has been mostly male since the early twentieth century, but in recent decades the proportion of women workers has increased.^{194,198}

The farm work of Mexican immigrants is considered highly "flexible." Characteristics include low pay (rising far more slowly than inflation), job insecurity, and absence of health insurance, pension contributions, occupational health protection, and other benefits typically provided to other workers.^{194,198} There is a wide range of job positions in the region, ranging from field croppers to fumigators, pesticide mixers,

assistant foremen, and foremen,^{195,198} and a worker may be assigned to a variety of jobs without adequate cross-training or supervision.

Another important aspect is the role of unions such as the Teamsters and United Farm Workers (UFW). These unions attacked the apple industry in Washington when producers in the state continued to accept Purépecha Indians (from the Mexican state of Michoacán) to maintain the flow of migrant workers.¹⁹⁸

Pesticides are used extensively in Yakima Valley agriculture, and worker exposures have been carefully described in a series of studies at the University of Washington.^{196,199–203} Exposures during farm work are intensified by long hours, absence of hand-washing facilities, and the lack of protective equipment and training.²⁰⁴ There is also evidence of take-home exposures, which may affect children. Among workers who handle pesticides, there is considerable concern about potential toxicity.¹⁹⁵ Potential health effects include irritation and inflammation of eyes and mucus membranes, allergic reactions, respiratory symptoms, neurologic toxicity following higher exposures, and nonspecific symptoms such as nausea and fatigue. Long-term effects may include cancer, neurotoxicity, and reproductive damage.

Environmental problems include the dispersion and persistence in the environment of many of the pesticides that are used. This concern is heightened by the recirculation of irrigation water, although there are currently efforts to eliminate this form of contamination.

A wide range of solutions is available, including training of both farmers and farm workers, interventions by community health workers, and promulgation and enforcement of regulations.²⁰⁵

► CHILDREN ARTISANAL MINERS IN NAMBIJA, ECUADOR

Nambija, meaning "the place no-one can find," is a remote gold-mining settlement of about 2000 people in the mountains of southern Ecuador, near the Peruvian border. The population is predominantly of indigenous Saraguro and mestizo background, many of whom migrated to Nambija in order to work as gold miners. The settlement consists of hundreds of dilapidated wooden dwellings high on a mountain that has been extensively damaged by years of mining operations.²⁰⁶

Mining is embedded in the social fabric of Nambija. Entire families, including the children, work at gold mining. Homes are often built directly over the openings of small mine tunnels, reflecting the "cottage industry" quality of the work. This small-scale, informal gold mining, known as "artisanal mining," is common in Latin America and elsewhere in the world.²⁰⁷ While artisanal mines may operate productively with techniques that protect health and the environment, more typically they are characterized by low technology, low productivity, unstable employment, high workforce turnover, low pay, little sanitation, lacking health and safety protection for workers, and poor environmental performance. Mining families often have no legal claim to the land they work. Legal and institutional oversight are rare. As many as 13 million people are estimated to work at artisanal mining worldwide, accounting for the bulk of production of minerals such as emeralds and tungsten, and for as much as a quarter of world gold production.^{207,208}

For the rural poor, artisanal mining is an alternative to unemployment and misery. It can be a force for local economic development. However, the health, environmental, and social costs of artisanal mining are high, as exemplified in Nambija. Workers extract gold from ore using liquid mercury, which forms an amalgam with gold that can be separated from ground ore. The mercury is then boiled off, leaving a residue of gold. Mercury toxicity has been well documented in the adults and children of Nambija.^{206,209,210}

Children become miners in different ways, starting as early as the age of five. Some may be hired directly by mine owners, or some may begin informally with *jancheo* (the act of gathering mineralized rocks from stockpiles and dumps), either on their own or together with their mothers as a way of contributing to family income. Mine work may occupy all of their time or part of it. In either situation,

schooling suffers. As children grow into the teen years, they become fully integrated into the mining workforce, graduating from *jancheo* to the full complement of tasks. Hazards other than mercury threaten the health and safety of artisanal miners in Nambija. In addition, toxic chemicals such as cyanide and acids are used. Injuries are common, the result of rock falls and subsidence, falls from heights, misuse of explosives, and the use of grinding machinery and hand tools. Inhalation of silica dust poses a risk of respiratory disease. Explosions and noisy machinery can damage hearing, and tasks such as hauling large loads and repetitive motions can cause musculoskeletal injuries. Women and children are especially susceptible to the effects of some chemicals, and may also be subject to abuse such as threats and physical and psychological assault from adult miners. Social problems such as alcoholism, violence, and prostitution are persistent in this setting.^{207,211,212}

Environmental impacts are also extensive.^{213–218} In streams and rivers downstream of the mining area, mercury is converted to organic forms and bioaccumulates. Land degradation, deforestation, and siltation of waterways are common as the result of nonsustainable excavation practices. On the local scale, while most homes have electrical service, well under half receive piped drinking water, and of these, many receive unprocessed water directly from the source. Fewer than one in five homes have sanitary services.²¹⁹

Gender roles are important in addressing problems of child labor. Children begin working in the mines alongside their mothers, who care for them and their family. Strengthening women's involvement in the community's social life advances social development, including concern for child labor, and may increase the chance of limiting it.^{220,221}

► WOMEN MAQUILADORA WORKERS ON MEXICO'S NORTHERN BORDER

With the end of the Bracero initiative, a temporary worker program, in 1964, large numbers of Mexican workers were deported from the United States. The population along Mexico's north border swelled, and social problems such as unemployment rose.²²² Partially in response to this problem, the Mexican government established its Border Industrialization Program in 1965, to encourage foreign (usually U.S.) companies to site assembly plants south of the border. Key to the program is a provision that allows firms to import components and raw materials without paying customs duties and to export finished products paying customs only on the value added—the labor—in Mexico.

The assembly plants, known as *maquiladoras*, grew slowly at first. In the 1980s, Mexico joined GATT and liberalized its trade restrictions, and the peso was repeatedly devalued, lowering the cost of Mexican labor. By 2000, when maquiladora employment peaked, over 3000 maquiladoras employed approximately 1.3 million workers, accounting for nearly 10% of Mexico's formal sector employment and 40% of Mexico's exports.²²³ (Maquiladora employment declined during 2001–2003 due to a downturn in the U.S. economy and competition from other low-wage countries, but some rebound occurred starting in 2003.) While three out of four maquiladoras are located in Mexico's border states (Tamaulipas, Coahuila, Chihuahua, Sonora, Baja California, and Nuevo León), one in four is now located farther south, in such booming cities as Monterrey.^{223,224} The concentration of economic activity along the border has made this region a magnet for Mexicans seeking employment.^{222,225}

At the same time, with the continued growth of globalization, Mexico has faced competition from other low-wage countries. In the years after 2000, at least 170 maquiladoras closed their operations in Mexico to move to China and other Asian countries. This migration, representing a loss of over 200,000 jobs, was widely noted in Mexico,²²² as the maquiladoras had emerged as a major factor in the national economy.²²⁶

The maquiladoras produce a wide variety of products, including electrical and electronic equipment, automobile parts, toys, clothing, and others.²²⁷ Labor-intensive assembly processes pose physical hazards such as repetitive motion, awkward work positions, and noise,

with risks of musculoskeletal disorders and hearing loss. Chemicals such as solvents, acids, and metals are used in cleaning metal parts, fabricating electronic components, and such operations as painting and gluing, affecting not only workers but the ambient environment as well. While epidemiologic surveillance data are unavailable, surveys of *maquiladora* facilities and communities have suggested that hazards are common (U.S. GAO, 1993; Takaro et al. 1999). Health problems reported include injuries, nonspecific symptoms such as headache, insomnia, and dizziness, neurologic symptoms such as paresthesias, adverse reproductive outcomes, and urinary tract disorders.^{106,224,226,228–234} Work practices such as inadequate breaks increase potential hazards, and with the workforce consisting predominantly of women, the presence of reproductive hazards is a special concern.

Other features of the United States–Mexico border aggravate the effects of these exposures. Many of the workers are migrants from elsewhere in Mexico, who arrive without financial resources, education, job skills, or experience. Housing and health services are inadequate, general environmental health risks such as water contamination are prevalent,^{235,236} and there is little job security due to the constant influx of new arrivals in search of work. Hence, while stress levels are high among *maquiladora* employees, they are also high among other workers in the same locations,²²⁹ suggesting that general features of the economic and social environment affect people both in and out of the foreign facilities. Environmental enforcement has never been rigorous in the region, and given the impulse to retain plants in the face of global competition, emissions control, waste management, and other environmental practices are often suboptimal. This combination of forces has made progress in environmental and occupational health extremely difficult to achieve.

Gender issues in the maquiladora industry deserve special mention. Much of the workforce consists of young women. While this represents newfound economic opportunity and independence for many women, it also offers opportunities for exploitation. There is evidence of wage discrimination, assignment to the most tedious tasks, and less labor protection and social security, especially in situations where women need flexibility in work hours because of responsibilities at home.²³⁷ There is also evidence of gender disparities in access to the most desirable jobs. While men hold 74% of technical positions and 64% of administrative positions, they account for fewer than 50% of production line jobs.²²⁴

► TEXACO AND THE ECUADORIAN INDIANS

Ecuador's vast jungle basin, known as the "Oriente," consists of more than 100,000 km² of tropical rainforest at the headwaters of the Amazon River. The region is home to some 500,000 people, including eight indigenous peoples such as the Cofán, Secoya, Siona, Huarorani, and Quichua. The region has historically been poor, with few health services and with high levels of malnutrition, infant mortality, and infectious disease. Traditional lifestyles relied on hunting, fishing, and agriculture.²³⁸

Oil deposits were discovered in the Oriente in the 1960s, and a consortium of oil companies, led by Texaco (later ChevronTexaco) and including Gulf and the national oil company CEPE (now known as Petroecuador), commenced operations. These included exploration, drilling and processing of oil, and construction of a 498-mile pipeline, the SOTE (Sistema Oleoducto TransEcuatoriano), across the Andes to the Pacific coast. These operations have greatly reshaped the region, creating an extensive network of roads, pipelines, and oil facilities. More than two billion barrels of crude oil have been extracted from the Ecuadorian Amazon.^{238,239,240}

According to local people who eventually sued ChevronTexaco, considerable environmental damage occurred. Road construction in the jungles resulted in deforestation of about 2.5 million acres.¹⁸⁹ At peak operation, ChevronTexaco was releasing some 4.3 million gallons per day of toxic wastewater directly into waterways and pits rather than reinjecting it into subsoil formations or treating it.¹⁸⁹ Contaminants included hydrocarbons such as benzene and polycyclic

aromatic hydrocarbons, metals such as mercury and arsenic, and salts. Oil spills from the pipeline were common; more than 60 major ruptures have been documented since 1972, discharging 614,000 barrels of oil—a quantity more than twice as large as the Exxon Valdez spill, and more than seven times the cumulative spillage from the 800-mile trans-Alaskan pipeline, which came on line in 1977 and carries more than twice the flow of oil (Knudson, 2003). Over 600 open, unlined sludge pits were abandoned.¹⁸⁹ Extensive contamination of streams and rivers followed—the same streams and rivers used for drinking, cooking, and bathing.²⁴¹ Burning of gas flares at hundreds of well sites released organic pollutants, particulate matter, and carbon dioxide into the air.

ChevronTexaco, in responding to lawsuits, counters that its “employees work hard to ensure that our operations around the world are managed in a safe and environmentally sound manner;” details of the company’s position can be found at <http://www.texaco.com/sitelets/ecuador/en/>.

Social changes have also occurred. Internal migration occurred as indigenous people relocated in search of employment and/or when forced out of damaged local environments. Oil cities arose and became known as settings of violence, prostitution, and alcohol abuse. Some ethnic groups, such as the Cofán, declined precipitously, while at least one isolated indigenous group, the Tetetes of Lago Agrio, apparently disappeared, a casualty of destabilized social circumstances and disease.

Several studies attempted to quantify the impact of the oil extraction and associated environmental damage on the health of local populations. These studies were distinguished by their “popular epidemiology” framework,²³⁸ an approach that helped orient the research to local needs and priorities, and overcome some barriers to conventional epidemiologic research. The results suggested lower levels of some cancers among indigenous people than among non-indigenous people.^{242,243} However, there were possible associations between proximity to oil fields and several cancer sites in adults^{244,245} and leukemia in children.²⁴⁶ Residents near contaminated streams was also associated with nonspecific symptoms such as eye and throat irritation and fatigue,²⁴⁷ and with spontaneous abortions (but not stillbirths).²⁴⁸

An interesting feature of the Ecuadoran situation is the use of litigation, beginning in U.S. courts and moving to Ecuadoran courts when the U.S. courts declined jurisdiction. This may signal a global trend. The efficacy of this approach, and its impact on environmental health, remains to be seen.

The Health of Hired Farmworkers

Don Villarejo • Marc B. Schenker

► OVERVIEW

For several decades, migrant and seasonally employed, hired farm laborers were identified as a “special population” in need of programs of government and/or philanthropic assistance. Thus, Migrant Health, Migrant Education, Migrant Job-Training, Migrant Legal Services, and, more recently, Migrant Head Start, were developed to respond to the needs of workers who often traveled great distances, often with their entire families, in search of farm work. In the first years of these programs, only U.S.-born “migrant” workers were eligible to be served. Subsequently, it was recognized that those workers who were employed on a “seasonal” basis in agriculture had very similar characteristics and needs, and the requirement of being U.S.-born was dropped from eligibility standards.

The composition of the hired farm labor force has dramatically changed since those early years of the “migrant” programs. For this reason, it is important to be clear about the population of interest in this chapter. The term “farmworker” can refer to three groups: farmers, unpaid family workers (usually members of the farm family), and hired workers. This paper is concerned with *hired farmworkers*, defined as persons who are employed on a farm to perform tasks that directly result in the production of an agricultural commodity intended for sale. Postharvest processing tasks are excluded from this definition. Note also that the nature of the employer is not specified in this definition. Individuals performing farm tasks might be working for a farmer, labor contractor, packer/shipper, or another type of labor market intermediary.

There is a marked absence of reliable data on the number of such workers, either today or at any time in the past. Thus, epidemiology in this population is severely restricted by the lack of reliable denominator data. In 1992, the authoritative federal Commission on Agricultural Workers (CAW) estimated the number of persons employed as hired farm laborers in the United States at 2.5 million individuals.¹ Most jobs filled by farm laborers are short term so that the corresponding employment figure (sometimes described as full-time-equivalents or FTE), equal to the annual average of monthly employment, is much lower, perhaps numerically half or less of the CAW estimate. In contrast, the self-employment of farmers and unpaid family members is estimated to be about 2.0 million.² Thus, directly hired farmworker and agricultural service (contract) worker employment was an estimated 37% of the national total of farm employment in 1992.

The relative importance of hired farm laborers in U.S. agriculture has increased in recent years. For example, in California, where virtually all hired farmworker employment and/or payroll is reported to both the state Labor and Employment Agency, and to the Workers Compensation Insurance Rating Bureau, the proportion of the total amount of all work on farms that was performed by farmers and unpaid family members dropped from 40% in 1950 to just 15% in 2001.³ Correspondingly, the share performed by hired workers increased from 60% to 85% of the total.³

As a result of this trend and other factors (see below), the reported employment of directly hired and contract farm laborers in California increased significantly in recent years.⁴ There is also evidence that a smaller, but nevertheless significant, increase of hired farm laborer employment during the past several decades occurred in some other important farm states, such as Oregon and Washington, but geographic variation exists in the United States.⁵

Three major factors account for the greater utilization of hired workers in U.S. agriculture. First, there has been a substantial growth in the importance of labor-intensive crops in the nation’s agriculture. For over 20 years, there has been a steady increase in the proportion of U.S. crop farm cash receipts derived from the sale of fruits and nuts, vegetables, and nursery and greenhouse products (F-V-N crops). As reported by the Census of Agriculture, in 1974, F-V-N commodities were just over one-sixth (17.3%) of farm cash receipts from crop sales.⁶ By 2002, the F-V-N share had increased to more than two-fifths (43.3%) of the total for all crops.⁷ U.S. farmers now receive more than twice as much from the sale of nursery and greenhouse crops as from wheat production (\$14.7 billion vs. \$5.9 billion in 2002).⁷

Since gross agricultural cash receipts may be reduced when production is high, owing to lower commodity prices when increases of supply exceed demand, an independent, and possibly more accurate, measure of the growth in fruit and vegetable production is the change of the physical output, measured in tons. U.S. fruit and vegetable production, in tons harvested, nearly doubled (+95%) between the population census years 1970 and 2000.⁸ Since population growth was about 38% during this period,⁹ increased per capita consumption of some fresh commodities and increased exports of many commodities accounted for more than half of the growth of production. Greater utilization of some other commodities, such as wine grapes or processing tomatoes, accounts for the remainder of the growth of production.

Second, sharply increased farm size is associated with supplementing farmer and family labor with hired labor. Among fruit and vegetable producers, the increase of size concentration is particularly dramatic. Between 1974 and 1992, the number of U.S. farms reporting 500 or more acres of harvested vegetables increased from 919 to 1416, and the corresponding aggregate acreage of vegetables harvested went from 1,145,703 to 2,028,928. For land in orchards, between 1974 and 2002, the number of U.S. farms with at least 500 acres of trees and/or vines grew from 972 to 1522, and the corresponding aggregate acres in orchards increased from 1,334,105 to 2,152,941.

Third, the steady, long-term decline in farming as an occupation has led to a greater reliance on hired labor to supplement or replace family labor. This is reflected in Census of Agriculture reports on workers directly employed for 150 days or more by U.S. farms (these longer-term hired laborers are described as “regular” workers by some economists). In 1974, nearly one in 10 (9.6%) U.S. farms reported they employed at least some of their laborers for this duration, and the

TABLE 43-1. FARM EMPLOYMENT, CALIFORNIA, 2003, BY CATEGORY OF EMPLOYMENT, USDA

<i>Category of Employment</i>	<i>January</i>	<i>April</i>	<i>July</i>	<i>October</i>
Direct-hire workers, 150 days or more	190,000	185,000	203,000	179,000
Direct-hire workers, less than 150 days	40,000	35,000	32,000	51,000
Agricultural service (contract) workers	75,000	67,000	125,000	118,000
Total	305,000	287,000	360,000	348,000

aggregate total was 712,715 such workers.⁶ By 2002, the proportion of farms employing “regular” hired workers had increased, and the total of such workers had grown to 927,708.¹⁰ Thus, in 28 years, the share of U.S. farms directly hiring workers for at least 150 days had increased, and the number of such workers climbed by 30%.

Interestingly, the increase in the hiring of “regular” workers by some farms has not been associated with increased direct hiring of short-term workers on U.S. farms. Between 1974 and 2002, the aggregate number of workers reportedly hired for less than 150 days fell sharply from 4,502,517 to 2,108,762. This figure is the aggregate of individual reports by farm operators of the number of persons hired for less than 150 days, and it is likely that a hired laborer could work on two or more farms and be counted multiple times. For this reason, this figure is often referred to as the *number of jobs* by economists, and should not be regarded as a count of individuals.

At the same time, there has been a very sharp increase in the use of labor contractors and other labor market intermediaries, especially from the mid-1980s to the present. Between 1974 and 2002, the number of U.S. farms reportedly utilizing labor contractors nearly doubled, from 119,385 to 228,692. Nominal contract labor expenses by farm operators grew in the same period by a phenomenal 575%, from roughly \$512 million to \$3.5 billion.

The greatest growth in labor contractor utilization in this period was in those states with a very high proportion of immigrants among the farm labor force, such as Arizona, Florida, and California. There is some evidence that the increased reliance on labor contractors is associated with the enactment of the Immigration Reform and Control Act of 1986, a law that imposed fines and possible imprisonment on employers who “knowingly hired” unauthorized immigrants; described as the *employer sanctions* provision of the law. For the very first time, every U.S. employer was required to demand that every employee, and prospective hire, document his or her eligibility for employment in the United States. A government-issued reporting form, Form I-9, requires both the worker and the employer to attest as to the verification of employment eligibility. This shift to labor market intermediaries may have significant health implications because of the insulation of farm operators from the farmworkers working on their farms.

Data from the U.S. Department of Agriculture’s Quarterly Survey of Agricultural Labor demonstrate that direct-hire short-term employees (<150 days) are far fewer in number than those directly hired and working 150 days or more, even during periods of peak employment (Table 43-1).¹¹ In contrast, contract workers are far more numerous than direct-hire short-term employees during all 4 months, and greatly exceed their number at peak periods.

During 1985, the first year for which strictly comparable data were reported, the number of direct-hire short-term workers was greater than the number of contract workers for all 4 survey months, and was twice as numerous in 2 of those 4 months. Thus, by 2003, the situation had been completely reversed.¹²

It is also of significance that there are very substantial regional differences in all of these developments. The Pacific and Northwest Region has especially benefited from the increased importance of fruit, vegetable, and nursery crop production. While Midwestern and Northeastern states have experienced substantial economic stress in the farm sector, the western states have enjoyed a boom in both production and net returns. For example, of the nation’s net increase of land in orchards of 1,282,318 acres between 1974 and 2002, the

Pacific and Northwest states alone accounted for 1,271,516 acres. In the case of harvested vegetable acres, the net increase on all U.S. farms was 628,976 acres, while for the Pacific and Northwest states it was 546,934 acres. Thus, the vast majority of the economic value of increased production of both of these types of crops was captured by the western states. Correspondingly, the employment of hired farmworkers increased most markedly in that region.

Less well appreciated has been the remarkable increase in dairy production in the western states during this same period. California is now the nation’s leader in fluid milk production and will surpass Wisconsin in cheese output within the next several years. Overall, the Pacific and Northwest states have experienced a doubling of the number of milk cows from 1974 to 2002; from 1,246,533 in 1974 to 2,590,308 in 2002. In the same states and period, the number of dairy farms fell from 8821 to 4813; correspondingly, the average number of milk cows per dairy farm shot up from 141 to 538 and continues to rise. Many more “milkers” have been hired to assist with the continuous tasks of caring for and milking the animals.

► U.S.-HIRED FARMWORKERS—CHARACTERISTICS

The U.S. Department of Labor conducts a large-scale, on-going national survey of workers employed in seasonal agricultural crop services, the National Agricultural Workers Survey (NAWS). Hired livestock laborers and certain other types of hired farmworkers are excluded from the survey. Begun in 1988 to assess the effects of the Immigration Reform and Control Act on the supply and characteristics of U.S. agricultural workers, the NAWS provides a detailed body of knowledge about this population, including demographic information, patterns of employment, working conditions, use of social services, and, beginning in 1999, information about health-care access.

The most recent published report of findings from the NAWS is based on 6472 personal interviews conducted between October 1, 2000, and September 30, 2002, in 80 or more randomly selected counties throughout the United States.¹³ The NAWS finds that the characteristic hired crop farm laborer is a young, low-income, foreign-born (mostly Mexican) male with low educational attainment who has only recently migrated to the United States (Table 43-2). Most U.S.-hired farmworkers are characterized by low socioeconomic

TABLE 43-2. CHARACTERISTICS OF U.S.-HIRED CROP FARMWORKERS, 2000–02, NAWS, N = 6,472

<i>Characteristics</i>	<i>Finding</i>	<i>Trend from 1990–92</i>
Age (median)	31 years	Unchanged
Male	79%	Increasing
Foreign-born	78%	Increasing
Educational attainment (median)	7 years	Unchanged
Undocumented immigrant	53%	Increasing
Household income (median)	\$10,000–\$12,499	Unchanged
Yearly farm work (median)	34 weeks	Increasing
Indigenous migrant	N/A	Increasing

status (SES), a characteristic that has long been associated with adverse health outcomes.

One surprising finding from the NAWS is that 16% of all workers interviewed were “newcomers,” having been in the United States for less than 1 year at the time of the interview. All but a handful of these were young men, and over 90% of them told government interviewers that they had entered the country without immigration authorization.

When asked about their ethnicity, the vast majority of all NAWS participants (83%) self-identified as Latino or Hispanic. Thirty percent live in poverty, as measured by their total household income in the year prior to the interview and using Federal poverty income standards for the corresponding household size and period.

An overriding fact about the participants in the NAWS survey is that more than half (53%) told government interviewers that they lacked immigration authority to work in the United States, that is, were undocumented. Apart from legal issues associated with their employment, the immigration status of such workers, by itself, creates enormous barriers in access to services and in their willingness to report abuses and other misconduct to appropriate authorities. In the post-September 11, 2001, period of border security anxiety, few undocumented workers choose to place themselves at risk of deportation by seeking out government agencies or service providers.

One of the more-difficult-to-measure characteristics of this population is the recent increase of the number of indigenous migrants from southern Mexico and Central America. Mayan, Mixtec, Zapotec, Triqui, and other native peoples are coming to the United States in very large numbers seeking employment. There is evidence that these recent arrivals, many of whom do not speak Spanish or English, relying instead on their own indigenous language, are displacing traditional *mestizo* (mixed race) immigrants in agricultural jobs in some regions of the United States.¹⁴ The NAWS does not report indigenous ethnicity but does comment that the share of foreign-born workers coming from the southern Mexican states of Guerrero, Oaxaca, Chiapas, Puebla, Morelos, and Veracruz doubled to 19% as compared with 1993–94 NAWS findings. Most indigenous migrants originate from these states.

An important finding from the NAWS is that roughly half of all crop workers interviewed said they could not read or speak English “at all” (53% and 44%, respectively). A substantial additional fraction said they could read or speak English “a little” (20% and 26%, respectively). This finding has important implications in all aspects of their employment and access to services. Cultural and linguistic barriers are substantial, and are increasing with the arrival of large numbers of indigenous migrants for whom Spanish is a second language.

Nearly three-quarters (72%) of crop farmworkers told NAWS interviewers that they had only one farm employer in the previous year. Those working for a labor contractor may actually perform farm tasks on many farms, but their formal employer is just the contractor. The NAWS found that the share of all crop farmworkers who were employed by a labor contractor was 21%, a sharp increase over the 11% who reported to NAWS in federal fiscal year (FY) 1989 that they were so employed. This finding of increased utilization of contractors in recent years is consistent with a wide range of other data on farm labor employment.

► U.S.-HIRED FARMWORKERS—ORGANIZATIONS

Historically, labor unions have proved to be extremely difficult to organize among hired farmworkers. Migrant status, seasonal employment, high turnover within the labor force, and immigration status have usually been cited as leading factors contributing to this difficulty. But some successes since the early 1960s, notably by the United Farmworkers Union, raised the hope that this historic difficulty would, at last, be overcome. However, those early successes have proved short-lived. At the present time, there are only five unions known to have active labor agreements with farm employers.

The total number of farm laborers under active union contract is about 28,000, or a little over 1% of the estimated national total of persons eligible.¹⁵

A less well-known aspect of farm labor organizing has been the growth of organizations based on home village networks, which are of particular importance among the indigenous migrants from southern Mexico and Central America.¹⁵ This binational networking provides both support systems for recent immigrants as well as leadership to address common problems.

► U.S.-HIRED FARMWORKERS—HEALTH STATUS

Relatively little is known about the health status of U.S.-hired farmworkers. There have been no national, cross-sectional assessments of the health status of this population that included a reasonably comprehensive physical examination, and few studies have been done in localized areas.¹⁶ Many of the hazards of agricultural work are common to everyone exposed to agricultural work hazards. However, studies of health among farmer owners and managers, which in themselves have been fewer than for other industrial sectors, may not reflect the status of farmworkers because of differences in age, ethnicity, economic status, work conditions, family structure, and health-related behaviors.

We have focused this chapter on research that has specifically addressed the health of hired farmworkers. Studies of mortality and morbidity of this population are hampered by the fact that an unknown, but presumably large, number of Mexican-born workers seek treatment in Mexico or return to their home community after an injury or a period of work in the United States. The magnitude of this movement and its effect on mortality rates is unknown.

Mortality

An early study of mortality in California analyzed all deaths from 1979–1981.¹⁷ Deaths from falls and machinery accidents (SMR = 380) and from other accidents (SMR = 310) were significantly elevated among farmworkers, as they are among farmers. Deaths from chronic obstructive pulmonary disease were also significantly elevated in this population (SMR = 147). The overall mortality of farmworkers was also significantly elevated (SMR = 166, 95% CI, 160–172).

A more recent report summarized proportionate mortality from death certificates of 26,148 farmworkers in 24 states for 1984–1993.¹⁸ Elevated proportionate mortality was found for injuries, tuberculosis, mental disorders, cerebrovascular disease, respiratory diseases, ulcers, hypertension, and cirrhosis. Reduced mortality was found from other infectious diseases, endocrine disorders, nervous system diseases, pneumoconiosis, arteriosclerotic heart disease, and all cancers combined. The increased mortality from injuries and respiratory disease is also seen among farm owners and managers, and reflects occupational hazards of farm work. The increase in tuberculosis mortality reflects higher endemic rates in countries sending farmworkers to the United States, lack of adequate medical care, and housing conditions among migrant and seasonal farmworkers.

Several studies have identified an increased risk of tuberculosis among hired farmworkers.^{19,20} The Centers for Disease Control and Prevention estimates that 1% of tuberculosis cases in the United States are among migrant farmworkers. Risk factors include being male, foreign-born or Hispanic, and having a history of alcohol abuse or homelessness.²⁰

Morbidity

The California Agricultural Workers Health Survey (CAWHS) was a large-scale, population-based assessment of the health of hired farmworkers conducted in 1999.²¹ CAWHS was a household survey based on selection in agricultural regions of California. A total of 970

participants (83% participation rate) completed a lengthy, structured interview, and two-thirds of these (652) successfully completed the physical examination and a private risk behavior interview.

The physical examination findings of the CAWHS reveal a high prevalence of adverse chronic health outcomes. Among male participants in all but the youngest age group, obesity (body mass index >30) was found at a significantly higher rate than in the general U.S. population (Fig. 43-1).²² The percentage of male workers who exhibited healthful weight was low in all age groups, and was just 4% in the age group 45–54 (which compares with a corresponding figure of 29% among U.S. males of the same age group).²² Female CAWHS participants also showed a significantly higher prevalence of obesity.

The prevalence of high serum cholesterol and high blood pressure among CAWHS participants was also elevated. Nearly one-fifth (18%) of male workers exhibited at least two of the three risk factors for chronic disease (obesity, high serum cholesterol, high blood pressure). Anemia was also common among both men and women.

The CAWHS survey and other studies of hired farmworkers show elevated rates of dental disease.²³ This is consistent with the lack of preventive health care in this population, most significantly due to the economic barriers to receiving nonemergency health services.

Infectious Diseases

In addition to tuberculosis, other infectious diseases are increased in the hired farmworker population. Some of these infections reflect diseases endemic to sending communities or countries that are carried to the United States. Reports of intestinal parasites²⁴ and malaria²⁵ reflect diseases from sending populations in Latin America. A recent report found that the seroprevalences of the tapeworm, *Taenia solium cysticercosis* (1.8%) and *T. solium taeniasis* (1.1%) were highest among hired farmworkers in a sample of Hispanic residents of Ventura County, California. The seroprevalences were only seen in adults, and prevalences were similar to the prevalences in Latin American countries where the disease is endemic.²⁶

HIV and AIDS are another concern because many hired farmworkers engage in high-risk behaviors, particularly solo males. A few local or statewide studies report a high prevalence of syphilis in this population.²⁷ The CAWHS survey documented elevated rates of many high-risk behaviors among men and women associated with STDs.²¹ These included sex with intravenous (IV) drug users, sex with prostitutes, and low frequency of condom use.

Many respiratory infections have been associated with agricultural work.²⁸ *Mycobacterium tuberculosis* may result from person to person transmission, or *M. bovis* infection may occur from infected cattle. Numerous respiratory infections, can result from exposure to

infected animals including bacterial agents (e.g., Anthrax, Brucellosis, Leptospirosis, psittacosis, Q fever, and Tularemia), viruses (e.g., Equine morbillivirus, Swine influenza, Avian influenza), and parasites (e.g., Ascariasis, Echinococcosis), can result from exposure to infected animals. Exposure to soil and its contaminants in agriculture may be a source of fungal infections such as Coccidiomycosis, Histoplasmosis, and Blastomycosis. There are few epidemiologic studies addressing the risk of infection among farmworkers, but these agricultural respiratory infections are likely to be increased in the farmworker population because of their work in the farm environment with potential for exposure.

Respiratory Disease

There are numerous studies documenting increased respiratory disease among farmers and farmworkers.²⁹ Respiratory diseases occur in agriculture from exposure to a wide range of toxicants including organic and inorganic dusts, allergens, microorganisms, mycotoxins, decomposition and silo gases, pesticides, fertilizers, fuel, and welding fumes. Diseases include respiratory infections, discussed above, as well as airway disorders, interstitial lung disease, and acute toxic injuries. A discussion of this topic is beyond the space available. However, recent research has begun to address these diseases among farmworker populations. Exposures occurring in western and southern agricultural settings have been of particular interest because of the labor-intensive crops harvested in that region, employing large numbers of farmworkers. Very high concentrations of dust exposure occur, independently associated with an increase in chronic respiratory symptoms (cough, phlegm, wheezing) and with increased airflow obstruction.^{30,31} Organic dust may be associated with occupational asthma from farming exposures, while inorganic dusts can result in both airway obstruction and interstitial disease.^{32,33}

Injuries and Musculoskeletal Disorders

Agriculture ranks with mining and construction as one of the three industries with the highest rates of fatal occupational injuries.^{34,35} The annual rate of fatal occupational injuries in agriculture is over five times the rate in the private sector, and there has been only a slight decline in the rate over the past decade.³⁵ The rate of fatal occupational injuries is slightly lower among Hispanic than non-Hispanic agriculture workers (20.2 versus 15.8 fatalities per 100,000 employed workers), but is significantly elevated in both ethnic groups. Risk of fatal injuries increases markedly for workers over 55 years of age, and the leading causes of fatal injuries is farm tractors. Motor vehicles are a particular hazard for farmworkers, including unsafe farm transportation vehicles.

Nonfatal occupational injury rates among farmworkers are high—estimated between ages of 45–59 years. There are an estimated 140,000 non-fatal disabling injuries in agriculture annually, although the exact number or the percentage occurring in farmworkers is unknown.³⁶ Risk of agricultural injuries is approximately 5–10 per 100 persons per year, but is higher in certain risk groups. Falls, sprains, machinery, and animals are among the most common causes. The most recent NAWs found that 24% of farmworkers surveyed reported at least one musculoskeletal problem in the past 12 months.¹³ The prevalence of musculoskeletal conditions has increased over the past decade, and also increased with increased years working in agriculture.

A significant missing component of surveys of foreign-born U.S.-hired farmworkers are those who have permanently left the United States and returned to their home communities. Mines and colleagues sought to find hired farmworkers who had permanently returned to Mexico after concluding a lengthy period of employment in the United States. The Bi-National Health Survey (BHS) was based on a census of seven villages in Zacatecas, and sought both returnees as well as those who were still working on U.S. farms.³⁷ One of the important findings of the BHS is the high prevalence (42%) of persistent pain which participants invariably attributed to

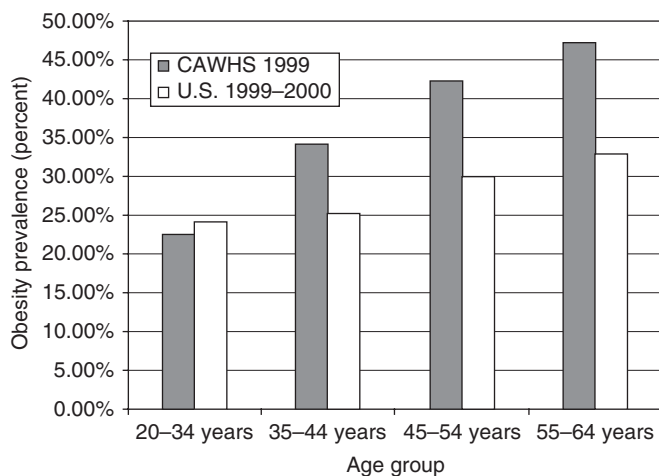

Figure 43-1. Obesity, male hired farm workers, 1999, California, CAWHS, N = 415.

their workplace exposures while working on U.S. farms. Half of these returnees preferred the Mexican health-care system to the U.S. system. Those too ill or injured to continue working decided to return to their home villages where their families provide care.

Adverse Reproductive Outcomes

Maternal health-care services to migrant farmworker women regarding prenatal care, weight gain during pregnancy, and birth outcomes have been assessed. It was found that national goals were not being met.³⁸ Linguistic and cultural barriers have proven to be formidable, particularly among indigenous migrants who do not speak English or Spanish and whose native language does not have a written form.³⁹ Counteracting this effect is the *Hispanic Epidemiology Paradox*, described below.

► PESTICIDE TOXICITY

It has been more than a decade since the Worker Protection Standard (WPS) regulations were implemented requiring additional protection for U.S.-hired farmworkers from the hazards of workplace exposure to agricultural pesticides. In California, the Department of Pesticide Regulation (DPR) sought to assess the effects of these important new workplace safety standards by conducting in-field inspections of compliance. This internal DPR review found widespread lack of full compliance: half of pesticide handler firms were out of compliance and just under three-fourths of field worker employers (farm operators and labor contractors) had not fully complied with WPS standards. There are no comparable compliance surveys on a national level. A recent report on WPS compliance among 267 migrant farm laborer families whose usual place of residence is South Texas found that about half (46%) had received pesticide safety training as required by WPS.⁴⁰

There are no national surveillance data on pesticide illnesses, and no estimates of risk by farmer versus farmworker status. The most comprehensive surveillance system is in California, where pesticide illnesses are a reportable disease, and all reported cases are investigated by the County Agricultural Commissioners. In California there are an estimated 0.024 fatalities and 1.38 hospitalizations per 100,000 person-years due to pesticides. Most fatalities are nonoccupational (e.g., due to intentional ingestion).⁴¹ Excluding antimicrobials reduces these rates to 0.019 deaths and 0.92 hospitalizations per 100,000 person-years. These rates are similar to other estimates for the United States.^{42,43,44}

The chronic effects of pesticide exposure among farmworkers are largely unknown. Concerns have been raised about cancer, adverse reproductive outcomes, and neurologic disorders, but hard data are largely lacking. The Agricultural Health Study is addressing chronic effects of agrochemical exposures, but the study population is composed of farmers, spouses, and pesticide applicators, and not farmworkers.⁴⁵

► CANCER

Epidemiologic and toxicologic data suggest that chronic low-level exposure to pesticides may be associated with an increased risk of some cancers.⁴⁶ As noted, there are little data on specific risks among farmworkers because of difficulties studying this population. One recent investigation used California Cancer Registry data for a case-control study of breast cancer among farm labor union members.⁴⁷ Mills and colleagues found an increased association of breast cancer prevalence among hired farmworker women who likely had greater exposure to certain specific agricultural chemicals. Several studies have observed an increased risk of prostate cancer among farming populations.⁴⁶ A cancer registry-based study of incident prostate cancers among Hispanic farmworkers found evidence of

increased prostate cancer risk associated with high levels of exposure to a variety of agricultural pesticides.⁴⁸

A study of mammography screening among Hispanic women living in Lower Rio Grande Valley farmworker communities found that lack of health insurance was the primary cause of not having a mammogram among women over 50.⁴⁹ This is consistent with the lack of preventive health care among farmworkers, directly attributable to lower socioeconomic status.

Cancer risk among Hispanic farmworkers due to occupational exposures should be considered in the context of overall cancer risk in this population. In general, Hispanic immigrants have lower overall cancer morbidity and mortality, particularly for smoking-related malignancies. However, cervical cancer rates are higher among the Hispanic than non-Hispanic population.⁵⁰

► RISK BEHAVIORS, ACCULTURATION

Acculturation is the phenomena that results when groups of individuals having different cultures come into continuous first-hand contact with subsequent changes in the original cultural patterns of either or both groups. Among immigrant farmworkers in the United States, several health-related behavioral changes have been associated with increased residence duration in the United States, and with specific acculturation scales.⁵¹ Studies of Hispanic immigrant populations, including farmworkers, show that several adverse health behaviors are associated with acculturation, including cigarette smoking, alcohol use, illegal drug use, and unhealthy diet.^{52,53} Some of these acculturation-associated changes have been observed in women and not men, but more research is needed to better characterize this phenomenon and to focus preventive efforts. It is interesting that recent immigrants are more likely to do farm work when their health behavior profile may be better. With increased duration of residence in the United States, some adverse behaviors increase as the likelihood of doing farm work decreases.

The CAWHS survey also found a relationship between obesity prevalence and the duration of U.S. residence for foreign-born hired farmworkers.²¹ The prevalence of obesity in each of three age groups was greater among those who had been U.S. residents for 15 years or longer as compared with those who had been in the country less than 15 years.

A study of mental health among Mexican migrant farmworkers in California found lifetime prevalences of any psychiatric disorder among men of 26.7% and among women of 16.8%.⁵⁴ Lifetime prevalence for any psychiatric disorder was lower among migrants than for Mexican-Americans or for the U.S. population, suggesting that acculturation may increase the likelihood of psychiatric disorders.

The *Hispanic epidemiologic paradox* refers to the observation that immigrant Hispanics have many health outcomes similar or better than the non-Hispanic population despite lower socioeconomic status.⁵⁵ Thus, many health indicators among Hispanics such as infant mortality, life-expectancy, mortality from cardiovascular diseases, and mortality from major types of cancer are better than would be expected based on socioeconomic status. However, some of these outcomes worsen with more time residing in the United States. For example, adverse pregnancy outcomes (preterm, low birthweight) double among women who have lived in the United States for more than 5 years.⁵⁶ While there have been challenges to the concept that a paradox exists, the explanation for the observations is likely to be multifactorial and relate in part to behavioral changes occurring with increased residence time in the United States and associated changes in health behaviors (acculturation).

A population at particular risk of adverse outcomes are the solo male farmworkers, many of whom migrate for work. This population is at particular risk for substance abuse and STDs. In the CAWHS study, more than one-fourth (28%) of male workers routinely engaged in binge drinking (average five or more drinks per episode) and nearly one-fourth (23%) reported having used drugs at some point in their lives (Table 43-3).

TABLE 43-3. RISK BEHAVIORS, MALE HIRED FARMWORKERS, 1999, CALIFORNIA, CAWHS, N = 413

Risk Behavior	Finding
Consume alcohol	64%
Drinks per episode—median	4
Average five or more drinks per episode	28%
Drinks per month—median	20
Alcohol use while at farm job	7%
Drug use—ever	23%
Threatened with violence at work	2%

► HOUSING CONDITIONS

The contribution of poor housing conditions to adverse health outcomes among farmworkers is unknown, but is likely to be significant. Crowded and substandard housing is likely to increase the risk of diseases due to aerosol transmission and poor sanitation conditions. In the CAWHS study, about 30% of participants were found to reside in unconventional dwellings such as sheds, garages, and temporary structures—even under trees in open fields or orchards.

Recent studies have documented pesticide exposures inside the housing of farmworkers with small children.^{57–60} Exposures may be from agricultural applications or from residential pesticides. In a study of 41 homes of farmworkers with children <7 years old in North Carolina and Virginia, agricultural, residential, or both pesticides were found in 95% of homes.⁵⁷

A study of risk behaviors for pesticide exposure among pregnant women living in farmworker households found that between 25% and 60% of women demonstrated risky behaviors related to handwashing, bathing, protective clothing, house cleaning, and other factors that could increase indoor pesticide exposures.⁶¹

► U.S.-HIRED FARMWORKERS—ACCESS TO CARE

Most hired farmworkers lack any form of health insurance. Among NAWS participants, only 8% said they have health insurance provided by their employer, and only 15% said they or members of their immediate family used Medicaid in the year prior to the interview, despite the fact that a very large share meets the income-eligibility requirements.

In the CAWHS sample, about one-ninth of the participants (11%) said they had employer-provided health insurance, but a larger share, one-sixth (16%), said their employer offered this benefit. Fewer workers had the coverage than were offered the opportunity because they said they could not afford to pay the share of the premium that their employer required.

Lacking any form of health insurance, most hired farmworkers report paying “out-of-pocket” for their most recent health-care visit.⁶² Faced with formidable financial barriers in seeking health-care services, some workers prefer to rely on home remedies, or return to Mexico when care is needed.

Importantly, when asked about their most recent health-care visit, male undocumented immigrants in the CAWHS sample were far more likely to say they had never gone to a doctor or clinic as compared with those who were documented or citizens.⁶² However, among females there was no significant difference regarding this measure of access to health-care services between undocumented workers and the other groups.⁶² The reason is that for many years, California has provided “emergency Medical” services for undocumented pregnant women, and extends the care from prenatal examinations through 4 months after giving birth. This additional form of coverage has clearly been of great benefit to undocumented women and their newly born children.

The available evidence indicates that most hired farmworkers seek medical care only when it becomes absolutely necessary. Among male participants in the CAWHS, nearly one-third (31.8%) said they had never had a doctor or clinic visit, half (49.5%) said they had never been to a dentist, and more than two-thirds had never had an eye-care visit.

There are only a few reports regarding health-care services for the children of hired farmworkers. Findings include evidence of late immunization,⁶³ child abuse and neglect,⁶⁴ iron deficiency,⁶⁵ psychiatric disorders,⁶⁶ and large numbers of children with untreated dental caries.⁶⁷ A study of nearly all of the children in a predominately farmworker community in California found that 70% of the children required a medical referral.⁶⁸

► SUMMARY

The health of hired farmworkers in this country is affected by several factors, each having an influence on acute and chronic conditions in the population. A major impact is the poverty affecting this group. This has its impact in diverse ways including lack of access to health care; decrease in preventive health services (e.g., dental, vision care, vaccinations), and poor housing conditions. Interestingly, the *Hispanic epidemiologic paradox* counteracts some of the expected effects of decreased socioeconomic effects in the population, with many health indicators being similar to those of the white population. Some health outcomes such as infectious disease, obesity, and diabetes reflect the lower socioeconomic status of the population.

A second major influence is the hazards of agricultural work. Agricultural hazards cover a broad spectrum that includes physical stresses (e.g., trauma, heat, cold), infectious agents, chemical hazards, psychosocial stresses, and the effects of repetitive trauma. The effects of agricultural work on numerous health outcomes have been documented, although studies among hired farmworkers have been done much less frequently. Data on this population is further limited by the lack of effective surveillance systems, a paucity of studies on chronic health effects, and the mobility of the population. Health status is further limited by inadequate medical care, workers' compensation for occupational injuries, and lack of legal rights due to illegal immigrant status.

Finally, behavioral and other changes associated with acculturation, disruption of families, and migration have an important impact on the health of hired farmworkers. Many of the behavioral changes associated with acculturation, particularly among women, are reflected in worsening of health status after longer residence in the United States.

Improvement in the health of hired farmworkers will require attention to all of these factors. Many of the occupational health hazards of farming also affect farmers and farm family members, but specific attention to the health status of hired farmworkers is needed because of the unique conditions under which they labor.

Women Workers

Karen Messing

In the United States, women are 46% of the paid workforce¹ and have one-third of the compensated occupational health and safety problems, resulting in 81% of claims on a per hour basis.² Although employed women live longer than unemployed women and housewives,³ risk factors present in some jobs may adversely affect women's health. Action to improve women's occupational health has been slowed by a notion that women's jobs are safe² and that any health problems identified among women workers can be attributed to unfit for the job, hormonal factors, or unnecessary complaining.

In the past, little research in occupational health has concerned women.^{4,5} However, the rise in the number of women in the labor force has sensitized public health practitioners, workers, and scientists to the necessity to include women's concerns in their occupational health activities.⁶ Recently, various institutions and governments have become interested in women's occupational health, and the amount of research specifically on women is growing.^{7,8}

Methods for examining women's occupational health are being developed, and gender comparisons are becoming more common.^{9,10} However, as interest grows, it is also necessary to consider the implications of using sex (biological differences) or gender (socially based differences) routinely as explanatory variables in occupational health research. From an equity perspective, it is also important to understand the causes of sex and gender differences in occupational health so that they not be used erroneously to justify job segregation or inequitable health promotion measures.⁵

Potential causes of sex differences in occupational health outcomes are multiple and are discussed below: job and employment patterns, biological specificity, and societal attitudes.

In the discussion about women that follows, many of the remarks will apply to some degree to other groups that have been subject to discrimination because of age, race/ethnicity, or social class.¹¹⁻¹³ Belonging to any of these categories may affect exposure to workplace hazards and create a context that affects responses to the hazards. Since each of these has its own interactions with work environment and health effects, only women will be discussed here.

► WOMEN WORKERS AND THEIR JOBS

Women are in different industries from men. Men are more prominent in primary (raw materials) and secondary (production) sectors of the economy, while women are more often in the tertiary (service) sector.¹⁴ Women are more likely to work for small companies.¹⁵

Women usually work in specific types of jobs in all countries where this has been studied. For example, in Québec, Canada, only one profession (retail salesperson) is found among the 10 most common jobs of women as well as among the 10 most common men's jobs. Both women and men most often work among a majority of their own sex (Table 44-1). In an analysis of tendencies in employment, Asselin¹⁷ classified professions as very disproportionately male if the

proportion of women in the profession was less than half their proportion in the labor force. By this criterion, she found that well over half of jobs were very disproportionately assigned to one sex (221 of 506 professions were very disproportionately male, while, by analogous criteria, 66 were very disproportionately female). Thus, women's jobs differ from men's.

Further, even within the same job title, men and women are often assigned to different tasks¹⁸⁻²⁰ and, therefore, exposed to different working conditions. For example, women in retail sales in Europe more often sell cosmetics and shoes, while men more often sell automobiles and electronic equipment.²¹ This type of unequal distribution of the sexes across jobs and tasks is called horizontal segregation.

There is also vertical segregation: women's concentration in the lower ranks can be inferred from the fact that, on the average, women earn 71.6% of what men do for full-time, full-year work.²² Women are still in a distinct minority in senior management positions.²³

Women work at specific schedules. Almost three times as many women work part-time as men.²⁴ Women's work also tends to be intermittent: 37.9% of women have spent every year since their first full-time job working at least part-time or part year compared to 72.9% for men.²⁵ Slightly more women than men hold multiple jobs (part-time or full-time).²⁶

A growing literature confirms that women's specific job situations result in a distinctive pattern of exposures. Even within the same jobs, physical and psychosocial exposures differ between the sexes,²⁷ and these are associated with differences in symptoms.²⁸ For example, women in the United States are more often exposed to risk factors for carpal tunnel syndrome,²⁰ such as highly repetitive work on assembly lines²⁹ and at computer keyboards.^{30,31} Women's low position in the hierarchy also exposes them preferentially to awkward and difficult work postures.³² Women are a majority among those who suffer from indoor air problems,³³ and they are especially likely to be exposed to asthmagenic substances at work.³⁴

In addition, equipment and workspaces may have been designed using criteria derived from male dimensions. Women are shorter on average than men and are proportioned differently.³⁵ If thought has not been given to making equipment adjustable, women may find, for example, that personal protective equipment is too large for them, that tool handles are too big, or that counters are too high.^{36,37} It has been found that women and men use different methods to accomplish the same tasks in offices;³⁸ some differences may be attributable to workspace design. The fact that women have breasts has not been taken into account in most biomechanical models, so some lifting and carrying equipment has not been designed well for women.³⁹ When women are forced to work in awkward positions due to workspaces designed for larger people, they suffer more musculoskeletal symptoms than men in the same jobs.⁴⁰

Lortie showed that many female hospital orderlies had adapted their lifting methods to their particular aptitudes; they had found ways to change lifting tasks into pushing and pulling tasks.⁴¹ However, in

TABLE 44-1. PRINCIPAL PROFESSIONS OF WOMEN AND MEN, QUÉBEC, CANADA, 2001¹⁶

<i>Profession (Women)</i>	<i>% of Women in the Profession</i>	<i>Profession (Men)</i>	<i>% of Men in the Profession</i>
1 Secretary	97.7	Information technology professions	74.2
2 Retail saleswoman, sales clerk	58.7	Truck driver	97.7
3 Cashier, teller	86.5	Retail salesman, sales clerk	41.3
4 Accounting clerk	87.8	Director, retail sales	63.3
5 Nurse	91.0	Janitor	79.2
6 Primary school teacher, kindergarten teacher	86.0	Mechanic, auto repair	99.1
7 Educational technician, primary or kindergarten	95.7	Manual materials handler	90.6
8 Office clerk	83.2	Driver, delivery	92.8
9 Waitress, bartender	97.1	Salesman, wholesale nontechnical	69.6
10 Counter food server, assistant cook	60.5	Construction helper	71.0
20 top professions of women	74.8	20 top professions of men	67.3

a rigid, repetitive sorting task, where there was little control over task parameters and where certain dimensions of the workstation caused problems for shorter workers, women had more work accidents than did men.⁴² A conclusion from the above results is that attention should be given to increasing the ability of workers to adjust all the parameters of their work context, so that it can be adapted to their particular characteristics and situations.

Sexual stereotyping and discrimination may also affect exposures for women and men. Discrimination against women in the workplace puts them at greater risk for adverse psychological outcomes.^{43,44} Sexual segregation may in itself have a negative effect on health.^{45,46} In addition, in workplaces where physically demanding operations are required, it was found that women overexerted themselves in response to a perception that they did not do their share of heavy jobs, while men could be induced to overexert themselves by appeal to their gallantry.⁴⁷

These differences in exposure patterns by sex support caution in using job titles to estimate exposure for both genders if a job exposure matrix has not previously been validated separately by gender. In addition, it is unwise to adjust relationships between job title and disease incidence for gender, thus treating gender as a confounder when it may be a proxy for specific exposures.^{9,48} Stratification by gender (as well as race, age, etc.) is desirable where numbers permit.

► WOMEN AND BIOLOGY

A number of studies have found a difference in symptoms between women and men workers even after controlling for workplace exposures to risk factors for musculoskeletal²⁸ or toxic³³ effects. These remaining differences could be due to residual unreported or unanalysed exposures, extraprofessional exposures, or physiological susceptibility. Biological sex differences are too extensive to be thoroughly discussed here, but a few major concerns will be mentioned.

Women and men differ, on average, on almost all anthropometric dimensions: height, weight, body segment length, sitting height, etc.³⁵ Their physical strength also differs; on average, women in a standing position can push or pull 56% of the weight that men can push or pull⁴⁹ and can lift about half of the weight men lift. Sex differences in other kinds of strength have also been described.^{50,51} However, differences within a sex are larger than average between-sex differences, and the degree of sex difference varies with the details of the task.^{52,53} Also, some evidence shows that young women benefit more than men from strength training,⁵⁴ presumably because they are less likely to have tried to increase their upper body strength previously. The importance of strength for women's occupational health is not clear. It is possible that increasing upper-body strength is associated with fewer musculoskeletal symptoms in the upper body,⁵⁵ but conclusive evidence for this has not been found.

A number of hormonal and physiological sex differences have been found or suggested that may lead to differences in susceptibility to disease, including occupational disease. These were reviewed by Wizemann and Pardue.⁵⁶ Some attention in the occupational health and safety literature has been given to differences in musculoskeletal symptoms (thoughtfully reviewed by Punnett and Herbert⁵⁷), in indoor air quality (reviewed by Hodgson and Storey⁵⁸), in respiratory health⁵⁹ and lung disease (reviewed carefully by Camp et al.³⁷), in metabolism of certain solvents,⁶⁰ and in reactions to lead.^{61,62} However, caution should be exercised in considering biological differences where within-sex differences may exceed between-sex differences.⁵ Also, in studying sex differences, there is a risk of false positives or false negatives, that is, of discovering sex differences where none in fact exist, or of missing true effects. These risks arise in any large set of studies, from the fact that, randomly, one in 20 studies of sex differences will result in statistical significance at the 0.05 level, and that, on the other hand, study power may be insufficient to reveal differences. In addition, since not all studies carefully check all relevant characteristics of their samples, age, fitness, or nutritional differences or even differences in sample size may be interpreted as sex differences. The public interest in sex differences may then result in hasty conclusions that have detrimental effects on public health policy and on the body of scientific knowledge.⁵

► WOMEN IN SOCIETY

Women's social roles affect their movements in and out of employment. Thus, the "healthy worker effect" (defined as a tendency for workers to be healthier than the general population) manifests itself in specific ways with women workers. Their reproductive health may affect their employment status, so that reproductive ill health may be more characteristic of working women than those not working.⁶³ Also, women have been found to be more likely than men to leave work because of a health problem but less likely to fail to be hired because of a health problem.^{64,65} They are also less likely to receive compensation for a work-related health problem^{66,67} and less likely to be assigned appropriate retraining even if compensated,⁶⁸ all factors which may affect their readiness to leave a job if they become ill.

Women's extraprofessional activities in the home can combine with paid work to produce health effects.^{69,70} Twice as many women as men report doing over 5 hour of housework per week⁷¹ and 55% more women take care of small children or the elderly.⁷² The extra time includes many tasks that can prolong or repeat exposures at work and result in accumulated fatigue, toxic exposures, or musculoskeletal symptoms.⁷³ Attention should be paid to the fact that indicators of family status such as marital status or the presence of young children can have different associations with the health status of male versus female workers.^{73,74}

► RESEARCH METHODS APPROPRIATE FOR STUDYING WOMEN WORKERS

For a long time, researchers neglected women workers, and many still do.^{5,9,75} When studies do include women, they often do so inappropriately.^{5,9,76} Descriptors representing the place of people in society (gender, race, class) pose a special problem for research in occupational health. These categories may be associated with specific probabilities of some biological characteristics (hormonal status, blood groups, nutritional status), but they also represent probabilities of different occupational and extraprofessional exposures. If researchers simply adjust (“control”) their analyses for sex/gender, or if they include sex/gender as a variable along with other exposure variables, the effects of gender-specific exposures may disappear from sight, and gender or sex in itself may falsely appear to contribute to a health problem. Therefore, information on women’s problems should be sought specifically.

However, problems in data collection can preclude women from being studied. For example, studies of the effects of agricultural exposures can be forced to eliminate women since only the husband of a farm family is identified as a farmer in most provincial records,^{77,78} although women farmers are also exposed to pesticides and the like.⁷⁹ Also, many death certificates have not contained information on women’s professions, in part because once a woman has retired she may be considered to be a housewife. Many registries still do not code or do not publish results by sex in their reports. Thus, a priority for research in women’s (and men’s) occupational health is establishment of appropriate databases.

Getting information on women’s occupational health problems poses certain additional challenges. Compensated work accidents and injuries are the usual statistics used to assess occupational health. Men have more compensated industrial accidents and illnesses per worker than women, although the male/female difference is attenuating as information systems and analytical tools improve.^{80,81} Health surveys show more occupational illnesses and accidents than those represented in the official compensation statistics, especially for women.^{82,83} Some of the difference may be due to women having less access to compensation, since they are less often in jobs where they are represented by unions.⁸⁴ Also, some jurisdictions use methods of compensation and of record-keeping that understate injuries and illnesses of women workers.⁸⁵ Some of the difference in compensation rate is a result of the difference in jobs and tasks—when comparisons are made within the same industry, sometimes women have more accidents than men, sometimes fewer.⁸⁶ It is easy to recognize that a leg broken in the workplace is an occupational problem, but an allergy or inflammation that develops more slowly is not readily associated with the job. Women average more industrial disease (as distinguished from accidents) than men,⁸⁷ and their problems may be underestimated since many industrial diseases go unrecognized.

Women’s illness and injury rates may also be artificially lowered by a technical factor. Because women tend to work fewer hours than men at paid jobs, accident rates of women appear lower when, as is usual, the rates are calculated per worker rather than per hour worked. Of 14 studies comparing women and men, reviewed in 1994, only two gave information on person-hours worked.⁸⁸ Studies still report work-related injuries on a per-worker basis.⁸¹

Some researchers have suggested that certified sick leaves might be a useful indicator of occupational health problems for both sexes, in complement to the usual methods that would detect occupation-related illness.⁸⁹ They found that sick leaves of nurses were related to various indicators of work load and to shift work.⁹⁰

Research instruments and standards that have been derived with male populations have sometimes been used without further validation on female populations.⁹ An example is strength testing done with instruments validated only for male populations.⁹¹ Some occupational prestige scales and social class scales use the husband’s job to ascribe a score to the wife.⁹² This causes problems when data on health are adjusted for social class, since some social class influences on health may be mediated through common family-revenue-dependent factors

such as nutrition, and others may be specific to the individual situation such as education-related, health-protective behavior.

Occupational health researchers trained in medicine have often limited their interest to pathologies rather than to indicators, signs, or symptoms of deterioration in physical or mental states, reasoning that the presence of pathology guarantees that the problem examined is worthy of serious consideration. However, a requirement for diagnosed pathology may be premature when studying women’s occupational health. Since the aggressors present in women’s traditional work have been understudied, and the effects of even well-known conditions on women workers are often unknown, identification of occupational disease in women’s work is embryonic.

The requirement for pathology has two further consequences. First, it forces the researcher to consider events that are rare among populations still at work. This requirement for populations of considerable size is a particular obstacle to identifying women’s occupational health problems because women work in very small workplaces.¹⁵ Second and more important, the risks found in women’s jobs are often undramatic and diffuse. In fact, obvious danger can be a reason for excluding women from particular jobs. Thus, epidemiological studies that seek to link isolated, identifiable risk factors such as chemical exposures to well-defined pathologies are not well adapted to discovering other types of problems that occur in women’s jobs, like aches and pains from prolonged static standing, unhappiness about discrimination.

► WOMEN’S OCCUPATIONAL HEALTH PROBLEMS

Women’s most common self-reported health problems are musculoskeletal problems, headaches, allergies including skin problems, and hypertension.^{93,94} Women are also much more likely than men to report psychological distress.⁹⁵ Workplace conditions are relevant to all these conditions. These subjects cannot all be reviewed thoroughly here, but a few points of interest can be mentioned in relation to some common health problems of women in the workplace.

Musculoskeletal Disorders

The major research area in women’s occupational health is probably musculoskeletal problems.⁵⁷ Women’s working conditions, particularly repetitive work, prolonged standing, and carrying heavy loads, may be at the source of some of these musculoskeletal problems. Where loads carried by men are usually inanimate, those carried by women are usually patients or children, who can interfere actively with the process, increasing the risk of injury. Nursing assistants and other medical personnel are particularly at risk for back injuries.⁹⁶

In many jobs assigned to women (as well as some assigned to men), the work cycle is under 10 seconds long, and the same movements are repeated many thousands of times in a day.⁹⁷ These movements can individually make trivial demands on the human body, but the enormous degree of repetition makes tiny details of the setup assume primary importance. A chair of the wrong height or a counter of the wrong width may cause constant overuse of the same tendons or joints, increased among those with heavy family responsibilities,⁹⁹ yet the observer sees no problem.⁹⁸

Many women’s jobs require static effort, exerted when muscles are contracted for long periods. For example, cleaning (dusting high surfaces, bending over toilets) requires long periods bent over or reaching up.¹⁹ This type of effort creates musculoskeletal and circulatory problems due to interference with circulation. Women’s jobs in North America as sales clerks, cashiers, tellers, and receptionists require long hours of standing without moving very much,¹⁰⁰ a position which is uncomfortable¹⁰¹ and is associated with varicose veins.¹⁰² (In Europe, Asia, Africa, and Latin America, these workers usually work sitting down.)

Health Effects of Stress

Any discussion with women (and often men) workers tends to identify “stress” as an important occupational health problem, which may be related to the headaches, hypertension, and psychological distress

commonly reported by women. We can ask whether women “really” have more such problems, but it is undeniable that women consult more health practitioners and take more medication for mental problems than men.⁸⁰ Several studies now link psychological distress, anxiety, and depression to women’s workplace conditions.^{103,104}

Examining women’s work-related mental problems involves several challenges. First, there is a history of disbelieving women’s reports of their physical ills and ascribing women’s physical problems to mental causes.¹⁰⁵ For example, women workers who complained of symptoms of exposure to neurotoxic agents have often been accused of “hysteria.”¹⁰⁶ Similar uncertainty has surrounded discussions of women’s high proportion of cases of sick building syndrome,¹⁰⁷ multiple chemical sensitivity,¹⁰⁸ and musculoskeletal disorders.¹⁰⁹ Therefore, it is necessary to be sure that physical causes have been excluded before ascribing women’s problems to stress.

Second, there is a problem in identification of mentally stressful working conditions of both women and men. Questionnaires such as the well-known Job Content Questionnaire¹¹⁰ use questions on repetitiveness and monotony (among others) to identify psychological job demands. However, repetition and monotony are found in jobs that require repeated physical movements such as assembly line production and data processing; it is hard to tell whether the effects found are from the psychological or physical stress, or both.

Stressful working conditions have been associated with both physical and mental outcomes for women.^{111,112} The work of Karasek and others has related several workplace variables (degree of job control, level of demand) to effects on the cardiovascular system, and these effects hold for both women and men.^{112,113}

Unfortunately, most scientists who have studied heart disease by occupation have restricted their samples to men.^{112,113} Although coronary artery disease is the most common cause of death among women, and as many women as men report hypertension, heart disease is still thought of as a man’s problem.¹¹⁴ Several professions that are commonly held by women are among the 10 professions with the highest diastolic blood pressure: laundry and dry cleaning operatives, food service workers, private child-care workers, and telephone operators.¹¹⁵ Stress from family responsibilities can combine with job strain to produce risks of cardiovascular disorders.¹¹⁶

For women, it is important to be careful in considering combined effects of home and job. Stress arising from interference between work and family can generate a number of health problems,^{69,117} including mental health problems.¹¹⁸ The characteristics of both paid work¹¹⁹ and of the home situation¹¹⁸ may facilitate or interfere with women’s efforts to reconcile work and family, so that difficulties in reconciling the two cannot be considered as a personal characteristic of women, but should be incorporated into workplace stressor assessment.

Violence

Although women suffer much less violence at work than men, they are found in some jobs with a high risk of violence, such as health-care worker, food server, bar attendant, convenience store clerk, and gas station attendant.^{120–122} Violence against women in the workplace can also arise from spillover from their domestic situation, with a violent partner carrying the violence into the work situation.¹²¹

Occupational Cancers

In the 1990s, researchers noted that women, especially African-American women, had been largely excluded from studies on occupational cancers.⁴ A lot of effort has been expended to stimulate interest in women’s occupational cancers, and women have been increasingly included in studies, although not yet enough for much information to have accumulated.^{75,123} Risks are becoming apparent, for example, among cleaners, hairdressers, agricultural workers, health-care workers, laboratory workers, and others exposed to chemical and physical risks.¹²³

In addition, several studies have identified teachers as a group particularly likely to contract breast cancer. This has been explained as a result of delayed childbirth among this occupational group.^{123,124} This points up the necessity to examine the whole issue of delayed

childbirth and its effects both on certain cancers and on fertility as an occupational health issue. It may be that childbirth is delayed in some occupations due to an incompatibility between professional and family responsibilities. This is another example of how women’s social situations are not dissociable from their likelihood to suffer from occupational disease.

Reproductive Problems Specific to Women

Menstrual symptoms are among the most commonly diagnosed disorders of women. During the mid-1980s, several researchers suggested that menstrual symptoms might be useful for the study of occupational effects on reproductive health, as well as indicative of health problems that should be addressed.^{125,126} Parameters of the menstrual cycle that can be studied in relation to occupation include regularity and length of cycle, length and volume of flow, and symptoms of pain and discomfort associated with the periods. The latter symptoms are common and can be studied in normal populations. Abnormalities of the menstrual cycle have been explored in relation to occupational exposures to mercury,¹²⁷ lead,¹²⁸ pesticides,¹²⁹ synthetic hormones,¹³⁰ organic solvents,^{131,132} carbon disulfide,¹³³ chemical exposures of hairdressers,¹³⁴ physically challenging work such as ballet dancing,¹³⁵ exposure to cold temperatures, irregular schedules,¹³⁶ and shift work.¹³⁷

Dysmenorrhea or painful menstruation occurs with increased prostaglandin production. Release by the endometrium during menstruation gives rise to increased abnormal uterine activity that produces ischemia and cramping pelvic pain. There may be other associated symptoms such as leg- or backache or gastrointestinal upset. Premenstrual syndrome (PMS) is a less well-defined diagnostic category that refers to a group of symptoms thought to occur during the days preceding the onset of menses. Since its diagnosis requires making an association with an event (menstruation) that has not yet occurred, reports of prevalence are not consistent.¹³⁸ One prospective study has suggested a link between PMS and productivity loss among female workers;¹³⁹ no studies have investigated productivity variations at any other time in the cycle.

Prevalence estimates of perimenstrual symptoms vary greatly between studies, according to age, parity, contraceptive methods, and other demographic characteristics. Dysmenorrhea was not associated with work in the reinforced plastics industry¹⁴⁰ or to exposure to toluene,¹⁴¹ but has been found in association with cold exposure, time pressure,¹⁴² and mercury exposure.¹²⁷ It was found at a high level among hairdressers, who are exposed to chemicals and work standing for prolonged periods.¹⁴³ Studies of the prevalence and etiology of back pain, a common occupational health problem among hospital workers, may be confused if perimenstrual back pain is not taken into account.¹⁴²

Pregnancy alters the shape of the body and thus the interaction with the work site.^{144,145} The high frequency of falls at work during pregnancy, especially in food service work, may be due to awkwardness due to a change in body shape,¹⁴⁶ but also to failure to adapt the work process. A study of precautionary leave or reassignment of pregnant workers exposed to dangerous working conditions showed that ergonomic considerations were the most common reason for giving such leave, with chemical and physical exposures following.¹⁴⁷ In jurisdictions where no such program exists, women may risk health damage due to exposures during pregnancy. For example, it has been found that, during pregnancy, certain working conditions (noise, lifting weights) are associated with higher blood pressure.¹⁴⁸ However, most research on pregnancy has been limited to fetal effects, and little information exists on the effects of conditions during pregnancy on the woman herself.

Information is also lacking on the relation between working conditions and age at menopause or menopausal symptoms. Age at menopause can be an indicator of exposure to environmental pollution, as shown by its relationship to smoking and a possible relationship to exposure to some chemicals.^{149,150} Belonging to a lower socioeconomic class is also associated with earlier menopause,¹⁵¹ so one might expect to find an association with manual work, but one large study showed no relation between heavy physical work and early menopause.¹⁵²

Health Hazards of Child Labor

Susan H. Pollack • Philip J. Landrigan

Child labor or youth work is defined in the United States as employment of children less than 18 years of age. While adolescents under age 18 are usually thought of as students, by senior year of high school 75% of U.S. teens are also working in a formal setting as employees.¹ More than five million U.S. children and adolescents are estimated to be legally employed after school, on weekends, and during the summer (U.S. Department of Labor). Several million more are believed to be employed under conditions that violate wage, hour, and safety regulations, and an uncounted additional segment work in areas that are not even covered by child labor laws.² Even as freshmen at age 14, almost a quarter of students hold jobs, and work in informal arrangements such as yard work, babysitting, work in family, or community agriculture is common much earlier.³ Despite the existence of laws that are intended to protect them, the number of young U.S. workers under age 18 who die each year has remained relatively constant in the past few years at about 68 per year; rates of younger teen occupational death are actually rising,¹ and more than 200,000 teens continue to be injured on the job every year.⁴ Child and adolescent work-related injuries and exposures and their resulting health effects are not just remnants of Dickensian history but remain an important public health issue in the twenty-first century, as the following cases illustrate. Each of the cases represents a sentinel health event, a single isolated event that serves as a marker for a whole group of youth at potential risk of exposure, injury, or death.

Case 1: A 16-year-old boy cleaning a grill in a Kentucky fast-food restaurant collapsed and died, despite rapid emergency medical response. He had no history of cardiac problems, huffing solvents, or other drug use. The cleaning solution was an unknown mixture of substances, but analysis was unfortunately impossible as it was thrown out during all the activity. Concern remains that the cleaning mixture, when heated, may have released fumes causing a fatal arrhythmia. Since fast food is one of the major industrial segments hiring youth, and most youth who work in food service end up also performing cleaning tasks of some type with cleaning chemicals at the end of their shift this unresolvable case continues to cause concern. (Kentucky Fatality Assessment and Control Evaluation program, personal communication 1994 and subsequent discussions with county Coroner.)

Case 2: A 17-year-old boy running a thriving T-shirt printing business out of his bedroom presented to adolescent clinic one cold Pittsburgh winter with fatigue and elevated liver enzymes. His symptoms and physical findings were felt to be a result of his solvent exposure. His family had inadequate resources to purchase a spray booth, but were also unwilling to see him give up his lucrative business. As a compromise, they agreed to have him move his business out of his bedroom into another room in the house. (L. Sanders, MD, Children's Hospital of Pittsburgh, personal communication 1993.)

Case 3: As a volunteer, summer, church youth-group project, twins are helping elderly people with home maintenance in an area of their state known for old houses with lead-based paint. The youth group comes in, scrapes and repaints houses in crews that work for

about a week each. No one has considered the lead exposure risk to volunteers scraping and generating lead paint dust. No specific training is provided nor is monitoring done. This scenario is repeated in Pennsylvania, Kentucky, and numerous other states.

Case 4: Just before Christmas in the early 1990s, a carload full of Kentucky teens returning to their factory work from an off-site lunch break crashed and all were killed. A few years later, a 17-year-old driving a truck to deliver newspapers on a rainy Sunday morning on a rural road failed to negotiate a curve and hit a tree. A substitute driver, he died after a week in the ICU without ever regaining consciousness. In 2005, the Kentucky legislature was considering passage of a version of Graduated Drivers Licensing that permits new drivers to carry two passengers and has an exemption for driving to work.

Case 5: A 16-year-old girl with diabetes was admitted to the inpatient hospital service with poor control of her sugars. During her hospitalization, it was discovered that she was working after school for a pizza maker. If orders came in fast and they were busy, she would not be permitted to take a dinner break, consequently her eating schedules were not consistent. It was suggested that she speak with her employer about the requirement under the law for such a break and the need to uphold that law for her medical well-being. She and her mother agreed, and after meeting with the employer, more regular dinner breaks were made available to her.

Case 6: A 16-year-old Ohio jockey was killed 5 weeks into a successful career when his horse broke a leg and fell over him in a November, 2005, race. Most experts agreed that neither age nor experience would have made a difference in the outcome.

Case 7: A 15-year-old boy was killed in a tobacco field when the rear wheel of the tractor he was driving went over the edge of a small ravine and the tractor rolled twice and landed on him. He had no Roll Over Protection System (ROPS) and no seat belt. He and another 15-year-old had been plowing all day on a farm without adult supervision. His 14-year-old brother almost rolled another tractor racing to the field to help him when he heard.

► HISTORICAL PERSPECTIVE

Child labor has a long history. In the Middle Ages, children worked in agriculture and as apprentices to artisans.⁵ In Colonial America, children who helped out on their own farms and households commonly were hired out to perform similar tasks for neighbors, a practice that has continued in rural areas almost without change. Under these conditions, proximity to family and social relationships provided some degree of protection for the child worker.⁶

Child labor underwent major expansion and restructuring during the eighteenth century as a consequence of the industrial revolution's need for large numbers of workers. Most mill owners preferred to hire children rather than adults because child workers were cheaper, more tractable, and as labor unions developed, less likely to strike.⁷ Families

sent children as young as 11, especially girls, to work in the mills, where the wages they could earn far exceeded the income of their parents at home on rural farms. These young girls often were victims of sexual exploitation outside of the workplace in addition to exploitation inside the factories, where they commonly labored for 12 or more hours a day, 6 days a week.⁸ Depiction of the horrors of child labor in the literature^{9,10} and art of the eighteenth and nineteenth centuries sparked great popular revulsion against the worst abuses, but the practice nevertheless continued.

In Britain, concern over the plight of working children stimulated passage of the first legislation protecting the health of all workers.^{5,7} The 1802 Health and Morals of Apprentices Act fixed the maximum number of hours of work for apprentices, forbade night work, and ordered the walls of factories to be washed twice each year and workrooms to be ventilated. In the United States, concerns about working children led to the enactment of compulsory education laws in the eighteenth and nineteenth centuries. For example, an 1874 New York State law mandated schooling for all 8- to 14-year-old children and proscribed work on school days.⁷

Despite federal and state legislation, child labor continued to be a major problem during the first third of the twentieth century, largely because of inadequate enforcement of existing statutes. The need for enforcement was demonstrated by the death of 146 women and children in the 1911 Triangle Shirtwaist fire in New York City, only 8 years after the passage of landmark child labor and fire protection legislation.¹¹

Between 1916 and 1930, Congress enacted three major pieces of child labor legislation, but the U.S. Supreme Court invalidated all three. Finally, in 1938, Congress passed the Fair Labor Standards Act (FLSA), which remains the major federal legislation governing child labor today. Major reductions in child labor occurred during the 40 years after passage of the FLSA. Although provisions of the Act helped to produce this decrease, automation, structural shifts in the American industrial economy, reductions in family size, and restrictive immigration policies all contributed to the declining use of child laborers.

After World War II, widespread emphasis on the personal and societal value of education and a generally strong economy combined to further decrease the prevalence of child labor in most sectors of the economy. The major exception was in agricultural employment, which was exempted from many of the provisions of the FLSA. Consequently, the employment of children in agriculture remained common and is to the present time relatively underregulated.

► CURRENT YOUTH EMPLOYMENT

The estimated 5 million legally working American youth under age 18 do not fully include several additional populations: an estimated 1.3 million youth living and working on family farms and ranches, migrant farmworker children working in the fields and adding to the piecemeal rate for which their fathers are paid (including both legal and illegal immigrants and U.S. born citizens), and children working in a variety of small family businesses. Although legal employment primarily includes youth ages 14 and above, farming, newspaper delivery, and other jobs are legal for even younger children, and children as young as age 11 do appear in workers' compensation databases.

Both the number of teens employed and the hours worked per week tend to increase with age, in part due to increased hours and job type permitted under federal regulation as they reach ages 16 and 17. Data from the 1988 census about the 50% of 16- and 17-year-olds then working at some point during the year indicated that they were working an average of more than 20 hours per week for almost half the year.² High frequency of job change has been reported as the norm for many high school workers, especially in the food service industry, but middle school students were noted to keep their summer jobs into the school year.³

Little specific was known about workers under high school age until recently. In October, 2001, an anonymous survey about

employment, injury, work-related habits, and school performance was administered to middle school students in five school districts and one urban school in Wisconsin chosen to be representative of the state as a whole, resulting in an analysis of replies by 10,366 students.³ About 58% of middle school students ages 10–14 reported working during the past summer (2001), and 60% of those students reported working at the same job during the school year. Two thirds of those who reported working were 12–13 years old. A third of the students were working more than 10 hours per week, including 5% working 40 or more hours a week. A third of the middle school employees were working between 7 and 11 pm, and 6% reported working after 11 pm (8% of females).

Weller et al.¹² conducted anonymous surveys in the classrooms of lower-income Hispanic South Texas middle school students in sixth through eighth grade in which 3008 students (56%) reported current or recent employment. Of the respondents, 63% were Hispanic. Only half of Hispanic children but 66% of white children reported current/recent employment. South Texas students reported working an average of 8 hours per week, but 12% worked more than 10 hours per week.

During the 1990s, increasing numbers of adolescents were being pushed into the workplace through the nationwide School to Work initiative and through local gang prevention, violence prevention, and juvenile justice-related job programs.¹³ It is unclear what effects the economic climate of the decade from 2000 will bring, though there is some suggestion that with cuts in summer job programs and poor economic times for at least a segment of the U.S. adult population, there may be fewer youth jobs available.

► LAWS PROTECTING THE HEALTH/SAFETY OF WORKING YOUTH AND THE WORK PERMIT SYSTEM

The Fair Labor Standards Act (FLSA) of 1938 remains the major piece of legislation regulating the employment of youth under age 18. Under the FLSA, no child under the age of 16 years may work during school hours, and a ceiling is set on the number of hours of employment permissible for each school day and school week. Employment in any hazardous nonagricultural occupation is prohibited for anyone less than 18 years old, and specific prohibitions are listed in the Hazard Orders (HOs). Thus, no one under age 18 may work in mining, logging, brick and tile manufacture, roofing, excavating, or as a helper on a vehicle or on power-driven machinery. Work with meat-processing machinery and delicatessen slicers is specifically prohibited.¹⁴ In agriculture, where the restrictions are much less stringent, hazardous work is prohibited only until age 16, and all work on family farms is totally exempted. According to the law, however, no child under age 16 working on a nonfamily farm is allowed to drive a tractor with an engine over 20 horsepower or to handle or apply pesticides and herbicides.¹⁵

The intent of the FLSA and HOs is to protect the safety of working youth. Despite a call by the National Academy of Sciences in 1998 for a national surveillance system to monitor adolescent occupational injuries, in 2006 there is still no such centralized mechanism for evaluating how well the FLSA actually protects children in the workplace. Yet without any data to suggest that current law is even doing enough to protect as it was designed to do, a number of initiatives have been undertaken in the past decade to weaken the HOs, leading to passage of permission to drive a motor vehicle for limited time and the elimination of box-crusher restrictions in supermarkets. Critics of the FLSA and HOs complain that job processes have changed and no updates have been done on restrictions. It is also true that new processes and machines have been invented, and many (such as the new stand-up mowers used in lawn care) are not even addressed under the current HOs.

Although the FLSA provides a broad framework for the regulation of child labor, most administration of the law occurs on a state level, largely through the work permit system. Work permits are issued to children by state and local school systems. This authority was

placed within the schools to allow for discretion in the issuance and rescission of a work permit based on a student's academic performance. In reality, however, most school systems, overwhelmed by more pressing responsibilities, virtually never exercise their discretionary authority. Administration of the FLSA in most states also suffers from a lack of centralized data collection on the number or types of work permits issued or the industries in which children are employed. Thus, in most states, only meager information is available on the number and ages of employed children or on the nature of their employment.

► ILLEGAL CHILD LABOR, ENFORCEMENT AND SITUATIONS WHICH VIOLATE OR AVOID THE LAW

While a small subset of child labor in the United States involves undocumented or "illegal" immigrants in fields, garment sweatshops, poultry plants, and construction, it is important to realize that the majority of illegal child labor refers to the employment of U.S. citizens under conditions which violate the wage, hour, and or safety laws.¹⁶⁻¹⁸ Examples include clocking out/failure to pay for time spent cleaning up an establishment at the end of a work shift, and failure to abide by hazardous order. Despite the FLSA, illegal employment of children continues to occur in all industrial sectors and often exists under sweatshop conditions. A sweatshop is defined as any establishment that routinely and repeatedly violates wage, hour, or child labor laws and the laws protecting occupational safety and health. Traditionally, these shops have been considered fringe establishments, such as those in the garment and meat-packing industries.¹⁹⁻²² Increasingly, however, restaurants and grocery stores, not typically considered to be sweatshops, also are sometimes satisfying the definition.

In an effort to quantify the magnitude of illegal child labor in the absence of readily available national statistics, the General Accounting Office (GAO) surveyed the directors of state labor departments in 1987. The GAO found that, in Chicago, half of the approximately 5000 restaurants met the criteria for sweatshops and about 25,000 workers were employed in such establishments. In New Orleans, 25% of the 100 apparel firms (employing 5000 workers) were estimated to be sweatshops. In Los Angeles and New York, anywhere from 500 to 2000 or more sweatshops were thought to exist.²³ The problem is not confined to large urban areas. In 1987, several high school students employed by a chain restaurant in a small West Virginia town quit after having tried unsuccessfully to negotiate with the manager to stop keeping them past midnight on school nights.

The critical importance of child labor law violations lies in their continued link to adolescent occupational injuries and deaths. In Suruda and Halperin's early study of 1984-87 Occupational Safety and Health Administration (OSHA) adolescent fatality investigations, 41% of the deaths occurred while adolescents were engaged in work that was specifically prohibited under the FLSA, and employer citations for safety violations were issued in 70% of those adolescent death investigations.²⁴ In Suruda's 2005 review of construction fatalities among workers ages 16-19, 76 teens under age 18 were killed during the 5 years of his study.²⁵ Half the deaths to these workers occurred under situations that were in apparent violation of existing child labor laws; 15 involved age violations (workers under age 16) and 28 involved violations of specific HOs (some involved both). Teen deaths were noted to occur at small, nonunion firms, many of which were exempt from both federal child labor law enforcement and from routine OSHA inspections because of their small size. The risk of work in situations not well covered under the law or under inspection programs was echoed by Derstine²⁶ in a study of 80 fatal adolescent injuries in 1992-1993. Of those 80, 31 occurred among children working in a family business. Half of those were among children less than age 14, and 28 were in agriculture. In a study of North Carolina adolescent occupational fatalities based on medical examiners reports, Dunn and Runyan also found that 86% of workers under age 18 who incurred fatal injuries were engaged in work that appeared to violate the FLSA.²⁷

► ADOLESCENT OCCUPATIONAL INJURIES AND FATALITIES

Injuries and deaths related to adolescent employment in the United States have been characterized quite extensively in the past two decades (Table 45-1). Approximately 70 youth die on the job every year.⁴ In small states, hundreds of teen workers are known to incur occupational injury each year, while in large states adolescent occupational injuries number in the thousands.

Occupational Fatalities from Injuries and Exposures

Numbers and rates of fatalities by age: In an October 2005 paper, Windau et al.¹ of the Bureau of Labor Statistics provide the most comprehensive and current broad summary of adolescent occupational injuries and fatalities in the United States. When examined in a variety of ways, the overall picture is still one that shows substantial risk of death and injury, and much work to be done in prevention, education, and enforcement of current child labor laws. The number of U.S. young worker fatalities averaged 68 per year from 1992 to 2000, decreased in 2001-2002, increased in 2003 primarily among workers under age 16, then decreased again in 2004 to almost half the number in 1992,³⁷ a decrease larger than that for adult workers in the same time. Fatality rates per 100,000 full-time equivalent workers were examined for the decade 1994-2004. During that time, the rate for workers older than 15 as a whole decreased 3%, primarily based on decreases in death rates of workers over age 55. For workers ages 15-17, the death rate bounced around, initially declining until 1998, increasing to the highest ever recorded in 1999 at 3.8% decreasing to 2.3% in 2002, and ending at 2.7% in 2004. Examining occupational deaths from 1994 to 2004 among teen workers more closely, workers ages 16 and 17 had a fatality rate of 3.0 per 100,000 while workers ages 15 had a rate of 4.7 per 100,000. During the time period, overall death rates of workers in most adult age groups declined by 1-5%, while the rate for 16- to 17-year-olds declined about 1% and the rate for 15-year-olds actually increased 9%. When 5-year periods were used as a time period for analysis, overall worker fatality rates declined 14% between 1994-8 and 1999-2003 while rates for 15- to 17-year-olds declined 6%; as a result, the worker fatality rates for 15- to 17-year-olds approached the same rate as for workers ages 18-34.

Death by industry and by cause/mechanism: Agriculture is the leading industry responsible for adolescent occupational fatalities, followed by construction.²⁵

More than half the adolescent occupational fatalities in the United States from 1998 to 2002 were related to transportation incidents.¹ This represented a 14% increase from the previous 5-year period and was a result both of both vehicle-related incidents on farmland and public roadways and incidents of workers being hit by vehicles. Vehicles or farm machinery were responsible for almost all of the deaths involving workers younger than age 14, and in about 25% of those cases the child was the driver/operator. There was a 17% increase in deaths among youth riding on farm vehicles as a passenger or outside helper. In most cases, victims fell from and were struck by the same farm vehicle. Deaths also increased for youth riding on other vehicles and as pedestrians. Among 16- to 17-year-old workers, 12% were killed driving a car or truck, while another 12% were killed in retail work, mostly as homicides. Work-related homicide decreased 44% between the two time periods. Deaths from being struck by objects and from fires/explosions also declined.

Deaths related to falls increased due to an increased number of falls from scaffolds. The risk in construction was also seen by the doubling of deaths that occurred while installing building materials, mostly on construction sites, at a time when most other work activity fatalities declined.

Occupational Exposure-related deaths: From 1980 to 1989, NIOSH found electrocutions were the third leading cause of occupational fatality among 16- and 17-year-olds, with higher rates than those for adult workers.⁴ Contact with an energized power line

accounted for more than half the cases. Windau in 2005 noted a doubling of electrocution deaths, accounting for 5% of fatalities to farm workers under age 18.¹ In a study of fatal teen construction injuries in 15- to 19-year-olds from 1984 to 1998, Suruda also noted the importance of electrocution, which led to more deaths than did roof falls, and was more common among youth deaths than adult deaths.²⁵

Poisonings constitute a small but persistent piece of adolescent occupational fatalities. Dunn and Runyan²⁷ reviewed 1980–1989 North Carolina Medical Examiner records of 71 youth less than age 20 years and found one poisoning death of an adolescent under age 18. Castillo et al.²⁸ reviewed 670 nonmilitary deaths of 16- and 17-year-olds in the National Traumatic Occupational Fatalities database during the same time frame (1980 to 1989). Poisonings were found to be responsible for 3.0% of deaths (20 males, 0 females). For 16- and 17-year-olds, the risk of occupational poisoning death was 1.5 times that for adult workers. In California during that same time period, Schenker et al.²⁹ found odds ratio of deaths by accidental poisoning on farm compared with off was 1.8 for 10- to 14-year-olds. Belville et al.³⁰ found that 2 of 31 occupational fatalities in New York State workers' compensation awards from 1980 to 1987 were caused by exposure to toxicants. Both aged 17 years, one was asphyxiated by carbon monoxide at a trucking storage depot, and one died of gas inhalation (probably hydrogen sulfide in a manure pit) while working on a dairy farm. In a review of 104 deaths of youth less than age 18 from 1984 to 1987 that resulted in OSHA investigations, Suruda and Halperin²⁴ found 12 deaths from asphyxiation. Abuse of substances available at work was implicated in three of those deaths, with one sniffing trichloroethane and two inhaling nitrous oxide. Deaths while cleaning tanks (enclosed space fatalities) have been reported in Canadian and Colorado adolescents.

Nonfatal Occupational Injury

As evidenced by Table 45-1 below, workers' compensation files have provided some of the most comprehensive available information in the United States on adolescent occupational injury, despite limitations that tilt the data toward undercounts. Reasons for undercounting include failure to recognize injured "students" as workers, lack of knowledge among teen workers and their families about workers' comp eligibility, and differences between states in indemnity requirements. Because of the part-time nature of much teen work, accurate injury rates are difficult to deduce, but data from the state of Washington suggests that adolescent occupational injury rates may exceed those of adult workers when adjusted for hours worked.³¹

TABLE 45-1. OCCUPATIONAL INJURY TO WORKING TEENS

State	Number Injured	Reference
Washington	4450 per year accepted workers' compensation claims for workers' aged 11–17	31
California	2104 injuries in 1991	32
New York	More than 1000 per year received workers' compensation (more than 8 lost work days to qualify)	30
Texas	More than 1000 per year reported to workers' compensation	33
Connecticut	Almost 800 per year	34
Massachusetts	400 per year treated in emergency departments and 5% of the state population under surveillance, thus potentially 8000 per year	35
Minnesota	Almost 750 per year	36
Rhode Island	An average of 500 per year accepted by workers' compensation	37
Kentucky	More than 400 per year reported to workers' compensation	38

Available emergency department data also provide a glimpse into the important role of work in the epidemiology of adolescent injury. A Massachusetts study³⁵ of adolescent emergency department visits for treatment of injuries found that 26% of the injuries with a known location among 17-year-olds occurred at work, and that work was the single most common location of injury in this age group, as it was among a surveyed group of 16- to 17-year-old Saskatchewan high school students.³⁹ In Massachusetts, 1 of every 30 adolescents aged 16–17 in the population received treatment in an emergency department for a work-related injury each year. In a 2005 study of CHIRPP data (Canadian Hospitals Injury Reporting and Prevention Program) for Canadian children, Lipskie and Breslin found 999 children ages 5–17 who had suffered an occupational injury between 1995 and 1998. Occupational injuries increased with age and were concentrated in two main areas: clerical/service and manual labor.⁴⁰

Injury severity: Ehrlich⁴¹ utilized the requirement for significant surgery as a proxy measure for severity in a study of WV workers' compensation claims from 1996 to 2000 and found that workers under 20 had an increased relative risk of lacerations, fractures, and amputations relative to adults over age 20 and had injuries that resulted in significant surgical procedures more often than adults. However, application of this study to child labor is limited by their inclusion of 18- and 19-year-olds.

Injury by commercial versus family business: In a community-based telephone survey of work and injuries among teenage agricultural workers in Washington state, Bonauto et al.⁴² found that rates of injury among both Hispanic and non-Hispanic teenage agricultural workers who were working for an agricultural business owned by a family member were higher than those who were working for an agricultural business not owned by a family member. Since teens employed in family farm businesses also were found to have worked more seasons and fewer hours per week, they would theoretically have more experience and less fatigue, but it may be that the type of tasks for which they are responsible pose the risk. Those tasks were found to include driving, animal care, and mechanic work.

Nonfatal Occupational Exposure

In a Washington state study of 1988–1991 workers' compensation awards to 17,800 adolescent workers ages 11–17 years, 4.9% of the awards resulted from toxic exposures.^{31,32} While workers' compensation records have provided the bulk of useful data on adolescent occupational injuries from many states, it is now clear from the work of Woolf et al.⁴³ that Poison Control Centers data can provide useful knowledge on both substances responsible for adolescent occupational poisoning and patterns of occupational poisoning. The Toxic Exposure Surveillance System database compiled by the American Association of Poison Control centers was analyzed for 1993–97 cases. Of the workplace toxic exposures in their system, 3% (8779 cases) involved adolescent workers under age 18, and the proportion of their cases that were teens increased over that time. There were 2 deaths, approximately 877 life-threatening cases, and an additional 14.2% were considered severe injuries. Approximately a third involved toxic inhalations, 27% involved eye exposures, 24% and skin exposures, and 19% involved ingestions. The most common agents were alkaline corrosives (13%), gases and fumes (12%), and involved cleaning agents (9%). Issues that arose from that data and also in Kentucky workers' comp data include the importance of poisoning from cleaning agents among youth working in food service. Because so many of those are poisoned while doing cleaning tasks in occupations that would not automatically suggest exposure to cleaning agents, the understanding has evolved that it is important for parents, emergency care providers, and researchers to examine tasks and not just occupational classifications when examining adolescent occupational exposures/injuries.

Noise is one of the few specific areas of adolescent occupational exposure that not only has been studied but also for which an intervention program has been designed, implemented, and evaluated.⁴⁴ From 1985 to 1988, audiometric assessment of 872 high school vocational

agriculture students was conducted in 12 central Wisconsin schools. Students with active involvement in farm work had more than twice the risk for mild and early noise-induced hearing loss compared with their peers who had no involvement in farm work. Larger exposures paralleled degree of hearing loss in at least one ear. Approximately 50% of adolescents employed on farms tested had evidence of some hearing loss in at least one ear; this was true for 74% in one of the higher-exposure groups. As with adult farmers who drive tractors, the left ear was most affected in adolescents doing farm work. (Farmers normally look over their right shoulder while driving, shielding the right ear with the head while placing the left ear closer to the engine noise). Few students employed on farms drove only tractors with enclosed cabs, which have been shown to be less noisy. Only 9% of students employed on farms reported the use of hearing protection devices (HPDs). Hearing deficits documented in the first year generally persisted into the second year. The use of amplified music and exposure to noise from snowmobiles or motorcycles had only weak associations with the prevalence of noise-induced hearing loss.

The Wisconsin findings have been echoed in North Carolina students, in which at least 30% of male adolescents in 4-H who were employed on farms reported being exposed to loud noises. Among 562 North Carolina adolescents with nonfarming work experience, 27% reported working around loud noises. Pechter noted noise exposure in construction and kitchen jobs in Massachusetts (Elise Pechter, unpublished report to NIOSH, 1998).

Additional exposures of concern include pesticide poisonings, green tobacco sickness (nicotine poisoning), repetitive motions problems, occupational dermatitis, and exposure to second-hand tobacco smoke and pulmonary sensitizers. Further discussion of these is beyond the scope of this chapter.⁴⁵

► OPTIONS AND SUCCESSFUL MODELS FOR PREVENTION

As in all injury interventions, the best approach to prevention includes a combination of education, engineering, and policy and enforcement options, and includes the necessity for surveillance in order to measure how any of these alone and in combination are working.

Education: Classroom and on-the-job training are both necessary, and need to involve parents, schools, and youth workers themselves as well as employers.

One example is the Wisconsin hearing conservation program⁴⁴ that was devised in response to studies of high school farm youth and hearing loss there. A 4-year hearing conservation program was designed, implemented, and evaluated in 34 Wisconsin junior and senior high schools. Its primary goal was to protect hearing by promoting the use of HPDs. Intervention group students ($n = 375$) received a five-component educational intervention over the course of 4 school years and three summers, including yearly hearing tests, whereas control students ($n = 378$) received only a baseline hearing test that was repeated in years 2 and 3. Agricultural and industrial arts teachers also were offered free hearing tests in year 2 in hopes that, through their involvement in the study, they also would increase their encouragement of students to use hearing protection. The educational intervention was modeled after an ideal, industrial hearing-conservation program. In addition to the hearing tests, it included (a) classroom-style education, including basics, of anatomy and physiology of the ear, a videotape of youth with hearing loss from noise in agricultural settings, and examples of music with deleted frequencies simulating hearing loss; (b) frequent reminders provided through periodic school visits and mailings home (every 6 weeks throughout the first 2 study years); (c) noise-level assessments done by students on their own farms using a sound-level meter; and (d) distribution of a variety of types of HPDs provided and replaced on a regular basis through the 4 years. Baseline HPD use was 23% among the intervention students versus 24% among controls. After the intervention, self-report of planned future use of HPDs was 81% among

intervention students versus 43% among controls. Students rated the most important interventions as the provision of free earmuffs and earplugs (94%), yearly audiometric exams (90%), and educational mailings to their homes (77%). Two factors believed by the research team to have been instrumental to the success of the program were the opportunity for the students to test sound levels at their own farm (almost two-thirds of compliant intervention students reported that this was a factor) and the repeated opportunity through the course of the study to practice fitting the earplugs correctly.

A second prevention example is a school-based interactive program—Health and Safety Awareness for Working Teens, implemented as part of school to work in Washington state. Teachers found it useful and easy to use, and it led to increased student knowledge.⁴⁶

A third educational effort that resulted in safer work practices involved the creation of active participatory stations in which students had to conduct farm tasks with simulated disabilities caused by farm injuries.⁴⁷

Enforcement: More inspectors, bigger fines, and serious judges would make employers less likely to risk the lives and well-being of teen employees.

Policy: Motor vehicles and teen drivers don't mix well, for play or work, and exemptions from teen driving laws should be limited as the data and logic behind them are not different on the way to work.

Engineering/Process change: Burn prevention can be improved by changing the time of filter change above grease to when it is cold, not hot.

► ACKNOWLEDGMENTS

The lead author would like to thank Ms Amelia Jones for her assistance in the preparation of this manuscript. This chapter is dedicated to all the children killed and injured at work since 1980, to the memory of the two New Jersey police officers who were killed on December 25, 2005, when they drove off a foggy drawbridge that had been opened while they were setting flares to protect the public, and to the memory of the 12 West Virginia coal miners who died after an underground explosion on January 1, 2006, when time ran out to save them.

Occupational Safety and Health Standards

Eula Bingham • Celeste Monforton

Until 1970, there was almost total reliance on state and local governments and the forces of the market to improve working conditions related to occupational injuries, death, and disease. For more than 50 years, state governments had attempted to inspect workplaces and to advise employers about hazards. Few of these programs, however, had adequate enforcement authority to compel abatement of dangerous conditions. In some states, no attempt was made by government to change workplace conditions, either by enforcement or by persuasion. Variations in state legislation resulted in comprehensive, strong regulation in some states (e.g., New York and Illinois) and nonexistent regulation in others (e.g., Mississippi). The doctrine of states' rights and a tradition of state regulatory activity in the area of labor standards protected this status quo.

Another traditional approach was to trust market and private sector mechanisms to provide worker protection. Workers' compensation insurance carriers made some attempt to improve workplace safety for economic reasons. Many carriers provided consultative service to their clients and charged lower rates to large companies that were successful in reducing injuries. Then, as well as now, insurance companies' consultative resources are limited and are not available to all who may need them; while it may be possible to provide economic incentives to large firms by basing their premium rates on accident experience, it is not possible to provide this same incentive to small firms, which have few employees to record a statistically significant accident experience. More importantly, these economic incentives are inadequate where health problems are concerned because occupational diseases are not often diagnosed as workplace related. Occupational diseases often have complex origins; many years may elapse between exposure and the appearance of symptoms, making physicians and compensation boards reluctant to attribute the symptoms to time spent with specific employers or to the exposure to particular working conditions.¹

A third approach evolved to cope with occupational safety and health problems; industry-based organizations filled the vacuum by producing guidelines for safe work practices for various types of industrial equipment and processes and for "acceptable" exposure limits to certain harmful substances. These "consensus standards" were adopted by the Occupational Safety and Health Administration (OSHA) in 1972 as federal standards.

Thus a long series of private, voluntary efforts and a slowly evolving pattern of government initiatives (e.g., the Walsh-Healey Act [1936], which authorized sanctions against federal contractors who violated standards) tested a variety of approaches to improving safety and health. These experiences served as the basis for broad federal legislation. As legislators had a record of approaches that had not

worked, it became clear that voluntary-compliance approaches and consensus guidelines would have to be backed by a technically experienced federal enforcement staff and that inadequate workplace safety and health efforts at the state level would have to be reshaped to meet national standards of effectiveness. The economic realities of the marketplace had overwhelmed voluntary efforts, and the weak incentives of workers' compensation programs and of the states appeared unable to act effectively because of a need to compete among themselves for industry and jobs.²

The Occupational Safety and Health Act (OSH Act) was signed into law in 1970 and was designed to address workplace hazards faced by private-sector employees in most industries including manufacturing, services, construction, and agriculture. The Federal Mine Safety and Health Act of 1977 (Mine Act) is a comparable law aimed specifically at workers employed in underground and surface coal, metal, and nonmetal mining operations.³ Both laws feature a strong standards-setting authority vested in the Secretary of Labor. The standards-setting process was open to labor, industry, and public inputs at all stages.

The word "standard" connotes uniformity, consensus, and regulatory power. OSHA and MSHA standards are an attempt, through the federal government's regulatory powers, to set a minimum level of protection for workers against specified hazards and to achieve that level through enforcement, education, and persuasion.

Sections 6 and 3(8) of the OSH Act govern the standards-setting process. They contain three major schemes under which standards can be promulgated: (a) a short-lived authority for adoption of existing consensus standards, (b) development and promulgation of new or amended standards, and (c) promulgation of temporary emergency standards. Likewise, the Mine Act includes provisions allowing the agency to promulgate new and emergency temporary standards and to amend existing standards; however, no authority was given to MSHA to adopt consensus standards. Instead, Congress stipulated by statute a number of interim standards, including mandates for mine operators to reduce coal mine dust levels to prescribed levels, offer chest radiographs to underground coal miners to detect pneumoconiosis, follow roof control and ventilation plans, and conduct safety exams and methane checks on every workshift.

► CONSENSUS STANDARDS

At the time the OSH Act was passed, a large body of consensus standards was already in existence, developed as guidelines by such groups as the American National Standards Institute (ANSI), the

National Fire Prevention Association (NFPA), and the American Conference of Governmental Industrial Hygienists (ACGIH). The standards represented industry's agreement on certain reasonable exposures, work practices, and equipment specifications. To establish as rapidly as possible a body of occupational safety and health rules already familiar to employers, Congress required adoption of these standards, but recognized that many were seriously out of date. The legislative history of the OSH Act emphasized that the standards would need to be constantly improved, and recognized that new standards were especially needed to prevent occupational illnesses.

Many of the consensus standards contained provisions that were irrelevant to safety and health (e.g., several pages of specifications for the wood to be used in ladders). The standards were adopted wholesale, however, without significant deletions, in the interest of speed. Competing priorities made it impossible to evaluate and amend the body of standards within the 2-year deadline allowed by Congress.

Thus, OSHA began with initial standards derived from previous industry use, which had these key weaknesses: They were unduly complex and obsolete. One standard, for example, prohibited the use of ice in drinking water, a rule that dated from a time when ice was cut from contaminated rivers. Certain standards were only tangentially related to the safety or health of workers, for example, the requirement for coat hooks in toilet stalls.

The consensus standards were guidelines and not designed for enforcement and the adjudicatory process. Provisions that should have been advisory became inflexible law. Threshold limit values reflected industry consensus as to acceptable practice and were not necessarily designed for the greatest protection to workers and often lacked documentation.

By 1978, OSHA removed the most inappropriate of these rules from the books. At that time, 1110 standards provisions were proposed for deletion; after participation by labor and the business community, 927 were finally eliminated.

► PERMANENT STANDARDS

The authority for setting permanent workplace safety and health standards is provided in Section 6(b) of the OSH Act and Section 101 of the Mine Act, and follows a multistep process:

1. Initiating the standards development project: The Secretary of Labor may begin the process on the basis of recommendations from the National Institute of Occupational Safety and Health (NIOSH) or other governmental agencies, petitions of private parties, research findings from any source, accident and injury data, congressional input, or court decisions.
2. Drafting the proposal: Agency staff assemble all the supporting documents, draft the preamble and regulatory text, and prepare economic and environmental impact statements to fulfill the requirements of the National Environmental Policy Act of 1969, the Regulatory Flexibility Act, the Small Business Regulatory Enforcement Fairness Act, the Paperwork Reduction Act, and various Presidential Executive Orders.
3. Appointing an advisory committee: An advisory committee may at the discretion of the Secretary be formed to provide expertise and guidance to the agency. The statute requires its composition and includes representatives of labor and industry, the safety and health professions, and recognized experts from government or the academic world.
4. Revising and reviewing the draft proposed rule: Agency scientists, engineers, and technical experts prepare the proposed rule, in consultation with attorneys from the Solicitor's Office, and may seek review by other agencies. In most instances, a proposed rule must also be approved by the White House's Office of Management and Budget (OMB).
5. Publishing the proposal in the Federal Register: The public is invited to comment. The broad issues debated during the

comment period include the agency's determination that (a) the hazard presents a significant risk to workers; (b) the proposed standard will substantially reduce the risk; and (c) the means of compliance are technologically and economically feasible.

6. Conducting informal hearings: Nearly always, public hearings are held to allow further public comment.
7. Analyzing the rulemaking record: Following the public hearings and after the end of the public comment period, the staff analyzes the entire rulemaking record. Major issues requiring policy decisions are defined and presented to the assistant secretary. Alternate approaches, if appropriate, are presented.
8. Preparing the final standard: The staff develops a proposed final standard based on the record of rule making and submits the document for internal review and final approval by the assistant secretary and OMB.
9. Publishing the final rule: The completed final standard is published in its entirety in the Federal Register. An interested party may challenge the validity of the standard by filing, within 60 days, a petition for review of the standard in a federal circuit court of appeals.

This process is only an outline. The length of time between steps may stretch for months or years. At times, proposals are abandoned after first hearings or public comment, and the decision to proceed with a rule making is reevaluated. If appropriate, an entirely new proposal is developed.

► TEMPORARY EMERGENCY STANDARDS

Both the OSH Act and Mine Act give the Secretary of Labor authority to issue "... an emergency temporary standard to take immediate effect upon publication in the *Federal Register* if employees are exposed to grave danger from exposure to substances or agents determined to be toxic or physically harmful or from new hazards." These standards are promulgated without the extensive public participation characteristic of permanent standards. The statutes require that emergency temporary standards (ETS) be replaced with a permanent standard within 6 months. ETS may be used as a "proposed standard" in the permanent standards proceedings. This provision of the act has been chilled because of unfavorable court decision. The last time OSHA issued an ETS was a 1983 update to its asbestos standard, but the emergency rule faced a legal challenge and was rejected by the court.⁴ As a result, OSHA was required to proceed with its usual notice and comment rulemaking.

► NATURE OF OSHA AND MSHA STANDARDS

OSHA standards are written to control risks even if exposure continues throughout a person's working life. The effectiveness of the technology available for controlling exposures and the characteristics of the hazard in the particular workplace determine how compliance with the standard will be achieved.

The standards are variable in several areas. The technical content necessarily differs according to the hazard being regulated, although it is possible to group related problems in a single standard. A specification approach or a performance approach may be employed, or the two approaches may be combined.

Specification standards tell precisely what protection an employer must provide. This approach has been used most often in developing safety standards. The advantage of specification standards is that they tell the employer exactly what must be done to "be in compliance" with the regulation. The disadvantage of specification standards is that they tend to be inflexible and may restrict an employer's efforts to provide equivalent protection using alternative—and sometimes more satisfactory—methods. In certain instances, employers may be granted

a variance if the agency determines that the alternative means of compliance will provide equivalent protection to workers.

The trend in OSHA and MSHA regulations is toward performance standards that set an exposure limit but leave the means of compliance largely to the decision of the employer. This greater degree of flexibility allows the employer to consider alternative methods and equipment and choose those most suited to their particular industry and worksite. Performance standards, however, do not give the employer carte blanche to substitute less effective means of protection (such as personal protective equipment) for engineering controls of dangerous emissions or other hazards.

Health standards are generally addressed by way of the performance, rather than the specification, approach. While many large corporations prefer performance standards in both the safety and health areas, small employers tend to prefer more specification in workplace standards. In some instances, OSHA publishes an appendix to the standard which provides employers an acceptable “specific” method of compliance.⁵

► HAZARDOUS WASTE AND EMERGENCY RESPONSE

An estimated 1.8 million workers are potentially exposed to hazardous waste or toxic materials as a routine part of their jobs or from spills or emergency incidents. This includes firefighters, police officers, and emergency responders. In 1986, Congress amended the Resource Conservation and Recovery Act of 1976 (RCRA) and the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA) under a law entitled the Superfund Amendments and Reauthorization Act (SARA). Among other things, SARA required OSHA to issue standards to ensure the health and safety of employees engaged in hazardous waste operations.⁶ OSHA’s standard, often referred to as HAZWOPER,⁷ is designed to protect workers in several distinct settings: cleanup operations at uncontrolled hazardous waste-disposal sites; cleanup at recognized hazardous waste sites (e.g., EPA Superfund sites); routine operations at hazardous waste treatment, storage, and disposal facilities; and emergency response activities at sites where hazardous substances have been or may be released.

The HAZWOPER standard requires employers to develop and implement a written safety and health program that identifies, evaluates, and establishes a means to control workers’ exposure to hazards at these sites. Moreover, the rule contains explicit training requirements, including at least 40 hours of initial training and three days of field experience for workers who are directly involved in cleanup work, and 24 hours of initial training and one day of field experience for workers who are occasionally at these sites. Annual refresher training is also required. Persons conducting the training must issue written certificates confirming that the student successfully completed the training, and anyone who does not have this written certification is prohibited from working at a hazardous waste operation.

► THRESHOLD LIMIT VALUES, PERMISSIBLE EXPOSURE LIMITS, AND ACTION LEVELS

Older occupational health standards (still used in developing countries) were based on threshold limit values (TLVs) developed by the ACGIH. In this system, maximum exposure limits were usually set based on the level of a contaminant known to produce acute effects, allowing some margin for safety and considering what was readily achievable by employers. Unfortunately, such limits do not protect against long-term chronic or subclinical effects on the body, such as changes in blood chemistry, liver function, or the reaction time of the central nervous system. In addition, these values were derived mainly for healthy, young, adult white males, not for the diverse makeup of working populations. In addition, TLVs were not designed to address the problem of irreversible health problems such as cancer.

Permissible exposure limits (PELs) are used in OSHA health standards. PELs are based on consideration of the health effects of hazardous substances. The lead standard, for example, contains a PEL of 50 µg of lead per cubic meter of air, averaged over an 8-hour period. In 1989, OSHA attempted to establish PELs for 164 unregulated substances and update the limits for 212 toxic air contaminants which were originally adopted by OSHA in 1971.⁸ OSHA’s PEL Update faced a strong legal challenge and the Court of Appeals eventually vacated the rule.⁹ As a result, most of the PELs currently enforced by OSHA are outdated and do not reflect current scientific knowledge on the health effects of these contaminants.

► MEDICAL REMOVAL PROTECTION

Medical removal protection (MRP) is a protective, preventive health mechanism complementing the medical surveillance portion of some OSHA standards. The lead standard, for example, calls for temporary removal for medical purposes of any worker having an elevated blood lead level. During the period of removal, the employer must maintain the worker’s earnings, seniority, and other employment rights and benefits as though the worker had not been removed. Under the Mine Act, coal miners with chest x-ray evidence of pneumoconiosis, as determined by NIOSH, are given the option of transferring to a less dusty job and maintaining their regular rate of pay.

Medical removal protection is essential; without it, the major cost of health hazards falls directly on the worker and the worker’s family in the event of illness, death, or lost wages. Without a requirement for the protection of workers’ wages and job rights, removal could easily take the form of transfer to a lower-paying job, temporary layoff, or termination. A worker who participates in the medical surveillance program might risk losing his or her livelihood. The alternative has sometimes been to resist participation and, thereby, lose the protection that surveillance offers.

An interesting leveraging effect of MRP is its role as an economic incentive for employers to comply with the workplace standards. For example, employers who do not comply with the lead standard will have a greater number of removals and thus will have higher labor costs over a long period, while employers who invest in control technology will experience savings from lowered removal costs.

► COMPLIANCE

To comply with the PELs, employers first conduct an industrial hygiene survey, including environmental sampling. This process identifies contaminants, their sources, and the severity of exposure. The employer then devises methods to reduce exposure to permissible levels. Methods commonly employed by industrial hygienists to control exposures fall into three basic categories: engineering controls, work practice controls (including administrative controls), and personal protective equipment.

Engineering controls employ mechanical means or processes redesign to reduce exposure. The contaminant may be eliminated, contained, diverted, diluted, or collected at the source. Examples of this type of control include process isolation or enclosure, such as is used in uranium fuel processing. Employee isolation or machine and process enclosure are also used to protect workers from excessive fumes or noise. Closed material-handling systems, product substitution, and exhaust ventilation are also commonly employed.

Work practice controls rely on employees to perform certain activities in a carefully specified manner so that exposures are reduced or eliminated. For example, employers may instruct workers to keep lids on containers, to clean up spills immediately, or to observe specific, required hygiene practices. Such work practices are often required to complement engineering controls. This is particularly true in cases where engineering controls cannot provide complete compliance with the standard. Noise hazards are often controlled by a combination of

engineering steps and work practices limiting the amount of time workers are exposed to excessive noise levels.

Personal protective equipment controls exposure by isolating the employee from the emission source. Respirators are a common type of personal protective equipment, used when protection from an inhaled contaminant is required. Personal protective equipment is used to supplement engineering controls and work practices. Often overlooked is the great importance of personal hygiene, which includes the use of protective clothing to provide barriers to both the worker and the worker's family, the provision for shower facilities, and the cleaning of protective clothing so that contaminants are not transferred to others.

Engineering control is the best method for effective and reliable control of worker exposure to many substances. It acts at the source of the emission and eliminates or reduces employee exposure without reliance on self-protective action by the employee. Work practices also act on the source of the emission, but rely on employee behavior, which requires supervision, motivation, and education for effectiveness. While personal protective equipment provides a cheaper alternative to engineering controls, it does so at the expense of safety and reliability. The equipment does not eliminate the source of the exposure, often fails to provide the degree of protection required (or fails to provide it with certainty in all cases), and may create additional hazards by interfering with vision, hearing, and mobility.

Individual differences in employees also affect the acceptability of personal protective equipment. For example, some employees develop infections from some ear-protection devices and respirator face pieces, and some who have impaired breathing cannot safely or comfortably use respirators. Additionally, personal protective equipment is made in standard sizes and facial configurations that may not properly fit female workers and unusually large or small workers.

OSHA should progress from a reactive, priority-setting system to one with an information-based approach. Highest priority must be given to hazards that cause irreversible adverse health effects. Court decisions have required the agency to establish a "reasonably necessary" approach, that is, determine the number of workers affected and the number protected by the new regulation. This has been translated into a risk assessment requirement. For example, OSHA's cancer policy¹⁰ could be modified to increase the speed with which the particular carcinogens are regulated, with priorities shaped according to the population of the workers exposed, current exposure levels, and the potency of a substance. Consideration should be given to the ways in which these substances are used in actual operations and to the likelihood of substantial accidental exposures.

These same criteria can be applied to other health hazards. In the safety standards area, a parallel process must occur, which should include guidance in the establishment of standards for reducing deaths due to inappropriately designed lock-out procedures, for reducing musculoskeletal injuries, and for controlling the development of stress-related diseases associated with newer technologies. Development of so-called generic standards, for example, hazard identification, reaches many workers in providing protection. These types of standards are difficult to promulgate because of the divergent industrial sectors and numerous employers coming under the regulation.

Critics of occupational safety and health standards encourage the use of theoretical economic models based on cost-benefit analysis. Common sense indicates that the numbers of workers exposed, the severity of hazards, and the technological feasibility must be considered in setting standards. These factors should be explicit in OSHA's priority-setting processes. Precise costs and benefits, however, cannot be measured.

The costs of standards compliance can be estimated with some precision. New equipment, engineering modifications, and work practices have readily measurable costs. Industry, however, sometimes overestimates these costs by several magnitudes in their testimony against standards: actual costs for vinyl chloride standards compliance turned out to be but a fraction of those indicated in public testimony.¹¹ More recently, even with the thoroughly worked and reworked estimates of the costs to comply with the cotton dust standard, it appears

that costs were overestimated by both the government and industry. OSHA has never had the authority to require facilities to open their financial books in preparing economic feasibility impact studies, so it must be content with voluntarily divulged economic data.

The benefits of regulation, however, are more difficult to calculate. One cannot count all accidents that were avoided as one cannot number the accidents and injuries that actually occurred. One cannot precisely identify the health benefits that will accrue in 10, 20, or 30 years from current reduced exposures to toxic substances or carcinogens. The data for prediction do not exist, and causality mechanisms in occupational disease are too complex to be defined with the same certainty as the costs of a new ventilating system.

The largest problem with cost-benefit analysis, however, is not lack of information—it is the impossibility of weighing lives spared against the dollar costs for prevention. Workers are coming to realize that hazardous-pay differentials are in fact based on a dangerously false assumption that lives can be valued and, in effect, "prorated" on a cash basis. Public debate over regulatory costs can begin to clarify this issue and to uncover the hidden social costs of failure to regulate out of deference to faulty labor market mechanisms. These hidden social costs include not only loss of life and health of workers, but also increased incidence of illness and death among families of workers exposed to some substances such as lead and asbestos, and disruption of family and community life due to death and disability of workers and to local environmental effects of industrial contaminants.¹²

► GLOBAL STANDARDS

Particularly important for OSHA, MSHA, and NIOSH is participation in international occupational health and safety forums to achieve full awareness of available research and enforcement experience, including those of the Commission of the European Communities, the International Labor Organization, the World Health Organization, and many foreign national governments. It is critical that the United States share information internationally and encourage other nations to adopt effective health and safety standards. Without comparable standards in other countries, U.S. industries can choose to export hazardous processes such as asbestos milling or pesticide formulation. This is doubly unacceptable because it not only exposes foreign workers to hazardous conditions but would tend to export jobs along with the hazards. Indeed, the failure to participate in the global efforts for health and safety standards could lead U.S. workers backward if U.S. occupational safety and health standards are considered to be a barrier to free trade under trade agreements, for example, the North American Free Trade Agreement (NAFTA) or the Central American Free Trade Agreement (CAFTA).

► CONCLUSION

Standards alone will not guarantee healthful, safe working conditions. Enforcement inspections to determine whether compliance exists are essential. Training and education of workers and employers is also necessary. Government cannot provide direct, constant enforcement of employee protection; this effort must be assisted by employer and employee participation.

Workers' rights to a safe and healthful workplace are facilitated in part by the existence of employer standards, by federal and state enforcement activities, but most of all by the workers' own knowledge and vigilance. The OSH Act and Mine Act recognize this fact. These statutes reinforce the workers' rights, with guarantees against reprisals by employers, when workers file and obtain abatement of health and safety hazards. Whether improvements come from voluntary employer action, from direct enforcement, or from labor-management negotiations, health and safety standards are essential to define the necessary levels of protection and the acceptable means of attaining them.

Ensuring Food Safety

Douglas L. Marshall • James S. Dickson

► INTRODUCTION

The objective of food processing and preparation is to provide safe, wholesome, and nutritious food to the consumer. The responsibilities for accomplishing this objective lie with every step in the food chain; beginning with food production on the farms, and continuing through processing, storage, distribution, retail sale, and consumption. Producing safe food is a continuum, where each party has certain obligations to meet and certain reasonable expectations of the other parties involved in the process. No single group is solely responsible for producing safe food, and no single group is without obligations in assuring the safety of food.

Food producers have a reasonable expectation that the food he or she produces will be processed in such a manner that further contamination is minimized. Food producers are an integral part of the food production system, but are not solely responsible for food safety. It is not practical to deliver fresh unprocessed food that is completely free of microorganisms, whether the food in question is of animal or plant origin. The environment in which the food is produced precludes the possibility that uncontaminated food can be grown or produced. However, appropriate methods can be utilized to reduce, to the extent possible, this level of background contamination. These methods are referred to as “Good Agricultural Practices” (GAPs).¹

Alternately, producers have an obligation to use these same reasonable practices to prevent hazards from entering the food chain. As an example, when dairy cattle are treated with antibiotics for mastitis, producers have an obligation to withhold milk from those animals from the normal production lot. Milk from these animals must be withheld for the specified withdrawal time, so that antibiotic residues will not occur in milk delivered to dairies. In contrast, production of salmonellae-free poultry in the United States has been an elusive goal for poultry producers. While it is not a reasonable expectation for producers to deliver salmonellae-free birds to poultry processors, it is reasonable to expect producers to use good livestock management practices to minimize the incidence of *Salmonella* within a flock.

Food processors have reasonable expectations that raw materials delivered to the processing facility are of reasonable quality and not contaminated with violative levels of any drugs or pesticides. In addition, processors have a reasonable expectation that processed food will be properly handled through the distribution and retail chain, and that it will be properly prepared by the consumer. The latter is particularly important, as processors have responsibility for products because they are labeled with the processor’s name, even though the food is no longer under processor’s control once it leaves the processing facility. Processors’ obligations are to process raw foods in a manner that minimizes growth of existing microorganisms as well as minimizes additional contamination during processing. These obligations extend from general facility maintenance to the use of the best available methods and technologies to process a given food.

Clearly, consumers have an important role in the microbiological safety of foods. However, it is not reasonable to expect every consumer to have a college degree in food science or microbiology. Consumers have a reasonable expectation that foods they purchase have been produced and processed under hygienic conditions. They also have a reasonable expectation that foods have not been held under unsanitary conditions, or that foods have not been adulterated by the addition of any biological, chemical, or physical hazards. In addition, consumers have an expectation that foods will be appropriately labeled, so that the consumer has information available on both composition and nutritional aspects of products. These expectations are enforced by regulations that govern production, processing, distribution, and retailing of foods in the United States. The vast majority of foods meets or exceeds these expectations, and the average consumer has relatively little to be concerned with regarding the food they consume.

Some consumers have advocated additional expectations, which may or may not be reasonable. For example, some would argue that raw foods should be free of infectious microorganisms. Initially, this would appear to be reasonable; however, in many cases technologies or processes do not exist in a legal or practical form to assure that raw foods are not contaminated with infectious agents. Two recent examples are the outbreaks of *Cyclospora* epidemiologically linked to imported raspberries and *Escherichia coli* O157:H7 in raw ground beef. With the exception of irradiation, technologies do not exist to assure that either of these foods would be absolutely free of infectious agents while still retaining desirable characteristics associated with raw food. Therefore, in some cases, the expectation that raw foods should be free of infectious agents may not be reasonable.

Consumers have several obligations regarding food safety. As part of the food production-to-consumption chain, consumers have similar obligations to food processors. Namely, not holding foods under unsanitary conditions prior to consumption and not adulterating foods with the addition of biological, chemical, or physical agents. Improper food handling can increase food-borne illness risks by allowing infectious bacteria to increase in numbers or by allowing for cross contamination between raw and cooked foods. In addition, consumers have an obligation to use reasonable care preparing foods for consumption, as do personnel in food service operations. As an example, consumers should cook poultry until it is “done” (internal temperature at or above 68°C) to eliminate any concerns with salmonellae.

Consumer education on the basics of food safety in the home should be a priority. Every consumer should understand that food is not sterile, and the way food is handled in the kitchen may affect the health of individuals consuming it. Although our long-term goal is to reduce or eliminate food-borne disease hazards, in the near term we need to remind consumers of what some of the potential risks are and how consumers can avoid them. In the end, it is the consumer who decides what they will or will not consume.

► COMMON FOOD-BORNE DISEASE HAZARDS

Contrary to popular consumer perception about the risk of chemicals in foods, major hazards associated with food-borne illness are clearly of biological origin.² The Centers for Disease Control and Prevention (CDC) has published summaries of food-borne diseases by etiology for the years 1993 through 1997 (Table 47-1).³ CDC groups food-borne disease agents in four categories; bacterial, parasitic, viral, and chemical. Greater than 95% of all reported outbreaks, food-borne illnesses are caused by microorganisms or their toxins. Fully 97% of reported cases are likewise linked to a microbial source. Only around 3% of the outbreaks and less than 1% of cases can be truly linked to chemical (heavy metals, monosodium glutamate, and other chemicals) contamination of foods. Furthermore, 97% of reported deaths are due to microbial sources. These data are from reported outbreaks. CDC estimates for the actual number of cases of food-borne disease caused by microbial agents are much higher due to underreporting (Table 47-2).

Bacterial agents are by far the leading cause of illness, with total numbers estimated as high as 76 million cases per year and deaths as high as 5000 annually in the United States.⁴ Costs are estimated to be \$9.7 billion annually in medical expenses and lost productivity in the United States.⁴ The high incidence of food-borne disease is paralleled in other developed countries.⁵ Enteric viruses are now recognized as the leading cause of food-borne infections, although the bacteria are better known. Predominant bacterial agents are *Campylobacter* spp., *Salmonella* spp., *Shigella* spp., and *Clostridium perfringens*. Food-borne bacterial hazards are classified based on their ability to cause infections or intoxications. Food-borne infections are usually the predominant type of food-borne illness reported. Food-borne outbreaks most often occur with foods prepared at food service establishments and at home (Table 47-3). Improper holding temperatures and poor personal hygiene are the leading factors contributing to reported outbreaks (Table 47-4).

Bacterial hazards are further classified based upon the severity of risk.⁶ Severe hazards are those capable of causing widespread

epidemics. Moderate hazards can be those that have potential for extensive spread, with possible severe illness, complication, or sequelae in susceptible populations. Mild hazards can also cause outbreaks but have limited ability to spread. Those involved with food production, processing, and service should pay careful attention to controlling these biological hazards by (a) destroying or minimizing the hazard, (b) preventing contamination of food with the hazard, or (c) inhibiting growth or preventing toxin production by the hazard. Control steps will follow in later sections of this chapter.

When investigating food-borne disease outbreaks, the most important factor is time.⁷ Prompt reporting of an outbreak is essential to identifying implicated foods and stopping potentially widespread epidemics. Initial work in the investigation should be inspection of the premises where the outbreak occurred. Look for obvious sources, including sanitation and worker hygiene. Food preparation, storage, and serving should be carefully monitored. Interview

those involved in the outbreak. Obtain case histories of victims and healthy individuals. Discuss health history and work habits of food handlers. Collect appropriate specimens for laboratory analysis, including stool samples, vomitus, and swabs of rectum, nose, and skin. Attempt to collect suspect foods, including leftovers or garbage if necessary. Specific tests for pathogens or toxins will depend on potential etiological agents and food type. Analysis of data should include case histories, illness specifics (incubation time, symptoms, and duration), lab results, and attack rates. All food-borne disease outbreaks should be reported to local and state health officers and to the CDC.

Bacterial Infections

Predominant bacterial infections transmitted via foods are salmonellosis, campylobacteriosis, yersiniosis, vibriosis, and shigellosis.⁸ Most causative agents are Gram-negative rod-shaped bacteria that are

inhabitants of the intestinal tract of animals. Indeed, federal and most state regulatory agencies consider foods of animal origin (meat, poultry and eggs, fish and shellfish, and milk and dairy products) potentially hazardous foods. One look at epidemiological data confirms this suspicion. That said, fresh produce (fruits and vegetables) is increasingly being implicated in outbreaks of both bacterial and viral agents.

Salmonellosis

Salmonella resides primarily in the intestinal tract of animals (humans, birds, wild animals, farm animals, and insects).⁹ Many people are permanent, often asymptomatic, carriers. Salmonellosis varies with species and strain, susceptibility of host, and total number of cells ingested. Several dozen serotypes cause food-borne outbreaks. Incubation time is 24–36 hours, which may be longer or shorter. Symptoms include nausea, vomiting, abdominal pain, and diarrhea, which may be preceded by headache, fever, and chills. Weakness and prostration may occur. Duration is 1–4 days with a low mortality rate (0.1%). High-risk very young and elderly may have a considerably higher mortality rate (3.8%).¹⁰ The condition needed for an outbreak is the ingestion of live cells (10,000) present in the food. For high-fat foods such as chocolate, 50 cells may be a sufficient infectious dose due to protective enrobement of cells by fat allowing survival in high acid gastric fluid during intestinal transit. Foods primarily involved in outbreaks include meat, poultry, fish, eggs, and milk products. *S. enteritidis* is present in raw uncooked eggs even with sound shells.¹¹ Most often, the bacterium is transferred from a raw food to a processed food via cross contamination. Control of *Salmonella* in foods can be accomplished in several ways. Avoidance of contamination by using only healthy food handlers and adequately cleaned and sanitized food contact surfaces, utensils, and equipment works best. Heat treatment of foods by cooking or pasteurization is sufficient to kill *Salmonella*. Refrigeration temperatures at or below 5°C are sufficient, as the minimum temperature for growth is 7–10°C. The prevalence of salmonellosis as a food-borne disease has prompted regulatory agencies to adopt a zero tolerance for the genus in ready-to-eat

TABLE 47-4. CONTRIBUTING FACTORS LEADING TO FOOD-BORNE OUTBREAKS, 1993–1997*

	Number	Percentage
Improper holding	938	37.0
Temperature	274	10.8
Inadequate cooking	400	15.8
Contaminated equipment	153	6.0
Food from unsafe source	490	19.3
Poor personal hygiene	282	11.1
Other		

*Olsen SJ, MacKinon LC, Goulding JS, Bean NH, Slutsker L. Surveillance for foodborne disease outbreaks—United States, 1993–1997. *MMWR*. 2000; 49(SS01):1–51.

foods. Presence of the bacterium in these foods (luncheon meats, dairy products, pastries, produce, etc.) renders them unwholesome and unfit for consumptions. These foods must then be destroyed or reprocessed to eliminate the pathogen.

Shigellosis

Four species are associated with food-borne transmission of dysentery, *S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*.¹² The disease is characterized with an incubation period of 1–7 days (usually less than 4 days). Symptoms include mild diarrhea to very severe with blood, mucus, and pus. Fever, chills, and vomiting also occur. Duration is long, typically 4 days to 2 weeks. *Shigella* spp. have a very low infectious dose of around 10–200 cells. Foods most often associated with shigellosis are any that are contaminated with human fecal material, with salads frequently implicated. Control is best focused on worker hygiene and avoidance of human waste.

Vibriosis

Most vibrios are obligate halophiles that are found in coastal waters and estuaries.¹³ Consequently, most food-borne outbreaks are associated with consumption of raw or undercooked shellfish (oysters, crabs, shrimp) and fish (sushi or sashimi).¹⁴ *V. parahaemolyticus* causes most vibriosis outbreaks in developed countries and is primarily food borne. *V. cholerae* is primarily water borne, but has been associated with foods from aquatic origin.¹⁵ Because *V. cholerae* is halotolerant, it can survive and grow in nonsalt foods. Hence, the bacterium has been spread through foods of terrestrial origin in addition to nonsaline fresh water. *V. vulnificus* is capable of causing very serious infections leading to septicemia and a high mortality rate (30–40%).¹⁶ This very high mortality rate is the highest of all food-borne infectious agents. Fortunately the incidence of *V. vulnificus* infections is extremely low. Consumption of raw oysters harvested from warm waters (U.S. Gulf Coast) among high-risk individuals (chronic alcoholics, severely immunocompromised) are factors involved with fatalities.¹⁷ Several other *Vibrio* species may be pathogenic.¹⁷ Incubation period for vibriosis is 2–48 hours, usually 12 hours. Symptoms include abdominal pain, watery diarrhea, usually nausea and vomiting, mild fever, chills, headache, and prostration. Duration is usually 2–5 days. Cholera typically expresses profuse rice water stools as a characterizing symptom. *V. vulnificus* infections can include septicemia and extremity cellulitis. Prevention of vibriosis includes cooking shellfish and fish, harvesting shellfish from approved waters, preventing cross contamination, and chilling foods to less than 10°C.¹⁸

Escherichia coli

There are six pathogenic types of *E. coli* associated with food-borne illness.¹⁹ The infectious dose for most strains is high (10⁶–10⁸ cells), although enterohemorrhagic strains may be much lower (2–45 cells). Enteropathogenic (EPEC) strains are serious in developing countries but rare in the United States. These strains are a leading cause of neonatal diarrhea in hospitals. Likewise, diffusely adherent (DAEC) and enteroaggregative (EAEC) *E. coli* strains are associated with childhood diarrhea. Enteroinvasive (EIEC) strains have an incubation period of 8–24 hours, with 11 hours most often seen. Symptoms are similar to *Shigella* infections, with bloody diarrhea lasting for several days. Enterotoxigenic (ETEC) strains are a notable cause of traveler's diarrhea. Onset for illness by these strains is 8–44 hours, 26 hours normal. Symptoms are similar to cholera, with watery diarrhea, rice water stools, shock, and maybe vomiting lasting a short 24–30 hours. Enterohemorrhagic or verotoxigenic strains (EHEC) are the most serious *E. coli* found in foods, especially in developed countries. *E. coli* O157:H7 is the predominant serotype among these shiga-like toxin-producing bacteria, although other serotypes are found. EHEC strains cause three syndromes.^{20,21} Hemorrhagic colitis (red, bloody stools) is the first symptom usually seen. Hemolytic uremic

syndrome (HUS), which is the leading cause of renal failure in children, is characterized by blood clots in kidneys leading to death or coma in children and the elderly. Rarely, individuals may acquire thrombotic thrombocytopenic purpura (TTP), which is similar to HUS but causes brain damage and has a very high mortality rate. Verotoxin strains have an incubation period of 3–4 days. Symptoms include bloody diarrhea, severe abdominal pain, and no fever. Duration ranges from 2 to 9 days. Vehicles of transmission include untreated water, cheese, salads, raw vegetables, and water. For O157:H7, ground beef, raw milk, and raw apple juice or cider are common vehicles. Prevention of *E. coli* outbreaks includes treatment of water supplies and proper cooking of food. Complete cooking of hamburgers is necessary for destruction of verotoxigenic strains.

Yersiniosis

Most environmental *Yersinia enterocolitica* strains are avirulent; however, pathogenic strains are often isolated from porcine or bovine foods.²² The disease is predominately serious to the very young or the elderly and is more common in Europe and Canada compared to the United States. Incubation period for the disease is 24 hours to several days with symptoms including severe abdominal pain similar to acute appendicitis, fever, headache, diarrhea, malaise, nausea, vomiting, and chills. It is not uncommon for children involved in outbreaks to experience unnecessary appendectomies. Duration is usually long: one week to perhaps several months. The majority of foods involved in yersiniosis outbreaks are pork and other meats. Milk, seafood, poultry, and water may also serve as vehicles. Control is achieved by adequate pasteurization and cooking and avoiding cross-contamination. Refrigeration is not adequate because the bacterium is psychrotrophic.

Campylobacteriosis

Three species are linked to food-borne diseases, *C. jejuni*, *C. coli*, and *C. laridis*.²³ *C. jejuni* is most often associated with poultry, *C. coli* with swine, and *C. laridis* with shellfish. *C. jejuni* gastroenteritis is the most frequent infection among the bacterial agents of food-borne disease (Table 47-1). Campylobacters and related pathogens *Arcobacter* spp. and *Helicobacter pylori* are microaerophilic and are thus sensitive to normal atmospheric oxygen concentrations (21% O₂) and very low oxygen concentrations (less than 3%). Growth is favored by 5% O₂. Disease characteristics are an incubation period of 1–10 days, 3–5 days normal. Symptoms include fever, abdominal pain, vomiting, bloody diarrhea, and headache, which last for 1 day to several weeks. Relapses are common. The infectious dose is low, 10–500 cells. Foods linked to outbreaks include raw milk, animal foods, raw meat, and fresh mushrooms. Control is achieved by adequate cooking, pasteurization, and cooling and by avoiding cross-contamination. Although gastroenteritis is the predominant clinical presentation of campylobacteriosis, chronic sequelae may occur. Guillian-Barré syndrome, which is a severe neurological condition, and Reiter's syndrome, which is reactive arthritis, are rare but serious consequences of campylobacteriosis. *H. pylori* is associated with chronic peptic ulcers.

Listeriosis

Listeria monocytogenes emerged as a cause of food-borne disease in 1981.^{24,25} Susceptible humans include pregnant women and their fetuses, newborn infants, the elderly, and immunocompromised individuals due to cancer, chemotherapy, and AIDS. The disease has a high, 30%, mortality rate. Incubation period is variable, ranging from 1 day to a few weeks.²⁶ In healthy individuals, symptoms are mild fever, chills, headache, and diarrhea. In serious cases, septicemia, meningitis, encephalitis, and abortion may occur. The duration is variable. The infectious dose is unknown, but for susceptible individuals it may be as low as 100–1000 cells. Foods associated with listeriosis are milk, soft cheeses, meats, and vegetables. Like *Y. enterocolitica*, the bacterium is psychrotrophic and will grow at refrigeration temperatures, though slowly. Control is best done by avoiding cross-contamination and adequately cooking food.

Clostridium perfringens

C. perfringens is a moderate thermophile showing optimal growth at 43–47°C, with a maximum of 55°C.²⁷ Large numbers of viable cells (>10⁸) must be consumed, which then pass through the stomach into the intestine. The abrupt change in pH from stomach to intestine causes sporulation to occur, which releases an enterotoxin. Furthermore, the bacterium can grow in the intestine leading to a toxicoinfection. The illness is characterized by an incubation period of 8–24 hours. Symptoms are abdominal pain, diarrhea, and gas. A cardinal symptom is explosive diarrhea. Fever, nausea, and vomiting are rare. Duration is short, 12–24 hours. Because of the large infectious dose, foods often associated with outbreaks are cooked meats and poultry that have been poorly cooked, such as gravy (anaerobic environment at bottom of pot), stews, and sauces. Outbreaks frequently occur in food service establishments where large quantities of food are made and poorly cooled. Control is best achieved by rapidly cooling cooked food to less than 7°C, holding hot foods at greater than 60°C, and reheating leftovers to greater than 71°C.

Other Bacterial Food-Borne Infections

Many other bacteria have been linked to food-borne diseases including *Plesiomonas shigelloides* (raw seafood), *Aeromonas hydrophila* (raw seafood), *Arizona hinshawii* (poultry), *Streptococcus pyogenes* (milk, eggs), and perhaps *Enterococcus faecalis*.²⁸ Their contribution to food-borne illness appears to be minimal, but they may contribute to opportunistic infections.

Nonbacterial Food-Borne Infections

Numerous infectious viruses and parasitic worms are capable of causing food-borne illness. All are easily controlled by proper heat treatment of foods. Difficulty with laboratory confirmation of viral agents as causes of food-borne illness leads to probable underreporting.^{29,30}

Infectious Hepatitis

Hepatitis A virus is a fairly common infectious agent having an incubation period of 10–50 days, mean of 4 weeks.³¹ Symptoms include loss of appetite, fever, malaise, nausea, anorexia, and abdominal distress. Approximately 50% of cases develop jaundice that may lead to serious liver damage. The duration is several weeks to months. The infectious dose is quite low, less than 100 particles. The long incubation period and duration of the disease mean that affected individuals will shed virus for a prolonged period. Foods handled by an infected worker or those that come in contact with human feces are likely vehicles (raw shellfish, salads, sandwiches, and fruits). Filter-feeding mollusks concentrate virus particles from polluted waters. Control is achieved by cooking food, stressing personal hygiene, and by avoiding shellfish harvested from polluted waters.

Enteroviruses

Noroviruses in the calicivirus family (Coxsackie, ECHO, Norwalk, Rotavirus, Astrovirus, Calicivirus, Parvovirus, and Adenovirus) are now considered the leading cause of food-borne gastroenteritis in the United States.² Other viruses most certainly are involved but our ability to isolate them from infected consumers and foods is limited. Incubation period is typical for infectious organisms, 27–72 hours.³¹ Symptoms are usually mild and self-limiting and include fever, headache, abdominal pain, vomiting, and diarrhea. Duration is from 1–6 days. The infectious dose for these agents is thought to be very low, 1–10 particles. Foods associated with transmission of viral agents are raw shellfish, vegetables, fruits, and salads. Control is primarily achieved by cooking and personal hygiene.

Parasites

Nematodes (roundworms) linked to food-borne illness in humans include *Trichinella spiralis*, *Ascaris lumbricoides*, *Trichuris trichiura*, *Enterobius vermicularis*, *Anisakis* spp., and *Pseudoterranova* spp.³² *T. spiralis* can invade skeletal muscle and cause damage to vital organs leading to fatalities. Incubation period of trichinosis is 2–28 days, usually 9 days. Symptoms include nausea, vomiting, diarrhea, muscle pains, and fever. Several days duration is common. Foods linked to the disease are raw or undercooked pork and wild game meat (beaver, bear, and boar). Control in pork is accomplished by (a) cooking to 60°C for 1 minute, (b) freezing at –15°C for 20 days, –23°C for 10 days, or –30°C for 6 days, or (c) following USDA recommendations for salting, drying, and smoking sausages or other cured pork products. *Anisakis simplex* and *Pseudoterranova decipiens* are found in fish and are potential problems for consumers of raw fish. The incubation period is several days with irritation of throat and digestive tract as primary symptoms. Control of these nematodes is by thoroughly cooking fish or by freezing fish prior to presenting for raw consumption. *A. lumbricoides* is commonly transmitted by use of improperly treated water or sewage fertilizer on crops.

Cestoda (tapeworms) are common in developing countries. Examples include *Taenia saginata* (raw beef), *Taenia solium* (raw pork), and *Diphyllobothrium latum* (raw fish).³² Incubation period is 10 days to several weeks with usually mild symptoms including abdominal cramps, flatulence, and diarrhea. In severe cases weight loss can be extreme. Control methods are limited to cooking and freezing. Salting has been suggested as an additional control technique.

Protozoa cause a large number of food-borne and waterborne outbreaks each year. *Entamoeba histolytica*, *Toxoplasma gondii*, *Cyclospora cayetanensis*, *Cryptosporidium parvum*, and *Giardia lamblia* cause dysentery-like illness that can be fatal.³² Incubation period is a few days to weeks leading to diarrhea. Duration can be several weeks, with chronic infections lasting months to years. Those foods that contacted feces or contaminated water are common vehicles. Control is best achieved by proper personal hygiene and water and sewage treatment.

Prions

Prions are small proteins found in animal nervous tissues (brain, spinal cord).³¹ They are capable of forming holes in brains of affected animals leading to neurological deficits. In cattle, prions are associated with bovine spongiform encephalopathy (BSE), and consumers of beef from affected animals are at risk of obtaining the human form of the disease called variant Creutzfeldt-Jakob disease (vCJD). Although this link is tenuous, a few human cases in Europe are thought to be based on consumption of contaminated nervous tissue in beef. The disease is characterized by progressive brain dysfunction ultimately leading to death. Little is known about the incubation period or the infectious dose, as this is a newly emerged condition. Meat and milk from affected animals are not considered a transmission risk.

► FOOD-BORNE BACTERIAL INTOXICATIONS

Food-borne microbial intoxications are caused by a toxin in the food or production of a toxin in the intestinal tract. Normally the microorganism grows in the food prior to consumption. There are several differences between food-borne infections and intoxications. Intoxicating organisms normally grow in the food prior to consumption, which is not always true for infectious microorganisms. Microorganisms causing intoxications may be dead or nonviable in the food when consumed; only the toxin need be present. Microorganisms causing infections must be alive and viable when food is consumed. Infection-causing microorganisms invade host tissues, and symptoms usually include headache and fever. Toxins usually do not cause fever, and toxins act by widely different mechanisms.

Staphylococcus aureus enterotoxin

Certain strains of *S. aureus* produce a heat-stable enterotoxin that is resistant to denaturation during thermal processing (cooking, canning, pasteurization).³³ The bacterium is salt (10–20% NaCl) and nitrite tolerant, which enables survival in cured meat products (luncheon meats, hams, sausages, etc.). Conditions that favor optimum growth favor toxin production, that is, high protein and starch foods. *S. aureus* competes poorly with other microorganisms, so if competitors are removed by cooking and *S. aureus* is introduced, noncompetitive proliferation is possible. The toxin affects the vagus nerve in the stomach causing uncontrolled vomiting shortly after consumption (1–6 hours). Other symptoms include nausea, retching, severe abdominal cramps, and diarrhea, which clear in 12–48 hours. Fortunately, fatalities are rare. Sources of the bacterium are usually from nasal passages, skin, and wound infections of food handlers. Hence, suspect foods are those rich in nutrients, high in salt, and those that are handled, with ham, salami, cream-filled pastries, and cooked poultry common vehicles. Control is accomplished by preventing contamination, personal hygiene, and no hand-food contact. Refrigeration below 5°C prevents multiplication, and heating foods to greater than 60°C will not destroy the toxin but will kill the bacterium. Prolific growth of the bacterium is possible in the 5–40°C range. Problems with the bacterium occur most frequently with foods prepared at home or at food service establishments, where gross temperature abuse has occurred.

Bacillus cereus enterotoxin

This spore-forming bacterium produces a cell-associated endotoxin that is released when cells lyse upon entering the digestive tract.³⁴ There are two distinct types of disease syndromes seen with this bacterium. The diarrheal syndrome occurs 8–16 hours after consumption. Symptoms include abdominal pain and watery diarrhea, with vomiting and nausea rarely seen. Duration is a short 12–24 hours. Foods linked to transmission of this syndrome are pudding, sauces, custards, soups, meat loaf, and gravy. The second, emetic, syndrome is similar to *S. aureus* intoxication. The incubation period is very short, 1–5 hours. Symptoms commonly are nausea and vomiting, with rare occurrence of diarrhea. Duration again is short, less than 1 day. This syndrome is commonly linked to consumption of fried rice in Oriental restaurants. Other foods include mashed potatoes and pasta. The infectious dose for both is thought to be at least 500,000. Because the bacterium forms spores, prevention of outbreaks is by proper temperature control. Hot foods should be held at greater than 65°C, leftovers should be reheated to greater than 72°C, and chilled foods should be quickly cooled to less than 10°C.

Botulism

This rare disease is caused by consumption of neurotoxins produced by *Clostridium botulinum*.³⁵ This spore-forming bacterium grows anaerobically and sometimes produces gas that can swell improperly processed canned foods. The bacterium produces several types of neurotoxins that are differentiated serologically. The toxins are heat-labile exotoxins. Two main food-poisoning groups (proteolytic and nonproteolytic) are found in nature. Nonproteolytic strains can be psychrotrophic and grow at refrigeration temperatures without the food showing obvious signs of spoilage (no swollen cans or off odor). Incubation period is 12–48 hours, but may be shorter or longer. Early symptoms, which may be absent, include nausea, vomiting, and occasionally diarrhea. Other symptoms are dizziness, fatigue, headache, constipation, blurred vision, double vision, difficulty in swallowing, breathing, and speaking, dry mouth and throat, and swollen tongue. Later, paralysis of muscles followed by the heart and respiratory system can lead to death due to respiratory failure. Duration is 3–6 days for fatal cases, several months for nonfatal cases. Treatment of suspect cases is by immediate administration of antisera, which can be useful if given early. Respiratory assistance is usually required.

Foods frequently linked to botulism are inadequately home-canned foods, primarily low-acid vegetables, preserved meats, and fish (more

common in Europe), cooked onions, and leftover baked potatoes. The bacterium generally will not grow at a pH of less than 4.6 or at a water activity below 0.85. Thus, high-acid foods, like tomatoes and some fruits, generally are safer than low-acid foods, like corn, green beans, peas, muscle foods, etc. Control is by applying a minimum botulinum cook (12 D) to all thermally processed foods held in hermetically sealed containers. Each particle of food must reach 120°C (and be held at that temperature for 3 minutes to reach a 12 D process). Consumers should reject swollen or putrid cans of food. Properly cured meats (hams, bacon, luncheon meats) should not support growth and toxin production by the bacterium.

A related illness caused by *C. botulinum* is infant botulism. The bacterium can colonize and grow in the intestinal tract of some newborn infants who have not developed a desirable competing microflora. The toxin is then slowly released in the intestines leading to weakness, lack of sucking, and limpness. Evidence suggests that infant botulism may be associated with sudden infant death syndrome. Consumption of honey by young infants has been linked to this type of disease.

► CHEMICAL INTOXICATIONS

Chemical hazards are minimally important as etiological agents of food-borne disease (Table 47-1). It should be noted that a number of chemicals, whether naturally occurring or intentionally added, have tolerance limits in foods. These limits are published in the Code of Federal Regulations, Title 21. Informal limits are available through FDA Compliance Policy Guidelines (Center for Food Safety and Applied Nutrition, Washington, D.C.). Prohibited substances (CFR 21, Part 189) are not allowed in human foods either because they have been shown to be a public health risk or because they have not been shown to be safe using sound scientific data.³⁶ Safe food additives are oftentimes referred to as Generally Recognized as Safe (GRAS) substances. There are no documented occurrences of food-borne disease associated with the proper use of insecticides, herbicides, fungicides, fertilizers, food additives, package material migration chemicals, and other industrial use chemicals.

Most human-made chemicals associated with food-borne disease find their way into foods by nonintentional means. Accidental or inadvertent contamination with heavy metals, detergents, or sanitizers can occur.³⁷ Although infrequently reported to CDC, most chemical intoxications are likely to be short in duration with mild symptoms. CDC does not attempt to link exposure to these chemicals with chronic diseases. There are measurable levels of pesticides, herbicides, fungicides, fertilizers, and veterinary drugs and antibiotics in most foods. In the vast majority of instances where these residues are found, levels are well below tolerance. Heavy metal poisonings have occurred primarily due to leaching of lead, copper, tin, zinc, or cadmium from containers or utensils in contact with acidic foods. Although usually considered minor contributors to human illness, toxic chemicals in foods may be significant contributors to morbidity and mortality of consumers. A number of toxic chemicals found in foods are of microbial origin. For example, mycotoxins are secondary metabolites produced by fungi.³⁸ The aflatoxins were the first fungal metabolite in foods regulated by the U.S. government. Grains and nut products are common carriers of these and other mold toxins. Other fungal toxins not associated with microscopic molds include toxic alkaloids associated with certain mushrooms. In this case, direct consumption of wild mushrooms that are frequently confused with edible domesticated species can lead to acute toxicity.³⁹ There are no current food processing or sanitation methods that can render these mushrooms acceptable as human food.

A number of seafood toxins are naturally associated with shellfish and some predatory reef fish.⁴⁰ Again, the ultimate cause of these intoxications is traced to the presence of microorganisms. Under favorable environmental conditions, populations of planktonic algae (dinoflagellates) are high (algal bloom) in shellfish-growing waters. The algae are removed from the water column during filter feeding of molluscan shellfish (oysters, clams, mussels, cockles, and scallops). The shellfish

then concentrate the algae and associated toxins in their edible flesh. Four primary shellfish intoxications have been identified: amnesic shellfish poisoning (ASP), diarrhetic shellfish poisoning (DSP), neurotoxic shellfish poisoning (NSP), and paralytic shellfish poisoning (PSP). ASP has been linked to mussels, DSP with mussels, oysters, and scallops, NSP with oysters and clams, and PSP with all mentioned shellfish. Control of shellfish toxins is best accomplished by monitoring harvest waters for the toxic algae. Postharvest control is not presently possible; however, depuration or relaying may be of some use.

Some marine fish harvested from temperate or tropical climates may contain toxic chemicals. Scombroid fish (anchovy, herring, marlin, sardine, tuna, bonito, mahi mahi, mackerel, bluefish, and amberjack) under time/temperature abuse during storage can support growth of bacteria that produce histidine decarboxylase.⁴⁰ This enzyme releases free histamine from the fish tissues. High histamine levels lead to an allergic response among susceptible consumers. Prompt and continued refrigeration of these fish after harvesting will limit microbial growth and enzyme activity. Fish most often associated with histamine scombrototoxicity are mahi mahi, tuna, mackerel, bluefish, and amberjack. Another form of naturally occurring chemical food poisoning found in tropical and subtropical fish is ciguatera. Like shellfish toxicity, ciguatera results when fish bioconcentrate dinoflagellate toxins through the food chain. Thus, large predatory fish at the top of the food chain can accumulate enough toxin to give a paralysis-type response among consumers. Fish associated with ciguatera poisoning are grouper, barracuda, snapper, jack, mackerel, and triggerfish. Again, monitoring of harvest waters is the essential control step to avoid human illness.

► PHYSICAL HAZARDS

Consumers frequently report physical defects with foods, of which presence of foreign objects predominate.⁶ Glass is the leading object consumers report and is evidence of manufacturing or distribution error. Most physical hazards are not particularly dangerous to the consumer, but their obvious presence in a food is disconcerting. Most injuries are cuts, choking, and broken teeth. Control of physical hazards in foods is often difficult, especially when these hazards are a normal constituent of the food, such as bones and shells. Good manufacturing practices (GMPs) and employee awareness are the best measures to prevent physical hazards. Metal detectors and x-ray machines may be installed where appropriate.

► ADMINISTRATIVE REGULATION

Several regulatory groups are involved in the regulation of food safety and quality standards, from local and state agencies to international agencies. Since there is tremendous variation within and between local and state agencies, this discussion will be confined to the national and international agencies that regulate food. At the national level, two federal agencies regulate the vast majority of food produced and consumed in the United States; namely, the U.S. Department of Agriculture (USDA)⁴¹ and the Food and Drug Administration (FDA).⁴²

U.S. Department of Agriculture

USDA has responsibility for certification, grading, and inspection of all agricultural products. All federally inspected meat and meat products, including animals, facilities, and procedures, are covered under a series of meat inspection laws that began in 1906 and have been modified on several different occasions, culminating in the latest revisions in 1996.⁴³ These laws cover only meat that is in interstate commerce, leaving the legal jurisdiction of intrastate meats to individual states. In the states that do have state-inspected meats, in addition to federally inspected meats, the regulations require that the state inspection program be “equivalent” to the federal program. Key elements in meat inspection are examination of live animals for obvious signs of

clinical illness and examination of gross pathology of carcasses and viscera for evidence of transmissible diseases. The newest regulations also require the implementation of an HACCP system and microbiological testing of carcasses after chilling. Eggs and egg products are also covered by USDA inspection under the Egg Products Inspection Act of 1970.⁴⁴ This act mandates inspection of egg products at all phases of production and processing. USDA inspection of meat processing is continuous; that is, products cannot be processed without an inspector or inspectors present to verify the operation.

U.S. Food and Drug Administration

FDA has responsibility for ensuring that foods are wholesome and safe, and have been stored under sanitary conditions, as outlined by the Food Drug and Cosmetic Act of 1938. This act has been amended to include food additives, packaging, and labeling. The last two issues relate not only to product safety and wholesomeness, but also to nutritional labeling and economic fraud. FDA is also empowered to act if pesticide residues exceed tolerances set by the U.S. Environmental Protection Agency. Unlike USDA inspection, FDA inspection is discontinuous, with food-processing plants being required to maintain their own quality control records while inspectors themselves make random visits to facilities.

Milk Sanitation

Perhaps one of the greatest public health success stories of the twentieth century has been the pasteurization of milk. The U.S. Public Health Service drafted a model milk ordinance in 1924, which has been adopted by most local and state regulatory authorities and has become known as the Grade A PMO (Pasteurized Grade A Milk Ordinance).⁴⁵ This ordinance covers all phases of milk production, including but not limited to animal health, design and construction of milk-processing facilities, equipment, and most importantly, the pasteurization process itself. The PMO sets quality standards for both raw and processed milk, in the form of cooling requirements and bacteriological populations. The PMO also standardizes the pasteurization requirements for fluid milk, which insures that bacteria of public health significance will not survive in the finished product. From a historical perspective, it is interesting to note that neither the public nor the industry initially embraced pasteurization, but that constant pressure from public health officials finally succeeded in making this important advance in public health almost universal.

International Administration

The Codex Alimentarius Commission, created by the Food and Agriculture Organization and the World Health Organization, has the daunting task of implementing food standards on an international scale.⁴⁶ These standards apply to both general and specific food categories and also set limits for pesticide residues in foods. Acceptance of these standards is voluntary and at the discretion of individual governments, but acceptance of the standards requires that the country applies them equally to both domestically produced and imported products. The importance of international standards is growing daily as international trade in food expands. Many countries find that they are both importing and exporting foods, and a common set of standards is critical in establishing trade without the presence of nontariff trade barriers.

Prerequisite Programs

In order to achieve the goal of producing a safe food product, food processors should have in place a variety of fundamental programs covering the general operation of the process and the processing facility. These programs are considered “prerequisites,” as without these basic programs in place, it is impossible to produce safe and wholesome foods, irrespective of the available technology, inspection process, or

microbiological testing. These prerequisite programs fall generally under the term “good manufacturing practices,” but also include sanitation, equipment and facility design, personal hygiene issues, and pest control.

Good Manufacturing Practices

GMPs cover a broad range of activities with the food-processing establishment. Although there is general guidance in the Code of Federal Regulations,⁴⁷ GMPs are established by the food processor, and are specific to their own operation. There is also general guidance on GMPs available from a variety of organizations representing specific commodities or trades. Specific applications of GMPs are discussed in the following sections, but GMPs also apply to activities that affect not only the safety of the product, but also the quality. As an example, a refrigerated holding or storage temperature may be set by a GMP at a point below that which is actually required for product safety, but is set at that point for product quality reasons. Conversely, if a raw material or partially manufactured product, which under normal circumstances would be kept refrigerated, were subsequently found to be at a higher temperature, it would be deemed to be out of compliance with the GMP.

GMPs may also focus on the actual production processes and controls within those processes. GMPs may be viewed as rules that assure fitness of raw materials and ingredients, rules that maintain the integrity of processed foods, and rules to protect the finished product (foods) from deterioration during storage and distribution. Other GMPs may address the presence of foreign materials in the processing area, such as tramp metal from equipment maintenance or broken glass from a shattered light bulb. These GMPs are established to provide employees with specific guidance as to the company's procedures for addressing certain uncommon but unavoidable issues.

While GMPs, by their nature, cover broad areas of operation, the individual GMP is usually quite specific, presenting complete information in a logical, stepwise fashion. An employee should be able to retrieve a written GMP from a file, and should be able to perform the required GMP function with little or no interpretation of the written material.

Training and Personal Hygiene

Personnel who are actually involved in food-processing operations should also understand the necessity for proper cleaning and sanitation, and not simply rely on the sanitation crew to take care of all issues.⁴⁸ In addition, all employees must be aware of basic issues of personal hygiene, especially when they are in direct contact with food or food-processing equipment. Some key elements, such as hand washing and clean clothing and gloves, should be reemphasized on a periodic basis. An important aspect of this is an emphasis on no “bare-handed” contact with the edible product, using utensils or gloves to prevent this from occurring. This information has been outlined by the U. S. Food and Drug Administration in the Good Manufacturing Practices section of the Code of Federal Regulations.

Pest Control

Pests, such as insects and rodents, present both physical as well as biological hazards.⁴⁹ While the consumer would undoubtedly object to the proverbial “fly in the soup,” the concerns with the introduction of biological hazards into the foods by pests are even greater. Integrated Pest Management (IPM) includes the physical and mechanical methods of controlling pests within the food-processing environment and the surrounding premises. At a minimum, the processing environment and the area surrounding the processing plant should be evaluated by a competent inspector for both the types of pests likely to be present, and the potential harborage for such pests. A comprehensive program should be established that addresses flying insects, crawling insects, and rodents, the objective being to prevent access to the processing environment. Given that it is impossible to completely deny

pest access to the processing environment, internal measures should be taken to reduce the numbers of any pests that enter the processing area. Since it is undesirable to have poisonous chemicals in areas surrounding actual food production, active pest-reduction methods should be mechanical in nature (traps, insect electrocuters, etc.).

Record keeping is an important aspect of pest management. Documentation of pest management activities should include maps and maintenance schedules for rodent stations, bait stations, insect electrocuters, an inventory of pesticides on the premises, and reports of inspections and corrective actions. There should be standard operating procedures for applying pesticides, and they should only be applied by properly trained individuals. Many food-processing establishments contract with external pest control operators to address their pest control needs.

► SANITATION

Sanitation is the fundamental program for all food-processing operations, irrespective of whether they are converting raw products into processed food or preparing food for final consumption. Sanitation impacts all attributes of processed foods, from organoleptic properties of the food to the safety and quality of the food itself. From a food processor's perspective, an effective sanitation program is essential to producing quality foods with reasonable shelf lives. Without an effective program, even the best operational management and technology will ultimately fail to deliver the quality product that consumers demand.

Sanitation programs are all-encompassing, focusing not only on the details of soil types and chemicals, but on the broader environmental issues of equipment and processing-plant design. Many food-borne microorganisms, both spoilage organisms and bacteria of public health significance, can be transferred from the plant environment to the food itself.⁵⁰ Perhaps one of the most serious of these microorganisms came to national and international attention in the mid-1980s, when *Listeria monocytogenes* was found in processed dairy products. *Listeria* was considered to be a relatively minor veterinary pathogen until that time, and not even considered a potential food-borne agent. However, subsequent research demonstrated that *L. monocytogenes* was a serious human health concern, and more importantly was found to be widely distributed in nature. In many food-processing plants, *Listeria* were found to be in the general plant environment, and subsequently efforts have been made to improve plant sanitation, through facility and equipment design as well as focusing more attention on basic cleaning and sanitation.

Sanitary Facility Design

Some of the basic considerations of food-processing facility design include the physical separation of raw and processed products, adequate storage areas for nonfood items (such as packaging materials), and a physical layout that minimizes employee traffic between raw and processed areas. While these considerations are easily addressed in newly constructed facilities, they may present challenges in older facilities that have been renovated or added on to. Exposed surfaces, such as floors, walls, and ceilings, in the processing area should be constructed of material that allows for thorough cleaning. Although these surfaces are not direct food contact surfaces, they contribute to overall environmental contamination in the processing area. These surfaces are particularly important in areas where food is open to the environment, and the potential for contamination is greater when temperature differences in the environment result in condensation.⁵¹ As an example, a large open cooking kettle will generate some steam that may condense on surfaces above the kettle. This condensate may, without proper design and sanitation, drip back down into the product carrying any dirt and dust from overhead surfaces back into the food. Other obvious considerations are basic facility maintenance as well as insect and rodent control programs, as all of these factors may contribute to contamination of food.

Sanitary Equipment Design

Many of the same considerations for sanitary plant design also apply to the design of food-processing equipment. Irrespective of its function, processing equipment must protect food from external contamination and from undue conditions that will allow existing bacteria to grow. The issue of condensate as a form of external contamination has already been raised. Opportunities for existing bacteria to reproduce may be found in the so-called "dead spaces" within some equipment. These areas can allow food to accumulate over time under conditions that allow bacteria to grow. These areas then become a constant inoculation source for additional product as it moves through the equipment, increasing the bacteriological population within the food. Other considerations of food equipment design include avoiding construction techniques that may allow product to become trapped within small areas of the equipment, creating the same situation that occurs in the larger dead spaces within the equipment. As an example, lap seams that are tack welded provide ample space for product to become trapped. Not only does this create a location for bacteria to grow and contaminate the food product, it also creates a point on the equipment that is difficult if not impossible to clean.

Cleaning and Sanitizing Procedures

Cleaning and sanitizing processes can be generically divided into five separate steps that apply to any sanitation task.⁵² The first step is removal of residual food, waste materials, and debris. This is frequently referred to as a "dry" cleanup. The dry cleanup is followed by a rinse with warm (48–55°C) water to remove material that is only loosely attached to surfaces and to hydrate material that is more firmly attached to surfaces. Actual cleaning follows the warm water rinse, which usually involves the application of cleaning chemicals and some form of scrubbing force, either with mechanical brushes or with high-pressure hoses. The nature of the residual food material will determine the type of cleaning compound applied. After this, surfaces are rinsed and inspected for visual cleanliness. At this point, the cleaning process is repeated on any areas that require further attention. Carbohydrates and lipids can generally be removed with warm to hot water and sufficient mechanical scrubbing. Proteins require the use of alkaline cleaners, while mineral deposits can be removed with acid cleaners. Commercially available cleaning compounds generally contain materials to clean the specific type of food residue of concern, as well as surfactants and, as necessary, sequestrants that allow cleaners to function more effectively in hard water.⁵³

When surfaces are visually clean, a sanitizer is applied to reduce or eliminate remaining bacteriological contamination. Inadequately cleaned equipment cannot be sanitized, as the residual food material will protect bacteria from the sanitizer. One of the most common sanitizing agents widely used in small- and medium-sized processing facilities is hot water. Most regulatory agencies require that when hot water is used as the sole method of sanitization, the temperature must be at or above 85°C. While heat sanitization is effective, it is not as economical as chemical sanitizers because of the energy costs required to maintain the appropriate temperature. Chlorine containing sanitizers are economical and effective against a wide range of bacterial species, and are widely used in the food industry.⁵⁴ Typically, the concentrations of chlorine applied to equipment and surfaces are in the 150–200 parts per million range. Chlorine sanitizers are corrosive and can, if improperly handled, release chlorine gas into the environment.

Iodine-containing sanitizers are less corrosive than chlorine sanitizers, but are also somewhat less effective. These sanitizers must be used at slightly acidic pH values to allow for the release of free iodine. The amber color of iodine sanitizers can give an approximate indication of concentration, but can also leave residual stains on treated surfaces. Quaternary ammonium compounds (QACs) are noncorrosive and demonstrate effective bactericidal action against a wide range of microorganisms. These sanitizers are generally more costly and not as effective as chlorine compounds, but they are stable and provide residual antimicrobial activity on sanitized surfaces. Food-processing plants

will frequently alternate between chlorine and QAC sanitizers to prevent development of resistant bacterial populations or will use chlorine sanitizers on regular production days and then apply QACs during periods when the facility is not operating (for example, over a weekend).

Another element in food plant sanitation programs is the personnel who perform the sanitation operations as well as the employees who work in the processing area. Sanitation personnel should be adequately trained to understand the importance of their function in the overall processing operation in addition to the training necessary to properly use the chemicals and equipment necessary for them to perform their duties.

► HAZARD ANALYSIS CRITICAL CONTROL POINT SYSTEM (HACCP)

The basic concept of HACCP was developed in the late 1950s and early 1960s as a joint effort to produce food for the manned space program. The U.S. Air Force Space Laboratory Project Group, the U.S. Army Natick Laboratories, and the National Aeronautics and Space Administration contributed to the development of the process, as did the Pillsbury Company, which had a major role in developing and producing the actual food products. Since that time, the HACCP system has evolved and been refined, but still focuses on the original goal of producing food that is safe for consumption.⁶

Since development, HACCP principles have been used in many different ways. However, recent interest in the system has been driven by changes in the regulatory agencies, specifically the U.S. Department of Agriculture—Food Safety and Inspection Service (USDA-FSIS), and the U.S. Food and Drug Administration. USDA-FSIS recently revised the regulations that govern meat inspection to move all federally inspected meat plants to an HACCP-based system of production and inspection.⁴³ FDA has also changed the regulations for fish and seafood, again moving this to an HACCP-based system for production.⁵⁵ It is likely, given current trends by federal agencies, that most commercially produced foods will be produced under HACCP systems within the next 10 years.

The goal of an HACCP system is to produce foods that are free of biological, chemical, and physical hazards.⁵⁶ HACCP is a preventative system, designed to prevent problems before they occur, rather than try to fix problems after they occur. Biological hazards fall into two distinct categories: those that can potentially cause infection and those that can potentially cause intoxications. Infectious agents require the presence of viable organisms in the food and may not, depending on the organisms and the circumstances, require that the organism actually reproduce in the food. As an example, *Escherichia coli* O157:H7 has an extremely low infectious dose for humans (possibly less than 100 viable cells), and as such the mere presence of the bacterium in foods is a cause for concern. In contrast, organisms involved in intoxications usually require higher numbers of the organism in the food to produce sufficient amounts of toxin to cause clinical illness in humans. However, some of the toxins involved in food-borne diseases are heat stable, so that absence of viable organisms in the food is not necessarily an indication of the relative safety of the food. *Staphylococcus aureus* is a good example, where it typically requires greater than 1,000,000 to 10,000,000 cells per gram of food to produce sufficient toxin to cause illness in humans.⁵⁷ However, because the toxin itself is extremely heat stable, cooking the food will eliminate the bacterium but not the toxin, and the food can still potentially cause an outbreak of food-borne illness.

Chemical hazards include chemicals that are specifically prohibited in foods, such as cleaning agents, as well as food additives that are allowed in foods but only at regulated concentrations. Foods containing prohibited chemicals or food additives in levels higher than allowed are considered adulterated. Adulterated foods are not allowed for human consumption and are subject to regulatory action by the appropriate agency (USDA or FDA). Chemical hazards can be minimized by assuring that raw materials (foods and packaging

materials) are acquired from reliable sources that provide written assurances that the products do not contain illegal chemical contaminants or additives. During processing, adequate process controls should be in place to minimize the possibility that an approved additive will be used at levels not exceeding maximum legal limits for both the additive and the food product. Other process controls and GMPs should also insure that industrial chemicals, such as cleaners or lubricants, will not contaminate food during production or storage.⁴⁷

Physical hazards are extraneous material or foreign objects that are not normally found in foods. For example, wood, glass, or metal fragments are extraneous materials that are not normally found in foods. Physical hazards typically affect only a single individual or a very small group of individuals, but because they are easily recognized by the consumer, are sources of many complaints. Physical hazards can originate from food-processing equipment, packaging materials, the environment, and from employees. Physical contaminants can be minimized by complying with GMPs and by employee training. While some physical hazards can be detected during food processing (e.g., metal by the use of metal detectors), many nonferrous materials are virtually impossible to detect by any means and so control often resides with employees.

HACCP Plan Development

Prior to the implementation of HACCP, a review should be conducted of all existing prerequisite programs. Deficiencies in these programs should be addressed prior to the implementation of HACCP, because an HACCP plan presumes that these basic programs are fully functional and effective. Development of an HACCP plan begins with the formation of an HACCP team.⁵⁸ Individuals on this team should represent diverse sections within a given operation, from purchasing to sanitation. The team is then responsible for development of the plan. Initial tasks that the team must accomplish are to identify the food and method of distribution, and to identify the consumer and intended use of the food. Having done this, the HACCP team should construct a flow diagram of the process and verify that this diagram is accurate.

The development of an HACCP plan is based on seven principles or steps in logical order (Table 47-5).⁵⁹ With the flow diagram as a reference point, the first principle or step is to conduct a hazard analysis of the process. The HACCP team identifies all biological, chemical, and physical hazards that may occur at each step during the process. Once the list is completed, it is reviewed to determine the relative risk of each potential hazard, which helps identify significant hazards. Risk is the interaction of “likelihood of occurrence” with “severity of occurrence.” As an extreme example, a sudden structural failure in the building could potentially contaminate any exposed food with foreign material. However, likelihood of the occurrence of such an event is small. In contrast, if exposed food is held directly below surfaces that are frequently covered with condensate, then the likelihood of condensate dripping on exposed food is considerably higher. An important point in the determination of significant hazards is a written explanation by the HACCP team regarding how the determination of “significant” was made. This documentation can provide a valuable reference in the future, when processing methods change or when new equipment is added to the production line.

The second principle in the development of an HACCP plan is the identification of critical control points (CCPs) within the system.

TABLE 47-5. SEVEN HACCP PRINCIPLES

Hazard analysis
Identify critical control points (CCP)
Establish critical limits for each CCP
Monitor CCP
Establish corrective action
Verification
Record keeping

A CCP is a point, step, or procedure where control can be applied and a food safety hazard can be prevented, eliminated, or reduced to acceptable levels.⁵⁹ An example of a CCP is the terminal heat process applied to canned foods after cans have been filled and sealed. This process, when properly conducted according to FDA guidelines, effectively eliminates a potential food safety hazard, *Clostridium botulinum*. Once CCPs have been identified, the third principle in the development of an HACCP plan is to establish critical limits for each CCP. These limits are not necessarily the ideal processing parameters, but the minimum acceptable levels required to maintain the safety of the product. Again, in the example of a canned food, the critical limit is the minimum time and temperature relationship to insure that each can has met the appropriate standards required by FDA.

The fourth principle, following in logical order, is to establish appropriate monitoring requirements for each critical control point. The intent of monitoring is to insure that critical limits are being met at each critical control point. Monitoring may be on a continuous or discontinuous basis. Presence of a physical hazard, such as metal, can be monitored continuously by passing all of the food produced through a metal detector. Alternately, presence of foreign material can be monitored on a continuous basis by visual inspection. Discontinuous inspection may involve taking analytical measurements, such as temperature or pH, at designated intervals during the production day. Some analytical measurements can be made on a continuous basis by the use of data-recording equipment, but it is essential that continuous measures be checked periodically by production personnel.

The fifth principle in the development of an HACCP plan is to establish appropriate corrective actions for occasions when critical limits are not met. Corrective actions must address the necessary steps to correct the process that is out of control (such as increasing the temperature on an oven) as well as address disposition of the product that was made while the process was out of control. A literal interpretation of the HACCP system and a CCP is that when a CCP fails to meet the critical limits, then the food product is potentially unsafe for human consumption. As a result, food produced while the CCP was not under control cannot be put into the normal distribution chain without corrective actions being taken to that product. Typically this means that the product must be either reworked or destroyed, depending on the nature of the process and the volume of product that was produced while the CCP was out of control. This argues for frequent monitoring, so that the actual volume of product produced during each monitoring interval is relatively small.

The sixth principle in the development of an HACCP plan is verification. Verification can take many forms. Microbiological tests of finished products can be performed to evaluate the effectiveness of an HACCP plan. Alternately, external auditors can be used to evaluate all parts of the HACCP plan, to insure that the stated goals and objectives are being met. An HACCP plan must also be periodically reviewed and updated, to reflect changes in production methods and use of different equipment. Another critical aspect of verification is education of new employees on the HACCP plan itself. As HACCP is phased in to many food-processing environments, many employees who are unfamiliar with the concepts and goals of HACCP will have to be educated on the necessity of following the plan. In one sense, USDA-FSIS regulations have guaranteed that meat processors will follow HACCP plans, as the penalty for not following the HACCP plan can be as severe as the loss of inspection at an establishment. However, HACCP is an excellent system for monitoring and improving production of food products, and many food processors will discover that HACCP plans offer many benefits, well above and beyond the legal requirements of the regulatory agencies.

The seventh principle in the development of an HACCP plan is the establishment of effective record-keeping procedures. In many respects, an HACCP plan is an elaborate record-keeping program. Records should document what was monitored, when it was monitored and by whom, and what was done in the event of a deviation. Reliable records are essential from both business and regulatory perspectives. From the business perspective, HACCP records allow a processor to develop an accurate longitudinal record of production

practices and deviations. Reviewing HACCP records may provide insight on a variety of issues, from an individual raw material supplier whose product frequently results in production deviations, to an indication of an equipment or environmental problem within a processing plant. From a regulatory perspective, records allow inspectors to determine if a food processor has been fulfilling commitments made in the HACCP plan. If a processor has designated a particular step in the process as a CCP, then they should have records to indicate that the CCP has been monitored on a frequent basis and should also indicate corrective actions taken in the event of a deviation.

► FOOD PRESERVATION

Normal microflora of foods are characterized by food type and growing/handling practices. Foods of plant origin have flora on outer surfaces. Animals too have flora on surfaces, but also have intestinal flora and secretion flora. Outside sources, such as soil, dust, water, humans, and equipment, can be significant sources of disease-causing microbes. Use of diseased animals for foods is dangerous because they often carry human pathogens. It should be noted that the inner tissues of plants and animals are generally sterile; however, cabbage inner leaves have lactobacilli, and animal intestinal tracts have numerous microbes. Pathogens found on fruits and vegetables are from soil origin (*Clostridium*, *Bacillus*) or from contaminated water, fertilizer, or food handlers. Some grain and nut products are naturally contaminated in the field with mycotoxin-producing molds. Soil is also a source of contamination of foods from animal origin. Animal feces can harbor coliforms, *Clostridium perfringens*, enterococci, and enteric pathogens. Milk from infected udders (mastitis) can carry disease-causing *Streptococcus pyogenes* and *Staphylococcus aureus*. Nonmastitic udders can shed *Brucella*, *Rickettsia*, and viruses.

Outside sources of contamination that are not normally associated with food can be important in terms of food safety. Soil and dust contain very large numbers and a large variety of microbes. Many microorganisms responsible for food spoilage come from these sources. Contamination is by direct contact with soil, water, or by airborne dust particles. Air can carry microorganisms from other sources such as sneezing, coughing, dust, and aerosols. Pathogens, mold spores, yeasts, and spoilage bacteria can then be disseminated. Organic debris from plants or animals is an excellent source. Microorganisms can grow on walls, floors, and other surfaces and act as a source of contamination during food processing and preparation. Airborne particles can be removed by filtration or by electrostatic precipitation.

Treated sewage may be used for fertilizer, although due to large amounts of toxic compounds, like heavy metals, it is not used often for this purpose.²⁹ Sewage can be an excellent source of pathogens including all enteric gram negative bacteria, enterococci, *Clostridium*, viruses, and parasites. Sewage that contaminates lakes, streams, and estuaries has been linked to many seafood outbreaks. In addition, water used for food must be safe for drinking and must be treated and free of pathogens. Furthermore, water must not contain toxic wastes. Water in food processing is typically used for washing, cooling, chilling, heating, ice, or as an ingredient. Stored water (reservoirs) and underground water (wells) are usually self-purifying.

Numbers and types of microorganisms found in foods depend on (a) the general environment from which the food was obtained, (b) the quality of raw food, (c) sanitary conditions under which the food was processed or handled, and (d) adequacy of packaging, handling, and storage of foods. General methods of food preservation are shown in Table 47-6. The Hurdle Concept uses multiple methods (multibarrier approach) to food preservation and is the most common. Examples include pasteurized milk (heat, refrigeration, and packaging) or canned beans (heat, anaerobiosis, and packaging).

Principles of Food Preservation

Principles of food preservation rely on preventing or delaying microbial decomposition.^{60,61} This can be accomplished by using asepsis or

TABLE 47-6. METHODS OF FOOD PRESERVATION

Methods	Description
Asepsis	Keeping microorganisms out of food, "aseptic packaging"
Removal	Limited applications, difficult to do, filtration
Anaerobiosis	Sealed, evacuated container, vacuum packaging
High temperatures	Sterilization, canning, pasteurization
Low temperatures	Refrigeration, freezing
Dehydration	Drying or tying-up water by solutes and hydrophilic colloids, lower water activity (a_w)
Chemical preservatives	Natural, developed, or added (propionic acid, nisin, spices), acids lower pH
Irradiation	X-Rays (ionizing) or UV (nonionizing)
Mechanical destruction	Grinding, high pressures, not widely used
Combinations	Most frequently employed, multiple hurdle concept

removal. Preventing growth or activity of microbes with low temperatures, drying, anaerobic conditions, or preservatives can also be done. Killing or injuring microbes with heat, irradiation, or some preservatives is certainly effective. A second principle is to prevent or delay self-decomposition, which is done by destruction or inactivation of enzymes (blanching) or by preventing or delaying autoxidation (antioxidants). The last principle is to prevent physical damage caused by insects, animals, and mechanical forces, which prevents entry of microorganisms into food. Physical barriers (packaging) are the primary means of protection. To control microorganisms in foods, many methods of food preservation depend not on the destruction or removal of microbes but rather on delaying the initiation of growth or hindering growth once it has begun.

For food preservation to succeed, one must be able to manipulate the microbial growth curve. Many steps can be done to lengthen lag phase or positive acceleration phase of a population. These steps include (a) preventing introduction of microbes by reducing contamination (fewer numbers gives a longer lag phase), (b) avoiding addition of actively growing organisms that may be found on unclean containers, equipment, and utensils, and (c) creating unfavorable environmental conditions for growth. The last step is the most important in food preservation and can be done by low water activity, extremes of temperature, irradiation, low pH, adverse redox potential, and by adding inhibitors and preservatives (Table 47-6). Some of these steps may only damage or injure microorganisms; hence, the need for multiple barriers becomes essential.⁶⁰ For each of these steps to be effective, other factors should be considered. For example, the number of organisms present determines kill rate. Smaller numbers give faster kill rates. Vegetative cells are most resistant to lethal treatments when in late lag or stationary phase and least resistant when in log phase of growth.

Asepsis/Removal

Keeping microorganisms out of food is often difficult during food production. Processing and post-processing, are much easier places to apply asepsis. Protective covering of foods such as skin, shells, and hides are often removed during processing, thereby exposing previously sterile foods to contaminating microbes. Raw agricultural commodities normally carry a natural bioburden upon entering the processing plant. Packaging is the most widely used form of asepsis and includes wraps, packages, cans, etc.

Removal of microorganisms from foods is not very effective. Washing of fruits and vegetables can remove some surface microorganisms. However, if wash water becomes dirty, it can add microbes to the food. Trimming is an effective way to remove spoiled or damaged parts. Filtration is good for clear liquids (juices, beer, soft drinks, wine, and water) but is of little value for solid foods. Centrifugation,

such as used in sedimentation/clarification steps, is not useful for removal of bacteria or viruses.

Modified Atmosphere Conditions

Altering the atmosphere surrounding a food can be a useful way to control microbes. Examples include packaging with vacuum, CO₂, N₂, or combinations of inert gases with or without oxygen. Some CO₂ accumulation is possible during fermentations or vegetable respiration. It is important to note that vacuum packaging can lead to favorable environments for proliferation of anaerobic pathogens such as *Clostridium botulinum*.

High Temperature Preservation

Use of high-temperature processing is based on destroying microbes, but may also injure certain thermotolerant microbes. Not all microorganisms are killed, that is, spore formers usually survive.⁶¹ Other barriers are combined with a thermal process to achieve adequate safety and product shelf life. Commercial sterilization used in the canning process usually destroys all viable microbes that can spoil the product. Thermophilic spores may survive but will not grow under normal storage conditions.

Several factors affect heat resistance of microorganisms in foods.⁶¹ Species' variability and the ability to form spores, plus condition of the microbial population, can affect heat resistance. Environmental factors such as food variability and presence of other preservative measures employed also dictate thermal resistance. For example, heat resistance increases with decreasing water activity. Hence, moist air heating is better than dry heating. High-fat foods tend to increase resistance of cells. The larger initial number of microorganisms present means a higher heat resistance. Older (stationary phase) cells are more resistant to heat than younger cells. Resistance increases as growth temperature increases. A microbe with a high optimum temperature for growth will generally have a high heat resistance. Addition of other inhibitors, such as nitrite, will decrease resistance. Likewise, high-acid foods (pH less than 4.6) will not generally support growth of pathogens. There is a time-temperature relationship that is a very important factor governing heat resistance of a microbial population. As temperature increases, the time needed for a given kill decreases. The relationship is dependent on type and size of food container. Larger containers require longer process times. Metal conducts heat better than glass, which can lower process times.

Microorganisms are killed by heat at a rate nearly proportional to the numbers present. This is a log order of death, which means that under a constant temperature, the same percentage of a population will die at a given time interval regardless of the population size (Fig. 47-1). For example, 90% die in 30 seconds, 90% of remaining in the next 30 seconds, and so on. Thus, as the initial number of

Figure 47-1. Typical heat inactivation curve for a bacterial population. D = 30 sec.

organisms increases, the time required for the reduction of all organisms at a given temperature also increases. Food microbiologists express this time-temperature relationship by calculating a number of constants. D value is the time required to reduce a population by one log cycle at a given temperature. Thermal Death Time (TDT) is the time needed to kill a given number of organisms at a given temperature. Thermal Death Point (TDP) is the temperature needed to kill a given number of organisms at a set time (usually 10 minutes; D_{10}).

In food canning, the time-temperature profile must be calculated for each size container, for each food type, and for each retort used. When done correctly, these time-temperature conditions provide a large margin of safety since one rarely knows the numbers and types of microbes in a given container, but one must assume that *C. botulinum* is present. To insure safety, inoculated pack studies are done using *Clostridium sporogenes* PA 3679, which is six times more heat resistant than *C. botulinum*. A known number of PA 3679 are added to cans fitted with thermocouples. Cans are then processed to 120°C (250°F) and held for various time periods. Survivors are enumerated to construct a thermal death curve for that particular food, and a D value is calculated. For canned foods, a 12D margin of safety is used. Thus, heat at a given temperature is applied for a time equal to $D \times 12$ log cycle reductions of PA 3679. Therefore, if a can had 10^9 spores, only 1 in 1000 cans would have a viable spore. Thus, the probability of survival for *C. botulinum* would be 1 in 10^{12} if a can is heated at 250°F for 3 minutes. A minimum botulinum cook is one where every particle of food in a container reaches 250°F and remains at that temperature for at least 3 minutes.

Several factors affect heat transfer and penetration into food packages. Food type (liquids, solids, size, and shape) determine mixing effects during heating. Conduction occurs with solid foods (pumpkin) and results in slow heat transfer because there is no mixing of contents. Convection gives liquids (juice) faster heat transfer due to mixing by currents or mechanical agitation. Combination of conduction and convection is observed with particles in liquid (peas), though heating is primarily by convection and depends on viscosity of liquid component. Container size, shape, and composition are important. Tall thin cans transfer heat faster than short round cans. Large cans take longer than small cans. Metal (tin, steel, and aluminum) containers transfer heat faster than glass resulting in shorter process times. Plastics can have rapid heat transfer due to thinness. Retort pouches, which are laminates of foil and plastic, have rapid heat transfer; however, pinhole problems can occur. Preheating foods prior to filling containers and preheating retort will shorten process time. Rotation or agitation of cans during processing increases convection giving faster heating.

Canning is the preservation of foods in hermetically sealed containers, usually by heat treatments. The typical sequence in canning is as follows. Freshly harvested, good-quality foods are washed to remove soils. Next, a blanch or mild heat treatment is applied to set color of fruits and vegetables, inactivate enzymes, purge dissolved gases, and kill some microorganisms. Clean containers are then filled to leave some head space. Hot packing is filling of preheated food to give faster processing, although cold packing can be done. Containers are sealed under vacuum then placed into a retort. The retort is sealed and heated with pressurized steam. After heating, cans should be rapidly cooled to avoid overcooking and to prevent growth of thermophiles. Cooling is done by submerging cans in a sanitized water bath, which can cause problems if pinhole leaks are present allowing water to enter containers.

Less severe heat processing is pasteurization, which usually involves heating at less than 100°C. Pasteurization has two purposes, to destroy all pathogens normally present in a product and to reduce numbers of spoilage microorganisms. This thermal process kills some but not all microorganisms present in the food. Pasteurization is used when more rigorous heat treatments might alter food quality. For example, overheated milk will coagulate, brown, and burn. Pasteurization should kill all pathogens normally associated with the product. This is useful when spoilage microorganisms are not heat resistant and when surviving microbes can be controlled by other methods. Another

reason for pasteurization is to kill competing microorganisms to allow for a desirable fermentation with starter cultures. Pasteurization is used to manufacture cheeses, wines, and beers. Milk pasteurization may use three equivalent treatments. Low Temperature Long Time (LTLT) treatment uses 145°F (63°C) for 30 minutes. High Temperature Short Time (HTST) uses 161°F (72°C) for 15 seconds. Ultra High Temperature or Ultrapasteurized (UHT) uses 138°C for only 2 seconds. UHT processes are used for shelf-stable products.

Heating at or below 100°C involves most cooking temperatures. Baking, roasting, simmering, boiling, and frying (oil is hotter but internal temperature of food rarely reaches 100°C) are examples of cooking methods. All pathogens are usually killed except spore formers. Microwaving does not exceed 100°C and can result in uneven heating. Microwave cooking should allow an equilibration time after removal from the oven for more even heating.^{62,63}

Low-Temperature Preservation

Low temperatures retard chemical reactions, and refrigeration slows microbial growth rates. Freezing prevents growth of most microorganisms by lowering water activity. Several psychrotrophic pathogens (*Listeria monocytogenes*, *Yersinia enterocolitica*, and nonproteolytic *Clostridium botulinum*) are able to multiply at refrigeration temperatures.⁶⁴ Among factors influencing chill storage, temperature of the compartment is critical.⁶⁵ Temperature of food products should be held as low as possible. Relative humidity should be high enough to prevent dehydration but not too high to favor growth of microorganisms. Air velocity in coolers helps to remove odors, control humidity, and maintain uniform temperatures. Atmosphere surrounding food during chill storage can affect microbial growth. Modified atmosphere packaging can help ensure safe chill-stored foods. Some plant foods respire resulting in removal of O_2 and release of CO_2 . Ultraviolet irradiation can be used to kill microorganisms on surfaces and in the air during chill storage of foods.

For chill storage to be effective in controlling microorganisms, the rate of cooling should be done rapidly. Temperature should be maintained as low as possible for refrigerated foods (less than 40°F). Thawing of frozen foods presents special problems because drip loss provides ample nutrients for microorganisms. In addition, thawing should be done as rapidly as possible and the food used as quickly as possible to avoid opportunity for microbial growth. Often, thawing is done at room temperature over many hours, which can lead to exposure of surfaces to ambient temperatures for extended periods. Another problem is incomplete thawing of large food items (turkeys). By cooking a large item that is not completely thawed, the internal temperature may not reach lethal levels to kill even the most heat-sensitive enteric pathogen. In fact, a spike in the number of salmonellosis and campylobacteriosis outbreaks occurs every Thanksgiving and Christmas holidays because of consumption of undercooked turkey and stuffing.

Drying

Foods can be preserved by removing or binding water. Any treatment that lowers water activity can reduce or eliminate growth of microorganisms. Some examples include sun drying, heating, freeze drying, and addition of humectants. Humectants act not by removing water but rather by binding water to make it unavailable to act as a solvent. Humectants in common use are salt, sugars, and sugar alcohols (sorbitol). Intermediate moisture foods are those that have 20–40% moisture and a water activity of 0.75–0.85. Examples include soft candies, jams, jellies, honey, pepperoni, and country ham. These foods often require antifungal agents for complete stability.

Preservatives

Food preservatives can be extrinsic (intentionally added), intrinsic (normal constituent of food), or developed (produced during fermentation).^{60,61} Factors affecting preservative effectiveness include

(a) concentration of inhibitor, (b) kind, number, and age of microorganisms (older cells more resistant), (c) temperature, (d) time of exposure (if long enough some microbes can adapt and overcome inhibition), and (e) chemical and physical characteristics of food (water activity, pH, solutes, etc.). Preservatives that are cidal are able to kill microorganisms when large concentrations of the substances are used. Static activity results when sublethal concentrations inhibit microbial growth.

Some examples of inorganic preservatives are NaCl, nitrate and nitrite, and sulfites and SO₂. NaCl lowers water activity and causes plasmolysis by withdrawing water from cells. Nitrites and nitrates are curing agents for meats (hams, bacon, sausages, etc.) to inhibit *C. botulinum* under vacuum packaging conditions. Sulfur dioxide (SO₂), sulfites (SO₃), bisulfite (HSO₃), and metabisulfites (S₂O₅) form sulfurous acid in aqueous solutions, which is the antimicrobial agent. Sulfites are widely used in the wine industry to sanitize equipment and reduce competing microorganisms. Wine yeasts are resistant to sulfites. Sulfites are also used in dried fruits and some fruit juices. Sulfites have been used to prevent enzymatic and nonenzymatic browning in some fruits and vegetables (cut potatoes).

Nitrites can react with secondary and tertiary amines to form potentially carcinogenic nitrosamines during cooking; however, current formulations greatly reduce this risk. Nitrates in high concentrations can result in red blood cell functional impairment; however, at approved usage levels they are safe.^{66,67} Sulfiting agents likewise can cause adverse respiratory effects to susceptible consumers, particularly asthmatics.^{68,69} Therefore, use of these two classes of agents is strictly regulated.

A number of organic acids and their salts are used as preservatives. These include lactic acid and lactates, propionic acid and propionates, citric acid, acetic acid, sorbic acid and sorbates, benzoic acid and benzoates, and methyl and propyl parabens (benzoic acid derivatives). Benzoates are most effective when undissociated; therefore, they require low pH values for activity (2.5–4.0). The sodium salt of benzoate is used to permit ease of solubility in foods. When esterified (parabens), benzoates are active at higher pH values. Benzoates are primarily used in high acid foods (jams, jellies, juices, soft drinks, ketchup, salad dressings, and margarine). They are active against yeast and molds, but minimally so against bacteria. They can be used at levels up to 0.1%.

Sorbic acid and sorbate salts (potassium most effective) are effective at pH values less than 6.5 but at a higher pH than benzoates. Sorbates are used in cheeses, baked or non-yeast goods, beverages, jellies, jams, salad dressings, dried fruits, pickles, and margarine. They inhibit yeasts and molds, but few bacteria except *C. botulinum*. They prevent yeast growth during vegetable fermentations and can be used at levels up to 0.3%.

Propionic acid and propionate salts (calcium most common) are active against molds at pH values less than 6. They have limited activity against yeasts and bacteria. They are widely used in baked products and cheeses. Propionic acid is found naturally in Swiss cheese at levels up to 1%. Propionates can be added to foods at levels up to 0.3%.

Acetic acid is found in vinegar at levels up to 4–5%. It is used in mayonnaise, pickles, and ketchup, primarily as a flavoring agent. Acetic acid is most active against bacteria, but has some yeast and mold activity, though less active than sorbates or propionates. Lactic acid, citric acid, and their salts can be added as preservatives, to lower pH, and as flavorants. They are also developed during fermentation. These organic acids are most effective against bacteria.

Some antibiotics may be found in foods, and although medical compounds are not allowed in human food, trace amounts used for animal therapy may occasionally be found. Bacteriocins, which are antimicrobial peptides produced by microorganisms, can be found in foods. An example of an approved bacteriocin is nisin, which is allowed in process cheese food as an additive. Some naturally occurring enzymes (lysozyme and lactoferrin) can be used as preservatives in limited applications where denaturation is not an issue. Some spices, herbs, and essential oils have antimicrobial activity, but such high levels are needed that the food becomes unpalatable. Ethanol has excellent preservative ability but is underutilized because of social stigma. Wood smoke, whether natural or added in liquid form, contains several phenolic antimicrobial compounds in addition to formaldehyde.

Wood smoke is most active against vegetative bacteria and some fungi. Bacterial endospores are resistant. Activity is correlated with phenolic content. Carbon dioxide gas can dissolve in food tissues to lower pH and inhibit microbes. Developed preservatives produced during fermentation include organic acids (primarily lactic, acetic, and propionic), ethanol, and bacteriocins. All added preservatives must meet government standards for direct addition to foods. All preservatives added to foods are GRAS, generally recognized as safe.

Irradiation

Foods can be processed or preserved with a number of types of radiation. Nonionizing radiations used include ultraviolet, microwave, and infrared. These function by exciting molecules. Ionizing radiations include gamma, x-rays, β -rays, protons, neutrons, and α -particles. Neutrons make food radioactive, while β -rays (low energy electrons), protons, and α -particles have little penetrating ability and are of little practical use in foods. Ionizing gamma, x-rays, and high-energy electrons produce ions by breaking molecules and can be lethal to microorganisms.

Ultraviolet (260 nm) lamps are used to disinfect water, meat surfaces, utensils, air, walls, ceilings, and floors. UV can control film yeasts in brines during vegetable fermentations. UV effectiveness is dose dependant. Longer exposure time increases effectiveness. UV intensity depends on lamp power, distance to object, and amount of interfering material in path. For example, humidity greater than 60% reduces intensity. UV will not penetrate opaque materials and is good only for surface decontamination. Infrared heats products, but has little penetrating power. Microwaves cause rapid oscillation of dipole molecules (water), which results in the production of heat. Microwaves have excellent penetrating power. However, there are problems with the time-temperature relationship because microwaves cause foods to reach hot temperatures too quickly. Also, microwave-treated foods rarely exceed 100°C. Thus, instances of microbial survival in these foods has been reported.^{62,63}

X-rays have excellent penetrating ability but are quite expensive. They are not widely used in the food industry. Gamma rays from radioactive sources (Cs¹³⁵ and Co¹⁵⁰) have good penetration and are widely used to pasteurize and sterilize foods. Electron beam generators also are gaining appeal as ionizing sources of radiation to process foods. Food irradiation is much more widespread in countries other than the United States. There is much untapped potential to use ionizing radiations to reduce or eliminate microbial pathogens in foods.^{70,71} This technology remains underexploited due to consumer weariness about the safety of the technology.^{72,73,74}

Fermentation

A number of foods use beneficial microorganisms in the course of their processing.⁶¹ Bread, cheeses, pickles, sauerkraut, some sausages, and alcoholic beverages are made by the conversion of sugar to organic acids, ethanol, or carbon dioxide. These three by-products not only serve as desirable flavors but also provide a significant antimicrobial barrier to pathogens. There have been instances where poorly fermented foods have been linked to food-borne illness. Furthermore, cheese made from unpasteurized milk has a distinctly higher risk of carrying pathogens than cheese made from pasteurized milk. Proper acid development and avoidance of cross contamination are essential control steps in manufacturing fermented foods. Alcoholic beverages have not been linked to food-borne disease other than excess consumption leading to ethanol toxicity.

► SUMMARY

Because of the predominance of hazardous biological contaminants found in raw foods, most food-processing unit operations are designed to reduce or eliminate these hazards. Successful implementation of these processing steps can greatly minimize the risk of food-borne disease transmission. Unsuccessful implementation or failure to recognize the

need for interventions sets the stage for production of potentially dangerous products. Because of the varied nature of foods, it is imperative that prudent processors understand the inherent risks of their products and ensure the proper application of interventions to reduce these risks. This fundamentally sound recommendation will help keep processed foods competitive in the marketplace and will help maintain and enhance consumer confidence in the safety of their food supply.

The intent of food processing is to deliver safe and wholesome products to the consumer. Basic food safety programs, including GMPs and sanitation, are the minimum requirements to achieve this goal. HACCP is a logical extension of these programs, and focuses on the prevention of hazards before they occur, rather than waiting for a failure to occur, and then addressing the problem. HACCP provides the most comprehensive approach to food safety in the processing environment, but is not foolproof. Perhaps the most challenging aspect is that, even with the best-designed and implemented HACCP plan, it may not always be possible to “prevent, eliminate or reduce to acceptable levels” the pathogen of concern. This is particularly true with foods that are purchased by the consumer in their raw state, and then cooked. A specific example is *Escherichia coli* O157:H7 in ground beef. Irrespective of the preventative efforts of the processor, it is not possible to ensure that the product is free of the bacterium, and there is no “acceptable level” of this organism in ground beef.

Water Quality Management and Water-Borne Disease Trends

Patricia L. Meinhardt^a

Water is a necessity for human survival, and access to safe drinking water is a required cornerstone of public health. In concert with improved pasteurization and refrigeration of foods and childhood immunizations, modernized sanitation methods and access to potable water have increased the life span and improved the general health of American citizens more than any other advancement in the field of medicine.¹ Conscientious water quality management and access to renewable water resources are vital to every sector of our industrialized society and every sector of our nation's agricultural economy.² Early American settlements located near water and water reserves were generally sufficient for our country's development and prosperity during initial phases of growth. However, even during these early periods of U.S. history, there were recorded instances where communities disappeared as a result of declining or contaminated water supplies. Currently, there is a water crisis in the United States that has resulted from population growth and urbanization placing pressure on fixed sources of freshwater available locally and, at times, regionally. These water access pressures have resulted in insufficient quantity and deteriorating quality of water supplies in many regions of the United States.

These water quantity and water quality challenges have arisen from the fact that the amount of water in the world is fixed at approximately 3.59×10^{20} gallons in all. Of this amount, only about 0.2 % is freshwater that is readily available for human use. Through the hydrologic cycle, freshwaters run to the sea and become saline, but evaporation of water from the sea and precipitation on land restores these freshwaters continuously so that the quantity of freshwater is also relatively fixed and limited. Ongoing stewardship and an increasing prioritization of water quality management will be essential in order to ensure access to a water supply that provides both the quantity and quality necessary to preserve this precious environmental resource.

Preservation of water quality and prevention of water-borne disease is a complicated task requiring a coordinated effort from many diverse stakeholders including health-care providers, local and national public health authorities, water utility practitioners and engineers, water quality and regulatory specialists, environmental scientists and engineers, basic science researchers, and water consumers. In order to work together to maintain and improve water quality management in the United States, each stakeholder must understand (a) the basic parameters of water use and sources; (b) the challenges of water source protection and water contamination; (c) the trends in water-borne disease and the health effects associated with exposure to contaminated waters; and (d) the provision of safe drinking water

and the treatment of wastewaters. The intent of this chapter is to provide an overview of each of these essential components of water quality management in the United States and the subsequent impact on water-borne disease and public health.

► FUNCTIONS OF WATER

The uses of water in any community are numerous and diverse, and the requirements for the quantity and quality of water for these multiple functions are wide ranging and multifaceted. Conventionally, it has been both convenient and economical to provide a single water supply sufficient in quantity to serve all uses and suitable in quality to meet community drinking water standards, even though only a small fraction of the total water supply used in a community is actually used for drinking water.

The uses and applications for water are numerous and include but are not limited to (a) drinking and food preparation purposes; (b) personal hygiene activities including bathing and laundering; (c) residential and commercial heating and air conditioning; (d) urban irrigation and street cleaning; (e) recreational venues including swimming and wading pools, waterparks, and hot tubs and spas; (f) amenity purposes such as public fountains and ornamental ponds; (g) power production from hydropower and steam generation; (h) commercial and industrial processes including bottled water and food production; (i) residential and commercial fire protection; (j) agricultural purposes including irrigation and aquaculture; and (k) the process of carrying away human and industrial wastes from all manner of establishments and community facilities.

The quantities required for each type of multiple water use in the United States vary substantially. The allocation of water use in U.S. communities is presented in Table 48-1 and reflects the fact that 40% of water use is residential use. In a typical American community, the average per capita consumption is between 50 and 100 gallons per day as illustrated in Table 48-2. In summer months, this demand may increase by 50% resulting from such activities as increased urban irrigation. It has been suggested that the U.S. per capita water usage could be substantially reduced by water conservation practices; these dramatic water savings are illustrated in Table 48-3. It is important to note that by comparison in Asia and Africa, per capita consumption may be a little as 13 gallons per day.

► TYPES OF WATER SYSTEMS

To service their residents, communities require sources of water, transmission pumps and mains, treatment plants, and distribution systems for delivering water to each user. Transmission systems and treatment

^aThis chapter is an edited version of the chapters previously prepared for earlier editions by John B. Conway and David A. Okun.

plants need to be designed for the maximum water usage day, which occurs generally in the summer months and is about 150% of the average daily demand. In addition, each distribution system should meet the peak demand during the day, which may be 150–300% of the maximum daily demand, being larger for smaller communities where the peak is determined by requirements for fire protection. Concomitant requirements include a sewerage system for collecting the wastewaters from each user in the community and treatment facilities for rendering the wastewaters suitable for disposal or reuse. Currently, some 80% of the U.S. population in more than 60,000 communities is served by water supply and sewerage systems. The remaining population, not always in rural areas, is served by individual wells and on-site disposal systems, generally septic tanks and tile fields for percolation of the septic tank effluents.

► PROPERTIES OF WATER

Water is a unique and remarkable substance. “Pure” water is a clear, colorless, tasteless, and odorless fluid. It is also a strong solvent and in nature washes gases from the atmosphere, dissolves minerals and humic substances from the soil through which it flows, and carries substantial quantities of silt as it moves through the environment. Many of the natural and man-made uses of water affect its quality, and, accordingly, water is seldom appropriate for human use without some kind of treatment. In addition, a varied array of microorganisms find their way into waters and, depending on environmental conditions, may replicate or expire. Some of these microorganisms are beneficial or at least not harmful while others may be pathogenic to man and other animals. Many scourges of mankind have been waterborne, and the potential for spread of enteric disease is always present, even today.

At normal atmospheric pressure, water freezes at 0°C and boils at 100°C. Due to the fact that water displays its greatest density at 4°C, ice floats on the surface, keeping bodies of water from freezing solid, an important phenomenon that keeps aquatic creatures alive and permits lakes and reservoirs to serve as sources of water even at sub-freezing temperatures. The specific heat of water is high, resulting in the ameliorating effects of large water bodies on global and regional

TABLE 48-2. ALLOCATION OF INTERIOR RESIDENTIAL WATER USE

climate and temperatures. The surface tension of water is also high, resulting in the concentration of many water contaminants on its surface in monomolecular layers.

Water is an important constituent of all living matter, constituting approximately 70% of the weight of the human body. It is a very effective and efficient medium for transferring nutrients and removing waste materials from the human body as well as maintaining thermostability through heat transfer and evaporation. The water intake of a typical adult varies from 1 to 3 quarts per day, about half of which is lost through evaporation from the skin and lungs and the other half through excretion of feces and urine. It is the challenge of managing human excreta properly if adequate sanitation is to be maintained and the spread of water-borne disease is to be prevented and avoided. Therefore, one primary goal of water quality management involves protecting water supplies for human use from damage by human use.

► SOURCES OF WATER

Water may be abstracted for use from any one of a number of points in its movement through the hydrological cycle illustrated in Fig. 48-1. The most suitable water source to be developed for use by any community depends on the quantity and quality of the source under consideration for development. The selection of the most appropriate water source for human use in a specific region may result from a wide variety of options available, including the most common sources of water listed below.³

Rainwater. Rainwater is the source of all freshwater in the world. It may be collected directly from roofs and other prepared catchment systems and stored in cisterns for later use. Since catchment areas for the direct capture of rainwater are necessarily limited in size, such water supplies are useful only for individual households or small communities. Households in the Southwest are examples of the former, and paved catchments in the country of Gibraltar are examples of the latter. The quality of rainwater is generally reasonable but it may be contaminated by gases and particles that are washed out of the atmosphere or by the accumulation of dust and other debris in catchment systems. For example, the gaseous sulfur and nitrogen oxides emitted from power plants that use fossil fuels react with atmospheric water forming dilute solutions of sulfuric and nitric acids. The precipitation of these acids or “acid rain” has resulted in serious environmental impacts on surface water quality and on the biota that depend upon water in affected areas.

Surface Water. The earliest sources of water for large communities in the United States were rivers and lakes, which readily provided the quantity needed for economic growth and development. However, the large drainage areas required for such run-of-river or lake supplies inevitably subjected them to activities such as urban and industrial development that resulted in degradation of the quality of water. In the United States, water supplies for the cities of Philadelphia, Cincinnati, and New Orleans are typical of run-of-river supply sources. Unfortunately, such water supplies have historically been the source of water-borne epidemics (e.g., in the nineteenth century) and still may pose water-borne disease hazards in situations where treatment is inadequate. The development of filtration processes and disinfection of water by chlorination at about the turn of the century rendered such surface waters suitable for community water supplies. However, since the onset of the chemical revolution beginning in the mid-twentieth century, waters obtained from large watersheds, such as those from the Ohio and Mississippi rivers, inevitably contained numerous synthetic organic chemicals used in industry and agriculture. Some of these water-borne chemical agents have been identified as being carcinogenic, mutagenic, teratogenic, or otherwise harmful to human health. Many of these chemical compounds are not readily removed in wastewater or water treatment processes or naturally degraded in the environment during passage downstream. As a result, it was the identification of many synthetic organic chemicals in the lower Mississippi

TABLE 48-3. WATER-SAVING IMPACT OF AVERAGE PERSONAL WATER USE EMPLOYING WATER CONSERVATION PRACTICES OR FIXTURES VERSUS TYPICAL WATER USE^{1,2}

Activity	Frequency	Circumstances	Water Used
Toilet	Four flushes per day	Conventional toilet Ultra-low flush toilet	3.5–7 gallons per flush 1.6 gallons per flush
Shower	Once a day for 5 minutes	Conventional showerhead Low-flow showerhead	3–8 gallons per minute 2.5 gallons per minute
Bath	Once a day	Full bathtub Tub 1/4 to 1/3 full	36 gallons 9–12 gallons
Shaving	Once a day	Open tap 1 full basin	5–10 gallons 1 gallon
Brushing teeth	Twice a day	Open watertap Brush and rinse	2–5 gallons 1/4–1/2 gallon
Washing hands	Twice a day	Open watertap 1 full basin	2 gallons 1 gallon
Cooking ³	Washing produce	Open watertap 1 full kitchen basin	5–10 gallons 1–2 gallons
Automatic dishwasher	Once per day—full load	Standard cycle Short cycle	10–15 gallons 8–13 gallons
Manual dishwashing	Once a day	Open watertap Full basin/wash and rinse	30 gallons 5 gallons
Laundry ⁴	1/3 load a day	Portion of full load Full load	35–50 gallons per full load 10–15 gallons for a full load
Car washing	Twice a month	Hose with shut-off nozzle 5 full, 2-gallon buckets	100 gallons per month 20 gallons per month

¹Numbers are based on approximate, average household use since water use will vary with individual habits and lifestyles, differing water pressure, and the age and model of appliances.

²The average per capita consumption of water by Americans is 50 gallons per day with 40 gallons attributed to interior residential use and additional 10 gallons for outdoor use.

³Real cooking figure will be higher to include boiling water, rinsing utensils, and other uses.

⁴Laundry figure is based on two full loads per person, per week.

River that provided the impetus for the passage of the Safe Drinking Water Act (PL 93-523) in 1974. The groundwork for this important act was provided by the Community Water Supply Survey conducted by the Public Health Service (PHS) in 1969,⁴ which indicated that many public water supply systems, particularly those serving small communities, were not providing adequate water service and were not in a position to meet appropriate drinking water standards.

A safer option is the use of smaller watersheds, which do not have naturally sustained flows during all periods of the year, but by storing wet-weather flows in reservoirs can provide substantial quantities of water for use during dry periods. Such small watersheds are generally found in upland areas and are often free of the major urban and industrial development that may result in the type of chemical pollution that has become such a growing concern for U.S. communities.

Figure 48-1. The water cycle. (Adapted from Fair GM, Geyer JC, Okun DA. Elements of Water Supply and Wastewater Disposal. New York: John Wiley & Sons; 1971.)

Communities such as Boston, New York, and San Francisco are examples of cities that have developed upstream water sources. The quality of these upstream sources has often been of such high quality that until recently the only treatment required has been disinfection. Pressure from development of previously protected watersheds is now threatening to degrade them and special efforts will continue to be required in the future to protect such important watersheds and preserve them. The watershed area serving New York City is currently undergoing extensive evaluation, and increased protection measures are under consideration for implementation.

Natural and human-made lakes may improve or degrade waters drawn from their originating watersheds. Improvement of water quality may result from storage in a lake providing opportunities for coagulation and sedimentation of colloidal and suspended solids that are tributary to the lake from rivers and streams. Some measure of disinfection is accomplished by exposure to sunlight provided that there is time for biochemical stabilization of organic matter and for degradation of water-borne microorganisms. Furthermore, storage in a lake or reservoir attenuates high levels of contaminants that may result from natural rainstorms or man-made contamination events on the watershed such as spills from tankers or transportation accidents.

On the other hand, storage in lakes or reservoirs may degrade water quality through processes such as eutrophication, biomagnification, and thermal stratification. *Eutrophication* or overnourishing of a water body occurs naturally as a result of influence of nutrient materials, particularly phosphorus and nitrogen, which support the growth of algae. In a standing body of water with adequate sunlight, these types of nutrients tend to accumulate in algae, and as the algae settle, the lake tends slowly to fill over time. Urban and agricultural development on a watershed adds significantly to sediment and nutrient input to a lake; the former reduces the capacity of lakes and the latter accelerates the process of eutrophication to the point where many of the former uses of the lake are adversely affected. The increasing concentrations of algae are difficult to remove in water treatment and they often impart unpleasant taste and odors to the water. Another impact of storage is the *bioaccumulation* of small concentrations of chemicals and other contaminants that are absorbed by aquatic life in the lake. This bioaccumulation process may affect the quality of aquatic life fished from these lakes and may also increase the levels of adverse contaminants beyond what they would be in an active flowing river.

Lake quality and water source protection is further affected by *thermal stratification*. During the summer months, warmer and lighter water accumulates in the upper layers of most lakes. The water density difference resulting from this temperature differential is sufficient to prevent the lower layers of the lake from obtaining atmospheric oxygen. The following processes may result: (a) organic matter reduces the dissolved oxygen in the lower levels of the lake often resulting in anaerobic conditions; (b) hydrogen sulfide and carbon dioxide begin to accumulate; (c) increasing acidity leads to increasing solution of such metals as iron and manganese; and (d) microorganisms tend to accumulate at the thermocline, the zone of rapidly changing temperature and density that separates the upper and lower layers of the lake. As a result of these hydrological phenomena, source water that may otherwise have been satisfactory for water supply become exceedingly problematic for use as a community water source.

Groundwater. Groundwaters are recharged by percolation of rainwater and runoff through the ground and are withdrawn by means of natural springs, wells, or infiltration galleries (horizontal wells). Groundwaters tend to be more highly mineralized than surface waters resulting from the solution of minerals that the groundwaters come in contact with as these waters percolate through the ground layers. However, these groundwaters are generally of higher sanitary quality since (a) they are not as likely to be subject to microbial pollution as surface water sources and (b) passage of water through soil strata often serves to improve their bacteriological quality. On the other hand, groundwater pollution, particularly from toxic waste discharges and leaching of landfills, has become a major problem in the United States and considerable care is

required to protect such valuable water resources. Unfortunately, once a groundwater aquifer is polluted with chemical contaminants, serious financial investment and many years of time may be required for the contamination to be remediated, if remediation is even possible.

In general, it is far more difficult to determine the yields of groundwater sources than of surface water sources. Yields of groundwaters are a function of the volume and size of soil interstices, and such determinations depend on extensive hydrogeological exploration, including the construction of test wells and the conduction of pumping tests. Accordingly, groundwaters have not generally been placed into service for community water supplies as often as surface water resources and are most frequently used primarily for smaller communities. On the other hand, some groundwater supplies have been over-pumped or "mined" where water withdrawals have exceeded water recharge. This overdraft has resulted in a steady lowering of the elevation of the water surface underground or water tables diminishing the amount that can be withdrawn and increasing the cost of pumping. Such excessive water withdrawals have also had a bearing on the ground surface above, threatening structures and increasing the potential for flooding in some communities.

The combined use of groundwaters in association with surface waters as a source of community water requirements continues to be explored as an option but requires engineering planning and hydrological study. In many communities, underground reservoirs may have major advantages over surface water reservoirs, such as: (a) no loss of water through evaporation; (b) water quality is often not as likely to be deleteriously affected by natural or urban and industrial pollution; (c) underground reservoirs do not require the expropriation of large areas of surface land; and (d) these waters may be located nearer to the community's points of use than are surface impoundments. In this combined scheme, water would be drawn from surface water sources during wet periods when groundwater reservoirs are also being recharged, and during dry periods, water withdrawal would be tapped from underground reservoirs.

A special category of undergroundwater sources is the artesian aquifer that is a confined aquifer under pressure and that is recharged at a higher elevation some distance away. When this water resource is tapped by a well, the water in the well rises above the confining layer and may often be free flowing. As an example, flowing springs originate from artesian aquifers since they are under pressure. It is important to note that artesian aquifers are less likely to be contaminated with either microbial or chemical pollutants than unconfined aquifers. Wells are constructed in a variety of ways and configurations, depending on the nature of the aquifer from which the water is to be withdrawn. Special precautions are required that ensure wells are protected from surface water runoff by being encased properly with the protective casing extending above the ground surface. After construction, wells must be disinfected before being tested for water quality and human consumption. Sampling of water from a well is pointless if the *sanitary survey* indicates that the well is not protected from contamination by surface runoff. A sample taken during a dry period may reveal good quality water, but the water will inevitably become contaminated by surface water runoff, if the wellhead and base structure are not adequately protected from contamination.

Ocean and Brackish Waters. These water sources are unsuitable for most communities' water supplies, but in conditions of dire necessity, freshwater can be obtained from them by use of one of several desalination processes. The most appropriate method for desalination of seawater is thermal distillation. Distillation is widely used in oil-rich areas where water is extremely limited such as in the Middle East and the West Indies. In brackish waters, where the salt content is less than 10% that of seawater, reverse osmosis or electrodialysis may be used, but all desalination methods are energy intensive. As the cost of energy continues to increase as compared with other costs, desalination is not likely to be a feasible option for most community water supplies except in situations where serious investment in providing water can be justified, such as for tourism or for individual, military, or political purposes.

Water Reclamation and Reuse. Far more attractive than desalination in water-scarce areas is the reclamation of wastewaters for reuse for nonpotable purposes.⁵ Water reuse is becoming increasingly attractive in communities where water resources are limited since a substantial portion of a community's water needs is dedicated for urban irrigation and other nonpotable uses. Impetus for water reuse has also resulted from the increasingly rigorous requirements for wastewater treatment that often lead to production of a water effluent of too high a quality at too high a cost to be discarded. Early water reuse technology developed from wastewater disposal by irrigation, a practice widely followed in Europe for more than a century. In the United States, early water reuse was exemplified by the utilization of the effluent from the Baltimore wastewater treatment facilities for use in the Bethlehem Steel Sparrows Point plant in the 1930s.

In the United States, the modern approach to water reuse is exemplified by the development of distribution systems for nonpotable waters for a variety of purposes including urban irrigation and residential and industrial use. Such dual distribution systems were pioneered in Colorado Springs, Colorado; Pomona and Irvine, California; and St. Petersburg, Florida. In these instances, the nonpotable distribution systems carry secondary wastewater effluent additionally treated by coagulation, filtration, and disinfection processes used for treatment of potable waters drawn from polluted sources. The main difference between the potable and nonpotable waters would be that the nonpotable waters would not be free of the chemical contaminants that are inevitably present in such wastewaters and that are not removed in wastewater treatment and may be hazardous if ingested over a long period of time.

In as early as 1958, the United Nations Economic and Social Council stated, "No higher quality water, unless there is a surplus of it, should be used for a purpose that can tolerate a lower grade."⁶ This conservation policy is being considered and potentially adopted in water-short areas of the United States. In Florida, for example, where consumptive use permits are required for all abstractions of water, a permit will not be issued if a lower-quality water can be used and is available for use. Nonpotable reuse is becoming so widely adopted that the American Water Works Association has published a *Manual on Dual Distribution Systems*⁷ and some 14 states have adopted regulations for water reclamation and reuse. In San Diego, California, at least one residential home builder offers a collection system for gray water from showers, bath tubs, and washing machines that can then be used to flush toilets and water lawns with the cost of this additional plumbing priced at less than \$2000.

Selection of Water Sources. Topography, climate, availability of untapped water resources, population density, land use, and myriad other characteristics differentiate each community's water source options from another and none are precisely like that of any other community. Therefore, a community government and its planning engineers faced with the need to provide a community's water supply must recognize that each situation is unique. The guiding principle in the selection of a water source is provided in the National Interim Primary Drinking Water Regulations promulgated by the U.S. Environmental Protection Agency (EPA) in 1976:

Production of water that poses no threat to the consumer's health depends on continuous protection. Because of human frailties associated with protection, priority should be given to the selection of the *purest source*. Polluted sources should not be used unless other sources are economically unavailable, and then only when personnel, equipment, and operating procedures can be depended on to purify and otherwise continuously protect the drinking water supply.⁸ (Emphasis added.)

Earlier drinking water standards established by the U.S. Public Health Service presented a similar focus. The primary concern for water quality had originally been prevention of the transmission of water-borne infectious disease, many of which had effectively been addressed with conventional filtration and disinfection with chlorine.

However, many cities throughout the United States opted for run-of-river supplies that were conveniently available even though they did not constitute the "purest" source. The relatively new threat to human health arising from the "chemical revolution" with the creation of many new long-lasting synthetic organic chemicals has given new meaning to the concern for selecting the "purest source." This is particularly important since detection methods for monitoring many of these chemical agents are not yet available or economically unfeasible for use by many communities. Community governments are given options in the selection of water sources, and prudence dictates a search for the "purest source." This search might entail development of groundwaters or upstream sources free of urban and industrial pollution. However, in situations where these water resources are not adequate in quantity to provide all the water required in a community, consideration should be given for developing high-quality sources for potable purposes with the consideration of reclaimed wastewaters for nonpotable purposes.

Protection of Water Sources. Where high-quality sources of water supply are available, whether surface or underground in nature, they are subject to despoliation from development and lack of protection of the watershed or recharge areas. In the United States, only in rare instances is the land of a community watershed or recharge area under the control of the water purveyor, and these areas are generally the responsibility of the local authorities that have planning jurisdiction. Even where a community water purveyor owns the land or the local authority that has dominion over the land is served by the water supply, the pressure for development of the watershed can lead to degradation of the water supply for the serviced community that resides many miles away from the watershed area. In a landmark case, water companies in the state of Connecticut attempted to sell portions of their wholly-owned protected watersheds for development. After considerable study, state legislation was enacted that forbade the sale of watershed lands for development. In response to a suit against the State of Connecticut by the water companies, the U.S. District Court upheld the state's position:

... the obvious purpose of the legislation is the protection of the health and welfare of the State's inhabitants ... watershed properties are critical to water purity ... the State is ensuring the ability of the water companies to provide pure water to its customers.⁹

More generally in the United States, local government authorities have planning jurisdiction over watershed lands and recharge areas and work closely with their water purveyor in developing land use strategies that protect the integrity of the community's water supplies. Such strategies include regulations specifying maximum densities, limits for impervious areas, setbacks from the banks of streams and reservoirs, and the definition of permissible activities on and near the watershed.^{10,11} The promulgation and enforcement of such regulations require strong stewardship and leadership on the part of elected and appointed government officials as these actions to protect water supply sources may sharply curtail the opportunities for financial profit from development of watershed or recharge areas.

In selecting appropriate water supply sources for a community, the greatest attention is generally given to the numerical limits for specific water contaminants in the posttreatment potable water. It may be more prudent to emphasize the "sanitary survey" of the end-user potable water which would ensure a high quality of water for water consumers by ensuring appropriate protective handling and distribution of water to the end-user. The drinking water regulations of 1976 state:

Knowledge of physical defects or of the existence of other health hazards in the water supply system is evidence of a *deficiency in protection of the water supply*. Even though water quality analysis have indicated that the quality requirements have been met, the deficiencies must be corrected before the supply can be considered safe.⁸ (Emphasis added.)

These water supply deficiencies include pollution of the water source, inadequate water treatment, cross-connections with sources of contamination, inadequate capacity resulting in low pressure, and insufficient operation of the water treatment facilities including inadequate disinfection and failure to provide stand-by facilities in the event of power or other equipment failure. In contention is whether or not the discharge of a pollutant upstream from a community water intake source is considered a “*deficiency in protection of the water supply*.” While many laws exist that intend to prevent the discharge of toxic substances into the environment in general and in water bodies in particular, implementation of these laws is uncertain at best. Little assurance can be given that a water supply drawn from a water source that drains large urban and industrial areas will, in fact, be free of potentially harmful chemical and microbial agents. Currently, the best course of action is to avoid discharging human, animal, and industrial wastes above water supply intakes and to avoid installing water supply intakes below waste discharges’ point sources.

► POTABLE WATER QUALITY AND REGULATION

Initially in the United States, protection of the nation’s public health was the responsibility of the individual states with federal initiatives in place for only interstate activities. The U.S. Public Health Service Drinking Water Standards were first adopted in 1914 to protect the health of the traveling public across the country. These standards were often adopted by individual states and eventually were applicable to water supplies throughout the United States. Initially these standards had limited application with the primary emphasis on physical and bacterial parameters: the first to ensure esthetic quality and the second to prevent the transmission of water-borne disease. These public health standards were updated periodically, and in 1962, the standards were extensively revised to include water-borne chemical and radiologic agents for the first time. Initially, the only chemical agents for which limits were established were heavy metals. Recognition of the problem of water-borne synthetic organic chemicals surfaced with the establishment of an upper limit for the chemical, carbon chloroform extract (CCE). This limit served as a comprehensive, gross surrogate for all synthetic organic chemicals, although it could not distinguish between chemical compounds that were innocuous versus harmful to human health. These initial standards required that water supply systems (a) provide adequate capacity to meet peak demands without development of low pressures; (b) assess the quality of water at the free-flowing outlet of the water consumer; and (c) administer the water system facilities under the responsible charge of personnel whose qualifications are acceptable to the regulatory agency.

It was not until passage of the *Safe Drinking Water Act (SDWA)* in 1974 that public water supply systems in the United States came under the federal aegis of the EPA. Under this law, the EPA was authorized to set national standards to protect drinking water and source water from naturally occurring and man-made water contaminants. The Safe Drinking Water Act passed in 1974 was amended in 1986 and 1996, and the numerous amendments, regulations, and proposed rules added to the SDWA are summarized in Table 48-4.¹²

Provision of the Safe Drinking Water Act (SDWA)

The SDWA authorized the EPA to set *drinking water standards* in the United States and develop regulations to control the level of contaminants in the nation’s drinking water. These drinking water standards are part of the Safe Drinking Water Act’s “multiple barrier” approach to drinking water protection that includes (a) assessing and protecting drinking water sources; (b) protecting wells and collection systems; (c) ensuring that water is treated by qualified operators; (d) ensuring the integrity of water distribution systems; and (e) providing information to the public on the quality of their drinking water. In most cases, the EPA delegates responsibility for implementing drinking water

TABLE 48-4. ENVIRONMENTAL PROTECTION AGENCY REGULATIONS REGARDING DRINKING WATER IN THE UNITED STATES FROM 1974–2003^{*}

Regulation	Year
Safe Drinking Water Act (SDWA)	1974
Interim Primary Drinking Water Standards	1975
National Primary Drinking Water Standards	1985
SDWA amendments	1986
Surface Water Treatment Rule (SWTR)	1989
Total Coliform Rule	1989
Lead and Copper Regulations	1990
SDWA Amendments	1996
Information Collection Rule	1996
Interim Enhanced SWTR	1998
Disinfectants and Disinfection By-Products (D-DBPs) Regulation	1998
Contaminant Candidate List	1998
Unregulated Contaminant Monitoring Regulations	1999
Groundwater Rule (proposed)	2000
Lead and Copper Rule—action levels	2000
Long Term 1 Enhanced SWTR	2002
Long Term 2 Enhanced SWTR	2003
Stage 2 D-DBP Rule	2003

standards to states and Indian nations. These drinking water standards apply to (a) public water systems that provide water for human consumption through at least 15 service connections or (b) systems that regularly serve at least 25 individual water customers. Public water systems include such entities as municipal water companies, homeowner associations, schools, businesses, campgrounds, and shopping malls. There are two categories of drinking water standards under the Safe Drinking Water Act:

- National Primary Drinking Water Regulation (NPDWR):** This primary standard is a legally *enforceable* drinking water standard that applies to public water systems. Primary standards protect drinking water quality by limiting the levels of specific contaminants that can adversely affect public health and are known to or anticipated to occur in water. These standards take the form of either (a) maximum contaminant levels (MCLs) or the maximum permissible level of a contaminant in water which is delivered to any user of a public water system or (b) treatment techniques (TTs) which are set rather than an MCL when there is no reliable method that is economically and technically feasible to measure a contaminant at particularly low concentrations.¹³ The list of National Primary Drinking Water Regulations, MCLs, potential health effects, and sources of each contaminant in drinking water are presented in Table 48-5.
- National Secondary Drinking Water Regulation (NSDWR):** This secondary standard is a *nonenforceable* guideline addressing contaminants that may cause (a) aesthetic effects such as undesirable tastes or odors; (b) cosmetic effects that do not damage human health but are still undesirable; or (c) technical effects that may cause damage to water equipment or reduce effectiveness of treatment for other contaminants in drinking water. The EPA recommends secondary standards to water systems but does not require systems to comply; however, states may choose to adopt them as enforceable standards. The EPA has established National Secondary Drinking Water Regulations that set nonmandatory water quality standards for 15 contaminants as “secondary maximum contaminant levels” or SMCLs.¹³ These secondary contaminants are not considered to present a risk to human health at the SMCL listed in Table 48-6.

TABLE 48-5. NATIONAL PRIMARY DRINKING WATER REGULATIONS AND MAXIMUM CONTAMINANT LEVELS (MCLs)^a

<i>Contaminant</i>	<i>MCLG^b (mg/L)^c</i>	<i>MCL or TT^b (mg/L)^c</i>	<i>Potential Health Effects from Ingestion of Water</i>	<i>Sources of Contaminant in Drinking Water</i>
■ Microorganisms				
<i>Cryptosporidium</i> sp.	zero	TT ^d	Gastrointestinal illness (e.g., diarrhea, vomiting, gastrointestinal distress)	Human and animal fecal waste
<i>Giardia lamblia</i>	zero	TT ^d	Gastrointestinal illness (e.g., diarrhea, vomiting, gastrointestinal distress)	Human and animal fecal waste
Heterotrophic plate count (HPC)	n/a	TT ^d	HPC is an analytic method used to measure the variety of bacteria that are common in water. Lower concentrations of bacteria in drinking water indicate better maintenance at the water treatment system.	HPC measures a range of bacteria that are naturally occurring in the environment
<i>Legionella</i> sp.	zero	TT ^d	Legionnaires' disease, a type of pneumonia.	Found naturally in water; multiplies in heating systems
Total Coliforms (including fecal coliform and <i>E. coli</i>)	zero	5.0% ^e	Not a health threat in itself, this indicator determines whether other potentially harmful bacteria may be present in water. ^f	Coliforms are naturally present in the environment as well as feces and fecal coliforms. <i>E. coli</i> originate only from human and animal fecal waste.
Turbidity	n/a	TT ^d	Turbidity is a measure of the cloudiness of water and indicates water quality and filtration effectiveness (e.g., whether disease-causing organisms are present). Higher turbidity levels are often associated with higher levels of disease-causing microorganisms such as viruses, parasites, and some bacteria. These organisms can cause symptoms such as nausea, gastrointestinal distress, diarrhea, and associated headaches.	Soil runoff
Viruses (enteric)	zero	TT ^d	Gastrointestinal illness (e.g., diarrhea, vomiting, gastrointestinal distress)	Human and animal fecal waste
■ Disinfection By-Products				
Bromate	zero	0.010	Increased risk of cancer	By-product of drinking water disinfection
Chlorite	0.8	1.0	Anemia; infants and young children: nervous system effects	By-product of drinking water disinfection
Haloacetic acids (HAA5)	n/a ^g	0.060	Increased risk of cancer	By-product of drinking water disinfection
Total Trihalomethanes (TTHMs)	none ^h	0.10	Liver, kidney, or central nervous system disorders; increased risk of cancer	By-product of drinking water disinfection
	n/a ^g	0.080		
■ Disinfectants
