Preparation of this edition was sponsored by the Association for Prevention Teaching and Research (formerly Association of Teachers of Preventive Medicine (ATPM)), Washington, DC. APTR is the national professional association of academic professionals dedicated to interprofessional health promotion and disease prevention education and research. APTR provides essential linkages to bring together individuals and institutions from all professions to advance health promotion and disease prevention. For more information about APTR, call 202/463-0550, e-mail info@aptrweb.org, or visit the www.aptrweb.org.

Contents

<i>Contributors</i>	xxiii	C. HEALTH ADVICE FOR INTERNATIONAL TRAVEL . . .	87
<i>Preface</i>	xxix	<i>Christie M. Reed, Stefanie Steele,</i>	
<i>Acknowledgments</i>	xxxi	<i>and Jay S. Keystone</i>	
<i>Historical Note</i>	xxxi		
Section I Public Health Principles and Methods	1	9 Diseases Controlled Primarily by Vaccination	101
Edited by Robert B. Wallace		A. MEASLES	101
1 Public Health and Preventive Medicine: Trends and Guideposts	3	<i>Walter A. Orenstein, Mark Papania, Peter Strebel, and Alan R. Hinman</i>	
<i>Robert B. Wallace</i>		B. MUMPS	105
2 Epidemiology and Public Health	5	<i>Francisco Averhoff and Melinda E. Wharton</i>	
<i>Robert B. Wallace</i>		C. RUBELLA	108
3 Ethics and Public Health Policy	27	<i>Susan E. Reef</i>	
<i>Colin L. Soskolne and John M. Last</i>		D. PERTUSSIS	111
4 Public Health and Population	39	<i>Margaret Mary Cortese and Kristine M. Bisgard</i>	
<i>Robert B. Wallace</i>		E. TETANUS	115
5 Public Health Informatics	49	<i>Katrina Kretsinger, John S. Moran, and Martha H. Roper</i>	
<i>David A. Ross and Alan R. Hinman</i>		F. DIPHTHERIA	117
6 Health Disparities and Community-Based Participatory Research: Issues and Illustrations	55	<i>Tejpratap S.P. Tiwari</i>	
<i>N. Andrew Peterson, Joseph Hughey, John B. Lowe, Andria D. Timmer, John E. Schneider, and Jana J. Peterson</i>		G. INFLUENZA	120
7 Genetic Determinants of Disease and Genetics in Public Health	63	<i>Mark Katz</i>	
<i>Fred Lorey</i>		H. HAEMOPHILUS INFLUENZAE INFECTIONS	124
Section II Communicable Diseases	75	<i>Michelle A. Chang, Brendan Flannery, and Nancy Rosenstein</i>	
Edited by Stephanie Zaza		I. VARICELLA AND HERPES ZOSTER	127
8 Control of Communicable Diseases	77	<i>Dalya Guris, Mona Marin, and Jane F. Seward</i>	
A. OVERVIEW OF COMMUNICABLE DISEASES	77	J. POLIOMYELITIS	133
<i>Richard P. Wenzel</i>		<i>Roland W. Sutter and Stephen L. Cochi</i>	
B. EMERGING MICROBIAL THREATS TO HEALTH AND SECURITY	79	K. PNEUMOCOCCAL INFECTIONS	137
<i>Stephen M. Ostroff and James M. Hughes</i>		<i>Robert B. Wallace</i>	
		10 Epidemiology and Trends in Sexually Transmitted Diseases	155
		<i>David Friedel and Suzanne Lavoie</i>	
		11 The Epidemiology and Prevention of Human Immunodeficiency Virus (HIV) Infection and Acquired Immunodeficiency Syndrome (AIDS) . . .	189
		<i>Alan E. Greenberg, D. Peter Drotman, James W. Curran, and Robert S. Janssen</i>	

12 Infections Spread by Close Personal Contact . . .	201	14 Control of Infections in Institutions: Healthcare-Associated Infections	333
A. ACUTE RESPIRATORY INFECTIONS	201	<i>R. Monina Klevens and Denise M. Cardo</i>	
<i>Javier Ena</i>		15 Viral Diseases Transmitted Primarily by Arthropod Vectors	341
B. VIRAL HEPATITIS	211	A. VIRAL INFECTIONS	341
<i>Joanna Buffington and Eric Mast</i>		<i>Elizabeth A. Kleiner and Richard P. Wenzel</i>	
C. ASEPTIC MENINGITIS	228	B. EPIDEMIOLOGY OF VIRAL HEMORRHAGIC FEVERS	352
<i>Jeffery L. Meier</i>		<i>James W. LeDuc</i>	
D. EPSTEIN-BARR VIRUS AND INFECTIOUS MONONUCLEOSIS	230	C. RICKETTSIAL INFECTIONS	362
<i>Jeffrey L. Meier</i>		<i>Marta A. Guerra and David L. Swerdlow</i>	
E. HERPES SIMPLEX VIRUS	232	D. Q FEVER	368
<i>Richard J. Whitley</i>		<i>Herbert A. Thompson and David L. Swerdlow</i>	
F. CYTOMEGALOVIRUS INFECTIONS	235	E. PLAGUE	370
<i>Anne Blaschke and James F. Bale, Jr.</i>		<i>J. Erin Staples</i>	
G. GROUP A STREPTOCOCCAL DISEASES	237	F. MALARIA	373
<i>Susan Assanasen and Gonzalo M.L. Bearman</i>		<i>S. Patrick Kachur, Alexandre Macedo de Oliveira, and Peter B. Bloland</i>	
H. MENINGOCOCCAL DISEASE	245	G. LYME DISEASE	386
<i>Montse Soriano-Gabarró and Nancy Rosenstein</i>		<i>Larissa A. Minicucci</i>	
I. TUBERCULOSIS	248	H. TRYPANOSOMIASIS	392
<i>Douglas B. Hornick</i>		<i>Louis V. Kirchhoff</i>	
J. LEPROSY	258	I. LEISHMANIASIS	394
<i>Kenrad E. Nelson</i>		<i>Mary E. Wilson</i>	
K. ACUTE GASTROINTESTINAL INFECTIONS	263	J. LYMPHATIC FILARIASIS	398
<i>Victoria Valls</i>		<i>Amy D. Klion</i>	
13 Diseases Spread by Food and Water	301	16 Diseases Transmitted Primarily from Animals to Humans (Zoonoses)	419
A. TYPHOID FEVER	301	A. VIRAL ZOONOSES—RABIES	419
<i>Pavani Kalluri and Eric D. Mintz</i>		<i>Charles E. Rupprecht</i>	
B. SHIGELLOSIS	303	B. BACTERIA	
<i>Anna Bowen and Eric D. Mintz</i>		1. Bacterial Zoonoses—Psittacosis	423
C. CHOLERA	304	<i>Lauri A. Hicks and Maria Lucia Tondella</i>	
<i>Margaret Kosek and Robert E. Black</i>		2. Tularemia	424
D. ESCHERICHIA COLI DIARRHEA	308	<i>Paul S. Mead</i>	
<i>Margaret Kosek and Robert E. Black</i>		3. Anthrax	427
E. YERSINIOSIS	310	<i>Sean V. Shadomy and Nancy E. Rosenstein</i>	
<i>M. Patricia Quinlisk</i>		4. Brucellosis	431
F. LEGIONELLOSIS	311	<i>Diane K. Gross and Thomas A. Clark</i>	
<i>Matthew R. Moore and Barry S. Fields</i>		5. Leptospirosis	434
G. AMEBIASIS AND AMEBIC MENINGOENCEPHALITIS	313	<i>Thomas A. Clark</i>	
<i>William Stauffer</i>		6. Non-Typhoidal Salmonellosis	437
H. GIARDIASIS	317	<i>John Painter, Michael Perch, and Andrew C. Voetsch</i>	
<i>Mary E. Wilson</i>		C. TOXOPLASMOSIS	440
I. DRACUNCULIASIS	320	<i>Jeffrey L. Jones and Jacob K. Frenkel</i>	
<i>Donald R. Hopkins</i>		D. TRICHINELLOSIS	443
J. HUMAN ENTERIC COCCIDIAL INFECTIONS	322	<i>Michael P. Stevens and Michael Edmond</i>	
<i>Katharine Bar</i>			

E. CLONORCHIASIS AND OPISTHORCHIASIS	445	25 Silicosis	591
<i>Kenrad E. Nelson</i>		<i>Stephen Levin and Ruth Lilis</i>	
F. CESTODE INFECTIONS	447	26 Health Significance of Metal Exposures	603
1. Taeniasis and Cysticercosis	447	<i>Philippe Grandjean</i>	
<i>Kenrad E. Nelson</i>		27 Diseases Associated with Exposure to Chemical	
2. Hydatid Disease (Echinococcosis)	448	Substances: Organic Compounds	619
<i>Pedro L. Moro and Peter M. Schantz</i>		<i>Stephen Levin and Ruth Lilis</i>	
17 Opportunistic Fungal Infections	461	28 Polychlorinated Biphenyls	675
<i>Michael A. Pfaller</i>		<i>Richard W. Clapp</i>	
18 Other Infection-Related Diseases of Public		29 Polychlorinated Dioxins and Polychlorinated	
Health Import	469	Dibenzofurans	679
A. DERMATOPHYTES	469	<i>Yoshito Masuda and Arnold J. Schechter</i>	
<i>Marta J. VanBeek</i>		30 Brominated Flame Retardants	685
B. HOOKWORM DISEASE: ANCYLOSTOMIASIS,		<i>Daniele F. Staskal and Linda S Birnbaum</i>	
NECATORIASIS, UNCINARIASIS	473	31 Multiple Chemical Sensitivities	687
<i>Laverne K. Eveland</i>		<i>Mark R. Cullen</i>	
C. OTHER INTESTINAL NEMATODES	476	32 Pulmonary Responses to Gases	
<i>Mark R. Wallace, John W. Sanders,</i>		and Particles	691
<i>and Shannon D. Putnam</i>		<i>Kaye H. Kilburn</i>	
D. SCHISTOSOMIASIS	480	33 Pesticides	707
<i>Ettie M. Lipner and Amy D. Klion</i>		<i>Marion Moses</i>	
E. TOXIC SHOCK SYNDROME (STAPHYLOCOCCAL)	483	34 Temperature and Health	725
<i>Arthur L. Reingold</i>		<i>Edwin M. Kilbourne</i>	
F. REYE'S SYNDROME	492	35 Ionizing Radiation	735
<i>Robert B. Wallace</i>		<i>Arthur C. Upton</i>	
Section III Environmental Health	501	36 Nonionizing Radiation	743
Edited by Arnold J. Schechter		<i>Arthur L. Frank and Louis Slesin</i>	
19 The Status of Environmental Health	503	37 Effects of the Physical Environment:	
<i>Arthur L. Frank</i>		Noise as a Health Hazard	755
20 Toxicology	505	<i>Aage R. Møller</i>	
A. PRINCIPLES OF TOXICOLOGY	505	38 Ergonomics and Work-Related	
<i>Michael Gochfeld</i>		Musculoskeletal Disorders	763
B. NEUROBEHAVIORAL TOXICITY	523	<i>W. Monroe Keyserling and Thomas J. Armstrong</i>	
<i>Nancy Fiedler, Joanna Burger,</i>		39 Industrial Hygiene	781
<i>and Michael Gochfeld</i>		<i>Robert F. Herrick</i>	
21 Environmental and Ecological		40 Surveillance and Health Screening	
Risk Assessment	545	in Occupational Health	789
<i>Michael Gochfeld and Joanna Burger</i>		<i>Gregory R. Wagner and Lawrence J. Fine</i>	
22 Biomarkers	563	41 Workers with Disabilities	795
<i>Michael D. McClean and Thomas F. Webster</i>		<i>Nancy R. Mudrick, Robert J. Weber,</i>	
23 Asbestos and Other Fibers	567	<i>and Margaret A. Turk</i>	
<i>Kaye H. Kilburn</i>			
24 Coal Workers' Lung Diseases	583		
<i>Gregory R. Wagner and Michael D. Attfield</i>			

42 Environmental Justice: From Global to Local803
Howard Frumkin, Enrique Cifuentes, and Mariana I. Gonzalez

43 The Health of Hired Farmworkers819
Don Villarejo and Marc B. Schenker

44 Women Workers827
Karen Messing

45 Health Hazards of Child Labor835
Susan H. Pollack and Philip J. Landrigan

46 Occupational Safety and Health Standards841
Eula Bingham and Celeste Monforton

47 Ensuring Food Safety847
Douglas L. Marshall and James S. Dickson

48 Water Quality Management and Water-Borne Disease Trends863
Patricia L. Meinhardt

49 Hazardous Waste: Assessing, Detecting, and Remediation901
William A. Suk

50 Aerospace Medicine909
Roy L. DeHart

51 Housing and Health919
John M. Last

52 Human Health in a Changing World925
John M. Last and Colin L. Soskolne

Section IV Behavioral Factors Affecting Health939
 Edited by Neal Kohatsu

53 Health Behavior Research and Intervention941
Kim D. Reynolds, Donna Spruijt-Metz, and Jennifer Unger

54 Tobacco: Health Effects and Control953
Corinne G. Husten and Stacy L. Thorne

55 Alcohol-Related Health Problems999
Brian L. Cook and Jill Liesveld

56 Prevention of Drug Use and Drug Use Disorders1013
Elizabeth B. Robertson and Wilson M. Compton

57 Community Health Promotion and Disease Prevention1023
Stephanie Zaza and Peter A. Briss

58 Risk Communication—An Overlooked Tool for Improving Public Health1029
David P. Ropeik

59 Health Literacy1035
Rima E. Rudd, Jennie E. Anderson, Sarah C. Oppenheimer, Lindsay E. Rosenfeld, and Carmen Gomez Mandic

Section V Noncommunicable and Chronic Disabling Conditions1041
 Edited by Ross Brownson

60 Screening for Early and Asymptomatic Conditions1043
Robert B. Wallace

61 Cancer1047
Leslie K. Dennis, Charles F. Lynch, and Elaine M. Smith

62 Heart Disease1071
Russell V. Luepker

63 Renal and Urinary Tract Disease1089
Rebecca L. Hegeman

64 Diabetes1101
Janice C. Zgibor, Janice S. Dorman, and Trevor J. Orchard

65 Respiratory Disease Prevention1113
David B. Coultas and Jonathan M. Samet

66 Musculoskeletal Disorders1125
Jennifer L. Kelsey and MaryFran Sowers

67 Neurological Disorders1139
James C. Torner and Robert B. Wallace

68 Disabling Visual Disorders1153
Dawn M. Oh and Kean T. Oh

69 Psychiatric Disorders1161
Evelyn J. Bromet

70 Childhood Cognitive Disability1173
Maureen S. Durkin, Nicole Schupf, Zena A. Stein, and Mervyn W. Sussner

71 Prevention of Disability in Older Persons1185
William H. Barker

72 Nutrition in Public Health and Preventive Medicine1195
Marion Nestle

73 Postmarketing Medication Safety Surveillance: A Current Public Health Issue	1205		
<i>Mirza I. Rahman and Omar H. Dabbous</i>			
Section VI Health-Care Planning, Organization, and Evaluation	1215		
Edited by F. Douglas Scutchfield			
74 The American Health-Care System: Structure and Function	1217		
<i>Glen P. Mays and F. Douglas Scutchfield</i>			
75 Structure and Function of the Public Health System in the United States	1239		
<i>F. Douglas Scutchfield and C. William Keck</i>			
76 International and Global Health	1251		
<i>Franklin M.M. White and Debra J. Nanan</i>			
77 Public Health Law	1259		
<i>Edward P. Richards, III and Katharine C. Rathbun</i>			
78 Public Health Management Tools	1267		
A. PLANNING FOR HEALTH IMPROVEMENT: MODELS FOR COMMUNITIES AND INSTITUTIONS	1267		
<i>K. Michael Peddecord</i>			
B. PUBLIC HEALTH LEADERSHIP DEVELOPMENT ..	1271		
<i>Kathleen Wright and Cynthia D. Lamberth</i>			
C. POLICY DEVELOPMENT	1272		
<i>Helen H. Schauffler</i>			
D. QUALITY ASSURANCE AND QUALITY IMPROVEMENT	1277		
<i>Richard S. Kurz</i>			
E. PUBLIC HEALTH MANAGEMENT TOOLS EVALUATION	1280		
<i>Thomas G. Rundall</i>			
79 Categorical Public Health Sciences	1285		
A. DISASTER PREPAREDNESS AND RESPONSE	1285		
<i>Theodore J. Cieslak, Scott R. Lillibridge, Trueman W. Sharp, George W. Christopher, and Edward M. Eitzen</i>			
B. MATERNAL AND CHILD HEALTH	1294		
<i>Lewis H. Margolis and Alan W. Cross</i>			
C. PREVENTIVE MEDICINE SUPPORT OF MILITARY OPERATIONS	1297		
<i>Robert L. Mott</i>			
D. PUBLIC HEALTH WORKFORCE	1300		
<i>Kristine M. Gebbie</i>			
E. FAMILY PLANNING	1303		
<i>Herbert B. Peterson, Andreea Creanga, and Amy O. Tsui</i>			
Section VII Injury and Violence	1317		
Edited by Neal Kohatsu			
80 Injury Control: The Public Health Approach	1319		
<i>Corinne Peek-Asa and Erin O. Heiden</i>			
81 Violence in the Family as a Public Health Concern	1329		
<i>Irene Hanson Frieze, Jeremiah A. Schumm, and Stacey L. Williams</i>			
<i>Index</i>	1335

Philippe Grandjean, MD, DMSc

Professor of Environmental Medicine
University of Southern Denmark, Institute of Public Health
Odense, Denmark
Adjunct Professor of Environmental Health
Harvard School of Public Health
Boston, Massachusetts
26. Health Significance of Metal Exposures

Alan E. Greenberg, MD, MPH

Professor and Chair
Department of Epidemiology and Biostatistics
George Washington University School of Public Health and
Health Services
Washington, District of Columbia
*11. The Epidemiology and Prevention of Human
Immunodeficiency Virus (HIV) Infection and Acquired
Immunodeficiency Syndrome (AIDS)*

Diane K. Gross, DVM, PhD

Epidemic Intelligence Service Officer
 Meningitis and Special Pathogens Branch
 Division of Bacterial and Mycotic Diseases
 National Center for Infectious Diseases
 Centers for Disease Control and Prevention
 Atlanta, Georgia
16B4. Brucellosis

Marta A. Guerra, DVM, MPH, PhD

Senior Staff Epidemiologist
 Viral and Rickettsial Zoonoses Branch
 Division of Viral and Rickettsial Diseases
 Centers for Disease Control and Prevention
 Atlanta, Georgia
15C. Rickettsial Infections

Dalya Guris, MD, MPH

Team Leader, Herpes Viruses Team
 National Immunization Program
 Centers for Disease Control and Prevention
 Atlanta, Georgia
9I. Varicella and Herpes Zoster

Rebecca L. Hegeman, MD

Associate Professor
 Clinical Internal Medicine
 Department of Internal Medicine
 University of Iowa Health Care
 Iowa City, Iowa
63. Renal and Urinary Tract Disease

Erin O. Heiden, MPH

Doctoral Student
 University of Iowa College of Public Health
 Iowa City, Iowa
80. Injury Control: The Public Health Approach

Robert F. Herrick, MS, ScD

Senior Lecturer
 Harvard School of Public Health
 Boston, Massachusetts
39. Industrial Hygiene

Lauri A. Hicks, DO

Epidemic Intelligence Service Officer, Respiratory
 Diseases
 Centers for Disease Control and Prevention
 Atlanta, Georgia
16B1. Bacterial Zoonoses-Psittacosis

Alan R. Hinman, MD, MPH

Senior Public Health Scientist
 Task Force for Child Survival and Development
 Decatur, Georgia
5. Public Health Informatics
9A. Measles

Donald R. Hopkins, MD, MPH

Vice President
 The Carter Center
 Atlanta, Georgia
13I. Dracunculiasis

Douglas B. Hornick, MD

Professor
 University of Iowa Carver College of Medicine
 Director of TB Chest Clinic and Clinical Services
 Division of Pulmonary, Critical Care and Occupational
 Medicine
 Iowa City, Iowa
12I. Tuberculosis

James M. Hughes, MD

Director, Program in Global Infectious Diseases
 Emory University, School of Medicine
 Atlanta, Georgia
8B. Emerging Microbial Threats to Health and Security

Joseph Hughey, PhD

University of Missouri
 Kansas City, Missouri
*6. Health Disparities and Community-Based Participatory
 Research*

Corinne G. Husten, MD, MPH

Director (Acting)
 Office on Smoking and Health
 Centers for Disease Control and Prevention
 Atlanta, Georgia
54. Tobacco: Health Effects and Control

Robert S. Janssen, MD

Director, Divisions of HIV/AIDS Prevention
 Centers for Disease Control and Prevention
 Atlanta, Georgia
*11. The Epidemiology and Prevention of Human
 Immunodeficiency Virus (HIV) Infection and Acquired
 Immunodeficiency Syndrome (AIDS)*

Jeffrey L. Jones, MD, MPH

Chief, Diagnostics and Epidemiology
 Parasitic Diseases Branch
 Division of Parasitic Diseases
 National Center for Infectious Diseases
 Centers for Disease Control and Prevention
 Atlanta, Georgia
16C. Toxoplasmosis

S. Patrick Kachur, MD, MPH, FACPM

Chief, Strategic and Applied Sciences Unit,
 Malaria Branch
 Centers for Disease Control and Prevention
 Atlanta, Georgia
15F. Malaria

Mark Katz, MD

Medical Epidemiologist
Global Disease Detection Division
Centers for Disease Control and Prevention
Nairobi, Kenya
9G. Influenza

C. William Keck, MD, MPH

Department of Community Health Sciences
Northeastern Ohio Universities College of Medicine
Rootstown, Ohio
*75. Structure and Function of the Public Health System
in the U.S.*

Jennifer L. Kelsey, PhD

Professor
Department of Medicine
Department of Family
Medicine and Community Health
University of Massachusetts Medical School
Worcester, Massachusetts
66. Musculoskeletal Disorders

W. Monroe Keyserling, PhD

Professor
Department of Industrial and Operations Engineering
University of Michigan
Ann Arbor, Michigan
38. Ergonomics and Work-Related Musculoskeletal Disorders

Jay S. Keystone, MD, MSc, FRCPC

Professor of Medicine
Tropical Disease Unit
University of Toronto
Toronto, Ontario, Canada
8C. Health Advice for International Travel

Edwin M. Kilbourne, MD

Director, Scientist Redirection Program
Director, Iraqi Interim Center for Science & Industry
Embassy of the United States of America
Baghdad, Iraq
34. Temperature and Health

Kaye H. Kilburn, MD

Professor Emeritus
Ralph Edgington Chair in Medicine
University of Southern California
Keck School of Medicine
Los Angeles, California
23. Asbestos and Other Fibers
32. Pulmonary Responses to Gases and Particles

Louis V. Kirchhoff, MD, MPH

Professor
Departments of Internal Medicine & Epidemiology
University of Iowa
Iowa City, Iowa
15H. Trypanosomiasis

Elizabeth A. Kleiner, MD, MS

Division of Infectious Disease
Medical College of Virginia
Virginia Commonwealth University
15A. Viral Infections

R. Monina Klevens, DDS, MPH

Medical Epidemiologist
Centers for Disease Control and Prevention
Atlanta, Georgia
14. Control of Infections in Institutions

Amy D. Klion, MD

Staff Clinician
Laboratory of Parasitic Diseases
National Institute of Allergy and Infectious Disease
National Institutes of Health
Bethesda, Maryland
16J. Lymphatic Filariasis
18D. Schistosomiasis

Neal D. Kohatsu, MD, MPH

Chief, Cancer Control Branch
California Department of Public Health
Sacramento, California
Associate Editor
Editor of Section IV: Behavioral Factors Affecting Health
Editor of Section VII: Injury and Violence

Margaret Kosek, MD

Assistant Scientist
Johns Hopkins Bloomberg School of Public Health
Baltimore, Maryland
13C. Cholera
13D. Escherichia coli Diarrhea

Katrina Kretsinger, MD, MA

Medical Epidemiologist
Meningitis and Vaccine Preventable Diseases Branch
Division of Bacterial Diseases
National Center for Immunization and
Respiratory Diseases
Centers for Disease Control and Prevention
Atlanta, Georgia
9E. Tetanus

Richard S. Kurz, PhD

Professor and Chair
Department of Health Management and Policy
St. Louis University, School of Public Health
St Louis, Missouri
78D. Quality Assurance and Quality Improvement

Cynthia D. Lamberth, MPH

Director, Kentucky Public Health Leadership Institute
University of Kentucky College of Public Health
Lexington, Kentucky
78B. Public Health Leadership Development

Philip J. Landrigan, MD, MSc

Professor and Chair
 Department of Community and Preventive
 Medicine
 Professor of Pediatrics
 Mount Sinai School of Medicine
 New York, New York
45. Health Hazards of Child Labor

John M. Last, MD, DPH, FFPH, FACPM, FRACP, FRCPC, FAFPHM, FACE

Emeritus Professor of Epidemiology
 Department, Epidemiology & Community
 Medicine
 University of Ottawa
 Ottawa, Ontario, Canada
3. Ethics and Public Health Policy
51. Housing and Health
52. Human Health in a Changing World

Suzanne R. Lavoie, MD

Professor of Pediatrics and Internal Medicine
 Chair, Division of Pediatric Infectious Diseases
 Virginia Commonwealth University Health System
 Richmond, Virginia
*10. Epidemiology and Trends in Sexually
 Transmitted Diseases*

James W. LeDuc, PhD

Director, Division of Viral and Rickettsial Diseases
 Centers for Disease Control and Prevention
 Atlanta, Georgia
15B. Epidemiology of Viral Hemorrhagic Fevers

Stephen M. Levin, MD

Associate Professor
 Department of Community and Preventive
 Medicine
 Mount Sinai School of Medicine
 New York, New York
25. Silicosis
*27. Diseases Associated with Exposure
 to Chemical Substances*

Jill L. Liesveld, MD

Clinical Associate Professor
 University of Iowa Carver College of Medicine
 University of Iowa Hospitals and Clinics
 Iowa City, Iowa
55. Alcohol-Related Health Problems

Scott R. Lillibridge, MD

Professor of Epidemiology
 Director, Center for Public Health Preparedness
 and Biosecurity
 University of Texas School of Public Health
 Houston, Texas
79A. Disaster Preparedness and Response

Ruth Lilis, MD[†]

Professor Emeritus
 Division of Environmental and Occupational Medicine
 Department of Community Medicine
 Mount Sinai School of Medicine
 New York, New York
25. Silicosis
*27. Diseases Associated with Exposure to
 Chemical Substances*

Ettie M. Lipner, MPH

Epidemiology Fellow, Office of Global Research
 National Institute of Allergy & Infectious Diseases
 National Institutes of Health
 Bethesda, Maryland

Preface

Public Health & Preventive Medicine is in its ninth decade of existence since being first published in 1913, and it therefore contains much of the lore of public health and preventive medicine over the twentieth century. With each edition, selecting the appropriate information to include has become increasingly difficult for several reasons. Nearly all the same public health and prevention themes and issues continue to be with us, and new knowledge, research, and practice information for public health and preventive medicine grow at a rapid rate. New diseases are being discovered and our knowledge of existing ones is constantly being refined and expanded. New microorganisms of public health import continue to be discovered and new conditions of public health importance have emerged. Behavioral science has helped us better understand how to promote healthful, hygienic behaviors and better educate our citizens and patients. Science and engineering have created occupational and other environmental exposures never before experienced. The increased survivorship of the populations of industrialized nations has heightened the importance of degenerative diseases, complex medical care programs, and the opportunities for prevention of disease. The population growth of our finite and frail planet may be causing present and future public health dilemmas that are not, yet, completely understood. There has been increasing attention to

the social and “unnatural” causes of human suffering and the recognition of human conflict as a public health problem. The increased convergence of public health practice and the delivery of clinical health services has created and elevated several topics that must be given some prominence.

Every attempt has been made to update the information and acquire new knowledge in this fifteenth edition of *Public Health & Preventive Medicine*. Although several new topics have been introduced in this edition, inevitably certain issues could not be fully considered. In particular, to keep this textbook at a reasonable size, there is somewhat less emphasis on the issues of developing countries and some topics worthy of extended length have been shortened. Some of the chapters have been adapted from those in the fourteenth edition, usually in situations where the previous author was unable to participate again. Full credit for the preserved portions of previous editions is not possible, but can be found by perusing those editions. Although the majority of the more than 200 contributors to this textbook are from North America, most of the themes presented here have universal application and the lore comes from scientists and practitioners worldwide.

Robert B. Wallace, MD, MSc

Acknowledgments

Many persons gave generously of their time in the preparation of the fifteenth edition of *Public Health & Preventive Medicine*. The scientific contributors were most responsive to comments and editorial suggestions, and many had colleagues, too numerous to mention, who skillfully gave of their time in facilitating manuscript preparation and in communicating with the section editors and the editorial office. Particular appreciation is noted for Julie Bobitt, Linsey Abbott, and

Nicole Schmidt who provided high-quality logistical and editing support for assembling the many contributions to this volume. Michael Brown and Maya Barahona of the McGraw-Hill Publishing Company also gave invaluable support, advice, and assistance in the assembly of this book. Finally, John M. Last, editor emeritus and the immediate past editor of the volume, has continued to provide skilled and welcome support for its content.

Historical Note

Milton J. Rosenau was a Harvard man, as was his principal collaborator, George C. Whipple. His successor, Kenneth Maxcy, moved to Johns Hopkins University. When Maxcy was in turn succeeded as editor by Philip E. Sartwell and the size of the writing team began to grow, the center of gravity of “Maxcy-Rosenau” was decisively located in Baltimore: twenty of the thirty-nine contributors to the tenth edition were on the Johns Hopkins staff, and all but two or three contributors were associated with schools of public health. In 1976, the Publisher invited the Association of Teachers of Preventive Medicine (ATPM) to assume responsibility for the eleventh and subsequent editions. After a search, John M. Last, from the University of Ottawa, was selected as editor. Under his leadership,

“Maxcy-Rosenau-Last” evolved in several ways, becoming more comprehensive and international and with an increased number of contributors. Under the auspices of the ATPM, the thirteenth edition was coedited by Last and Robert B. Wallace, from the University of Iowa. Wallace became the editor for the fourteenth edition. The current fifteenth edition has been edited by Wallace with the capable assistance of Neal Kohatsu, now at the California Department of Public Health. More than 200 authors from diverse disciplines and geographic situations have contributed to this edition. John Last continues to be an active contributor to this volume and to public health in general.

Public Health & Preventive Medicine

Public Health Principles and Methods

Public Health and Preventive Medicine: Trends and Guideposts

Robert B. Wallace

There are varied definitions of public health. Recent volumes from the U.S. Institute of Medicine have addressed the definitions and functions of public health^{1,2} in a careful and thoughtful way, and described several pathways to healthier communities. The field of preventive medicine, the interface between public health and medical practice, is also critical to the health of populations, but is in a faster transition as the roles traditionally performed by physicians in population medicine are reconsidered and the structure of public health evolves. In the meantime, the health needs of the public are as acute as ever and demand all of the energy, skill, and science that public health and preventive medicine can muster.

Fortunately, there have been rapid and important advancements in public health and preventive medicine. Some have come as a result of inexorable achievements in productive science, and others were prodded by special public health emergencies and problems, or organizational changes in the delivery of preventive and curative health services. Many advancements in both practice and knowledge have been evolutionary, but in a few instances, there have been fundamental enhancements to our knowledge of the universe and their applications to the public health sciences. While there may be disagreements about what these achievements have been, and indeed some may not yet be fully recognized, the past several years have witnessed several striking and rapidly advancing trends. The following are some of the important trends that have shaped public health and preventive medicine, particularly within industrialized countries.

- *Increased incorporation of business and administrative practices into prevention and public health service delivery.*

While general administrative principles and practices have long been a part of public health education and program delivery, the administrative and business emphasis that has swept through most sectors of Western society has also had a clear impact on public health practice. The further application of “industrial standards,” quality improvement techniques, outcome measures, and complex accounting practices have changed the vocabulary and skills requisite for modern public health practice.^{3,4} With this has come more emphasis on outcome measures. The emphases on both practice guidelines and evidence-based practice have yielded a further orientation toward both traditional and new outcome measures as indicators of community health. More sophisticated measures are in development, and more comprehensive attempts at program performance monitoring are occurring. As more sophisticated, detailed, and measurable outcomes are developed, this monitoring may not only evaluate specific public health or community programs, but may also work toward

assessing the entire public health, health education, and clinical service structure within a community.

- *Changes in the definition of the group or population, the fundamental unit of public health.*

In general, “the population” that is both the target of preventive and public health programs and interventions has been historically defined as referring to geographic boundaries, due to their encompassing nature and concordance with governmental jurisdictions. That is, of course, still the case, but there has also been a trend toward increasing delivery of comprehensive clinical services to large groups of individuals defined administratively rather than geographically, often referred to as “managed care.” With the health and programmatic information available on these groups and the increasing ability to apply and evaluate public health and preventive services to them, the fundamental public health target group is no longer solely defined in the spatial sense. This has led to the need and opportunity for new partnerships among various private and public health organizations and agencies in order to deliver more effective and efficient public health services.⁵ In certain respects, this phenomenon has further blurred the boundaries between community-based programs and clinical, preventive, and curative services, thus increasing the need to update and redefine the tasks necessary for complete public health and prevention service delivery. However, the emergence of these new groups that are programmatically important and for whom health information is available has probably served to heighten public health program accountability to a higher proportion of the general population than ever before.

- *Enhanced conceptualization and measurement of personal health status.*

This has taken several forms and, while not totally new, has been increasingly incorporated into health status assessment. Perhaps the most important is the increased use of the so-called “quality-of-life” (QOL) measures.⁶ While the scope and measures of QOL techniques are not consensual, the supplementation of traditional measures of morbidity and mortality with measures and indices of symptoms and syndromes, less well-defined clinical conditions and entities, physical function and disability, affective states and the behavioral manifestations of mental diseases, social functions within and outside the family, and economic well-being and risk status irrespective of health status have added importantly to the understanding of health and optimization of health status. This has changed the meaning and benchmarks for “healthy communities.”

In keeping with the theme of enhanced administration in public and preventive services, health status measures for groups and individuals increasingly have become intertwined with the “health” status of preventive and curative programs and service delivery units. That is, the health of members (consumers) of various administered health-care units (providers) can be partially assessed or inferred by process measures of the programs themselves, such as rates of vaccine delivery or early disease detection programs.

- *Increased codification and interpretation of scientific findings relevant to prevention and public health.*

One of the early important and continuing exercises in defining the scientific and evidentiary basis for clinical preventive practice was performed by what is now the Canadian Task Force on Preventive Health Care⁷, followed by the continuing reports of the U.S. Preventive Services Task Force⁸, and many others. Making explicit the scientific basis for preventive practices and interventions and using this evidence to structure practice guidelines has had many important effects, including (a) placing greater priority on effective interventions, (b) educating health practitioners on the strengths and limitations of various interventions, (c) providing one basis for program evaluation of these effective interventions, and (d) identifying the research gaps in these preventive and public health interventions. Parallel tracks of creating guidelines for curative medicine, often called “evidence-based medicine”⁹ have made similar and important contributions. More recently, a similar effort has been developed under the banner of “evidence-based public health.”⁹

- *Establishment of goals for communities to attain improvement in health status.*

This exercise has been a part of strategic program planning for a long time, but in the past decade it has been elevated to explicit goal setting for communities and larger jurisdictions. While national goals for health status improvement¹⁰ may be useful at the local level, most public health officials and community organizations would rather have goal setting performed at the local level. This allows engagement of local professionals and other citizens and takes greater account of local priorities, needs, and perceptions of the most compelling health problems to which limited resources should be allocated.

- *Application of more advanced community health information systems.*

This takes many forms, but accurate, comprehensive, and timely community health data are an essential requisite of goal setting and program performance monitoring. Clinical and public health information are both essential and interrelated, raising special issues of ethics and privacy, as well as access. However, the information revolution should allow better program management and assessment, and with appropriate controls should serve the prevention and public health communities in ways not previously possible.¹¹

In summary, the current era has been a time of clear change for both preventive medicine and public health. This book attempts to capture and review these changes for the practitioner and student of these strategically important disciplines.

Epidemiology and Public Health

Robert B. Wallace

Epidemiology is the basic science and most fundamental practice of public health and preventive medicine. We can study health and disease by observing their effects on individuals, by laboratory investigation of experimental animals, and by measuring their distribution in the population. Each of these ways of investigating health and disease is used by the epidemiologist. Epidemiology is therefore the scientific foundation for the practice of public health.

The word “epidemiology” comes from epidemic, which translated literally from the Greek means “upon the people.” Historically, the earliest concern of the epidemiologist was to investigate, control, and prevent epidemics. This chapter deals with the scientific principles that are the foundation of epidemiology. We then address the sources and characteristics of information used to assess the health of populations. Next, we discuss the ways this information can be analyzed. Finally, we show how to use epidemiology in controlling and preventing health problems.

► HISTORY

Epidemiology has roots in the Bible and in the writings of Hippocrates, as does much of Western medicine. The *Aphorisms of Hippocrates* (fourth to fifth century BC) contain many generalizations based on prolonged and careful observation of large numbers of cases. The introductory paragraph of *Airs, Waters, Places* offers timeless advice on good environmental epidemiology:

Whoever would study medicine aright must learn of the following subjects. First he must consider the effect of each season of the year and the differences between them. Secondly he must study the warm and the cold winds, both those that are common to every country and those peculiar to a particular locality. Lastly, the effect of water on the health must not be forgotten. When, therefore, a physician comes to a district previously unknown to him, he should consider both its situation and its aspect to the winds. Similarly, the nature of the water supply must be considered Then think of the soil, whether it be bare and waterless or thickly covered with vegetation and well-watered, whether in a hollow and stifling, or exposed and cold. Lastly consider the life of the inhabitants themselves, are they heavy drinkers and eaters and consequently unable to stand fatigue or, being fond of work and exercise, eat wisely but drink sparingly?¹

Epidemics of infection seriously concerned physicians in ancient times, although often they could do little more than observe

Note: This is a revision of a chapter from the 14th edition, originally written by Carl W. Tyler, Jr., and John M. Last; revised by the editor.

the victims and record mortality. Their limited knowledge rarely permitted effective intervention. Until the Renaissance, physicians based their approach more on impressions than real numbers. John Graunt is often regarded as the founder of vital statistics. He first published his numerical methods for examining health problems in *Natural and Political Observations on the Bills of Mortality* in 1662. He was the first to attempt this approach.

Epidemiology was first applied to the control of communicable diseases and public health through quarantine and isolation, even though ideas about disease transmission and microbiology and epidemiology were rudimentary. Johann Peter Frank, a physician who became “director-general of public health” (in modern terminology) to the Hapsburg Empire, systematized and codified many rules for personal and communal behavior in the eighteenth century. His work contributed to public health and is published in *System einer vollstandigen medicinischen Polizey* (1779).

Careful clinical observation, precise counts of well-defined cases, and demonstration of relationships between cases and the populations in which they occur all combine in the method upon which epidemiology depends. This method was first developed in the nineteenth century. Modern epidemiologists hold John Snow² in high esteem. He painstakingly collected the facts about sources of drinking water that he related to mortality rates from cholera in London. This proved a classic demonstration of the mode of transmission about 30 years before Koch isolated and identified the cholera *Vibrio*. Snow’s great contemporary, William Farr,³ defined and clarified many basic ideas of vital statistics and epidemiology. Among his most important contributions were the following: (a) the scope of epidemiology, (b) the concept of person-years, (c) the relationship between mortality rate and probability of dying, (d) standardized mortality ratios, (e) dose-response relationships, (f) herd immunity, (g) the relationship between incidence and prevalence, and (h) the concepts of retrospective and prospective study. He also developed the first effective classification of disease, the direct ancestor of the nosology that we still use today. *Vital Statistics* (1885), an edited volume of excerpts from Farr’s annual reports to the registrar-general, is perhaps the best textbook of epidemiology ever written, graced by beautiful writing and well-chosen tables to illustrate the text.

Methods of epidemiological investigation have evolved since the mid-nineteenth century. The case-control study reentered medicine from the social sciences in the third decade of the twentieth century. The cohort study came into use after World War II, as a means of identifying risks associated with heart disease, lung cancer, and other emerging public health problems. Epidemiological “experiments” as now conducted in randomized trials are essentially modern innovations. Statistical methods and electronic computation have greatly improved epidemiological analysis. Present indications suggest expanding potential and an exciting future for epidemiology. Population-based medicine makes community assessment and diagnosis important for determining the need for health services. An increasingly broad

interface between clinical medicine and epidemiology is called clinical epidemiology. Molecular epidemiology promises to let epidemiologists link genetic and many other biological markers to health conditions, thereby creating new potential approaches to intervention. Case-control studies are adding rapidly to our understanding of cause-effect relationships in many chronic and disabling disorders. Epidemiological methods can also help in evaluating health services.

What does this brief history of epidemiology teach? First, the community and environment influence the health of humans, as do our own inherited characteristics. Second, knowing how a disease is transmitted permits us to control and prevent it, even though we may not know the causal agent. Third, even the simplest information about vital events, illnesses, and populations can detect and analyze epidemiological problems. Finally, epidemiology can help find, investigate, analyze, control, and prevent a wide range of health problems.

► DEFINITION

Epidemiology is both the basic science of public health and its most fundamental practice. Therefore, we need to examine both aspects of its meaning.

Science

Epidemiology was originally defined as the scientific study of epidemics. An epidemic is the occurrence in excess of normal of an illness, health event, or health-related behavior that occurs in a specific place or among a group. Reports of cholera by John Snow and childbed fever by Holmes are among the classic examples. In recent years, excessive use of tobacco, called by some “the brown plague,” and the acquired immunodeficiency syndrome (AIDS) are examples of modern epidemics.

Because the word “epidemic” may lead to chaotic, unreasoned responses to health problems, journalists use the term more often than epidemiologists. Other words, such as outbreak and cluster, are employed by practicing public health professionals to avoid unreasoned public response.

In current use, however, the definition of epidemiology is broader and recognizes the application of this basic science of public health to the control and prevention of health problems. The following definition, recently agreed upon by an international panel, is widely accepted:

Epidemiology is the study of the distribution and determinants of health-related states and events in specified populations and the application of this study to the control of health problems.⁴

Some terms in this definition require discussion. *Distribution* relates to time, place, and person. The relevant population characteristics include location, age, sex, and race; occupation and other social characteristics; living places; susceptibility; and exposure to specific agents. In addition, the distribution of the exposed cases needs to examine time as a factor. Relationships in time reveal information about trends, cyclic or secular patterns, clusters, and intervals from exposure to inciting factors to the onset of disease.

Determinants include both causes and factors that influence the risk of disease. Many diseases have a single necessary cause. When the agent of disease causes a single, specific condition, as occurs with the tubercle bacillus or the lead in lead-based paint, we know the necessary cause. In addition, there are usually many other determinants. They fall into two broad groups: (a) host factors that determine the susceptibility of the individual and (b) environmental factors that determine the host’s exposure to the specific agent. Host factors include age, sex, race, genetic or constitutional makeup, physiologic state, nutritional condition, and previous immunological experience. Environmental factors include all conditions of living. Among these factors are family size and composition; crowding; hygienic conditions; occupation; and geographic, climatic, and seasonal circumstances.

Characteristics of individuals or populations, identified by the term “lifestyle,” may include such factors as use of tobacco, alcohol, and automobiles. Past and present environment—including the period of intrauterine life—may influence exposure and susceptibility to disease.

Practice

The practice of a science is best defined by what the scientist does. Langmuir points out that, “the basic operation of the epidemiologist is to count cases and measure the population in which they arise.”⁵ The practice of epidemiology, therefore, is the scientific process that detects, investigates, and analyzes health problems, followed by applying this information to the control and prevention of these problems. This practice requires health problems to be the subject of public health surveillance, epidemiological investigation, and analysis. The findings of this analysis linked to health policy can lead to the control and prevention programs intended to resolve health problems. Evaluation of control and prevention is also the responsibility of the practicing epidemiologist as is the clear and persuasive communication of the scientific findings to the public, policy makers, and program staff.

Uses of Epidemiology

The most important use for epidemiology is to improve our understanding of health and disease—a goal shared by all the disciplines and branches of the biomedical sciences. Morris⁶ defined seven uses of epidemiology: historical study, community assessment, working of health services, individual risks and chances, completing the clinical picture, identification of syndromes, and the search for causes (Table 2-1). Each deserves brief comment.

Historical Study

The classic question “Is health improving?” can be answered only by comparing experience (rates) over time; this is one essential routine activity in all health services. Sometimes when the data are closely examined, unexpected trends appear. For example, asthma deaths increased unexpectedly in children and young adults in Britain and other countries in the 1950s, and continued to increase into the mid-1960s, before the cause—self-use of isoprenaline nebulizers—was discovered. Removing the offending product from the market halted the unfortunate trend.

Community Assessment

What are the health problems? This question can be answered in many ways. For example, what proportion of school children have become regular cigarette smokers by various stages of their progress through school? Or what proportion of people always or never use seat belts when driving or riding in cars? Answers to such questions

TABLE 2-1. USES OF EPIDEMIOLOGY

Historical study: is community health getting better or worse?
Community assessment: what actual and potential health problems are there?
Working of health services
Efficacy
Effectiveness
Efficiency
Individual risk and chances
Actuarial risks
Health hazard appraisal
Completing the clinical picture: different presentations of a disease
Identification of syndromes: “lumping and splitting”
Search for causes: case-control and cohort studies
Evaluation of presenting symptoms and signs
Clinical decision analysis

have prognostic and also diagnostic value. Community assessment makes it possible to predict the impact of future health problems by known effects of many risk factors.

The Search for Causes

This is the most obvious use for epidemiology. Most hypothesis-testing studies (discussed later) have the primary aim of identifying causal factors, or at least of risk factors for disease. This chapter cites many examples of such studies.

Working of Health Services

Are all needed services available, accessible, and used appropriately? Are children receiving necessary immunizations? Can pregnant women begin prenatal care before the end of the first trimester of pregnancy? Do known contacts of persons with sexually transmitted diseases receive follow-up and treatment? Information on these and many other questions is often gathered routinely or by special survey. Health service administrators should not only always think of these simple routine questions, but should be alert to less obvious potential gaps in coverage. For example, the census will state the numbers of elderly persons who live alone. Is all or only a small portion of these known to the public health nurses and others who provide home surveillance and care?

Individual Chances

What is the risk that a person will die before the next birthday? Actuaries who evaluate the risks for persons seeking life insurance have calculated answers based on probabilities derived from experience. This has become a prominent activity of epidemiologists who work on risk assessment and has led to many new insights, for example, about occupational and environmental risks and the hazards associated with immunizations.⁷

Identification of Syndromes

Epidemiologists are called “lumpers and splitters” because epidemiological investigations sometimes make it possible to group together several differing manifestations of a condition or to separate seemingly identical diseases into more than one category. The latter are more common than the former; examples include the differentiation of hepatitis A from hepatitis B and the distinction between several varieties of childhood leukemia. Examples of “lumping” include the identification of many manifestations of tuberculosis. At one time, each group of symptoms and signs had a different name, such as phthisis, consumption, or pleurisy. Addiction to tobacco is the underlying cause of a variety of outcomes. Among them are respiratory cancers, chronic obstructive pulmonary disease, and a portion of the risk of coronary heart disease. All these conditions could result from “tobaccoism.”

Completing the Clinical Picture

One of Morris’ original illustrations of this use for epidemiology was the demonstration that myocardial infarction occurs commonly in women as well as in men. An important difference is that this condition occurs in women at older ages and presents more often as “ruptured ventricle”; this causes sudden death. Last used the technique of “completing the clinical picture” to construct a model⁸ of what might occur in the average general practice population. In the course of a year, facts known and seen by the physician may be amplified by epidemiological study even though they might be unidentified, undiagnosed, or in a single practitioner’s experience and only the submerged part of the iceberg of disease.

Other Uses

Clinical epidemiologists have defined other uses for epidemiology that do not fit any of Morris’ original seven uses. One important use is the evaluation of presenting symptoms and signs of disease. Analyzing the data in hospital charts and relating symptoms and complaints to final diagnoses makes it possible for an epidemiologist to

study clinical outcomes, including assessing the adverse effects of therapy. A related use is clinical decision analysis.⁹ This technique is a rigorous quantitative method used to decide the best method of managing patients with particular diseases. This procedure involves the use of decision trees. Decision trees are algorithms in which the probability of an outcome for each different decision is predicted based on clinical experience.

Epidemiological Method

Epidemiologists use a wide range of scientific information, including clinical findings, laboratory data, and field observations. In the end, it is the reasoning of the epidemiologist that ties these facts together. This reasoning is the logic behind disease control and prevention measures.

Epidemiological reasoning is fundamental and straightforward. First, we define events or clinical cases using careful, specific, and objective observations. Next, we count these events or cases and orient them to time, place, and person. Then we determine the population at risk and calculate rates of occurrences for the events or clinical cases. This requires the use of nothing more complicated than long division. We put the events or cases in the numerator according to their relevant characteristics. The next step involves using a denominator of the portion of the population at risk and characterizing this group in the same way as those in the numerator are characterized. At this point, we calculate rates of occurrence in the group of cases. These rates are then compared with the rates of occurrence in other population groups. Finally, using this information, we draw inferences about the events that define the health problem and the agent or agents that cause it. These rates also provide information about the host and the environmental factors that influence the risk of occurrence and the transmission of the health problem. Using this information and collaborating with other health professionals, we propose control measures and then continue the observations required to assess the control program.

In identifying a health problem or case, many kinds of clinical examination may be employed. The patient’s history may reveal information about exposure to risk, incubation period, susceptibility, occupation, residence, course of disease, or other factors. Physical examination can classify individuals not only about whether they have the condition under study, but as to type, stage, and duration of disease. Laboratory tests are valuable for a similar purpose. In addition, they are essential in revealing clinically inapparent cases, and they often shed light on the pathogenesis of the condition. Field observations are the sine qua non of the epidemiological method.

Viral hepatitis is an example of the ways that clinical, laboratory, and field studies can interlock. Epidemic jaundice, mentioned by Hippocrates, has occurred in wars from ancient times to the present. Medical investigators used needle biopsies, a technique developed in the 1940s, to show generalized parenchymal inflammation accompanied the acute disease. Epidemiological studies soon distinguished hepatitis A (“infectious hepatitis”) from hepatitis B (“syringe jaundice”). Both were shown to be due to filterable agents, presumably viruses. However, hepatitis A had the epidemiological features of a fecal-oral transmission. Hepatitis B, on the other hand, was clearly blood borne and transmitted by inadequately sterilized hypodermic needles or other medical equipment. No cross-immunity protected people with one form of hepatitis from the other. Subsequent studies showed further differences. Hepatitis A had a shorter incubation period, was more contagious, and had a briefer period of abnormal serum transaminase activity than did hepatitis B.¹⁰ Later epidemiological studies revealed the pattern of sexual transmission of hepatitis B among male homosexuals. In 1965, Blumberg and colleagues found Australia antigen in the serum of patients who had multiple transfusions and, in 1967, this was unequivocally associated with hepatitis B.¹¹ Subsequently, Blumberg received the Nobel Prize for his work. In 1970, Dane and coworkers¹² identified and described the virus, and in 1971, Almeida and colleagues¹³ found that the surface particles, hepatitis B surface antigen (HBsAg), represented Australia antigen. HBsAg was extremely valuable in screening carriers for

hepatitis B and in developing a vaccine. Vaccines developed independently in the late 1970s in France and in the United States have been rigorously tested in laboratory and field trials. Both are of proven efficacy and safety in preventing hepatitis B in susceptible individuals. Among their users are health professionals, patients in renal dialysis units, infants born to mothers carrying hepatitis B, and men who have sex with men (MSM). The virus of hepatitis A was identified in 1973 and successfully grown in tissue culture in 1979. This led to preparation of hepatitis A viral antigen, paving the way for serological tests for hepatitis A antibody. Detection of this antibody, found in some 70% of adult urban Americans, suggested a high prevalence of subclinical cases. Vaccine preparation was made possible by such advances. As hygiene and sanitation improve, infants and children are spared. The result is that more serious cases occur among adults in contrast to the previous pattern of subclinical and mild cases among children. Vaccination against the disease is therefore more desirable than ever.

Epidemiological features of hepatitis B among MSM have been a useful model to follow in the investigation of AIDS. Both conditions have the same pattern of distribution in this subset of the population. Case-control studies have shown that many persons who contract AIDS, like hepatitis B, are MSM who engage in anal intercourse and have many partners.¹⁴

The tools employed in this illustration of the epidemiological method are clinical, immunological, microbiological, pathological, demographic, sociological, and statistical. None of these approaches is uniquely epidemiological; it is their employment in particular ways with particular objectives that is the epidemiological method.

In epidemiology, unlike in clinical medicine, the concern is not with individual cases but with all the cases in a defined population. Furthermore, the entire range of manifestations of the condition must be considered in relation to the population from which the cases arise.

Epidemiological Sequence

An orderly sequence characterizes epidemiology: observing, counting cases, relating cases to the population at risk, making comparisons, making scientific inferences, developing the hypothesis, testing the hypothesis, experimenting and intervening, and evaluating. This sequence describes the actions we take whenever a “new” condition occurs. The relationship between cigarette smoking and lung cancer illustrates the stages in this epidemiological sequence.

1. *Observing.* Scientific observations on smoking and cancer appeared in the *Journal of the American Medical Association*¹⁵ in 1920 and in the *New England Journal of Medicine*¹⁶ in 1928. In the following decade, *Science* documented that smokers had a shorter life expectancy than did nonsmokers.¹⁷
2. *Counting Cases or Events.* Vital statistics trends showed an increase in deaths caused by lung cancer in the United States beginning in the 1930s.
3. *Relating Cases or Events to the Population at Risk.* Increased death rates from lung cancer reported in national vital statistics attracted the attention of health department officials. Registrars of vital statistics in countries where smoking was an established lifestyle characteristic reported a similar trend.
4. *Making Comparisons.* Studies of British physicians reported by Doll and Hill¹⁸ and of contacts of American Cancer Society volunteers reported by Hammond and Horn¹⁹ in the 1950s provided definitive comparisons between smoking and lung cancer. (In addition to identifying this threat to the health of the public, the studies of Doll and Hill established the contemporary criteria for epidemiological associations.²⁰)
5. *Developing the Hypothesis.* Since cigarette smoke contains more than 2,500 chemical components, some of which are carcinogenic in animals,²¹ only a small logical step was required to go from inference to hypothesis.
6. *Testing the Hypothesis.* The hypothesis that smoking caused lung cancer lent itself to testing by means of a case-control

study. A small case-control study done in Germany during 1938–1939 was overlooked in the turmoil of World War II. Epidemiological studies designed to test the hypothesis were conducted in postwar Britain by Doll and Hill¹⁸ and in the United States by Hammond and Horn.¹⁹ Both studies showed consistent relationships between the present occurrence of lung cancer and a history of cigarette smoking, with a dose-response relationship. Subsequent case-control studies produced similar results. Reports of cohort studies soon followed. Both kinds of investigations confirmed the association and demonstrated other adverse effects.²²

7. *Making Scientific Inferences.* Several observations led to valid scientific inferences about the association of tobacco smoking and lung cancer. Among them were (a) clinical observations, (b) national trends in mortality from several countries associated with the increased prevalence of cigarette smoking, (c) epidemiological comparisons made in large groups representing different segments of national populations in more than one country, and (d) the biological effects of tobacco smoke. All of these observations led to the inference that smoking increased the risk of dying from this disease.
8. *Conducting Experimental Studies.* Laboratory animal studies with beagles showed that exposure to tobacco smoke produces the precancerous lesions followed by squamous cell carcinoma in both animals and humans.
9. *Intervening and Evaluating.* Action by public health and voluntary health agencies reduced cigarette smoking rates. A decline in mortality trends in smoking-related causes in the United States and other countries followed this reduction. One of the most important steps in this process was the issuance in 1964 of the first Surgeon General’s *Report on Smoking and Health*. These reports continue, and in 2006 an important report on the harms of secondhand smoke was issued.

► FOUNDATIONS OF EPIDEMIOLOGICAL PRACTICE

Putting the epidemiological method into practice requires skill in a unique set of tasks.

Surveillance

Surveillance as an element of epidemiological practice is “the ongoing systematic collection, analysis, and interpretation of health data essential to the planning, implementation, and evaluation of public health practice, closely integrated with the timely dissemination of these data to those who need to know. The final link in the surveillance chain is the application of these data to prevention and control.” This definition is part of the plan for the national coordination of disease surveillance of the Centers for Disease Control and Prevention (CDC).²³ It is based in part on the one proposed by Langmuir in 1963.²⁴

The surveillance of public health problems is the first important task for the practicing epidemiologist, because it is the means for detecting problems for the life of the surveillance system. Public health surveillance uses established data collection procedures and sets. This approach uses a minimum of data items and is intended to detect changes in the occurrence of health events in time to control and prevent health problems. Health problems can therefore be detected and confirmed quickly and intervention initiated. Surveillance focuses on descriptive information that is analyzed according to time trends and the rates of occurrence estimated. These findings are fed back to the health personnel who originated the data. Health policy makers who need this information also receive reports of these findings.

Investigation

Surveillance information can trigger epidemiological investigations by public health surveillance reports. Epidemiological investigations

can begin because of any of a number of other initiating events, such as news articles, phone calls, or other health departments or colleagues with similar responsibilities.

The investigation of an epidemiological problem, whether it is an epidemic of acute infection or a long-term condition such as cancer, begins with careful observation and a detailed description. The basic steps of an epidemiological investigation are discussed below.

Analysis

The analysis of epidemiological data goes through a series of orderly steps, beginning with a careful and detailed description of cases or events. The description ought to include direct observations of persons influenced by the health event. In addition, the environment in which they live and work, the risk factors related to the event, and information about the agents that might have caused the health problem require careful description. The observations need to be quantified. The analysis progresses to comparison groups. The epidemiologist then compares occurrence rates among groups according to specific characteristics of the groups, that is, looking for a dose-response relationship, and may ultimately reach the point of complex and sophisticated quantitative analysis.

Evaluation

Evaluation addresses well-defined problems, such as the effectiveness of a drug or vaccine. It involves the assessment of a problem-solving action. Consequently, the first essential step is a detailed description of the problem and the action intended to solve it. Evaluation includes the assessment of the effectiveness of specific agents. In addition, evaluation can assess contraceptive effectiveness, smallpox eradication, or the effectiveness of screening for cervical cancer.

Other Essential Tasks

Communication, information systems, management, including team building and human relations, and consultation are essential but not unique to the practice of epidemiology.

Communication

Communicating epidemiological information clearly and persuasively is essential to effective practice. Just as a clinician must persuade a patient to take pills or undergo surgery, an epidemiologist must persuade professional colleagues, public officials, and the public that epidemiological findings warrant action to control and prevent a health problem.

Information Systems

Please see the chapter on public health informatics in this section.

Management and Teamwork

Epidemiologists also need to develop management skills because they rarely work alone. Even in the investigation of a small outbreak, the assistance of a public health nurse may be essential. Subsequent analytic work often requires collaboration with statistical personnel, computer staff, or secretarial professionals. In these circumstances, epidemiologists need to understand the basic concepts of management, beginning with planning and including organizing, team building, directing, and evaluating management.

Human relations are a key part of every management process. Epidemiologists cannot ignore these relationships. Practice and observation are the best ways to learn these skills. Many health professionals deal with human relations in a clinical, patient-to-professional situation. Epidemiological practice requires working in teams, although essential team members may not be professionals. Nonetheless, their skills are indispensable to conducting epidemiological work, and they deserve respect.

Consultation

Consultation with colleagues in epidemiology, other fields of public health, clinical medicine, or public groups is part of the professional practice. Consultation requires a special kind of communication skill; it is difficult to offer scientifically sound advice in a persuasive yet dispassionate manner.

Presentation Skills

The ability to present epidemiological information to professional and public groups is as much a part of epidemiology as doing a case count or computing a relative risk. This skill differs from that of consultation because a presentation is most often a single event in which an epidemiologist discusses the investigation, often presenting complex information orally and visually to a large group. Consultation, on the other hand, is a process that requires information gathering, often involves interviewing, and may conclude with a presentation. Distinguishing between these two is important because of the emphasis of skill in presentation. Without this skill, important epidemiological work may have little health or scientific impact.

Relationship to Other Public Health Professions

The unique discipline of epidemiology interacts with a host of other professions.

Statistics

Statistics is closely allied to epidemiology. Epidemiologists need to know enough statistics to calculate rates and to decide how likely it is that differences in comparison groups could be due to chance. Statisticians support epidemiological studies in many ways, for example, helping determine sample size, choosing samples, ensuring data quality, selecting the correct approach to complex analysis, and interpreting findings.

Laboratory Science

Laboratory science is often the key to correctly identifying a disease agent and an environmental exposure. Microbiologists, immunologists, toxicologists, biochemists, and behavioral and survey research scientists all contribute to epidemiological investigations. Laboratory determinations help characterize host susceptibility and assess carrier and preclinical disease states. Perhaps most important, the laboratory provides the greatest predictive capability possible in arriving at a case definition.

Health Policy

Epidemiologists optimize their contribution to public health when the problems they address influence health policy. Policy decisions often seem remote from the practice of epidemiology because epidemiologists may equate policy with politics. However, epidemiologists influence policy to some degree almost every time they issue a report.

Health Service and Program Management

Epidemiology often provides health service programs and provides the information that sets the standards of care. Epidemiological evaluation of effectiveness may determine the product used in nationwide programs and the schedule for administering preventive agents, such as vaccines, or conducting screening examinations, such as cervical cancer screening with cytology.

► SURVEILLANCE

Definition

Because it often marks the beginning of the epidemiological sequence, the definition of surveillance warrants reinforcement. "Surveillance is the ongoing systematic collection, analysis, and interpretation of

health data essential to the planning, implementation, and evaluation of public health practice, closely integrated with the timely dissemination of these data to those who need to know.”²³ Implicit in this definition is a link between surveillance and prevention and control efforts. This link leads to the formation of a cycle. This cycle brings together the evaluation of prevention and control and the detection of subsequent epidemics through the continued collection, analysis, and interpretation of data into a system of public health surveillance.

While the concept of surveillance in epidemiology goes back centuries—at least to Graunt and Farr—the practice of surveillance continues to evolve. Its most important modern milestone was the clear and precise definition given to this practice by Langmuir in 1963. He stated that surveillance was “the continued watchfulness over the distribution and trends of occurrence through the systematic collection, consolidation, and evaluation of morbidity and mortality reports and other relevant data,”²⁴ and the reporting of this information to all of those who needed to know, implicitly including health officials, clinical physicians, and the public.

One instance in which surveillance influenced public health and helped control an epidemic is AIDS, as it was discovered in Los Angeles County. A more detailed account at the end of this section describes how a health department epidemiologist detected the first cluster of cases reported from that area.

Surveillance is not the same as epidemiological research. The CDC definition explicitly points out the need for timeliness and for dissemination, while it clearly links surveillance to public health action. While surveillance may identify problems in need of research, it is a problem-finding process with an immediate relationship to public health action, rather than a problem-solving process.

Surveillance systems provide information for urgent as well as routine action. In that sense they also differ from health information systems. Health information systems include the registration of births and deaths, the routine abstraction of hospital records, and general health surveys. Most often these systems differ from surveillance systems. Health information systems may report findings episodically rather than at regular intervals. In addition, reports of this information may describe events not related to specific deadlines, or they may not relate to the prevention or control of a specific health problem. Nonetheless, data from health information systems are important components of the practice of surveillance depending on how the information is used. Birth weight recorded on a birth certificate, for example, is important because it is essential information in doing surveillance for the birth of premature infants.

Purpose

In the practice of epidemiology and public health, surveillance has the following three generic purposes: (a) surveillance may identify public health problems, (b) surveillance may stimulate public health intervention, and (c) surveillance may suggest hypotheses for epidemiological research. More specifically, surveillance data can serve a host of important public health functions. Among them is the detection of epidemics, including significant individual cases, such as botulism, in which a single event triggers public health action. In addition, surveillance data can pick up changes in long-term trends. The use of laboratory data for surveillance can detect changes in disease agents. Intervention programs often use surveillance data to plan and set program priorities and to evaluate the effects of public health programs. Information from surveillance systems helps to project the occurrence of health problems in the future, as has been reported concerning the HIV/AIDS epidemic.

To ensure that a surveillance system fulfills its purpose, the problem a surveillance system addresses needs a clear definition. Objectives for the system should establish the case (or the event) definition and the times and details for issuing surveillance reports. Because of its role in initiating public health action, Thacker and Berkelman propose that this practice be called “public health surveillance”²⁵ rather than epidemiological surveillance.

Surveillance Cycle

Public health surveillance embodies a systematic cycle of public health actions. The cycle includes (a) collection of pertinent data in a regular, frequent, and timely manner; (b) its orderly consolidation, evaluation, and descriptive interpretation; and (c) prompt distribution of the findings (Table 2-2). Dissemination must focus on the distribution of information. Two groups must receive these data. Of first importance are those who provided the data. They will need to confirm or correct the data. Next are those who take action on the data. The cycle is ongoing. Updating and correcting the data is essential because new information may require a change in the response of the public health system. Under rare circumstances, surveillance may be ended, as was done when smallpox was eradicated, because the public health problem under surveillance is resolved.

The surveillance cycle is applicable to a wide range of public health problems, depending on the purpose and objective of the system. Initially, surveillance focused on the detection of epidemics and the characterization of seasonal fluctuations in infections. Now, the surveillance cycle is also used for injury control, a select group of cancers, certain cardiovascular diseases, and high-risk and unintended pregnancies, to cite a few illustrations.

Characteristics of a Surveillance System

An effective system of public health surveillance has seven essential attributes:

1. Simplicity
2. Acceptability
3. Sensitivity
4. Timeliness
5. High predictive value positive (PVP)
6. Flexibility
7. Representativeness

What do these terms mean when put in the day-to-day practice of epidemiology? *Simplicity* is the characteristic of being clear and easily understood, rather than complex and difficult to understand. Uncomplicated data are easier to maintain, aggregate, interpret, and distribute promptly. *Acceptability* refers to the attribute of being straightforward and free from unintended emotional content. This is a special problem for health problems such as surveillance of abortion or sexually transmitted infections. Acceptability is essential because most public health surveillance systems rely on the cooperation of individuals and organizations to provide objective, unbiased data. *Sensitivity* is a term most often used in connection with screening tests, such as Pap smears. Sensitivity measures the likelihood that

TABLE 2-2. THE SURVEILLANCE CYCLE

a diagnosis of a health problem is correct. This is important in the practice of surveillance because public health surveillance serves as a way to screen for health problems in a community. Just as screening tests must be highly sensitive if they are to detect abnormalities, a public health surveillance system must be highly sensitive. A sensitive system can detect and characterize epidemics, as well as seasonal and long-term trends. A surveillance system must also have a *high PVP*. PVP is another term associated with screening. PVP, when used for a surveillance system, means that those persons reported to have the condition under surveillance have a very high probability of actually having that condition. A system with a low PVP wastes valuable public resources by collecting inadequate data and by requiring unproductive effort on incorrectly identified epidemics. *Timeliness* refers to the fact that data are reported promptly after they are gathered. Surveillance data are important and cannot remain at the point of collection without being sent to the place where data are being edited and analyzed. This is a key characteristic of a surveillance system for two reasons. First, reports based on information obtained need distribution with a very short lag time. Prompt action is necessary to halt additional morbidity or mortality quickly. Second, data collection and processing must be regular and prompt. Punctual editing and revision improve the quality and consistency of the data that are essential to decision-making information. *Flexibility* refers to the need for a surveillance system to be versatile and adaptable. This characteristic is important because such systems are often called upon to adapt to new health problems. For example, when penicillinase-producing *Neisseria gonorrhoeae* infections were first detected and the first clusters of AIDS cases discovered, surveillance documented the spread and transmission of these new epidemics. Finally, surveillance systems must accurately *represent* the health status of the community, that is, the system needs to be *representative*. Data collected by the system need to correctly portray the occurrence of health events over time. They must characterize geographic distribution and characterize the problem in the population.²⁶

Data Sources

Vital Statistics

Information about births and deaths, that is, vital events, has been collected, classified, and published at least since the middle of the seventeenth century in several European countries. Now the *International Statistical Classification of Diseases and Related Health Problems*²⁷ provides the standard nomenclature that categorizes causes of death, disease, and injury.

Mortality. Death is, for the epidemiologist, the least equivocal measure of ill health. A death certificate is a public document of legal, medical, and health importance. It provides information about time, date, and place of death; place of residence; sex, race, birth date, birthplace; marital status and usual occupation; and also cause of death for each individual. It is the basic document for determining the number of deaths, calculating death rates, and estimating the probability of mortality and life expectancy by each variable included on the death certificate.

In developed countries, the occurrence of mortality in a population is almost completely reported, but specific items on the death certificate may not be accurate. Sex and age are recorded with close to 100% accuracy, but race, marital status, and occupation are not. The greatest problems arise in certifying the cause of death. While most people who die of an injury or of cancer have their cause of death correctly certified, persons who die of other causes may not. Cause-of-death certification may change according to current medical interests, perceptions, and philosophies. Moreover, autopsy information received after the death certificate is completed may not appear on the official certificate. The result is that secular and international comparisons are difficult. Some conditions may be difficult to study unless the cause of death is confirmed by interviewing individuals who know the decedent. Other conditions require a review of medical records, or

verification of death certificate information through comparison with autopsy reports.

Fertility. Information from birth certificates is increasingly important as epidemiologists turn more to the reproductive health problems. These documents characterize births by sex of the infant, place of residence, place of occurrence, birth date, birth weight, length of gestation, and other characteristics of both parents. Birth data are essential to estimating pregnancy rates and perinatal, neonatal, and infant mortality. They are also often the most appropriate denominators in estimating the occurrence of events, such as rates of birth defects.

Birth registration is more complete than death registration. Nonetheless, some items are not as well reported as others. Information that is not reported fully deserves special care when used for epidemiological study. Among these items are race, ethnicity, marital status, and length of gestation.

Other Certified Events. Marriage and divorce are legally certifiable events that are often related to health. They describe changing characteristics of human populations and human relationships.

Vital Record Linkage. Vital record linkage provides a broad base of information important to the practice of public health. By linking birth and infant or maternal death certificates, for example, describing trends in detail is possible. Record linkage enables trends to be examined over long periods and broad geographic areas.

In the past, health data for individuals in one set could not be related to individuals in a population in another data set. For example, hospital discharge statistics cannot be linked to death certificates. Thus, information for patients receiving a new treatment might be lost unless hospital discharge data were linked to death certificates. In working with birth certificates, relating information in birth certificates to information on infant death certificates is often impossible. This can be true of infants even when birth and death both occur on the same day, let alone when it occurs many months later. A method is needed to assemble and connect, or link, data in different sets. If, for example, data in medical charts were connected with data in birth and death certificates, epidemiological studies of birth factors associated with premature mortality might be possible. This procedure must ensure that the same individual is counted only once. The term *record linkage* describes this method and procedure.²⁸

The result is among the most powerful tools available for epidemiological studies. There are three prerequisites. They are: (a) the unique identification of individuals even if they change their names, (b) a method of abstracting and storing relevant health and vital information, and (c) a technique for matching information from different sites and settings over long periods. The final step is output of statistical tables. Record linkage systems with these qualities have been operational for many years in the Oxford region of England, in Scotland, in Sweden, and in Canada.

A record linkage system makes it possible to relate significant health events that are remote from one another in time and place. For example, a patient who received a particular antibiotic drug may be treated elsewhere at some future time for a blood dyscrasia caused by the antibiotic. In a different situation, a worker employed for a short time in the nuclear energy industry may die of cancer. The death may occur many years and several occupations later. As an isolated sequence, this would have no significance. However, if appropriate analytic techniques are used to analyze large data files in a comprehensive linked record system, many such sequences can be identified. Record linkage makes it possible to discover significant associations between events and their underlying cause. An important advantage of epidemiological studies that use record linkage is the very large numbers of observations available.

Record linkage studies have successfully identified previously unknown or doubtful occupational cancers,²⁹ and can assess other occupational risks, for example, exposure to formaldehyde.³⁰ They have made it possible to calculate the risks associated with exposure to ionizing radiation, both in medical and in occupational settings.^{31,32}

The epidemiological method is a form of historical cohort study (see below). The investigation usually begins by using personal identifiers to identify those individuals in a population exposed to the risk that is under examination. Past medical records or records from places people have worked can determine the kind and level of exposure. The computer file mortality database is searched to find the causes of death of these individuals whose cause-specific death rates can then be calculated. Computer files for death certificates can verify the identity of individuals in the study. This and certain other aspects of the method require access to personal information that is normally strictly confidential. Access to this information is limited to staff who have signed an oath to preserve the confidentiality of the documents.

In Canada, the national mortality database is the central element in many successful record linkage studies. Details of all deaths in Canada since 1950—personal identifying information and cause of death—have been coded and stored electronically. All the death certificates are preserved.

Canada has made effective use of record linkage, in part, by using simple, standard, readily available documents for the origin of the data. If all items of information are available from two sources, for example, a past medical record or employment history and a death certificate, the two can be matched precisely. This gives an extremely high probability that they relate to the same individual.

Similar procedures to set up a national mortality database began in the United States in 1979. The system in the United States, the National Death Index (NDI), uses magnetic tapes of death records sent to the National Center for Health Statistics (NCHS) by the individual states. These tapes contain standard identifying information. Among the items are the decedent's first and last names and middle initials, father's last name (especially for females), social security number, birth date, sex, state of birth and of residence, marital status, race, and age at death. Names can be matched with other records to be linked with NDI records either by exact spelling or Soundex Code. Soundex is a system based upon phonetic spelling that is effective in other record linkage systems.

Health Reports

Estimates of morbidity, particularly those for infectious disease reporting, are based on a national system of notifiable diseases that has operated in the United States since 1920. Reports from physicians sent through health departments to CDC make up most of the entries in this database, but information provided by clinics, health systems, hospitals, and laboratories is also important. This approach to surveillance has proved effective in characterizing seasonal trends, showing temporal relationships to explain trends, and detecting epidemics, although notification of this kind is incomplete. The current program of measles elimination proves this point in its use of surveillance to detect and control outbreaks. Thacker and Berkelman²⁵ cite a series of national surveillance systems that include some of those mentioned above and also others that are based on information from medical examiners, emergency rooms, and public clinics.

Hospital Records

More than 100 years have passed since Florence Nightingale³³ effectively used hospital statistics to point out the serious problems faced by patients in hospitals. Subsequently, hospital records have proved essential to the acquisition of clinical data, demographic information, sociological data, information about the quality of medical care, economic data, and administrative information such as the site of care and type of service. Few data sources offer such a rich spectrum of information.

Nonetheless, hospitals and other clinical records have unique problems. Items of key importance to studies of past events may not have been collected consistently or at the same level of accuracy, and there may be problems in legibility and interpretation. In some institutions, retrieving the entire record for a given individual may not be possible; there are legal and ethical restrictions in many jurisdictions.

Summary information about hospital discharges can be analyzed from survey data. The National Hospital Discharge Survey (NHDS)

has been published in the United States every year since 1965. These data have been used for many purposes, including epidemiological study.^{34,35} NHDS is based on a stratified probability sample of discharges. Since not all strata are represented in the same way, interpretation of NHDS reports requires a detailed understanding of sampling procedures. Other hospital discharge abstraction systems also exist. Data from programs managed by the U.S. Center for Medicare and Medicaid Services (CMS) are based in part on financial information taken from hospital bills. Because each state in the United States has an individual plan for each of these programs, data from CMS programs must be interpreted based on a detailed understanding of the database.

Disease Registries

There are two kinds of registries: (a) population-based and (b) others. Population-based registries provide the data most useful for epidemiological purposes. This kind of registry has information about all cases of specific disease in a geographically defined area that relates to a specific population. Data of this kind can be used to calculate rates of occurrence and are also useful for estimating survival rates and rates of disease progression and of mortality from a specific cause. The Surveillance, Epidemiology, and End Results (SEER) centers supported by the U.S. National Cancer Institute illustrate this kind of population-based registry for cancer.

Disease-case registries are most often kept at a hospital, health system, or treatment facility. They provide detailed documentation of patients with specific conditions cared for in that facility, but they are not usually population-based for two reasons. First, rarely does a single facility discover all of the cases that occur in a specific area. In addition, a population residing in the catchment area for a health-care facility is even more rarely counted or characterized in detail.

Health Surveys

Health surveys provide extremely valuable information. In the United States, CDC's NCHS has conducted nationwide household interview surveys since 1957. These interviews are taken from a probability sample of the civilian population of the United States who are not residing in institutions. They are carried out on a recurring basis and gather a core of information on disability, the characteristics of health problems, and the kinds of care the respondent has undergone. In addition, detailed questions are added to each survey to explore health problems related to a specific system of the body or group of diseases in greater depth. Two of the most important are the National Health Interview Survey, which is a health interview, and the National Health and Nutrition Examination Survey. These surveys are in the field continuously and findings available through CDC's NCHS.

Also, recognizing the importance of information about health-care services and utilization to population health, NCHS now conducts the National Ambulatory Medical Care Survey (NAMCS), the NHDS, and the National Nursing Home Survey. Information about health-care facilities, including family planning clinics, and surveys of the health-care workforce are now part of the spectrum of NCHS surveys.^{36,37}

The need for information about risk factors related to chronic diseases led the CDC to initiate the Behavioral Risk Factor Surveillance System (BRFSS).³⁸ This system uses telephone interviews to collect information about chronic disease risk factors such as obesity, treatment for blood pressure, alcohol use, and exercise. The monthly collection of information about these risk factors permits the characterization of seasonal variations and long-term trends. Perhaps most important, this system gives health professionals and the public current information about these risk factors.

The National Survey of Family Growth (NSFG) conducted by NCHS assesses the use of family planning services, contraceptive practice, and surgical sterilization.³⁹ It also gathers information about the determinants of family size and composition. Information from this survey has proved useful in epidemiological studies of human reproduction and the safety of widely used methods of fertility control.

Data Collection

Public health surveillance relies on three approaches to data collection.

1. The first is used in urgent situations, such as an active and ongoing epidemic. Under these circumstances, health agencies initiate surveillance by contacting those data sources most likely to have current information. Called by some “active” surveillance, this approach ensures that reporting will be timely and characterized by simplicity, acceptability, and sensitivity. This approach has the possibility of sacrificing representativeness by weighting responses toward a preselected group of reporting sources. It may also limit the predictive value if reporters need to identify cases before the diagnostic workup is complete, thereby leading to the reporting of cases that do not fulfill the definition.
2. Provider-based data collection is the approach most frequently used by the national notifiable disease surveillance system. Referred to by some as “passive” surveillance, this approach is simple, acceptable, and flexible. It is rarely as sensitive as health agency-based surveillance, and it may not be timely or representative. Nonetheless, its value in describing seasonal and long-range trends and promoting the detection of epidemics has withstood the test of time for public health professionals.
3. Finally, the sentinel approach has its roots in the surveillance of occupational health problems and is now being applied more widely. The use of birds to detect lethal levels of odorless gases, such as carbon monoxide in mines, may have been the earliest form of sentinel surveillance. Concern about epidemic infections has led to the use of sentinel animal flocks to detect arthropod-borne viruses that cause encephalitis and herald the occurrence of epidemics of this infection in humans. Rutstein and his colleagues have proposed that this concept be extended to a broader range of occupational health problems⁴⁰ and to the health-care system more generally.⁴¹

Computers and electronic communications permit surveillance information to be transmitted widely, in great detail, and on a timely basis. For decades, notifiable disease reporting relied on information reported on postcards. These cards gave the aggregate numbers of cases of infectious diseases. Health departments mailed the cards each week. Computers now permit cases to be characterized individually yet confidentially. Communication, now often via the Internet, ensures that the information is available on a timely basis. Computer networks have the potential of making this information available to a wide range of skilled epidemiological analysts and of eliciting a timely public health response. CDC has developed a software package called Epi Info.⁴² This software helps with the collection, recording, and transmission of surveillance information. It is also an important tool for field investigations and epidemiological surveys. A computer telenetwork, the National Electronic Surveillance System (NETSS),⁴³ now reaches state and many major local health departments, providing electronic surveillance reports. The Information Network for Public Health Officials (INPHO) now permits a wide range of reports, as well as data, to reach health officials to support their policy decisions.

Data Quality

The quality of health data is an increasingly important issue as information plays a more significant role in detecting epidemics, discovering new public health problems, and developing health policy. Just as epidemiologists are concerned about the quality of information they receive from others, they also want to know that the data they collect themselves are of good quality. Four dimensions of data quality are especially important:

1. Data input must be of high quality. In a one-dimensional check of data input, all variables should be within an appropriate

range. A surveillance system concerned with childhood lead poisoning, for example, ought not to include a person 50 years old. A two-dimensional check of input would ensure that pairs of variables were reasonable. For example, a surveillance system for the nutritional status of pregnant women should not include a 17-year-old woman with 10 children. Moreover, data should be logically consistent so that a child with measles reported to have begun on November 1, 1998, ought not to have had a birth data in 2005.

2. Management of data records is essential to ensuring data quality. Records will need to be uniquely identified and carefully tracked so that they can be retrieved and verified. The status of record completion will need to be documented, particularly in household and telephone interview surveys. Confidentiality is a point of tension in records management. Striking the balance between ensuring the privacy of an individual and permitting a public agency to meet an urgent public need will always be difficult to resolve. The current AIDS epidemic demonstrated this problem repeatedly. Many conflicts may be resolved by using identification numbers instead of names. However, some events will be rare enough that individuals might be identified simply by knowing the disease they have, their age, sex, and county of residence, especially if the county is not a populous one.
3. Data output must be of excellent quality. One-dimensional, two-dimensional, and logic checks are as important in handling data output as they are in checking data entry. Computer programs that produce the output should create totals for columns and rows added up for each table rather than being brought forward from an earlier computation. Imputation procedures deserve critical examination so that they are relevant to the way the output will be interpreted and used. In short, epidemiologists need to examine every piece of relevant data and to ask “Will this make sense to the people who need this information?”
4. Data archives are the final dimension of data quality. Keeping an archive of public health information requires more than the final output. It also requires enough of the intermediate computations that questions can be answered quickly and intelligently. These inquiries may come from other researchers, the media, or the public. In keeping an archive of epidemiological data, two questions need to be addressed. First, how will the issues of public accountability and individual confidentiality be addressed? Second, if an important question comes up, can the answer be retrieved in 3 seconds? An hour? Two days? Not at all? Ultimately, data collected by public agencies are in the public domain. Nevertheless, an epidemiologist must consider the measures appropriate for a public agency to use in preserving individual privacy and making data accessible to others. Among those likely to need public data are researchers, journalists, and individual citizens.⁴⁴

Data Reporting

The reporting of public health surveillance data needs to consider four approaches. The first is descriptive. A typical report contains case counts of the diseases that are nationally notifiable. Aggregated case reports are often present and entered into tables for geographic jurisdictions. Next, graphs of surveillance data permit a visual analysis. A histogram that shows the distribution of cases of a given disease in a specific area over a stated period is often called an “epidemic curve.” Line graphs can display cases over time to help characterize temporal relationships in disease occurrence. Graphs that display historical data can signal changes in disease trends. Maps often provide an effective graph of the geographic distribution of a disease. Spot maps illustrate the distribution of individual or small groups of cases. The use of shading differentiates the relative intensity with which a disease or other public health problem occurs over a wide area. Sequences of maps illustrate changing disease distributions over

time. Three-dimensional maps may also show differing intensities of health problems over an area. Computer mapping using data that describe cases by county of occurrence and residence helps determine whether epidemics are being transmitted across jurisdictional boundaries.

Finally, quantitative analysis of surveillance data may help detect important changes in the trends of health events. Using a moving average in analyzing national trends in fertility is a regular part of the monthly *Vital Statistics Report*⁴⁵ published by NCHS. Epidemics can be detected using time series analysis. Analyzing trends in excess mortality graphically, using periodic regression or autoregressive, integrated moving averages are time-honored ways of identifying influenza epidemics.⁴⁶ Excess mortality among the aged during periods of unusual heat waves can also be detected with these methods.⁴⁷

Dissemination

The findings from public health surveillance must be distributed to two groups immediately: (a) those who provide data so that it can be verified and (b) those responsible for public health actions. When surveillance detects urgent public health problems, such as an epidemic, an immediate telephone response is required. For years, CDC has sent data on notifiable disease surveillance and on epidemic field investigations to state and local health officials before the information is published in the *Morbidity and Mortality Weekly Report (MMWR)*.

Surveillance information is now disseminated in a series of reports based on the *MMWR*. Besides the weekly publication, CDC issues other special *MMWR* reports and an annual summary of notifiable diseases.⁴⁸ CDC also publishes public health and epidemiological findings in many refereed professional journals. Surveillance data characterize historical trends and project those trends into the future. Recently, CDC compiled its guidelines for prevention into a single publication that is supplemented with additional details on an electronic compact disc. The World Health Organization (WHO) maintains a worldwide reporting system. The information in this system appears in the *WHO Weekly Epidemiological Record*.⁴⁹ These reports are augmented by quarterly, annual, and occasional special supplements.

Applying Public Health Surveillance: Two Case Studies

The following are two important historical examples of how public health surveillance using basic, available tools, can assist in understanding important diseases.

Using Vital Data: Community Diagnosis Based on Mortality Registration

Community diagnosis assesses health problems of a specific population in a defined geographic area using public health surveillance data. Vital records are often used as the first approach. Holland and colleagues' *European Community Atlas of Avoidable Death* (second edition)⁵⁰ has been an excellent, readily accessible publication that illustrated this use of vital data.

Community diagnosis, carried out in detail and directed at intervening in a health problem, is a stepwise process, as follows:

1. Defining the condition to be diagnosed.
2. Estimating the size, characteristics, and occurrence of the condition.
3. Refining the diagnosis based on additional data.
4. Estimating and characterizing the population in need of service.
5. Reevaluating the diagnosis.

Vital data can also help diagnose problems for communities smaller than the European community. In addition, community diagnosis for small areas often needs to examine data that cannot be evaluated using statistical testing. In these instances, detailed knowledge

of the locality and judgment of the community situation needs to be applied to reach a valid diagnosis that is acceptable to the community members. McGrady has analyzed cancer deaths in Fulton County, Georgia.⁵¹ His approach to grouping census tracts succeeds in solving some problems of community diagnosis. By clustering census tracts according to differences in cancer mortality rates, he created areas that had appropriate health and epidemiological characteristics, even though local officials and residents had not perceived them as such for other social or economic purposes.

In another vital record application, birth certificates can analyze unintended fertility in communities. One approach uses teenage birth and fertility rates, out-of-wedlock birth, and marital births by birth order.⁵² Health officials have adapted this approach using other measures more suited to the needs of their own communities.

Using Reports to Health Departments:

The AIDS Epidemic

In mid-1981, an epidemiologist at the Los Angeles County Health Department realized that the five reports he had received of a rare kind of pneumonia caused by *Pneumocystis carinii* might be an epidemic. The disease reports came from three different hospitals and had involved men between 29 and 36 years of age. Typically, this kind of pneumonia occurs among people who have depression of their immune system, which can occur, for example, when people receive cancer chemotherapy. At one hospital, a large university medical center, the clinician caring for these patients had already recognized this unusual occurrence.⁵³

A month later, a report from another part of the United States documented the occurrence of this same kind of pneumonia. In addition, some patients had other unusual infections and a rare form of cancer, Kaposi's sarcoma. This group of 26 individuals ranged in age from 26 to 51 years. Twenty of them lived in New York City, six in California; eight had died within 24 months after diagnosis of Kaposi's sarcoma; all were male homosexuals.⁵⁴ Within the next year, CDC received 355 additional case reports. Five states—California, Florida, New Jersey, New York, and Texas—accounted for 86% of the reported cases. This was the beginning of the AIDS epidemic.

A cluster of people with an unusual infection that affected previously well individuals was picked up by an astute clinician and an observant epidemiologist. The epidemiologist knew that even five cases of this kind represented an unusual occurrence, perhaps even an epidemic. He took the following four key actions:

1. He confirmed each case.
2. Next, he provided a clear, brief (no more than seven lines of text in the original report) description to a central public agency (CDC, in this instance).
3. Third, he identified the common characteristics of the individuals.
4. Finally, he ensured that the reports stimulated others to search for additional clusters of cases by distributing them to health professionals, including colleagues in epidemiology.

The original group of five reports published in June 1981 and augmented a month later by 26 more cases increased more than 10-fold by June 1982, to 355 cases and by August 1983, to 1972 cases. As of December 1988, almost 83,000 cases of AIDS had been reported in the United States, and more than 46,000 people have died of AIDS. WHO has reported the occurrence of AIDS from all over the world. Laboratory examination of frozen human serum shows that the virus that causes this disease has been present in humans at least since 1959.

► INVESTIGATION

An investigation is an examination for the purpose of finding out about something. It differs from surveillance because when doing an investigation one assumes that a problem already exists. Moreover,

an investigation may use information from an established data collection system, but it goes farther and gathers new information. Analysis, on the other hand, involves the study of a problem by breaking it down into its constituent parts. In carrying out an investigation, therefore, an epidemiologist must have some idea as to what analysis will ultimately be necessary.

Exactly what must be found out depends in part on what is already known. The classic epidemiological triad of host, agent, and environment first mentioned in the discussion of *determinants*, is a useful framework for thinking about epidemics. The epidemiologist often knows about the host as to signs and symptoms of an illness, or health event, and the number of people in the epidemic. This holds true for epidemics of infection, acute noninfectious problems, such as unexplained deaths in a hospital, and chronic disease problems, as illustrated by the occurrence of endometrial cancer and estrogen use.

When the investigation is complete, however, we must know about the host and have information on a wide range of risk factors for the health problem. In addition, we need detailed information about the agent to which the host is exposed and the environment of the exposure. Ultimately, we require effective control measures. This requires that the epidemiologist know how the agent is transmitted and, if possible, its portal of entry.

Epidemiological investigations meet both public service and scientific needs. If, for example, a community faces a health problem that is likely to continue to spread and about which the approach to control is uncertain, then the epidemiologist has an important role. Epidemics of viral infections that occur in presumably immunized young people, as has been the case of measles epidemics on college campuses, illustrate this problem. Moreover, public concern may also require the epidemiologist to provide assurance that no epidemic exists and none is threatening. Concern about transmission of AIDS by exposure to medical waste in public places is one such example, even though this environmental problem is not a real hazard for transmitting disease.

Scientific need is a second important reason for an epidemiologist to do a detailed field investigation. This kind of investigation recently led to the discovery of Lyme disease and legionnaires' disease. Field investigation also identified the causal association between vinyl chloride exposure and angiosarcoma of the liver, as it was for oral contraceptive (OC) use and hepatocellular adenoma, and a wide range of other health conditions.

Preparing for an Investigation

Preparation for an epidemiological field investigation has three general elements: (a) notification of essential people and organizations, (b) identification of materials needed for the investigation, and (c) travel planning. The notification process will have begun before the epidemiologist departs for the field. However, initial reports require confirmation. In addition, the date and place of investigation, and its purpose, needs the concurrence of supervisors, health officials, where the investigation is being done, and other officials whose regions may include that area. Failure to notify these individuals can bring the investigation to a halt, limit access to people who have essential information, or lead to a withdrawal of support personnel needed to complete the investigation. Before going to the field, materials must be assembled to help with the investigation. Depending on the nature of the problem, the epidemiologist may want reprints of scientific articles. In addition, other items may be useful. Among them are the following: (a) copies of sample questionnaires, (b) spreadsheets for line lists or the coding of data, (c) data calculation capacity, (d) a portable computer, (e) a camera, (f) containers for laboratory specimens, (g) pocket references on microbial, physical, or chemical agents, and (h) means for accessing the Internet.

Basic Steps of an Investigation

The following 10 steps are essential considerations in every epidemiological investigation. It is this list to which practicing epidemiologists return more than any other (Table 2-3).

TABLE 2-3. STEPS IN AN EPIDEMIOLOGICAL INVESTIGATION

1. Determine the existence of an epidemic
2. Confirm the diagnosis
3. Define and count the cases
4. Orient the data in terms of time, place, and person
5. Determine who is at risk of having the health problem
6. Develop and test an explanatory hypothesis
7. Compare the hypothesis with the proven facts
8. Plan a more systematic study
9. Prepare a written report
10. Propose measures for control and prevention

1. *Ensure the existence of an epidemic.* The first important decision is to determine if an epidemic exists. A preliminary count of people with similar symptoms is often the first criterion for this decision. Laboratory confirmation may be absent. It may even be inappropriate because of the urgent need to begin an investigation.
2. *Confirm the diagnosis.* The epidemiologist needs to know the diagnosis of the health problem being addressed. The number of cases is sometimes too great to do a history and physical examination on every person. Collection of laboratory specimens must then follow quickly, although decisions about epidemic control are often made before laboratory confirmation is available. Using this preliminary information, the epidemiologist must formulate a case definition of the health problem. The symptoms for the case definition are written down, as are the essential physical signs. Measurements of levels of severity of the health problem, or disease, must be determined. Confirming each reported case may not be possible, and laboratory specimens may be obtained on only 15–20% of the cases. In some large epidemics, a sample of cases gave the essential information about the agent, the host, the method of transmission, the portal of entry, and the environment of the disease. This proved to be the only way to deal with one epidemic in 1985 when *Salmonella* contaminated milk processed in Illinois and involved more than 200,000 individuals.⁵⁵ Epidemiologists set up control measures more quickly using this approach than by an exhaustive detection of every ill individual.
3. *Estimate the number of cases.* Case finding often begins with a single report or a small cluster of cases. Initially, the epidemiologist casts a wide net, using a preliminary case definition that is sensitive and excludes as few true cases as possible. After making a preliminary estimate, the epidemiologist must make a key judgment. Should all cases be studied or is the epidemic so large that investigating a sample will lead to a decision more quickly? If only a sample is selected, then only the most severe cases should be studied because they are the ones of most value. Outlying observations deserve special attention because explaining their relationship to the epidemic is often the key to understanding its mode of spread. Given a workable definition, the epidemiologist must count the cases and collect data about them. Once the ill persons are identified, the characteristics of the illness from beginning to the present and the demographic characteristics of each individual need to be determined. Next, data on the places where the ill people live, work, and have traveled to, and the possible exposures that might lead to health impairment all must be documented. Among the questions the epidemiologist may want to answer are the following: What signs and symptoms are the most important? Are any of them pathognomonic? What is the laboratory test most likely to confirm the diagnosis? Can both the exposure to the presumed source and the severity of the illness be characterized at different levels? What must be done to identify the people with these problems?

Should long-term follow-up be necessary? Are there any inapparent or subclinical cases? What role do they play in determining the future size of this epidemic or the susceptibility of the people in this community?

4. *Orient the data as to time, place, and person.* Data on each case must include the date of onset of the illness, the place where the person lives and/or became ill, and the characteristics of each individual, including age, sex, and occupation. A simple histogram, often called “the epidemic curve,” shows the relationship between the occurrence of cases and their times of onset.⁵⁶ The spatial relationships of cases are often shown best on a spot map. Maps, for instance, help show that the cases occurred in proximity to a body of water, a sewage treatment plant, or its outflow. Characterizing individuals by age, sex, and other relevant attributes permits the epidemiologist to estimate rates of occurrence and compare them with other appropriate community groups.
5. *Determine who is at risk of having the health problem.* The epidemiologist will calculate rates at which a health problem, or disease, occurs using the number of the population at risk as the denominator, while the number of those individuals with the problem form the numerator. If the original reports of an illness come from a state surveillance system, then the first estimations of rates may be based on a state’s population. If the epidemic occurs only in school-age children from a particular school, however, the population at risk may be only the children who attend that school. Those not ill must be characterized by the same attributes as those who are ill, that is, age, sex, grade in school, or classroom.
6. *Develop an explanatory hypothesis.* During a field investigation, comparing the rates of occurrence among those at greatest risk with other groups helps the epidemiologist develop hypotheses to explain the cause and transmission of a health problem. Besides examining rates, other approaches to developing hypotheses of cause include further, more detailed interviews with ill individuals or with local health officials and residents, careful examination of outlying cases, or describing the epidemic in more detail. Depending on the extent of the epidemiologist’s field library, reference to current and historical literature can stimulate new hypotheses.
7. *Compare the hypothesis with the established facts.* The hypothesis that explains the epidemic must be consistent with all the facts the epidemiologist knows. If the hypothesis does not do so, then it must be reexamined. It should do more than just strengthen speculation, explaining the cases at the peak of the epidemic. The epidemiologist may need to repeat the interview of case subjects, reassess medical records, gather additional laboratory specimens, and repeat calculations.
8. *Plan a more systematic study.* When the initial field investigations and preliminary calculations are complete, the investigator may need to conduct one or more case-control studies. The data for such studies may be in hand, but more often additional information will be needed. It may be collected by either interviewing subjects in more detail or surveying the population. Sometimes, a serological survey or extensive sampling of the environment for chemical or biological agents will generate new facts. Sometimes a visual record helps, requiring extensive photography or video taping of a work process. If there is a food-borne infection, a detailed food history is necessary. If a water-borne infection is suspected, a food and liquid intake history stimulates additional causal associations. For example, a water-borne epidemic may be discovered by knowing the number of glasses of water drunk by each person, thereby permitting the epidemiologist to estimate a dose-response relationship. An occupational illness might be determined by a specific machine that each worker used and the number of hours that each one used it.
9. *Prepare a written report.* Preparing a written document is an essential step in any epidemiological investigation. An

epidemic report need not be a publishable paper. However, it should be a benchmark in the conduct of an investigation, just as a hospital discharge summary is for patient care or a thesis is for the advancement of a scholar. The epidemic report is an essential public health document. It may be the basis for action by health officials, who may close a restaurant or face a major industry’s attorneys in court. For the public, it may provide information for those concerned about the epidemic, its spread, and the likelihood that others will be involved. A report may have scientific epidemiological importance in documenting the discovery of a new agent, a new route of transmission, or a new and imaginative approach to epidemiological investigation. Moreover, many investigative reports are useful in teaching.

10. *Propose measures for control and prevention.* The ultimate purpose of an epidemiological investigation is to control a health problem in a community. The epidemiologist is part of the team that develops the approach to control and prevention.

The establishment of a surveillance system for the population at risk is an important element in ensuring the effectiveness of the control program. This is an essential element of an epidemiologist’s responsibility in fulfilling a public need and carrying out a scientific study.

Designing an Investigation

Descriptive Study

Epidemiological investigations often start with case reports, evolve to become a series of cases, and then go on to include ecological studies, cross-sectional studies, or surveys that describe the problem and perhaps suggest causal hypotheses. Working with information from case reports or a series of cases is often the first step in a field or community investigation. For an epidemiologist concerned with the clinical details of an illness, the causal agent, the environmental facilitators, and other risk factors, additional information will be needed. Demographic, social, and other behavioral characteristics and possible exposures to biological, physical, or chemical agents are also essential.

Ecological Studies

Ecological studies compare the frequency of events that occur in different groups. This type of study compares data and examines correlations useful in generating hypotheses association. The positive association of dietary fat intake and regional breast cancer occurrence is one important hypothesis generated through an ecological study. Because ecological studies compare groups, rather than individuals, caution is required in drawing conclusions and identifying associations. The hazard found in interpreting studies of this kind is labeled “the ecological fallacy.”⁵⁷ It is a bias or error in inference that occurs when an association observed between variables on an aggregate level is assumed to exist at an individual level. This kind of fallacy has also been found, for example, in studies of drinking water quality and mortality from heart disease. This correlation is not a causal association because the criteria for such an association (which are discussed later in the section titled “Analysis”) were not fulfilled. On the other hand, ecological studies are usually quick, easy to do, use existing data, and generate or support new hypotheses.

Cross-Sectional Studies

Cross-sectional studies simultaneously evaluate exposure and outcome in a population. This approach is another important step to developing evidence for a causal association. As an illustration, consider the possibility that a group of women had cervical cytology done during the same examination when a culture for herpes simplex virus was taken. If a statistically significant association existed between premalignant cervical cells and the recovery of herpesvirus from cultures, this finding would be an important step toward a causal association. However, a cross-sectional study would not permit the epidemiologist to decide if the virus was present before the cells

became premalignant or if premalignant cells are highly susceptible to viruses. This approach is often useful at the time of an epidemic investigation. It helps to determine the extent of the epidemic in a population and to assess the susceptibility of those in the population at risk. This approach is not an appropriate way to study rare events, events of short duration, or events related to rare exposures. Moreover, cross-sectional studies are not appropriate for assessing the temporal relationship between exposure and health event or outcome.

Analytical Studies

Analytical studies may be observational or experimental. In an observational study, the epidemiologist assigns subjects to case and comparison groups. This assignment may take place after an event has occurred (retrospectively) or before an event has happened (prospectively). The investigation of an epidemic, such as infections following childbirth, or a study based on clinical observation, such as the occurrence of angiosarcoma of the liver in vinyl chloride workers, is typically observational and retrospective. In these instances, the epidemiological study had to be confined to observations about events that had already taken place. Moreover, the epidemiologists used data that had already been collected and assigned people to groups based on the presence of disease or exposure that had already occurred. If cases of postpartum infection had been carefully defined and assigned to case (of postpartum infection) or control (no infection) groups, the study would be observational and prospective.

In an experimental study, on the other hand, subjects are observed under predetermined conditions. Random clinical trials are examples of experimental epidemiology. Both the case definition and the experimental conditions would be carefully defined before the study began. Carefully designed approaches to data and specimen collection and the observations to be made are specified and categorized before the study begins. The individuals being observed in an experimental study may be allocated to different groups on a probabilistic basis.

This section addresses the design of epidemiological studies, only mentioning analytical approaches. The following section, Analysis, deals with analytical issues in more detail and gives examples of ways in which they might be handled.

Observational Studies

Observational studies are categorized as case-control or cohort. In a case-control study, the risk of exposure to a presumed cause by those with a health problem (the case group) is compared with that of those who do not have that problem (the control group). The frequency with which the exposure occurs is compared in the two groups, and the strength of association is measured as an odds ratio. The epidemiologist evaluates the likelihood that such an association could occur because of chance using statistical confidence intervals.

Case-Control Studies

Case-control studies begin with a case group of individuals who have the health problem under investigation. The outcomes typically studied using this design are those that are rare or have a long latent, or incubation, period such as cancer. Conditions that require detailed records are well suited to study using this design. Among these records are hospital charts, pathology reports and specimens, and laboratory documentation, such as electrocardiograms, x-rays, other imaging techniques, or a wide range of biomarkers. For health problems that are rare, or develop over long periods, the case-control design yields findings in a short time and with a minimum resource requirement. More information on case-control studies can be found in general textbooks on epidemiological methods.

Cohort Studies

Cohort studies begin with a group of individuals, without the diseases of interest, characterized as to exposure to hypothesized causes of those diseases. The comparison group is one that is not so exposed, but has similar demographic, behavioral, and biological characteristics. The groups are compared and characterized using the rates with

which the health problem occurs in each group. The strength of association is measured using relative rates; its occurrence due to chance is evaluated statistically by stating the p value, and the precision of the relative risk or odds ratio is shown by the confidence intervals.

Retrospective, or historical, cohort studies may look back in time by reviewing recorded events, or they may require that subjects be observed during the future. Those done by reconstructing records of exposure and health outcomes are called retrospective cohort studies because they look back over time. Those that follow similar groups with different exposures into the future are called prospective cohort studies. The study of American veterans of the Vietnam War, who were exposed to Agent Orange, is an example of a retrospective cohort study.^{58,59} On the other hand, many reports on cardiovascular disease in Framingham, Massachusetts, illustrate prospective cohort studies.⁶⁰ The most difficult problems that cohort studies pose for epidemiologists is, if the study is retrospective, finding records that are comparable for both the exposed and unexposed subjects. If the study is prospective, finding the resources and motivating the staff is usually the greatest challenge. Conducting studies of this kind is difficult because the need for meticulous recording is required for a long time, usually years, and often decades.

The advantages and disadvantages of these two study designs are shown in Table 2-4. Case-control studies are advantageous when the epidemiologist is studying a rare condition (for example, a condition that occurs no more often than once in every 100 people in the population under study). In addition, this approach can evaluate an association between disease and exposure relatively quickly. Moreover, it is especially useful if the investigator has limited resources and is dealing with a health problem that has a long latency or incubation period. Of the advantages for cohort studies, on the other hand, three are especially important. The first is that a cohort study provides an opportunity to describe the natural history of a health problem. In addition, the epidemiologist can directly estimate the rate at which the health problem is occurring and take the findings to people who are not epidemiologists.⁶¹

Bias can distort the findings of any study, whatever its design. Bias is the "deviation of results, or inferences from the truth, or processes leading to such deviation."⁶⁴ Bias can occur in any approach to study design. The most generic categories of this kind of deviation are selection bias and information bias. Selection bias occurs when comparison groups differ from each other in some systematic way that influences the outcome or exposure that is being investigated. This form of bias is a more frequent problem in case-control studies, but it can occur in both approaches to study design. A study of OC effectiveness in women using two different kinds of pills illustrates this point. Such a study might be biased if the group taking one kind of pill included only women who had given birth (confirming their ability to become pregnant) with another group, none of whom had been pregnant. This selection of subjects leads to a bias that might distort the comparison of effectiveness of the two agents.

The role of information bias is important when an exposure or health outcome is measured systematically in different ways for subjects in the case and control groups. This can be related to the inability to collect comparable information, to systematically different approaches to observing the two groups, or to differences in the quality of the information collected. A comparison of surgical complications in two groups, one of which underwent surgery in a hospital with another that had the operation done in an ambulatory facility, helps illustrate information bias. People in hospitals are often observed hourly overnight and for a day or more thereafter. On the other hand, people undergoing ambulatory surgery are observed only during the first four hours after surgery. In this instance, the bias favors the detection of more postoperative complications in the hospitalized subjects than in the others.

Gathering Information

Data gathering is an essential part of "finding out about something." Investigations most often involve interviewing and record review.

TABLE 2-4. COMPARISON OF ADVANTAGES AND DISADVANTAGES OF CASE-CONTROL AND COHORT STUDIES

	<i>Case-Control Studies</i>	<i>Cohort Studies</i>
Advantages	Excellent way to study rare diseases and diseases with long latency Relatively quick Relatively inexpensive Requires relatively few study subjects Can often use existing records Can study many possible causes of a disease	Better for studying rare exposures Provides complete data on cases, stages Allows study of more than one effect of exposure Can calculate and compare rates in exposed, and unexposed Choice of factors available for study Quality control of data
Disadvantages	Relies on recall or existing records about past exposures Difficult or impossible to validate data Control of extraneous factors incomplete Difficult to select suitable comparison group Cannot calculate rates Cannot study mechanism of disease	Need to study large numbers May take many years Circumstances may change during study Expensive Control of extraneous factors may be incomplete Rarely possible to study mechanism of disease

Anytime an interview is required, a friendly, persuasive introduction should precede questioning. Training of interviewers, therefore, should include practicing both the introduction and the questions.

The form in which the information is gathered may differ from one investigation to another. In field investigations of epidemics or in surveys, such as childhood immunization surveys, a line listing may suffice. An illustration of this approach is shown in Table 2-5. More complex investigations may need a detailed interview form, sometimes using visual aids for memory, such as pictures of medication packages.

Identifying the respondent and recording information for follow-up or record retrieval are among the first items gathered. If follow-up or verification of information is needed, then information about family, friends, and neighbors may also be important.

Responses to questions, both for interview and record abstraction, should be simple and in a form that is easy to code. Initial data collection of items, such as age, should be gathered in terms of individual years; grouping of these items is better done at the time of tabulation and analysis. Avoiding open-ended questions as much as possible reduces the difficulties in tabulating and analyzing the resulting information.

Pretesting the data gathering form or interview is essential. Simulating an interview with a respondent or abstracting a chart that represents a typical case should be followed by simulating some of the unlikely circumstances.⁶²

Case finding, that is, searching for and gathering information from subjects for the case and comparison groups, is essential to an investigation. Initially, a study should include a wide range of those at risk of the health problem. Being sure that the entire population at risk is being considered at the beginning of the investigation is generally easier than it is to make a second trip to the community.⁶³

If members of the comparison group are matched to specific individuals in the case group, then the forms for both case and comparison individuals must be able to be linked for analysis. Choosing comparison groups is not easy. The epidemiologist must think carefully before selecting the easiest way. If the cases, for example, are all hospitalized, the question of using control subjects from the hospital or from the

neighborhoods where the cases normally lived deserves careful study because both groups should come from the environment where exposure occurred.

Using Judgment in Field Investigations

The judgment of experienced epidemiologists regarding field investigations rests on a series of questions. The first is: When do you do a field investigation? Public need and scientific importance are the most frequent determinants of this answer. A community faced with a health problem of uncertain cause that cannot be controlled or that has created public alarm can be a public health emergency. The community’s urgent need may be satisfied only by an immediate, competent epidemiological investigation. Scientific importance, while rarely isolated from public need, is more often determined by the nature of the problem. This was the case in legionnaires’ disease,⁶⁴ the initial studies of penicillinase-producing *Neisseria gonorrhoeae* infection,⁶⁵ and the more recent epidemic of Brazilian purpuric fever. A form of *Haemophilus aegypticus* with a new plasmid type caused this new condition.⁶⁶ In each of these instances, the etiologic agent required that an epidemiological investigation be done in the field with intensive and highly technical laboratory support.

Once in the field, when does an epidemiologist ask for help? Since a single health professional rarely carries out an epidemic investigation, key questions must be asked before the field work begins. Among the foremost are: Will there be enough people available to ensure a successful investigation? Will these people have the necessary skills? What are the technical support requirements, in terms of data collection and analysis, specimen gathering, computer science, and laboratory science? Since the answers to these questions will change as the investigation evolves, the epidemiologist must reexamine each of them repeatedly.

How detailed should an investigation be? This question is best answered by considering the reasons for undertaking the investigation. Responding to public need is the principal determinant. This needs to include recommendations for control measures and addressing public information requirements, even if the epidemiologist is not communicating with the media personally. After fulfilling this obligation, the epidemiologist needs to assess the value of the investigation regarding changes in health policy for a larger population. Finally, the epidemiologist must evaluate the overall scientific importance of the field work.

Before leaving the site of a field investigation, the epidemiologist should have affirmative answers to four questions:

1. Is it possible to do a quantitative analysis of the data?
2. Is the analysis sufficient to permit the epidemiologist to make preliminary recommendations about control measures to local health and other officials?
3. Is it possible to give responsible officials a report that would permit them to initiate control measures and provide

TABLE 2-5. ILLUSTRATIVE PARTIAL LINE LISTING MEASLES EPIDEMIC IN A HIGH SCHOOL

<i>Case No.</i>	<i>Identifier</i>	<i>Grade</i>	<i>Sex</i>	<i>Date of Onset</i>
1	SA041870	09	M	April 24
2	DA101666	12	F	April 22
3	LB020570	09	F	April 25
4	DB061470	09	M	April 27
5	SB040569	10	F	April 22

a credible explanation of the occurrence of the health problem to the public?

4. Will the person responsible for supervising the investigation from its institutional base find the report of the investigation acceptable?

If the epidemiologist cannot answer these questions satisfactorily, the investigation must continue. Epidemiologists who do field investigations should always be prepared to *go back for the facts*, but it is best to get all of the facts in the first place.

Communicating the investigative findings clearly is essential, particularly when the epidemiologist completes the field work. Who needs to know these findings? As a rule, the epidemiologist informs those who reported the first cases in the epidemic first. They are the practitioners who will know if the facts are correct and the public health actions are sensible. If the official and professional personnel responsible for control of the health problem are not part of this group, then they, too, must receive a report. This report describes both the field investigation and the scientific rationale control and prevention. Then those who permitted, enabled, or facilitated the field work should be told of the findings and proposed actions. This group deserves the courtesy of hearing from the investigator, rather than the public media. Finally, the public and the media must be informed. The control and prevention actions are the responsibility of public officials in that community because these measures will occur in their community. Therefore, it is those officials rather than the investigating epidemiologist who should discuss the problem, the investigative findings, and the approach to control and prevention to the community and the media.

► ANALYSIS

Epidemiological analysis is the identification and logical separation of the component parts of a health problem, followed by the careful study of each, using statistical analysis and logical inference. Analysis requires correct identification of each component and determining the relationships of these parts. Analysis builds on a foundation of careful *investigation*. However, analysis goes beyond investigation in that analysis focuses on comparisons and relationships while investigation emphasizes careful observation. In some cases, analysis identifies the need to return to vital statistics, or another source of existing health information, or additional field investigation. The process of analysis can be applied to descriptive studies, case-control studies, and cohort studies.

The process of analysis must be orderly. It interacts with the investigation of an epidemiological problem and anticipates the issues that arise during the analytical process of an epidemiological study.

Analysis proceeds from the simple to the complex. Starting with careful description by counting cases, analysis proceeds to percent distributions, risk and rate estimation, and comparison. Only then should an analyst begin to apply more sophisticated, quantitative techniques.

Description

Detailed description is the foundation of epidemiology. Characterizing the individuals who are the cases in an epidemic or who have health problem needs to include the clinical characteristics of the condition and information on time, place, and person. This is important because these cases are essential in calculating rates and risks needed to solve an epidemiological problem. A line listing (Table 2-5) that shows relevant characteristics of the cases also helps determine how to characterize the population at risk. A graphic description of the cases will strengthen the description. One way to do this uses an “epidemic curve,” as noted above.

The population at risk provides the denominator for calculating rates. Estimating rates is essential to make comparisons between the case groups and other groups. The population at risk will need to be categorized by the same characteristics, using the same intervals as

the cases in the numerator of the rate estimates. The first estimate, therefore, usually requires putting the number of cases, or events, that occurred in a given time and in a given population within a geographic area in the numerator. The number of those in the population at risk for the same time and area is the denominator.

The population at risk needs to be determined as precisely as possible. In an epidemic reported from a large area, the initial estimate of the population at risk is likely to include many people who are not really at risk of the reported infection. Subsequent studies of the communities in that area are likely to identify one in which almost all who are ill reside. Additional inquiry may show that only the ones who attend a particular school or work in a single factory are really at risk. If, for example, the epidemiologist detects an unusual cancer, then the people with this tumor need characterization. If the only individuals with this unusual cancer do a specific job, such as working with vinyl chloride, then only people who work with that chemical are cases in the epidemiological investigation.

Selection of a comparison group, usually part of the study design and investigative process, warrants review during analysis. An initial study that covers a community may not be sufficiently sensitive, or even appropriate, if those with the health problem under analysis prove to reside in a specific area of the community. For example, if all the ill people live downwind from an industrial effluent, then they decide the area for study. Under such circumstances, omitting data from the analysis may be necessary although it may seem a waste of effort or a risk of losing statistical power.

The two measures most frequently used are cumulative incidence and incidence density. Cumulative incidence, often called the attack rate in an epidemic, is the proportion of a population initially free of a health problem which then develops the health problem. When applied to an epidemic, the cumulative incidence refers to the average population at risk and to a specified period of time, usually that time in which the epidemic occurred. Cumulative incidence is a measure of the probability, or risk, of developing a particular condition during a specified period for the individuals in the population observation.

Incidence density, on the other hand, is a measure that includes *population and time*. Incidence density is a measure of the rate at which those in a population initially free of a health problem develop that particular problem during a given time. The measure most often used is person-years. Incidence density is often calculated for annual periods using standard health information. The data used include vital statistics and notifiable disease reports in the numerator, and midyear population for the denominator. Alternatively, estimates of incidence density may be made in a cohort study. In this instance, enrollment in the study to a predetermined point in time, such as the onset of the health problem, defines the time period for the measure.

A particular type of incidence density, the case-fatality rate, is estimated using the number of deaths as the numerator and the total number of cases in the denominator. During the years 1970–1986, for example, an estimated 790,500 ectopic pregnancies occurred in women who live in the United States; 752 of them died. The case fatality for ectopic pregnancy during this period is, therefore, 9.5 per 10,000 ectopic pregnancies.⁶⁷

Comparison

Calculating and comparing rates is the key to analyzing the cause of a problem and determining the strength of association between a risk factor and health problem. Realizing that rates do not describe the magnitude of a problem is important. Case counts state the size of a health problem. Rates describe the intensity, or severity, and the relative frequency with which events occur. Comparing rates for different geographic areas helps identify the place in which a health problem is most intense. Comparison of age- and sex-specific rates characterizes the age and gender groups at greatest risk of having the disease or health problem in a population.

Quantitative comparisons of rates and risks are easier when using the 2 × 2 tables (see an example in Table 2-6). These tables summarize data by distributing it into the four cells. This is done according to

TABLE 2-6. FEATURES OF THE 2 × 2 TABLE

		Health Event or Disease		
		Present	Absent	Total
Exposure	Present	a	b	a + b
	Absent	c	d	c + d
	Total	a + c	b + d	a + b + c + d

- a = Those with both disease and exposure
- b = Those exposed who have no disease
- c = Those diseased but not exposed
- d = Those neither diseased nor exposed
- a + c = All those with disease
- a + b = All those with exposure
- b + d = All those free of disease
- c + d = All those without exposure
- a + b + c + d = All those at risk

the relevant exposure and the health problem or disease. Examining data this way enables the epidemiologist to assess the occurrence of disease in relation to exposure using a number of measures. Arranging data in a 2 × 2 table makes analysis easier by displaying the information needed to calculate incidence rates. These rates compare the risk that an individual will experience due to the health problem under investigation depending on that person’s exposure to the presumed risk factor. Calculating the ratio of the rates in the exposed and unexposed groups gives the relative rate, or relative risk. When the relative rate is equal to 1.0, then there is no evidence of an association between health problem and exposure. However, if it is greater than one, the epidemiologist has evidence that there may be an association between exposure and event. Estimating the confidence intervals surrounding the ratios that do not include one gives added information about the significance and precision of the finding. If, on the other hand, the ratio is significantly less than one, presumably the exposure protects against the occurrence of the health problem.

In a measles epidemic in a school, the index case was a student in the tenth grade as were a total of 474 other students, 21 of whom were ill. The cumulative incidence for measles in the class with the index case is, therefore, 21 per 474 or 4.4 %, as shown in Table 2-7. Hypothesizing that students in this class might have greater risk of measles than those in the other classes is reasonable. This latter group includes 49 students with measles and a total of 1356 in the 3 other classes.

The cumulative incidence in the other classes is 49 per 1356, or 3.6%. The ratio of the cumulative incidence for these two groups of students is 1.2 (4.4/3.6 = 1.2), a figure that could have occurred because of chance, since the confidence interval (0.7, 2.0) includes 1.0. Being a classmate of the person who is the index case is therefore not a risk factor.

Comparisons in case-control studies use the odds ratio. This measure compares the risk of exposure in a group with a health problem to the risk of the same exposure in a population that does not have the problem. Confidence limits are interpreted for odds ratios as they were for relative rates. Those ratios greater than 1.0 with confidence limits that do not include 1.0 indicate that an association is likely. Those that are significantly less than 1.0 indicate a protective effect.

The use of this measure, to show both a causal and a protective effect, is illustrated by studies of OC use and tumors in women. A study of OC use in women with benign tumors of the liver by Rooks and her colleagues⁶⁸ shows a causal association. Of the 79 women with this rare tumor, 72 had used OCs at some time in their lives. In a group of 220 control subjects, however, 99 had never taken OCs. These data appear in Table 2-8, panel A. The odds ratio of 12.6 is significantly greater than one, and it has confidence limits that are greater than 1.0.

A study of OC use concerned with ovarian cancer uses the same measure to show a protective effect.⁶⁹ Of women with ovarian cancer, 242 had not used OCs for even as long as 3 months, while 197 had used OCs for more than 3 months. Of the control subjects, 1532 had never used OCs and 2335 had used them. Table 2-8, panel B, shows that the odds ratio is 0.5, a figure significantly lower than 1.0. This indicates a protective effect by OCs against ovarian cancer.

Comparisons can estimate the potential impact of a health problem. The *risk difference*, also called attributable risk or excess risk, can measure impact as well as the strength of association. The risk difference is the risk in the exposed group minus the risk in the unexposed group. The use of this measure is illustrated in applying it to the lung cancer and smoking data of Doll and Hill¹⁸ (Table 2-9).

These data show that lung cancer occurred in three individuals who did not smoke cigarettes. These three people are the numerator for the measure. The study included 42,800 person-years of observation of people who did not smoke tobacco. The lung cancer rate in these subjects is 7 per 100,000 person-years. Among individuals who smoked cigarettes, 133 developed lung cancer in 102,600 person-years, an incidence density of 130 per 100,000 person-years. Since the risk difference is the risk in the exposed (smokers) minus the risk in those not exposed, the attributable risk for smoking and lung cancer in this study is 123 (130 – 7 = 123).

TABLE 2-7. FEATURES OF A COHORT STUDY IN A 2 × 2 TABLE USING DATA FROM A MEASLES EPIDEMIC IN A SCHOOL

		Disease (Measles)		
		Present	Absent	Total
Exposure	Present (10th grade)	21 (a)	1423 (b)	1474 (a + b)
	Absent (Not 10th grade)	49 (c)	1307 (d)	1356 (b + d)

- **Cumulative Incidence in the Exposed Group**

$$\frac{a}{a + b} = \frac{21}{21 + 453} = 0.044 \text{ or } 4.4 \text{ per } 100$$

- **Cumulative Incidence in the Unexposed Group**

$$\frac{c}{c + d} = \frac{49}{49 + 1,307} = 0.036 \text{ or } 3.6 \text{ per } 100$$

- **Relative Risk** = $\frac{a / (a + b)}{c / (c + d)} = \frac{21 / 474}{42 / 1,356} = \frac{0.044}{0.036} = 1.2$

TABLE 2-8. FEATURES OF CASE-CONTROL STUDIES IN A 2 × 2 TABLE

■ A. Causal, or Positive Association

		Disease (Liver Tumor)	
		Present	Absent
Exposure (Oral contraception)	Present	72 (a)	99 (b)
	Absent	7 (c)	121 (d)

$$\text{Odds ratio} = \frac{a/c}{b/d} = \frac{ad}{bc} = \frac{(72)(121)}{(99)(7)} = 12.6^a$$

■ B. Protective, or Negative Association

		Disease (Ovarian Tumor)	
		Present	Absent
Exposure (Oral contraception)	Present	197 (a)	2335 (b)
	Absent	242 (c)	1532 (d)

$$\text{Odds ratio} = \frac{(197)(1532)}{(2335)(242)} = 0.5^b$$

^a95% confidence interval is between 5.5 and 28.6, $p < 0.0001$.
^b95% confidence interval is between 0.4 and 0.7, $p < 0.0001$.

Other measures of potential impact include the attributable risk percent, the population attributable risk, and the population attributable risk percent. The *attributable risk percent* is a measure of the percent of all deaths that can be attributed to the exposure being studied. This measure is also called the etiologic fraction and sometimes the attributable proportion. Using the lung cancer and smoking data of Doll and Hill,¹⁸ the attributable risk divided by the risk in those who smoke (then multiplied by 100) calculates this measure. The attributable risk percent of smoking for death caused by lung cancer, therefore, is 95% $(123/130) \times 100 = 95\%$. The data from this study means that 95% of all deaths due to lung cancer can be attributed to cigarette smoking.

The *population attributable risk* is a measure of the excess disease rate in the total population. It can be estimated by subtracting the incidence density in the population not exposed to a causal risk from the incidence density for the total population. For example, if the risk of death from smoking for lung cancer is 54 per 100,000 population, and the risk of death from lung cancer is 7 per 100,000 the population attributable risk of death from lung cancer caused by smoking is 47 per 100,000 $(54 - 7 = 47)$. These illustrative data are recent estimates for the United States⁷⁰ and estimates reported by Doll and Hill.¹⁸

The *population attributable risk percent* is the proportion of the rate of a disease that exists in a community, or population, because of a specific exposure. In the case of lung cancer deaths and smoking in

the United States, for example, the population attributable risk is estimated to be 47. The death rate caused by lung cancer is 54 per 100,000. Using these data, the population attributable risk percent is 87% $[(47/54) \times 100 = 87]$. This percent differs from attributable risk percent. The attributable risk percent considers the characteristics of exposure, that is, smoking rates, in the entire population rather than that of a special group of individuals who are the subjects of a study.

These measures, their formulas, and examples are discussed in more detail in textbooks on epidemiology.

Epidemiological analyses measure the strength of the association between exposures and outcomes. These associations are characterized as direct and causal if they are positive, or direct, but protective, if negative. Associations that appear direct, but are the result of the interaction with another variable are indirect; they are often the result of confounding. Associations may also be artifactual. Distinguishing these different forms of association requires knowledge of confounding, effect modification, and chance, and also the other criteria for judging epidemiological associations.

Bias

Some authorities identify many forms of bias;⁷¹ however, most bias falls into two major groups: selection bias or information bias.

Selection Bias

Selection bias may occur when systematic differences exist between those selected for a study and those who are excluded. Refusal to participate in a study or respond to a questionnaire may introduce selection bias. This bias occurs when those who refuse or are not able to respond differ in exposure pattern and disease risk from those who do. Selecting case and comparison subjects from hospitalized groups may also introduce bias if, for example, the hospitalized patients used as control subjects do not represent the population from which those with illness have come. In addition, comparing subjects who have died with others who are still living may introduce bias. Selection bias includes, and is sometimes used synonymously with, ascertainment bias, detection bias, sampling bias, or design bias.

Information Bias

Information bias occurs when there are systematic differences in the way data are gathered from controls and cases. For example, if one set of questions is used to evaluate the exposure in the control subjects, and another set is used for the case subjects, the information about the groups may differ systematically. This could easily lead to distorted inferences. If, in a clinical study, one group is observed more frequently than another, the probability of making an observation will be greater in the one observed more frequently. This kind of bias could occur in a study comparing the effectiveness and safety of two approaches to patient care. If one approach was used for subjects seen in an ambulatory clinic while the other required hospitalization, those in the hospital might be seen more frequently than those in the clinic. Information bias may include observer, interviewer, measurement, recall, or reporting bias. Definitions of these terms are discussed in detail in other writings.

Confounding

Comparisons may differ from the truth and therefore be biased when the association between exposure and the health problem varies, because a third factor confounds the association. A confounding factor may distort the apparent size of the effect under study. Confounding may occur when a factor that is a determinant of the outcome is unequally distributed among the exposed and unexposed groups being compared. For example, age can confound the findings of a study if the age distribution of two populations differs. Age adjustment, or stratification, evaluates the confounding effect of age differences, as it can for other confounding factors. For example, the effects of occupational exposure upon respiratory disease are often confounded by tobacco smoking.

TABLE 2-9. MEASURES OF ASSOCIATION AND IMPACT, AN ILLUSTRATION BASED ON SMOKING AND LUNG CANCER

Cigarettes Smoked Daily	Lung Cancer Cases	Person-Years of Risk	Incidence Density (per 100,000 person-years)
None	3	42,800	7
1-14	22	38,600	57
15-24	54	38,900	139
25+	57	25,100	227
All smokers	133	102,600	130
Total	136	145,400	94

Effect Modification

Effect modification is a change in the measure of association between a risk factor and the epidemiological outcome under study by a third variable. The third variable is an effect modifier. An effect modifier provides added information about an association by helping to describe an association in more detail.

Effect modification is illustrated by the association between intentional injury and the sex of the children and adolescents in a study from Massachusetts.⁷² The data for individuals younger than 20 years of age in Massachusetts, the incidence density for intentional injury, is half as great for girls as for boys. The top panel of Table 2-10 shows these data. Nonetheless, age modifies this main effect, as shown in the bottom panel of Table 2-10. For children younger than age 5, girls have an incidence density 60% greater than that for boys. In the age interval 5–9 years, the rate for girls becomes just one-third of that for boys. The overall association, or main effect, that is, intentional injury associated with male sex, therefore, is not uniform for all age intervals in this study. The effect is modified by age.

Although effect modification and confounding both occur because of the way a third variable influences an epidemiological association, these two concepts are different. While effect modification gives more information about the association, confounding distorts the association. Effect modification is inherent in the nature of the association; confounding is not. A confounding factor is not a consequence of exposure to the risk factor and can occur even in the absence of the risk. A confounding factor exerts its influence by being unevenly distributed between the study groups. It is possible, therefore, for a variable to be an effect modifier, a confounding factor, both, or neither. Moreover, a single variable may both modify and confound the same main effect in a single study.

Stratifying an epidemiological analysis by an effect modifier adds knowledge about the association because it describes the effects of such a factor. Statistical testing to determine the probability that the study population contains groups that differ from the total population helps to validate the presence of effect modification. Stratification also adjusts for, or neutralizes, the effects of a confounding factor.

Many analyses require the epidemiologist to stratify for a number of effect modifiers or confounding factors. Analytical complexities of this kind require the use of multivariate analysis. This analytical approach permits the epidemiologist to adjust simultaneously for a number of potential confounding variables. It uses regression analysis that involves multiple factors. Multivariate analysis may assume an additive, straight-line relationship between variables and involve the use of multiple linear regression. Alternatively, the multivariate approach may assume a multiplicative relationship between variables and use multiple logistic regression analysis. Other, more specialized textbooks deal with these analytic approaches in more detail.

Chance

Chance can play two roles in epidemiology. It may account for an apparent association and make it appear real when it is not. (This may

be called a type I, or alpha, error.) Alternatively, chance may lead to an association being overlooked, or missed, when it truly exists. (This may be called a type II, or beta, error.) Statistical *significance testing* helps evaluate the role of chance by permitting an epidemiologist to determine the probability that an association actually exists. Assessing *statistical power* helps evaluate the probability that an association would be detected if it were present.

In epidemiology as in other sciences, we must often decide whether a difference between observations is statistically significant. Two questions arise: What does “statistically significant” mean? How can we test for statistical significance? A complete answer to these questions demands a thorough understanding of statistics. Other, more detailed books on statistics cover this subject. The reference list at the end of this chapter gives the titles of some of these textbooks. The following discussion is all that space permits in such a book as this. We assume that the reader is familiar with the terms and concepts of elementary statistics.

When data have a normal or Gaussian distribution, 5% of observations lie more than two standard deviations from the mean or central value. Conventional practice, therefore, is that the 5% level is a suitable point to set for observed differences that are judged statistically significant. In the conventional notation, the probability of an observation falling in this range is less than 5%, or $p < 0.05$. This level of statistical significance is suitable for many purposes in epidemiology. However, we are sometimes justified in insisting upon higher levels, for example, a difference that could occur by chance less often than once in 100 times, that is, $p < 0.01$, or less often than once in 1000, that is, $p < 0.001$. When we set a 5% level, that is, $p < 0.05$, one observed difference in 20 can occur just by chance and, therefore, be statistically significant. When many comparisons are being made in sets of data (for example, in multivariate analysis), 1 in 20 of the correlations will, on the average, be statistically significant due to chance alone.

Interpretation

Interpreting epidemiological data requires that causal associations between exposure and outcome be correctly identified using specific objective criteria. Although we have focused on the measurement of association, the identification of bias, and the role of chance up to this point, these criteria include, but go beyond, measurement and chance. The initial criteria used to distinguish causal associations from indirect and artifactual ones were applied to a study of epidemic infections by Koch⁷³ and can be stated as follows:

1. The causative agent must be recovered from all individuals with the disease.
2. The agent must be recovered from those with the disease and grown in pure culture.
3. The organism grown in pure culture must replicate the disease when introduced into susceptible animals.

Such rigorous criteria ensure that studies adhering to them are very likely to identify causal associations correctly. Nonetheless, they are restrictive, and, had they been adhered to inflexibly, some important epidemiological associations would not have been found. The association of smoking and lung cancer is one.

In the mid-1960s, criteria more suited to contemporary health problems became the topic of heated scientific debate. Sir Austin Bradford Hill²⁰ in his first presidential address to the section of Occupational Medicine of the Royal Society of Medicine in England proposed a set of criteria more suited to contemporary health problems. Serious objections to the work of Hill and Sir Richard Doll were raised by many respected scientists, including Sir Ronald Fisher. In the United States, the Surgeon General of the U.S. Public Health Service convened an Advisory Committee on Smoking and Health. This committee promoted use of criteria similar to those proposed by Hill. These criteria can be summarized as follows:⁷⁴

1. *Chronological relationship:* Exposure to the causative factor must occur before the onset of the disease.

TABLE 2-10. EVALUATING COMPARISONS WITH EFFECT MODIFICATION: AN ILLUSTRATION USING INTENTIONAL INJURIES AMONG CHILDREN AND ADOLESCENTS IN MASSACHUSETTS

Effects	Female	Male	Relative Risk
■ By Incidence Density^a			
All Ages	53.6	97.9	0.5
■ By Age (Years)			
0–4	17.0	10.6	1.6
5–9	7.4	21.8	0.3
10–14	40.5	59.7	0.7
15–19	131.0	259.8	0.5

^aIntentional injuries per 100,000 person-years.

2. *Strength of association*: If all those with a health problem have been exposed to the agent believed to be associated with this problem and only a few in the comparison have been so exposed, the association is a strong one. In quantitative terms, the larger the relative risk, the more likely the association is causal.
3. *Intensity or duration of exposure*: If those with the most intense or longest exposure have the greatest frequency or severity of illness while those with less exposure are not as ill, then the association is likely to be causal. This can be measured by showing a biological gradient or a dose-response relationship.
4. *Specificity of association*: If an agent, or risk factor, can be isolated from others and shown to produce changes in the frequency of occurrence, or severity of the disease, the likelihood of a causal association is increased.
5. *Consistency of findings*: An association is consistent if it is confirmed by different investigators, in different populations, or by using different methods of study.
6. *Coherent and plausible findings*: This criterion is met when a plausible relationship between the biological and behavioral factors related to the association support a causal hypothesis. Evidence from experimental animals, analogous effects created by analogous agents, and information from other experimental systems and forms of observation are among the kinds of evidence to be considered.

Interpreting epidemiological data, therefore, requires two major steps. One, the criteria for a causal association must each be carefully evaluated. The second is an equally careful assessment of the association to identify bias and evaluate the role of chance. Undue emphasis may be given to the role of chance. As a result, Sir Austin Bradford Hill in speaking to the Royal Society said of tests of statistical significance “such tests can, and should, remind us of the effects that the play of chance can create, and they will instruct us in the likely magnitude of those effects. Beyond that they contribute nothing to the ‘proof’ of our hypothesis.”²⁰

Using Judgment in Analysis

The following points are important when applying judgment to epidemiological analysis. They are:

1. Start with data of good quality and know the strength and weakness of the data set in detail.
2. Make careful description of the first step.
3. Determine the population at risk as precisely as possible.
4. Selecting the comparison, or control, group is one of the most difficult judgments to make. As a rule, try to choose subjects for comparison who represent the case group and come from the place where the exposure under study is most likely to have occurred.
5. Reduce the data analysis to a 2×2 table where possible.
6. The strongest case for an epidemiological association is one that meets all of the causal criteria.
7. Carefully determine the role that bias, including confounding, may have played in distorting an association.
8. In assessing an association, do not rely on tests of statistical significance alone. Remember the words of Sir Austin Bradford Hill. He stated ... “there are innumerable situations in which they [tests of statistical significance] are totally unnecessary—because the difference is grotesquely obvious, because it is negligible, or because, whether it be formally significant or not, it is too small to be of any practical importance.”²⁰

► EVALUATION

Evaluation, for an epidemiologist, is the scientific process of determining the effectiveness and safety of a given measure intended to control or prevent a health problem. Evaluation can involve a clinical

trial that tests effectiveness of a drug, vaccine, or medical device and the occurrence of adverse side effects. Evaluation also assesses intervention programs in communities, as was done with the fluoridation of water on the prevention of dental caries. Evaluation may also assess the effectiveness of measures to control an epidemic.

Those who work in evaluation make a distinction between the terms effectiveness, efficacy, and efficiency. The effectiveness of a therapeutic or preventive agent or an intervention procedure is determined during its use in a defined population. Efficacy, on the other hand, is evaluated in terms of the benefit that such an agent or procedure produces under the conditions of a carefully controlled trial. Efficiency evaluation assumes that therapeutic or preventive agents and intervention procedures are effective and safe. Efficiency, therefore, concerns the assessment of resources in terms of money, human effort, and time.

Characteristics of Epidemiological Evaluation

The epidemiological evaluation of a health problem has special characteristics. First, the health problem is usually well defined. This means that the epidemiologist does not need to be deeply concerned with questions such as “Is there an epidemic?” Second, because the problem definition is clearer, epidemiological evaluation customarily has specific and explicit objectives that can be quantified. Third, a case definition for the health problem has often been formulated in detail before the epidemiologist begins field work. Finally, careful planning of an evaluation study is often essential, so that a complex set of study design issues need to be carefully addressed.

Epidemiologists evaluate a wide range of issues. An epidemic of an infection, such as measles, may require an evaluation of vaccine effectiveness. An unusual cluster of abnormal cytology reports may suggest either an unusual cluster of cancer cases or a problem with screening procedures for this condition. The epidemiologist may also evaluate therapeutic and preventive measures in carefully designed clinical trials in the community. Such measures may include an assessment of the effectiveness of media interventions in children,⁷⁵ vaccine efficacy,⁷⁶ or promoting healthy workplace behaviors.⁷⁷ Epidemiologists may also evaluate programs intended to improve the health of entire communities, despite the specific method of intervention used, as is done in program evaluation. Worthwhile efforts like this have been made in controlling epidemics of infection and with programs to prevent unplanned pregnancy. In addition, carefully organized community trials have been used to evaluate the prevention of cardiovascular disease, nutritional deficiencies, and dental health problems.

The need for carefully designed clinical and community trials to evaluate prevention programs and agents has led some writers to characterize this as “experimental epidemiology.”⁷⁸ The scientific desirability of carrying out randomized, blinded, controlled clinical trial of a therapeutic or preventive intervention is undeniable. Nonetheless, epidemiologists may need to evaluate health problems in communities that exist, because a presumably effective form of intervention did not adequately prevent or treat a health problem. This topic is discussed in connection with vaccine efficacy during outbreaks, when a randomized trial is not feasible either in terms of resources or the urgency of the immediate problem.

Systematic Reviews and Meta-analysis

Systematic reviews and meta-analysis are critically important tools to combine and synthesize the results of different research studies. Meta-analysis uses statistical methods to obtain a numerical estimate of an overall effect of interest. Its primary aim is to enhance the statistical power of research findings when numbers in the available studies are too small. It is more objective and quantitative than a narrative review. In public health and clinical medicine, meta-analysis is often applied by pooling results of small randomized controlled trials when no single trial has enough cases to show statistical significance, but there are many examples of meta-analyses of observational studies.^{79,80}

Although meta-analysis is an important new tool for the epidemiologist, it has some pitfalls. First, the problems of bias take on

new dimensions. One, called publication bias, results from the tendency of authors and editors to put studies into print that have positive findings in preference to those that show no association. In addition, authors tend to select or emphasize studies that confirm their own viewpoint by applying the criteria for inclusion in a meta-analysis that varies from one study to another, thereby supporting their own beliefs.

► APPLYING EPIDEMIOLOGY TO PUBLIC HEALTH

Epidemiology, as the scientific basis for the practice of public health, has important applications to resolving high-priority contemporary health problems. This closing section highlights three basic applications.

Epidemic Control

Epidemiology applied to the control of epidemics is still relevant to contemporary public health practice. While the AIDS pandemic is well recognized, epidemics of many other types also occur. A recent estimate, for example, indicated that several thousand epidemics occur in the United States each year.

Program Practices and Operations

Preventive health service programs that affect the health of large population groups and geographic areas are also influenced by the work of epidemiologists. The package inserts for OC pills have information for women in their reproductive years that is taken directly from the findings of epidemiological studies. Safeguards against the risks of environmental and occupational exposures, such as those of radon, asbestos, vinyl chloride, and tobacco smoke, are based on epidemiological research. Immunization policy also rests on the scientific work of epidemiologists.

Policy Development

Epidemiology is essential to the development of scientifically responsible public health policy. Within the past decade and a half, the countries of North America have analyzed the health problems faced by their citizens and proposed important new approaches to policy development, focusing on nationwide health objectives. If these objectives are to be met, professionals throughout public health and preventive medicine will play essential parts. The role of epidemiology and its practicing professionals is, however, not always clearly recognized. Nonetheless, epidemiologists will be involved in carrying out every essential task of the profession. *Surveillance* will be required to provide a baseline description of the epidemiology of each health problem and the ways in which it changes and evolves. *Investigations* will be carried out in communities as unexpected clustering occurs of uncontrolled infections. In addition, emerging new infections, automotive and other vehicular injuries, suicides, homicides, workplace fatalities, disabling exposures to chemical and physical agents, and persisting problems of neoplasia and cardiovascular diseases continue to limit the quality of life. *Analysis* will uncover previously unknown risk factors and ineffective prevention measures. *Evaluation* will lead to the development of new community preventive services and improved clinical treatment. Effective communication will be increasingly important to epidemiology as complicated scientific studies influence the behavior of individuals and the laws and regulations that govern communities.

What evidence is there that epidemiology can have this kind of impact on the health of a population? The eradication of smallpox from our planet is one such bit of evidence. The role of epidemiology in this worldwide effort is now well documented. The development of the Planned Approach to Community Health (the PATCH process)⁸¹ has already begun to show how communities can use public health

surveillance to define the baseline of the health problems they face. The provision of epidemic and epidemiological assistance by local, state, and national public health agencies illustrates the ways in which investigations influence public health. How the sum of all these actions influences health and the quality of living will be determined by the policies, programs, and practices through which they act. Epidemiology plays an important part in developing the scientific base for this kind of societal change. It seems fitting that epidemiologists also play a role in seeing that the outcome of these changes is a desired one.

Ethics and Public Health Policy

Colin L. Soskolne • John M. Last

Nations, communities, professional organizations, and their leaders aspire to uphold values that are respected by the group as a whole. These values, at the core of group identity, set the tone for ethical conduct among group members. There is often concern about questions of “right” and “wrong,” with moral values, human rights, and duties pertaining to behavior as a member of the group. Norms of ethical conduct are sought for the group, anchored in its core values. In this way, professional organizations, like society at large, distinguish between acceptable and unacceptable conduct. Moral philosophy provides frameworks for dealing with beliefs and practices and provides the basis for ethical conduct.

Significant national public policy differences can be attributed to differences in national values. For instance, the United States was founded on libertarian values, while Canada was founded on egalitarian values. Many in the United States do not believe in taxation for the common good, whereas in Canada this value prevails. Hence Canada has a system of publicly funded universal access to health care, while the United States does not. Even so, there is substantial consistency among human communities regarding some aspects of conduct, for instance, almost universal taboos against murder and incest. But social or group values, behavior, and policies have differed widely over time and among civilized societies in such matters as infanticide, abortion, euthanasia, capital punishment, slavery, and child labor. Many people were relatively indifferent until recently to the integrity of life-supporting ecosystems and the environment on which all societies, indeed all humankind, are ultimately dependent for their health and well-being. As evidence mounts that human activities are endangering long-term sustainability, larger numbers of people are expressing concern, although rarely matching this with action to conserve the earth’s nonrenewable resources.

In Judeo-Christian and Islamic nations, many aspects of acceptable conduct derive ultimately from ancient roots, such as the Ten Commandments, whence evolved laws that have been codified to protect society’s members. These laws have established precedent for civilized social behavior. Translating science into laws that support policy has ethical dimensions. The range of ethical concern includes ensuring integrity in professional roles, the duty for community engagement in research, and communication practices among stakeholders and policy makers.

Educating students of public health in matters of ethics is now commonplace. This should help to produce more effective guardians of the public health, particularly as vested interests influence the roles of public health professionals and their ability to protect the public interest.

Note: Chapter in Public Health and Preventive Medicine, 15th edition. Edited by R.B. Wallace, F Douglas Scutchfield, Arnold Shechter, et al.

► ETHICS, MORALITY, VALUES, AND LAW

Ethics addresses issues of conduct among members of any group in society. Morality relates more to society’s notion of what is “right” and “wrong” on the broad social level of interaction. Ethics and morality focus on normative behaviors for the group and for society, respectively. Community standards of morality, or the moral values of society, are the basis for many laws, whether these laws are determined by statute (enacted in a legislative body) or case law (based on precedents from previous judgements rendered in a law court).

In general, we regard laws as a way of upholding the values of society. While some actions may be legal, they can be unethical. For instance, Apartheid (separate development) in the former South Africa (1948–1994) and racial segregation in the Southern United States through the early 1960s may have been legal, but their foundations and application were deemed immoral and unethical by most people elsewhere in the world.

At the professional level, it is illegal to assist a suicidal act, but it is ethical for a physician to act so as to avoid prolonging needlessly the pain and suffering sometimes associated with the process of dying. This dilemma continues to be the subject of much legal and ethical debate, even involving the President and Congress of the United States early in 2005 in attempts to alter unanimous court decisions about refraining from efforts to prolong life support for a brain-dead woman. Community standards are also influenced by social values, which fluctuate more than moral values. An example is American attitudes toward alcohol that led to the constitutional amendment on Prohibition in 1922, and then to its repeal 13 years later.

In the health field, some epidemiologic studies have become part of general knowledge and popular culture, affecting social values and human behavior in many ways. Changing social values about health have often led to behavior change, sometimes reinforced by laws or regulations such as those that improved standards of food handling, which led to safer working conditions and labor laws, better housing conditions, and, more recently, to smoke-free environments. Increased awareness of the hazards of smoking and sidestream smoke have transformed social values in many western nations, making smoking unacceptable in many settings where previously it was the norm.

Many communities have restricted smoking in confined spaces and public places such as aircraft, public buildings and transportation systems, theatres, cinemas, taxis, and restaurants. Often, the standards have been codified in laws and regulations, and have led to changes in public health policy on taxing tobacco products. The crowning achievement is the UN Framework Convention on Tobacco Control, approved by the World Health Assembly in 2002 (<http://www.who.int/tobacco/framework/en>). This had been signed by 102 nations and ratified by 57 as of 2005. A similar sequence can be traced in evolving attitudes to and public health policies on impaired driving, domestic violence and child abuse, and (without regulations or laws) diet and exercise in relation to coronary heart disease.

One approach to assessing the “rightness” or “wrongness” of an action, or of a proposed action, is the framework provided through the principle-based approach to ethical analysis.¹ Other approaches, such as virtue-based and deontology or duty-based approaches have their place in ethical analysis. Another approach is casuistry,² that is, the case-based approach. Like law, this draws on precedent to determine the ethical appropriateness of an issue under consideration. It is beyond the scope of this chapter to address all approaches, so we confine ourselves to the principle-based approach.

► PRINCIPLES OF BIOMEDICAL ETHICS

In western industrial nations, many principles of ethics have descended from Aristotle, whose *Ethics*³ (fourth century BCE) discussed many actions aimed at achieving some good or desirable end. Aristotle’s concepts of ethics resemble in some ways the biblical precepts of the Old Testament and the teachings of Jesus of Nazareth. Aristotle’s philosophy and the Judeo-Christian beliefs were modified by John Stuart Mill and Immanuel Kant, whose names are associated respectively with theories of ethics called utilitarian (greatest good for the greatest number) and deontological (recognizing rights and duties to behave in certain ways, generally because they conform to religious beliefs or other widely held moral values).

Much of medical ethics is founded upon four principles, respect for autonomy, non-maleficence, beneficence, and justice.

Respect for autonomy refers to the individual’s right to self-determination and respect for human dignity and freedom. This includes the need to tell the truth (veracity) and to be faithful to one’s commitments (fidelity).

Non-maleficence refers to taking actions that will not result in harm, derived from the ancient medical maxim, *primum non nocere* (first, do no harm).

Beneficence refers to the need through one’s intended actions to do good, which members of the public health professions like to think is the main function of public health; although, sometimes we are viewed by others as “do-gooders,” interfering busybodies whose paternalist interventions are unwanted and sometimes resented.

Justice refers to social and distributive justice, requiring fairness in the distribution of risks and benefits, and to the need for equity and impartiality across all members of the greater community.

These four principles are upheld as far as possible in all aspects of decision-making in health care and public health. However, it is unlikely that all four principles can operate with equal weight in relation to every action to be considered. A natural tension operates among the four principles. The principle-based approach to ethical analysis allows us to be transparent in the rationale for our actions. In applying this approach to ethical analysis, we articulate our arguments for placing greater weight on one over other principles. Thus, in public health practice, when we must restrict an individual’s freedom (respect for autonomy) by confining an infectious person in the interests of justice, we justify this action because of our need to do good. In this example, the well-being of the majority would be at risk of exposure to infection if the infectious person(s) were not isolated, and in some instances, apparently healthy contacts were not quarantined.

In modern medical practice and research, many entirely new situations have arisen. Some are a consequence of advancing medical science (e.g., the problems presented by organ and tissue transplants, intensive care life support systems, genetic engineering, new reproductive technologies). Others are a result of changing social values. An example of changing social values, with important implications for medical ethics, is the increasingly widespread belief that women should be able to control their own reproductive systems, rather than have imposed upon them the view held sincerely by many people for religious or other reasons, that it is sinful to interfere with natural reproductive processes, whether to reduce the risk of pregnancy or to

terminate an unwanted pregnancy. There is great variation in the extent to which individuals and groups in society regard interference with pregnancy as tolerable, sinful, or criminal. The variation may be related to conflict between a moral value (right to life) and a social value (freedom of choice). In the United States, few issues have led to such bitter and acrimonious argument. In other nations, a degree of amity has been achieved among proponents and opponents of reproductive choices for women.

In the United States, in 2004–2005, the administration attempted to reduce the effective weight of science in Advisory Committees on public health policy by advancing instead nonscientific notions founded on fundamentalist religious and neoconservative ideologies, despite protests from many leaders of scientific thought (http://www.ucsusa.org/global_environment/rsi/index.cfm). Some of these actions have been accompanied by use of pejorative phrases, such as “junk science,” in reference to such bodies of expert opinion as the Intergovernmental Panel on Climate Change. *Ad hominem* attacks on expert opinion have no place in scientific research or in its practice.

In the discussion that follows, the principles of respect for autonomy, non-maleficence, beneficence, and justice are applied to show how we try to arrive logically at “correct” decisions when we are faced with ethical tensions and ambiguous situations in public health research and practice. Some of the ambiguities are as difficult to resolve as the ethical problems of clinical practice. There is not always a “right answer”; therefore, it is preferable to apply logically the principles of biomedical ethics rather than to rely on *ex cathedra* statements of “expert” opinion. However eminent the experts may be, *ex cathedra* statements are often flawed. Finally, in applying these principles the context, including local values and laws, are relevant and important for determining the most appropriate course of action.

► RIGHTS AND NEEDS: COMMUNICABLE DISEASE CONTROL

The concept of contagion has been recognized for centuries. Many communities have reacted to the threat of contagion by identifying persons suffering from “contagious” diseases and sometimes by segregating or isolating them. These customs date back to the leper’s bell and the lazaretto. Since the fourteenth century, the practice of quarantine has arisen; this led to development of procedures aimed at restricting freedom of movement of apparently healthy people in contact with persons thought to be contagious. These procedures were codified by Johann Peter Frank⁴ and subsequently reinforced by laws and regulations in organized societies all over the world.

Notifying cases of infectious disease means that individuals are labelled, and in practice this has often meant that they carry a stigma. Isolation and quarantine, of course, restrict freedom. Notification, isolation, and quarantine can be applied to individuals, to families, even to entire communities. These practices are widely accepted features of communicable disease control. Stigmatizing by notifying and restricting freedom infringes individual autonomy, but these practices are generally held to be necessary restrictions whose purpose is to benefit society as a whole.

Until recently, there has been little objection to measures aimed at controlling communicable diseases. The need of society for protection has been considered paramount over the rights of the individual case or the contact. When smallpox, cholera, poliomyelitis, diphtheria were prevalent, few people questioned the actions of public health authorities who notified and isolated cases, quarantined contacts, sometimes severely infringing the freedom and dignity of entire families. Some diseases, for example, tuberculosis, carried considerable social stigma—which was worst of all in cases of syphilis. These features of communicable disease control have been tolerated because they were believed to be necessary for effective control.

Reactions to essentially the same phenomena, when they arise in relation to cases of AIDS and HIV infection, have been subtly different. The first wave of the AIDS epidemic in the United States hit hardest at an already stigmatized group, male homosexuals, who had

only recently been able to break free from age-old prejudices. The hostile reaction toward persons with AIDS among many members of “respectable” society was aggravated by homophobia and by exaggerated notions about how the infection could be acquired. Combined with the rising demand for equity and justice in dealing with minority groups in society, it heightened awareness of the need to provide health-care services with justice and equity for all.

Widely publicized instances of victimization of AIDS patients—homosexual men hounded out of their jobs, men of Haitian heritage and hemophiliac children rejected by schools, even communities—aroused public opinion on the side of compassionate and humane management of these patients. A second wave of the epidemic affected intravenous drug users who shared needles, and this group did not attract so much sympathy, although, infants infected with HIV have generally been recognized as “innocent victims” of the epidemic.

Health professionals should recognize when they are being swayed by such value judgements, and they must resist such pressures. Public health workers need to know and understand the behavior patterns associated with the transmission of HIV; without this understanding it is impossible to prepare effective strategies and tactics to control the HIV epidemic. Moreover, even if somebody contracts AIDS or HIV infection as a consequence of behavior that some members of the health professions might regard as a sin or a crime, we all have an obligation to apply our professional skills impartially and nonjudgementally, especially in an emergency room setting. The only alternative is to make a referral to an otherwise competent professional or hospital. The patient’s life cannot be left in jeopardy. These circumstances also can exert grave pressures on professionals. In central Africa in the early years of HIV/AIDS, some health professionals were politically forced to leave their countries for writing about the AIDS problem in their countries.

The social reactions to AIDS and HIV infection have led to much discussion about ethical aspects of management. A diagnosis of HIV infection even to this day carries a grave burden of not only cost, but also of both stigma and concern for one’s life. The diagnosis, thus, must not be lightly made, nor the test for HIV antibody lightly undertaken: both voluntary testing and communicating the results of a positive test must be accompanied by careful counselling of all persons concerned, and their sexual or otherwise intimate partners.⁵ Health workers have a particular obligation not to discriminate against persons who are HIV antibody positive or who suffer from AIDS. The obligation of physicians and nurses to care for patients with HIV infection is no less than the obligation to care for patients with any other contagious disease. Moreover, HIV infection is considerably less contagious than conditions such as tuberculosis or streptococcal infection from which in former times many physicians and nurses died after being infected by patients.

For epidemiologic surveillance, public health authorities need data on the prevalence of HIV infection. The World Health Organization and many national authorities agree that unlinked anonymous HIV testing is the best way to generate prevalence data.⁶ Aliquots of blood, taken for other purposes from large representative populations, are tested for HIV antibody after all personal identifiers have been removed. Suitable populations include pregnant women and newborn infants.

In the United Kingdom and in the Netherlands, it was held for a time that anonymous unlinked testing is unethical, because identifying and counselling cases and their sexual partners was regarded as a higher moral responsibility than determining community-wide prevalence trends. In some developing nations, where prevalence of HIV infection is very high, public health authorities have taken a different view: they believe that the need for prevalence data is urgent enough to justify compulsory testing—but as neither treatment nor counselling are feasible in some countries, results of the tests are withheld even from persons found to be HIV antibody positive.

The rules that have evolved regarding testing and reporting for AIDS and HIV infection are a variant on rules and procedures for identifying, notifying, and initiating control measures for other sexually transmitted diseases, or indeed for many other forms of communicable

disease. These rules are not draconian. With the exception of Cuba, where HIV antibody positive persons were for some years subject to enforced quarantine, there have been no serious intrusions on personal liberty. There are other severe sanctions: restrictions on employment, life and health insurance, freedom to move from one nation to another (it makes no epidemiologic sense and violates human rights, but HIV antibody-positive aliens are denied entry visas to the United States and to some other countries.⁷

Many monographs on AIDS include extensive bibliographies⁸ on its ethical dimensions. Not only are human rights and legal arguments appropriate in deciding the handling of any new contagion, but the best available knowledge on how transmission does and does not occur needs to be brought to bear when conducting an ethical analysis. Ultimately, consideration of the four principles will require that we do more good than harm. Stigmatization and the threat of stigmatization can serve to cause great public health harm simply by virtue of pushing behaviors underground and not allowing access for controlling the spread of infection. Supportive and compassionate environments likely always result in better control than do oppression and stigmatization. Several physicians who have been at the forefront of work on HIV/AIDS epidemiology and control have written and spoken widely about the related issues of ethics and human rights.⁹

► INDIVIDUAL RIGHTS AND COMMUNITY NEEDS: ENVIRONMENTAL HEALTH

The rights of individuals have to be balanced against the needs of communities in other respects, besides control of communicable diseases. Most orderly societies have laws or regulations aimed at protecting people against tainted foodstuffs, unsafe working conditions, and unsatisfactory housing, though the strength of these laws and regulations is very variable and enforcement is often lax. Frequently, it is necessary for aggrieved parties to resort to litigation before an issue can be resolved. Community values and standards have lately shifted toward greater control over environmental hazards to health, reflecting widespread and growing concern about our deteriorating environment. In Canada, the Law Reform Commission proposed strict legal sanctions to protect the public from the consequences of “crimes against the environment”¹⁰ but a code of environmental ethics, such as that proposed by Bankowski,¹¹ would be a better solution: those who pollute the environment harm themselves as well as everybody else, so it is in everybody’s interest to follow the edicts of such a code. The question of whether environmental health is a basic human right is being debated.¹²

Sometimes health is adversely affected by environmental conditions, but correcting these conditions may have unpleasant economic repercussions, such as massive unemployment, and may be opposed by the people whose health is threatened. Public health specialists then are in the situation portrayed by Dr. Stockmann in Ibsen’s play, *An Enemy of the People*. It is difficult to decide the best course of action in such situations, but a useful guideline is to consider the ethical principles of justice and non-maleficence: what is the fairest way to deal with the situation? Which of the competing priorities will harm the fewest people over the longest period?

The Bush administration has significantly weakened laws and regulations on environmental and occupational health and safety, for example, relaxing standards on arsenic in drinking water, air quality emissions, and much else in response to political and ideological pressure from its supporters, despite strong scientific evidence of the harm this can do. Transnational corporations, with tacit or occasionally explicit support from some national governments and the World Trade Organization, have often attempted to weaken or emasculate aspects of public health laws and regulations aimed at protecting the population from unnecessary occupational and environmental health risks. Such actions are motivated by desire for greater profits and are opposed by advocacy groups for public health and environmental protection. Public health scientists, notably epidemiologists, toxicologists, and environmental scientists, not infrequently are drawn into decision-making discussions with legislators, often with considerable

media attention. In such circumstances, it is the ethical duty of all public health scientists to uphold the public good and to avoid doing the bidding of corporations whose primary *raison d'être* has become one of making profits for their shareholders.

► RISKS AND BENEFITS

Faced with an outbreak of smallpox in 1947, the public health authorities of the City of New York vaccinated about five million people in a brief period of six weeks or so. The human costs of this were 45 known cases of postvaccinial encephalitis and four deaths¹³—an acceptable risk in view of the enormous benefit, the safety of a city of eight million, among whom thousands would have died had the epidemic struck, but a heavy price for the victims of vaccination accidents and their next of kin.

Similar risk-to-benefit ratios have to be calculated for every immunizing agent. Consider measles: there is a risk somewhere between one in a million and one in five million of subacute sclerosing panencephalitis (SSPE) as an adverse effect of measles vaccination.¹⁴ Measles is close to elimination from North America (despite recent flare-ups). If we continue to immunize infants against measles after its elimination, there will be an occasional case of SSPE or some other unpleasant adverse consequence, perhaps an episode with many cases of septicemia from a contaminated batch of vaccine. This fact, and the cost of measles vaccination in face of competing claims for other uses of the same funds, is an incentive to stop using measles vaccine; but the risk of stopping will be the return at some later date of epidemic measles, perhaps not until there is a large population of virgin susceptibles. History could repeat itself: mortality rates as high as 40% occurred when measles was introduced into the Americas by European colonists several hundred years ago. High death rates would be unlikely in the era of antibiotics, but the morbidity and complication rates would be troublesome in a non-vaccinated population. Similar risk-cost-benefit debates arise in relation to other vaccine-preventable diseases, and the risks of adverse reactions to most other immunizing agents are greater than the risks of measles vaccine, but the risks of not immunizing are almost always greater.¹⁵

One duty of all who conduct immunization campaigns is to ensure that everybody is aware of the risks as well as having the benefits clearly explained to them. In short, informed consent is an indispensable prerequisite. This becomes especially important when children are not admitted to school until their parents or guardians can show evidence of immunization, that is, when immunization is mandatory rather than voluntary.

In the United States and some other countries, the threat of litigation in the event of vaccination mishaps is a deterrent to immunization procedures, even a threat to the manufacturers of vaccines. But health-care providers can be sued for negligence if they fail to immunize vulnerable persons or groups, as well as for damages if there are adverse reactions—a Hobson's choice. In Britain, France, Switzerland, New Zealand, and some other countries, the threat of litigation has been removed by legislation providing for a standard scale of compensation for accidents and untoward effects associated with immunization programs. A bill with similar provisions was enacted by the United States Congress in 1986, but must be matched by comparable provisions at state level before it can be implemented and as of 2005 that has not been fully achieved (<http://www.usdoj.gov/civil/torts/const/vicp/about.htm>).

Acceptable Risks

In many other situations we trade risks against benefits. The use of diagnostic radiography (x-rays) is an example. The epidemiologic evidence demonstrates that a single diagnostic dose of x-ray may harm the developing human fetus.¹⁶ But, there are medical conditions in which this small and distant future risk is acceptable because the alternative is a larger and more immediate risk, such as serious complications of untreated renal disease. Diagnostic imaging techniques,

such as ultrasound, have removed what was previously a difficult clinical decision when x-rays were the only resort of the obstetrician who suspected fetal malposition or disproportion, but diagnostic x-rays remain the best procedure for some conditions.

Health administrators and hospital staff members also accept the small risk of malignant disease among radiographers and other health workers occupationally exposed to x-rays, and the risk of fetal loss among operating room staff exposed to waste anesthetic gases—but not all the occupationally exposed individuals are informed of this admittedly small risk, as they ought to be by those in positions of responsibility.

Mass Medication

Risk-benefit calculations are required for all forms of mass medication, not only for immunizations. The possibility of adverse effects or idiosyncratic reaction always exists. The opposition to fluoridation of drinking water is based in part on the unfounded fear of cancer or some other terrible disease as a consequence. The apparent association between fluoridation and cancer has been shown by epidemiologic analysis to be spurious,¹⁷ although the debate has continued, because opposition to fluoridation is based mainly on emotional and political grounds rather than on science. Indeed, this is a political rather than a public health issue, in which the catch-phrase of the anti-fluoridation movement—"keep the water pure"—is difficult to rebut. Other political arguments with some ethical foundation rest on the claim that fluoridation is a paternalist measure, inflicted upon the population whether they like it or not. According to this argument, people in a free society should be able to choose for themselves whether to drink fluoridated water. Responsible adults can choose, but for infants and small children, fluoridated drinking water makes all the difference between healthy and carious teeth. Using the ethical principle of beneficence, public health authorities argue that infants and small children should receive fluoride in sufficient quantity to ensure that their dental enamel can resist carcinogenic bacteria. However, this is seen by some as an obsolete paternalistic approach to the problem of dental caries in children.

Some people have a genuine conscientious objection to mass medication such as fluoridation of drinking water or immunization of their children against communicable diseases. Opting out can be difficult. Opting out of fluoridation means the trouble and expense of using special supplies of bottled water. To opt out of immunization can mean exclusion of one's children from schools that make entry conditional on producing a certificate testifying to successful immunization against measles, poliomyelitis, and to some other diseases including mumps and rubella. The argument in favor of immunization is strengthened by reports of epidemics of paralytic poliomyelitis among children of members of religious sects that oppose immunization.¹⁸ Children, it can be argued, should not be exposed to risks because of their parents' beliefs. In many jurisdictions, courts have intervened to save the lives of infants and children requiring blood transfusions that their parents object to for religious reasons; but, the circumstances are different when immunizations are offered to healthy children with the aim of protecting them against diseases that are rare anyway. This is a difficult dilemma when the immunizing agent has adverse effects. The principles of beneficence and non-maleficence appear to cancel each other out in the debate about at least some vaccines; there remains another argument based on the principle of justice or equity: all infants deserve the protection of vaccines, even though a small proportion of infants may be harmed.¹⁹

Privacy and Health Statistics

Many people are troubled by the thought that intimate information about them is stored in computers, accessible in theory to anyone who can operate the keyboard. Of course, the same information has long existed in narrative form in medical charts, where it was as easily accessible to unauthorized readers as it now allegedly is to unauthorized computer operators. As many as a hundred people are authorized

to make entries in the hospital chart of the average patient in an acute short-stay general hospital bed, and all must read the chart if their entry is to make sense in context. In this respect, the confidentiality of the physician-patient relationship, the cornerstone of the argument for privacy, is a myth.²⁰

Computer storage and retrieval of health-related information greatly enhances the power of analysis to reveal significant associations between exposures and outcomes. Much of our recently acquired knowledge about many causal relationships has come from routine analyses of health statistics and from epidemiologic studies that have made use of existing medical records. Examples include the associations between rubella and birth defects, cigarette smoking and cancer, exposure to ionizing radiation and cancer, adverse drug reactions such as the thromboembolic effects of the oral contraceptive pill, excess deaths from use of certain antiasthmatic drugs, and so on.

Community benefit outweighs any harm attributable to invasion of privacy, especially as that harm is theoretical—respect for autonomy remains intact. In some nations, for example, Sweden and Australia, government-appointed guardians of privacy oversee the uses of medical and other records when these are requested for research purposes.

Resistance to use of routinely collected medical records for epidemiologic analysis has come not only from guardians of privacy, but also from special interest groups who would prefer that inconvenient facts should not be disclosed. Industrial corporations sometimes have tried to prevent disclosure of the adverse effects of occupational or environmental exposures, which it has not been in their financial interests to have widely known. Even governments that ought to have the public interest as their first priority have been known to suppress information derived from analyses of health statistics when it is politically inconvenient for such information to be publicized. Public health workers and epidemiologists must be alert to the risk of these forms of “censorship” and must be prepared to defend access to sources of health-related information.

Applying the principle of beneficence, it is desirable not only to maintain data files of health-related information, but to expand them. Available ideas as well as available information should be used for the common good, while simultaneously respecting the individual's right to privacy. Statistical analysis of health-related information has been so convincingly demonstrated to be in the public interest that there is no rational argument against continuing on our present course and expanding further the scope of these activities. This argument applies with particular force to the use of linked medical records, potentially the most powerful method of studying rare diseases and those with very long incubation times.

In the mid-1990s, the European Union issued a privacy directive that would have all but excluded any potential for the conduct of linkage studies. Powerful logical arguments presented by advocates for epidemiological and social research led to modification of the European Union directive to allow access to personal information for public health-related research.²¹

Health workers have an obligation to respect the confidentiality of the records that they use. Irresponsible disclosure of confidential details that can harm individuals is not only unethical, but can arouse public opinion against collection and use of such material. Properly used, health statistics and the records from which they are derived do not invade individual privacy. As Black²² has pointed out, the argument that individual rights are infringed in the interests of the community is an example of a “false antithesis”—the rights of the individual are congruent with the needs of the community, not in conflict, because as a member of the community, every individual benefits from analyses based on individual health records.

Generally, the law reinforces this ethical position while upholding respect for autonomy by safeguarding privacy. For example, a U.S. Court of Appeals ruled in favor of preserving the confidentiality of medical records used by the Centers for Disease Control and Prevention in an epidemiologic study of toxic shock syndrome attributed to the use of certain varieties of vaginal tampon. Lawyers for the manufacturer of these tampons had tried to subpoena the records so that they could call the women as witnesses and presumably challenge

their testimony. The court ruled that it would not be in the public interest to establish a precedent in which records of epidemiologic importance could be used in this sort of adversarial situation; this would be a deterrent to those aspiring to conduct future epidemiologic studies, and to participants in such studies.²³ However, in 1989 a U.S. Circuit Court ruled in favor of a tobacco company, granting access to clinical records that had been the basis for another epidemiologic study.²⁴ The issue of confidentiality of medical records, and their subsequent use for epidemiologic analysis, remains open; the potential threat that courts may grant access to hostile interest groups is a deterrent to patients if they are asked to give informed consent to the use of their medical records for epidemiologic study, and to epidemiologists, unless this matter can be clarified. In 1990, the Society for Epidemiologic Research agreed, after much debate, that research data should be shared with outside parties who might wish to reanalyze raw data.²⁵ Reasons for reanalysis ought not to influence the right of access.

With the introduction of the Personal Information Protection and Electronic Documents Acts (PIPEDA) in Canada and their equivalents in other countries, much concern for access to health information for research purposes has resulted.²⁶ In the United States, the Health Insurance Portability and Accountability Act (HIPAA) was signed into law on August 21, 1996. Effective April 14, 2003, this Act requires that covered entities secure confidentiality documentation from researchers before disclosing health information. However, negative consequences of this legislation for the conduct of epidemiologic research have been noted.²⁷

Informed Consent

The process and procedures for obtaining informed consent²⁸ should be clearly understood by all engaged in health research and practice. The process consists of transfer of information and understanding of its significance to all participants in medical interventions of all kinds, followed by explicit consent of the person (or responsible proxies) to take part in the intervention. The task of informing is important; someone senior and responsible should conduct it. The obtaining of informed consent should not be delegated to a junior nurse or a medical student.

Consent is usually active, that is, agreement to take part; sometimes it is passive or tacit, that is, people are regarded as taking part unless they explicitly refuse. Consent need not be written: the act of offering an arm and a vein for the withdrawal of a sample of blood implies consent; the essential feature is in the understanding of the purpose for which the blood is being taken. Concepts of respect for autonomy vary. In some cultures, patients regard their personal physician as responsible for decisions about participation; in other cultures, a village headman, tribal elder, or religious leader is considered to have responsibility for the group, in which individuals do not perceive themselves as autonomous. Nonetheless, each individual in such a group should be asked to provide consent to whatever procedure is being conducted as part of a public health intervention or epidemiologic research project.

An egregious violation of informed consent was the Tuskegee Experiment where, over several decades, the natural history of syphilis was investigated. In conducting this research, approvals by United States' government agencies allowed an experiment to continue without the need to disclose to participants (predominantly black citizens) the diagnosis of syphilis so that newer treatments could have been administered. The overriding interest of the experiment dominated decision-making, namely to see what the effects of untreated syphilis would do to the men enrolled in this prospective cohort study. The wrong done to the victims was belatedly recognized and on May 16, 1997, President Clinton publicly apologized to one of the last survivors for what had happened to him and other victims of this unprincipled experiment (<http://www.med.virginia.edu/hslibrary/historical/apology/whouse.html>). A teaching module based on this experience is provided at <http://www.asph.org/UserFiles/Module2.pdf>.

Obligations of Epidemiologists

The Helsinki Declaration and its revisions²⁹ govern the conduct of all health workers in contact with people. This Declaration calls for respect for human dignity (autonomy), avoiding harm to people, and equity in dealing with people.

The obligation of epidemiologists to respect the Helsinki Declaration is inviolable. However, sometimes epidemiologists are dealing not with individuals but with the aggregated records of very large populations; it is not then feasible to obtain the informed consent of every individual whose records have contributed to the statistics.³⁰ Sometimes the records are those of deceased persons. Epidemiologists are then expected to abide by a code of conduct such as that formulated by the International Statistical Institute for official statisticians.³¹ This is made formal in many nations by requiring those who work with official records to take an oath of secrecy. However, in some countries, for example, Sweden, France, West Germany, there have been public and political concerns about access to and use of official statistics such as death certificate and hospital discharge data. There have even been proposals to respect the privacy of the dead by withholding from death certificates the cause of death when the cause carries a stigma such as AIDS, although the motivation may really be to avoid embarrassing next of kin.

Although respect for privacy is a paramount concern of epidemiologists in both surveillance and research, sometimes privacy must be invaded, for example, when sexual partners must be traced as part of control measures for sexually transmitted diseases. Individual integrity, if not autonomy, is respected by obtaining informed consent whenever possible to these invasions of privacy. The Canadian Institutes of Health Research (CIHR) embarked on a major initiative to examine the role of secondary use of information in health research. A report was produced in 2002 documenting the utility of epidemiologic enquiry to great public advantage.³²

► ETHICAL RESEARCH AND ETHICAL PRACTICE IN THE PUBLIC HEALTH SCIENCES

The focus of this chapter is on ethics related to research with some implications for ethical public health practice. The difference is the distinction between data-driven research and the application of research findings to public health practice. Public health surveillance and epidemic investigation are often in a grey area, partly research and partly practice. Program evaluation is considered to be an aspect of routine public health practice, although here too there may be grey areas.

Since the 1980s, procedures have evolved for reviewing research proposals that are funded by public agencies and some other sources. While there are no formal ethical review requirements for much research funded privately (for example, for research undertaken by pharmaceutical or industrial corporations), academic researchers involved in such research are required to submit their research intentions to ethical review by the academic institution with which they are affiliated.

While no formal ethical oversight procedures exist for public health practice, public health practitioners must be concerned about interventions when there is no scientific basis for their existence. Public health action in the absence of evidence may be unethical.

Policy Statements, Guidelines, and Codes of Conduct

Since its inception over 100 years ago, the American Public Health Association has issued a steady stream of policy statements dealing with every aspect of public health practice and science. A policy review (<http://www.apha.org/> Search on legislative policies) shows that a great many have had ethical dimensions, touching on issues including autonomy, informed consent, beneficence, non-maleficence, truth telling, integrity, conflicts of interest, equity, and justice, in both general and specific terms, in relation to a host of specific issues and problems. In the early 1990s, APHA began to develop guidelines for

the ethical practice of public health. These were adopted by the APHA Governing Council in April 2002 and continue. (Search “ethical guidelines” at <http://www.apha.org/>).³³ Other public health organizations similarly have a long history of concern about ethical aspects of public health science and practice. In the United States, the Public Health Leadership Society published *Principles of the Ethical Practice of Public Health* in 2002 (see <http://www.phls.org/>). This document relates 12 ethical principles to the 10 essential public health services discussed elsewhere <http://www.phls.org/docs/PHLEthicsbrochure.pdf>.

Ethics Guidelines for Epidemiologists

Several ethical problems have preoccupied many epidemiologists,^{34,35} who have devoted much effort to defining the issues and formulating appropriate responses. Groups that have discussed or developed guidelines include the Society for Epidemiologic Research,³⁶ the Industrial Epidemiology Forum,³⁷ the Swedish Society of Public Health Research Workers,³⁸ the Australian Epidemiological Association, the International Epidemiological Association,³⁹ the International Society for Environmental Epidemiology,⁴⁰ and the American College of Epidemiology.⁴¹ Most epidemiologic studies, whether for public health surveillance or for research, involve human subjects (participants) and must therefore abide by the Helsinki Declaration and its revisions, respecting human dignity. Research and surveillance must not harm people,⁴² and informed consent is usually a *sine qua non*.

Ethics Review

A mandatory requirement for funding of all research involving human participants as subjects in research studies is that the research proposal must demonstrate on critical appraisal by expert reviewers that it complies with ethical requirements. In the United States, all research supported by public funds and almost all supported by private foundations or other sources must be reviewed by an Institutional Review Board (IRB). The same procedures exist in all the countries of the European Union and most, if not all, other countries in the developed world. IRBs in the United States and their equivalents elsewhere are made up of members from the scientific community, one or more experts on biomedical ethics, and lay members from community groups (frequently the members include a lawyer and a representative of one or more religious groups). Ethical review includes scrutiny of the scientific merits of a research proposal, because poor quality scientific research design is *ipso facto* unethical; but obviously the main thrust of the review is directed at examining whether the proposed research is ethically acceptable. The criteria for acceptability are rigorous, spelled out in detail in published manuals produced in the United States by the National Institutes of Health (<http://ohsr.od.nih.gov/guidelines/graybook.html> and <http://ohsr.od.nih.gov/guidelines/guidelines.html>), in Canada by the three principal national research-granting agencies (http://www.pre.ethics.gc.ca/english/pdf/TCPS%20June2003_E.pdf), in the United Kingdom by the Medical Research Council (<http://www.nature.com/cgi-taf/DynaPage.taf?file=/nature/journal/v352/n6338/full/352746b0.html&filetype=pdf>, <http://www.york.ac.uk/res/ref/kb.htm>, http://www.dh.gov.uk/PolicyAndGuidance/ResearchAndDevelopment/ResearchAndDevelopmentAZ/ResearchEthics/fs/en?CONTENT_ID=4094787&chk=5GkN4Q, and <http://www.corec.org.uk/>), and in other nations by agencies of comparable stature. The Council for International Organizations of the Medical Sciences (CIOMS) has produced an over-arching series of internationally approved guidelines for ethical review of biomedical research, including research in all public health sciences involving the participation of human subjects, as well as similar ethical guidelines for research with animal subjects (http://www.cioms.ch/frame_guidelines_nov_2002.htm).

The features of research proposals assessed in ethical review, in addition to scientific merit, include evidence of compliance with requirements for informed consent, absence of conflicting interests,

TABLE 3-1. REQUIRED ELEMENTS IN AN INFORMED CONSENT FORM

- A statement that the study involves research.
- An explanation of the purposes of the research.
- An explanation of the expected frequency, type of activities or procedures, and duration involved in the subject's participation. A description of the procedures to be followed.
- Identification of any procedures which are experimental.
- A description of any foreseeable risks or discomforts to the subject.
- A description of any benefits to the subject or to others, which may reasonably be expected.
- A statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained.
- For research involving more than minimal risk, and explanation as to whether any compensation and/or medical treatments are available if injury occurs and, if so, what they consist of, or where further information may be obtained.
- An explanation of whom to contact for answers to questions about the research and subjects' rights, and whom to contact in the event of a research-related injury.
- A statement that participation is voluntary, refusal to participate will involve no penalty, and the subject may discontinue participation at any time.
- Consent form is written in uncomplicated language appropriate to the subject population's level of comprehension.
- A statement regarding any financial interests the researchers may have in the particular study or research program.
- Note: Additional consent requirements may apply for research involving certain populations (i.e., assent forms may be required for minor subjects, translated consent forms are required for subjects who speak a different language).

sensitivity to cultural variations, minority rights, provision for interaction with research participants (i.e., subjects) while the study is in progress and feedback of the research findings on its completion, and various other requirements listed in Table 3-1.

Ethical review is a mandatory prerequisite and is generally well received by research workers, although there are sometimes complaints about excessive bureaucratization of the process, for example, with requirements for the research workers to reproduce at their own expense multiple copies of all relevant documents for all members of the IRB or its equivalent. Occasionally, the process takes on an adversarial quality, which is regrettable, and may in itself be unethical. Some privately funded research, including some studies undertaken by pharmaceutical and industrial corporations and some clinical trials of alleged innovative therapeutic regimens, evades ethical or indeed scientific review. Studies with such absence of official approval may have dubious scientific merit and may depart in various ways from acceptable ethical standards, and they should therefore be viewed with suspicion. The World Association of Medical Editors has proposed sanctions against publication of findings from such work in the mainstream scientific media. Information and discussion of this are available at <http://www.wame.org>.

Impartiality and Advocacy

Epidemiology, like all sciences, strives for objectivity, so it ought to be impartial. Often, however, epidemiologic findings reveal dangers to health that require activist campaigns aimed at changing the *status quo*, sometimes in direct opposition to established custom and social, economic, commercial, industrial, political interests and institutions. The discovery that smoking causes lung cancer is a good example that now has, after some 50 years of disinformation, been brought to a close: the epidemiologists who identified this massive public health problem became advocates for better health and opponents of the tobacco industry, and of the many institutions of society that encouraged

the use of tobacco. Advocacy and scientific objectivity are uneasy bedfellows; and epidemiology is not "value-neutral." In many situations, since the early days of the controversy about the connection between smoking and lung cancer (long ago resolved and no longer a controversy) public health workers in general, and epidemiologists in particular, have had to wrestle with the problem of reconciling impartiality with advocacy of measures to enhance health. Despite this, epidemiologists for hire have promoted the interests of the tobacco companies.⁴³⁻⁴⁶ These mercenary colleagues have helped to perpetuate an epidemic of tobacco-related premature death and morbidity worldwide for five decades.⁴⁷ This conduct persists not only in relation to tobacco, but in relation to other environmental toxicants.⁴⁸

Standards of scientific rigor in biomedical research have risen considerably in recent years, but episodes of gross violations occasionally come to light. One form of flawed research is sometimes on the indistinct boundary between sloppy, careless science on the one hand, and, on the other hand, outright fraud that can occur when data are altered after the fact, or when some observations in a series are discarded. Serious violations of research ethics range all the way from sloppy research protocols to misrepresentation and gross scientific fraud. There has been enough concern about serious violations to prompt the Institute of Medicine of the National Academy of Science⁴⁹ to issue guidelines that include a requirement, increasingly often mandatory, for rigorous observance of protocols, maintenance and preservation of research log-books, and other measures aimed at deterring such unethical conduct and facilitating its detection when it occurs. Integrity in science requires us to condemn plagiarism, fabrication, and the falsification of data. In the late 1980s, the United States Public Health Service established an Office of Scientific Integrity (OSI). The name subsequently changed to the Office of Research Integrity (ORI), which promotes integrity in biomedical and behavioral research supported by the U.S. Public Health Service at about 4000 institutions worldwide. ORI monitors institutional investigations of research misconduct and facilitates the responsible conduct of research through educational, preventive, and regulatory activities. Any person applying for funding-support from the U.S. Government to conduct research must be attached to an organization that has in place mechanisms for addressing even allegations of scientific misconduct.^{50,51}

Conflicts of Interests

Conflicts of interests have worried several professional associations in the United States and other countries. Concern has arisen because of some high-profile episodes. For example, research that had been completed and submitted for publication has been "leaked" to an industrial corporation or pharmaceutical company, which has then hired its own scientists, paying a fee to encourage criticism aimed at discrediting the work even before it is published. In several instances, pressure was applied with the aim of preventing publication of results that might have proved to be damaging to commercial interests. It is not known how often research on aspects of the public health has been "censored," that is, withheld altogether from publication, because of intimidation, bribery, or more subtle pressure; nor is it known whether similar situations have arisen in other fields of science. This and related problems have preoccupied biomedical science editors⁵² and are frequent topics of discussion and debate on the Listserv of the World Association of Medical Editors, which has published edited transcripts of some of these discussions on its website (<http://www.wame.org>). Problems attributable to interference with free publication of research findings are much more widespread and more serious than the high-profile crimes of scientific fraud and plagiarism and require wider public disclosure than they usually receive.

Population Screening

Screening is the application of diagnostic tests or procedures to apparently healthy people with the aim of sorting them into those who may have a condition that would benefit from early intervention, and those

who do not have the condition. An ideal screening test would sort people into two groups, those who definitely have and those who definitely do not have the condition. In our imperfect world, screening tests sometimes yield false positive or false negative results. A false positive test exposes individuals to the costs and risks of further investigation and perhaps unnecessary treatment, and imposes economic burdens on the health-care system that would better be avoided. A false negative screening test result could have disastrous consequences if persons suffering from early cancer are incorrectly reassured that there is nothing wrong with them. An important use for epidemiology is the calculation of false positive and false negative rates, and the predictive value of screening tests; these calculations must be borne in mind when deciding whether it is ethical to apply a particular test as a population screening procedure. For example, if a condition has a prevalence of less than 1 in 1000, the test costs \$3 per person and the predictive value of a positive test is less than 80%, we could question whether the use of resources for the screening test is ethically as well as economically acceptable.

Moreover, screening for evidence of inapparent disease is an explicit action by specialists in preventive medicine aimed at intervening in ways that can change the lives of people who previously thought themselves to be well. Such persons can react in several ways to the knowledge that they have a disease or condition requiring treatment; they may assume a “sick role”—develop symptoms, lose time from work, become unduly worried about themselves.⁵³ Some people who previously considered themselves to be healthy may perceive as gratuitous or paternalist the intervention of the well-meaning specialist who found something wrong—especially if the intervention makes them feel worse, as treatment for hypertension may do. Questions of medical etiquette as well as ethics can arise. Screening programs are often conducted by staff in public health rather than personal health-care services. It is essential for public health workers to communicate results to personal physicians responsible for the care of individuals with positive tests. At the very least, a positive test result can arouse anxiety (though it can also allay anxiety); it often leads to inconvenience, expense, sometimes to discomfort, distress. A false positive test result can lead to needless anxiety and expense. Counseling must be carefully planned and built into all screening programs to minimize anxiety. This is an ethical imperative.

More complex questions and moral ambiguities arise in genetic screening and counseling. For instance, among others, genetic screening for Huntington’s disease, Tay-Sachs disease, and Duchenne’s muscular dystrophy is feasible.⁵⁴ In Huntington’s disease, a positive screening test result has appalling implications for the person concerned, though early experience with volunteers from high-risk families has suggested that many prefer to know than not to know their status (<http://www.dartmouth.edu/~cbbc/courses/bio4/bio4-1997/LindseySternberg.html>). If Tay-Sachs disease, Duchenne’s muscular dystrophy, or other genetic defects, including cystic fibrosis, are detected on screening early in pregnancy, termination is regarded by many authorities as the most humane action.^{55,56} (<http://www.biomedcentral.com/1472-6939/2/3>)

► HEALTH EDUCATION/HEALTH PROMOTION

Public health workers regard health education with enthusiasm: what could be more beneficent than providing information about risks to health and actions that could be taken to reduce these risks? Such actions encourage all to take greater responsibility for their own health. Often laws or regulations act synergistically with such forms of health education as advice about immunizations and admonitions against tobacco addiction. But other issues arise when health educators, with or without the help of laws or regulations, seek to control addiction to tobacco or alcohol use. Some civil libertarians hold that everyone has a right to use alcohol or tobacco. This may be true, so long as their use does not harm others, such as children of smoking parents or road users who may be killed or maimed by impaired drivers—which unhappily is all too often the case.

At the other extreme are those who would prohibit alcohol use altogether and would indict smoking parents or pregnant women for child abuse. Economic interests and the well-being of communities dependent upon the alcohol and tobacco industries, it is argued, also have to be taken into account in deciding how to deal with the public health problems associated with tobacco and alcohol use. These are complex economic and political as well as ethical questions. No cash crop is as lucrative as tobacco, and in many parts of the developing world as well as in the United States, tobacco has replaced food crops. Worse, in Africa, trees are being depleted to provide fuel for flue-cured tobacco, contributing to the advance of deserts.⁵⁷ These facts, as well as the annual world-wide toll of tobacco-related premature deaths, provide strong support for the argument that the economic well-being of tobacco-producing communities is best safeguarded by converting to food crops as rapidly as possible. The ethical principles here are beneficence and justice—and the battle against maleficence.

When to bring public attention to new scientific evidence poses ethical questions for scientists in public health. Prematurely alarming the public with consequent harms (such as fear, decline in property values, and the like) has to be weighed against respect for autonomy. At what point is it appropriate to disclose scientific findings and with what degree of confidence? These are challenging problems, best dealt with by open discussion among experts on a case-by-case basis. It is impossible to formulate a general rule to cover all situations. Sometimes, courageous individuals in government or industry disclose evidence of actual or potential harm even at the risk of harsh disciplinary action by their employers. They are the whistle-blowers, and in most countries, including the United States, they are vulnerable despite legislation that might protect them from wrongful dismissal. The ethical or moral problem here applies to their employers and elected officials who allow them to suffer when in a just world they would be rewarded for drawing attention to the risks or harms to the public that they have disclosed.

Occupational Health

Specialists in occupational health deal with several constituencies, among which there is sometimes an adversarial relationship: management and shareholders, workers, government regulatory agencies, public interest groups. It is essential to deal impartially with all. Although often paid by industry, physicians who provide occupational health services have an obligation to preserve the confidentiality of individual workers, revealing only facts that are essential for management to know about workers’ health, and then only after obtaining informed consent to release such facts. They have an equal obligation to inform workers of hazards to which they may be exposed in the course of their work—an obligation reinforced by “right-to-know” legislation. The American Occupational Medical Association in 1976 published a Code of Conduct⁵⁸ covering these and other aspects of behavior in relation to workers’ health. The International Labour Office has also addressed codes⁵⁹ in its fourth edition of the *Encyclopaedia of Occupational Health and Safety*.

Population Policies and Family Planning Programs

All nations have population policies, sometimes explicit, more often implicit. These policies range from encouragement of couples to have or refrain from having children, commonly with related laws or regulations on access to and use of contraceptives, to vaguely visualized policies implied by the appearance in popular newspapers and women’s magazines of articles on birth control that contain statements about methods and their efficacy. Most western nations provide government funds for support of family planning clinics that are accessible without charge to women with low or no income.

There are considerable international variations, however, in the constraints on access to such clinics by girls near the age of puberty who are or may soon become sexually active. There are also great variations in the nature and extent of sex education, especially education about contraception, and in access to effective contraceptive

methods. Predictably, these variations are associated with corresponding international variations in pregnancy rates.⁶⁰

Some nations, notably the two most populous, India and China, and one of the most crowded, Singapore, have provided strong economic incentives or even introduced coercive measures (disincentives), such as enforced sterilization or abortion, aimed at restricting the perceived alarming rate of population growth. Other nations have adopted pronatalist policies when their leaders have perceived a threat of being overwhelmed by extraneous population groups.

In all nations that have government-supported family planning programs, public health workers are directly involved in day-to-day management and have the task of implementing government policies. Even if these policies are implicit rather than explicit, their general direction is usually clear. In a free society, however, public health workers have an obligation to consider each patient or client as an individual with her own unique life situation, problems, and requests, not just another case to whom the policies being promoted officially at the time must necessarily apply. The aspirations of women and couples to have or refrain from having children are powerful and very personal. Staff members of family planning clinics have an obligation to offer advice and treatment, and an equally important obligation not to enforce their own or official views on individual clients.

► EQUITY AND JUSTICE IN RESOURCE ALLOCATION

Public health is inherently concerned with the fourth of the four principles: justice. The fair and equitable distribution of scarce resources to protect, preserve, and restore health is the domain of public health. Public health workers, therefore, frequently become advocates for health-care systems that provide access to needed services without economic or other barriers. Historically, public health workers have often provided the impetus to establish some sort of social security system with unimpeded access to health care for all members of society, regardless of income, with access based only on need. In almost every nation that has social security, public health workers are prominent among the organizers and administrators. Moreover, if health services are offered to population groups that do not attract fee-for-service practice, these are often run by staff from the public health services. When analysis of health statistics reveals regions or districts and population groups that have unmet needs, public health workers often take the initiative to meet these needs.

The principle of justice (i.e., equity) goes further. The allocation of funds for health care is often based on political or emotional grounds, and on the ability of eloquent and aggressive advocates for glamorous high-technology diagnostic and therapeutic services to promote these interests. Funds sometimes are allocated for expensive equipment and devices, perhaps on dubious grounds, while badly needed public health services such as water purification plants in need of renovation, or logistic support for immunization programs, go without funds. It is an ethical imperative for public health workers to be as aggressive as circumstances require, in obtaining an equitable share of resources and funds for public health services. Public health is analogous to trench warfare; constant vigilance is needed in a world of competing interests and where the glamor of prevention lives in the shadow of high technology health care.

► INTERNATIONAL HEALTH

International health is concerned with the interlocking and interdependent relationships among all the people and nations on Earth.

For many years, the rich nations have provided support for health care, public health, and medical research in the poorer nations. Until recently, no one questioned this; it was regarded as mutually beneficial. There has been concern about the “brain drain”—the hemorrhage of talent from poorer nations that send their best and brightest young people abroad for advanced training, and lose them permanently to the rich nations. This has been regarded as a necessary price

to pay for development assistance. Now, other difficulties are perceived. Questions have been raised about the appropriateness of technology transfer from rich to poor countries, about the use by research workers from rich countries of the large populations and the challenging unsolved health problems, with the aim of addressing priorities as perceived in rich countries, but without regard for perceived problems and priorities in the poorer nations. This has been described as “ethical imperialism.”⁶¹

Other problems are associated with the disparity between rich and poor nations. These include the export from rich to poor nations of problems attributable to affluence and industrial development—tobacco addiction, traffic injury, exploitation of workers (often women and children who work for starvation wages), and environmental pollution including hazardous wastes.⁶²

Other problems arise in connection with the differing values and behaviors that prevail in some developing nations. The status of women may be very different from that of western industrial nations, customs such as female circumcision, child marriage, infanticide may be found. Sometimes developing nations are ruled by a repressive military dictatorship without regard for equity in health care. International health workers who encounter such phenomena are in a difficult situation. To speak out against customs that they deplore, or against the actions of repressive rulers, is unlikely to help the people of the country, and may expose the health worker to the risk of being deported, or worse, arrested, tortured, imprisoned. Yet it is morally repugnant to remain silent. One option is to engage in dialogue with local people with a view to culturally sensitive education that may result in social change in the future.

International health workers should be able to speak out more forcefully against the health-harming exported practices of the industrial nations, such as the promotion of infant formula in societies that lack facilities to sterilize infant feeds, the dumping of drugs that have not been approved for use in industrial nations, the advertising of tobacco.

► PATERNALISM AND PUBLIC HEALTH

Benevolence is an integral principle for ethical public health practice. We believe in doing good, and historically we have an impressive record—the sanitary revolution, the control of almost all major communicable diseases, the elimination of many such diseases from large areas they formerly dominated, and the worldwide eradication of smallpox. The new challenges presented by the “second epidemiologic revolution”⁶³—coronary heart disease, many cancers, traffic injury, and the like, as the main causes of premature death and chronic disability—have led us to respond by aiming to change human behavior. Many of the behaviors we seek to change are perceived as being pleasurable to those who practice them, and our efforts to initiate change are resented. If we wish to promote better health, we should be sure that our exhortations and admonitions are based on solid evidence of efficacy. There is a long tradition of advocacy by public health workers, but in the past this may have been as often associated with preaching as with teaching. In this respect, the aim of public health services ought to be to enlighten the people about risks to health, and to assist people in gaining greater control over environmental, social, and other conditions that influence their own health. We have an obligation to work with people, empowering them, doing whatever may be necessary to promote better health—in short, doing things with, not to, people. This is the main thrust of the Ottawa Charter for Health Promotion.⁶⁴

Is There a “Right to Health”?

The Universal Declaration of Human Rights (1948) (<http://www.un.org/Overview/rights.html>) does proclaim that health is a human right, but how to implement related articles in the Declaration across countries, where so many of the 30 human rights articles are not applied, remains a challenge. Social activists have proclaimed the

concept of health as a fundamental human right, but here are some of the problems associated with this view. If there is a right to health, there must also be a duty to provide this right; whose duty is it?

The answer may be that it is the duty of the individual whose health is the “right” in question—but this leads to the idea of blaming the victim when health is impaired. A further difficulty arises when we try to define what is meant by “health.” There is often confusion between concepts of health and concepts of quality of life. Nobody would describe the theoretical physicist Stephen Hawking as healthy; he has been slowly dying of amyotrophic lateral sclerosis for many years, but they have been immensely productive years, and judging from his own testimony,⁶⁵ they have been happy years. There are many other examples of severely disabled people whose lives have been happy and productive—just as there are examples of perfectly “healthy” people who lead miserable lives. Probably it is wise for public health workers to avoid being drawn into discussions of the supposed “right to health.”

Methods in Ethics

How should we deal with the dilemmas and ethical ambiguities that arise in public health practice and research? Essentially, the answer is the same in public health as in clinical practice. Several monographs provide some guidance.^{1,66,67} Enough has been said to make clear the fact that often there is no easy answer. At times, we must choose with the certain knowledge that not all parties will be satisfied with the decisions that we must make. These decisions can be extremely difficult. An orderly, systematic approach is helpful.

First, we should apply the generic problem-solving model: clearly identify the problems that we are confronting. Next, we should identify the available options and decide whose problems we are dealing with—particular persons, communities, health-care workers, organizations, institutions, and so on. We must gather all the available information and evaluate it carefully, trying as far as possible to set priorities among the options that have to be considered. We must also consider the consequences of the decisions that have to be taken, relating these to the values, beliefs, and community standards that prevail. Having done all these, we must choose among the options, and act. Finally, we must evaluate or review the consequences, often on an ongoing basis—remembering that often there is no “right answer,” but a series of alternative approaches each of which is both satisfactory and unsatisfactory. One of the most difficult aspects of biomedical ethics to comprehend is the fact that the more securely we may think we can grasp the philosophical principles, the harder it may become to arrive at a satisfactory answer to the problem. However, by recognizing the context within which one is operating, an understanding of the underlying social values will often provide insight into why certain paths have been pursued in preference to others. Working with moral philosophers can help to explicate current paradigms and identify alternatives to promote community health and well-being. A practical application of this approach can be found in Soskolne.⁶⁸

The Philosophical Basis for Public Health

All public health workers should ask themselves “Why am I doing this?” The aims of public health are to promote and preserve good health, to restore health, and to relieve suffering and distress. We often judge our success by reduction of infant mortality rates and increases in life expectancy, but seldom attempt to measure, let alone record and analyze data on relief of suffering and distress, such as may be associated with chronic unemployment or homelessness. Clinicians responsible for intensive care services and for the care of elderly infirm patients have been obliged to consider carefully the question of “quality of life” now that life-prolonging measures are so widely used. There is growing concern about the “quality of death” as well as with the quality of life.⁶⁹ In public health practice, we may require a similar reorienting of focus so that we consider more consciously than hitherto some less tangible measures of outcome than

infant mortality rates and life expectancy. Included in this is the need for us to consider carefully the impact of “improved” human reproductive performance on all the other living creatures with which we share planet earth.⁷⁰

This may be especially desirable in developing nations, where spectacular gains in infant mortality have been achieved, thanks to the expanded program on immunization, oral rehydration therapy, growth monitoring, and the like. Innumerable infants and small children who would have died just a few years ago are being kept alive. What will become of them? Will they starve now, because there are so many more mouths to feed? Will they receive an education? Will they have a lifetime of meaningful work? Will they die eventually, rich in years and experience, surrounded by a loving family? The answers to these difficult questions will depend upon our response to challenges more subtle than the reduction of infant and child mortality rates. The goals of the programs that are part of the strategy of “Health for All by the Year 2000,” or the Millennium Development Goals (MDGs) for 2015 (http://www.developmentgoals.org/Achieving_the_Goals.htm) refer in places to the quality of life, but the supporting documents are vague about how to influence this. The search for ways to enhance quality of life has high priority among the aims of public health in the new century. In the MDGs, 48 new indicators are identified to help in their attainment.

Ethics and morality are based upon the most fundamental values of our culture, deriving from many centuries of tradition. We can trace beliefs that have descended from biblical lore and from the ancient Greek philosophers, reinforced by ideas from the great monotheistic religions, Judaism, Christianity, and Islam. We can trace the influence of rapidly advancing knowledge and changing values in our time. Some of our beliefs are enshrined in codes of conduct, others are ill-defined but firmly held—and vary among subsets of the population according to complex traditions handed down from one generation to the next.

This review gives some idea of the range and complexity of the ethical issues and moral challenges that arise in public health practice and research. It does not address the nature of the relationship between person-oriented and population-oriented ethics. These are intermingled in a complex pattern, and often reflect some dissonance in our value system. We spare no effort or expense in striving to prolong lives of infants with incurable liver disease, by finding donors for liver transplants; we maintain indefinitely on life-support systems some patients who are in a persistent vegetative state from which they cannot recover. Yet we do little to prevent many diseases that far more commonly take the lives or destroy the joy of life for vastly larger numbers of people, such as infants who are the victims of fetal alcohol syndrome and young adults who are permanently brain-damaged by injuries sustained in traffic collisions. We spend enormous amounts and invest great emotional effort in heroic interventions for advanced coronary heart disease, but spend relatively little on measures that might reduce the magnitude of this public health problem.

Such actions raise philosophical questions about the meaning of our culture, questions similar in nature to those raised by thoughtful critics of the arms race who wonder whether our huge investments in weapons to preserve our freedom are enslaving us in fear and paranoia, and critics of our environmental development policies that rely on exploitation rather than on learning to live an interdependent existence with all the other living creatures on our planet. The challenges for the health of future generations in a world of depleting ecological capital and ever growing scarce resources will be legion. The Millennium Ecosystem Assessment released in March 2005 (<http://www.maweb.org/en/index.aspx> and <http://www.millenniumassessment.org/en/index.aspx>) should encourage us to recognize that in addition to the traditional four principles of bioethics, there should be the following:⁷¹

- Protect the most vulnerable in society, including the unborn, children, indigenous peoples, disadvantaged minorities, marginalized communities, and the frail elderly

- Involve communities in our research, ensuring the community relevance of our work
- Ensure integrity in public health by serving the public health interest above any other interest
- Embrace the precautionary principle as an approach to more effectively protect the public health

Educating and Socializing Students in Public Health

The need to sensitize students in the various disciplines of public health to questions of ethics and integrity in this field of research and practice is apparent from the foregoing. Indeed, since about 2000, curricula in public health training programs have begun to insist on at least some amount of training in ethics and integrity in public health sciences.^{72,73} Future ethical challenges in public health will be addressed only if success can be achieved in preparing new generations of researchers and practitioners to face them, remembering in all situations that our core value in public health is to work to protect the public interest over any other. Yet, only one text on case studies in public health ethics is known to have been published.⁷⁴

Since the mid-1990s, the U.S. National Institutes of Health, through its Office of Human Subject's Research, has required of all intramural researchers that some ethics training be demonstrated. Indeed, completion of a computer-based training course is an educational requirement for all researchers in NIH's Intramural Research Program, and other NIH employees who conduct or support research involving human subjects. This also is an educational requirement for members of NIH's 14 Institutional Review Boards. More information can be found at <http://ohsr.od.nih.gov/cbt/cbt.html>

For extramural researchers, a free Web-based course is available. It was developed at the National Institutes of Health for physicians, nurses, and other members of clinical research teams. This online course satisfies the NIH human subjects training requirement for extramural researchers obtaining Federal funds and is accessible at: <http://www.cancer.gov/clinicaltrials/learning/page3>. The two-hour tutorial is designed for those involved in conducting research involving human participants. People who take the course will have the option of printing a certificate of completion from their computers upon completing the course.

Further, in the United States, the Association of Schools of Public Health (ASPH) project, since 2003, has provided online training modules on a range of topics from a number of authors in a model curriculum. It is available at <http://www.asph.org/document.cfm?page=782>.

In Canada, the Interagency Advisory Panel on Research Ethics, in April 2004, launched its online "Introductory Tutorial" for the Tri-Council Policy Statement: "Ethical Conduct for Research Involving Humans" at <http://www.pre.ethics.gc.ca/english/policy/initiatives/tutorial.cfm>. These online training resources for the more responsible conduct of research involving people make such training all the more accessible. Evaluation of the effectiveness in achieving the goals of such training will be needed. The single greatest challenge, however, still remains in how to implement ethics in the professions.⁷⁵

Public Health and Population

Robert B. Wallace

Public health focuses on health issues in populations. Carrying out the mission of public health and achieving its goals, therefore, depend on the factors that change the size and characteristics of the population whose health is at stake.

The relationship between health and population dynamics, through the study of demography, guides the need for changes in public health practice. Changes in health influence vital events, including births, deaths, and divorce, in turn leading to population changes. Migration, the movement of people from place to place, is another demographic force that leads to new health issues and problems.

Four such issues illustrate the relationship between public health and population:

1. *Teenage pregnancy*: Teenage pregnancy is a serious public health issue. It creates preventable health problems for both infant and mother. Teenage pregnancies are often unintended. In addition, they may interfere with education, personal development, and socioeconomic advancement for the young mother and father, and therefore the infant. In addition, teenage pregnancies have an important demographic impact on future generations.
2. *Aging*: As the death rate declines in most parts of the world, life expectancy increases, and the number and ages of older people increase. Moreover, when low or declining fertility accompanies the decline in mortality, the proportion of older persons also increases and the median age of the population increases. The result for public health is that the spectrum of health problems and health-care needs become drastically different.
3. *Urbanization*: In 1950, fewer than 30% of the world's population lived in cities. After the year 2000, more than 40% are residing in an urban area.¹ Urbanization creates health problems related to the need for housing and sanitation, improved food supply, better urban transportation, and the redistribution of preventive and other health services.
4. *Refugees and other migrants*: An estimated 19 million refugees, persons "of concern" to the United Nations High Commissioner for Refugees, are dispersed throughout the world.² Refugees and other migrants may bring with them serious public health problems such as severe malnutrition and infections. In addition, their encampments may have unexpected levels of violence.

This chapter should enable a public health practitioner to carry out the following tasks:

Note: This chapter, revised and updated by the editor, was originally written by Carl W. Tyler, Jr. and Charles W. Warren for the 14th edition.

1. Identify useful sources of information about *population and vital statistics*
2. Calculate basic measures of population change
3. Identify determinants of population change
4. Understand four contemporary critical issues related to population change

► POPULATION DATA AND MEASUREMENTS

Data Sources

Population data are essential to defining and measuring public health problems and the groups of people in which they occur. Nonetheless, public health practitioners often find that, while the need for information of this kind is great, their knowledge of existing data sources prevents them from calculating the measurements required to evaluate public health problems. Census, regular national surveys, and vital registration statistics are the most fundamental sources of data about populations, and are reviewed below. However, there are a growing number of additional population resources available, including special surveys and censuses, privately or locally conducted population estimates, and a variety of indices that allow for local and regional population estimates.

Census

A census is an enumeration of a population that has these essential characteristics:

- Each individual is enumerated separately.
- The characteristics of each individual are recorded separately.
- Those enumerated reside in a precisely defined area.
- Enumeration takes place within a defined and reasonably brief period and in reference to a well-defined time period.
- Enumeration is repeated at regular intervals.³

In the United States, the census enumerates people first by mail and later by personal interviews of those not responding to mail inquiry. It covers the nation and its territories and makes data public for areas as small as groups of city blocks. (There are certain limits on the information provided in these tabulations because of the need to protect the privacy of individuals.) By law, the census is conducted every 10 years. Because of its importance to political representation, as specified in the Constitution, and public concern about use of data by governing bodies, as well as the inevitable missing data and need for statistical modeling and extrapolation, the census in the United States has been a source of controversy. Nonetheless, its importance to the health of the public is undiminished.

Population-Based Surveys

A survey differs from a census in that it is not an enumeration of individuals, and it need not include all members of the population. Nonetheless, most surveys characterize individuals separately rather than in groups, and the sample represents a precisely defined group of people from a specific area. The distinction between a census and a survey is not always sharply delineated. In some instances, a sample of those included in an enumeration must respond to more questions than the total population, and the sample is still considered part of the census. In other cases, data from a national census may be used to establish the sampling frame for surveys at a later time. The topics of these surveys cover such issues as health, fertility, the use of health services, employment, and education.

The Current Population Survey. A series of national population-based surveys, called the Current Population Survey, is conducted each month in the United States. Although this series focuses more on economic issues than others, its information describes important characteristics of the national population. Among them are such issues as family composition (including births and ages of children), mobility, school enrollment, marital status, living arrangements, work experience, and multiple job holdings.

Health Surveys. In the United States, the National Center for Health Statistics (NCHS) of the Centers for Disease Control and Prevention (CDC) conducts a series of surveys that are always in the field, collecting information on the health of American citizens. These include several surveys of health professionals and institutions, such as the National Master Facility Inventory; hospital and surgical care through national hospital discharge information; a sample of ambulatory and primary care activities, the National Ambulatory Medical Care Survey; and long-term care through the National Nursing Home Survey. In some instances, follow-up data on patient outcomes, through the Center for Medicare and Medicaid Services, is provided. In addition, NCHS provides data to health officials, their agencies, researchers, and the public through a series of ongoing population-based surveys. These include (a) the National Health Interview Survey (NHIS; reported annually and based on surveys that began in 1957); (b) the National Health and Nutrition Examination Survey (NHANES), now continuously in the field and assessing health status through more extensive questionnaires and biological examination and measurement, begun in 1960; and (c) the Hispanic Health and Nutrition Examination Survey (HHANES). Each survey measures a different aspect of health in the population of the nation. NHIS gathers information using interview responses. Plans have been formulated for surveys of follow-up and long-term care on a sample of individual, consenting respondents to these surveys. In addition, the National Survey of Family Growth (NSFG) gathers information on family formation, determinants of infant health, and health practices of women between and during pregnancies.⁴

Health behavior is the specific topic of two surveillance systems initiated by the National Center for Chronic Disease Prevention and Health Promotion (NCCDPHP) of CDC. The Behavioral Risk Factor Surveillance System (BRFSS) gathers information about cigarette smoking, seat belt use, cardiovascular risk factors, and alcohol use by people aged 18 years and older. The BRFSS began as a one-time survey of 28 states and the District of Columbia in 1981. Now it is a series of ongoing, random-digit-dialed telephone surveys done in an increasing number of states that began with 15 in 1984 and now includes all 50 states and all U.S. territories.⁵ The second system monitors health risks in youth and young adults who range in age from 12 to 21 years. Named the Youth Risk Behavior Surveillance System (YRBSS), this system gathers information about six categories of behavior as follows: (a) risk factors for injury, both intentional and unintentional; (b) tobacco use, including smoking and oral use; (c) alcohol and other drug use; (d) sexual behavior that is a risk for unintended pregnancy and the transmission of sexually transmitted infection; (e) diet; and (f) physical activity. This system samples

younger Americans in two settings: (a) high school students in the 9th through 12th grades and (b) people in households who are between 12 and 21 years of age.⁶ Internationally, with an emphasis on developing countries, data on births and fertility are available from the Population Council⁷ and the Population Reference Bureau.⁸ Many other data resources are available, particularly through the United Nations and through demography centers at universities, foundations, and national government population agencies worldwide.

Vital Data (Birth, Death, Marriage, and Divorce)

The registration of vital events, specifically births and deaths, provides important data for defining public health problems at almost every level of society, including cities, counties, states, nations, and the world. In the United States, vital registries are maintained at the national level by NCHS. At the state level, state health departments and state centers for health statistics perform this function. In some metropolitan areas, vital statistics are gathered and analyzed by the health departments for the immediate jurisdiction, for example, New York City. The registration of other events of health and social importance, specifically marriage and divorce, is also done at the national, state, and local levels.

Other Sources

Migration is an important determinant of population size and distribution. Census information is often available to study internal migration and evaluate its effects. Assessing international migration is, however, more complex. In the United States, annual reports from the Immigration and Naturalization Service provide the official information. For a wider range of countries, special studies by the United Nations and private organizations, such as those noted above, offer useful data. Unfortunately, the rules for movement across geographic boundaries, especially international borders, make the collection of reliable data much more difficult than that done by census, survey, or vital registration.

Some areas of the world, such as northern and eastern Europe, maintain national population registries based on unique individual identification numbers assigned to each person at birth. This type of registry offers opportunities to study problems that require knowledge of the demographic, social, and economic events experienced by individuals over their lifetimes.

Demographic Measures

The relation between health problems and the populations in which they occur requires assessment, if they are to be controlled and prevented.

Rates

A rate is a quotient in which time is an essential element and a distinct relationship exists between the numerator and denominator.

Crude Rates. A crude rate is one in which all of the events that occurred in a given time and population are in the numerator. The population of the area at the midpoint of that time period is the denominator. By convention, it also contains a constant multiplier of 1000. A death rate, for example, might have a numerator of 75 people who died during a given year and the denominator of the midyear population, 10,000, of the community in which they lived. In this instance, the death rate for the community in that year would be 7.5/1000 population. This rate is the crude death rate (CDR). If the same community had 150 births during the same year, the crude birth rate (CBR) would be 15.0/1000. The crude rate of natural increase (CRNI) is equal to the CBR minus the CDR; in this illustration the CRNI would be 7.5/1000, or 0.75%.

Standardized Rates. Comparing rates among different populations is often difficult if the demographic characteristics are not

known in detail. Comparing standardized rates more accurately reflects the mortality decline that the United States sustained over the twentieth century, the rates can be adjusted for different demographic characteristics of contrasted populations or the same population over time. Of course, it is essential to know how rates are standardized, so that the rates observed are the ones desired. Other references deal with standardization of vital rates in more detail.⁹

Period and Cohort Rates. A period rate is one in which the events of concern occur in the population being observed during a specified time interval. A cohort is a group of people who experience a major event in the same short, clearly defined time period, usually a year. The most common demographic cohorts are birth cohorts and marriage cohorts. Cohort rates measure events that occur (subsequent to the defining event) to a cohort of people over many periods of time. Population studies are often based on birth cohorts, as was done in the cohort analysis of fertility reported by the NCHS, where further information on U.S. cohort fertility rates is available.¹⁰ The analysis of fertility by marriage cohorts helps us to understand changes in fertility or family structure. Epidemiologists use cohort analysis to study groups according to their exposure to a specific agent hypothesized to cause, or prevent, a health problem. If the problem relates to occupational exposure, the cohort may be analyzed by date of employment. Frost's study of mortality caused by tuberculosis is a classic public health report using cohort analysis.¹¹

Fertility

The CBR, which uses all births in the numerator and the total population (regardless of gender or age) in the denominator, is the most fundamental fertility measure. The general fertility rate (GFR) also uses all births in the numerator. However, the denominator is women of childbearing age, most often defined as women 15–44 years of age. Some authorities prefer to use 49 years as the older age limit. The age-specific fertility rate (ASFR) is calculated using births to women in a specific age interval (usually 5 years, but sometimes single years of age) as the numerator and women in the same age interval in the denominator. Each of these measures is a period rate and is customarily multiplied by a constant of 1000.

The total fertility rate (TFR) is the sum of all of the ASFRs by single years of age. This measure characterizes a synthetic cohort of women of reproductive age. By using data for a short period, usually 1 year, it addresses the question, "If the women in this population continued to have children at the rate they did this year, how many would they have, on average, when they finished bearing their children?" If the sum of age-specific fertility rates totaled 3000 live births per 1000 women in a given year, each woman would average 3 children. This assumes that these rates continue unchanged for the remainder of her reproductive years. (The TFR may be expressed per 1000 women or per 1 woman.) The true cohort rate for fertility is referred to as the completed fertility rate. This measure is customarily based on surveys rather than vital data.

Mortality

The CDR, which uses all deaths in the numerator and the total midyear population in the denominator, is the most fundamental mortality rate. The age-specific death rate (ASDR) is calculated using deaths that occur among those in a specific age interval as the numerator. The population in the same age interval is the denominator. Each of these measures is a period rate and is customarily multiplied by a constant of 1000. Rates for specific causes of death add an important dimension to mortality analysis. Most often, the cause of death is based on vital registration and the International Classification of Diseases (ICD) coding system. Using this coding, deaths are classified by cause and are the numerator of the rate. The population, or an appropriate segment of the population, is the denominator. The rate is usually multiplied by a constant of 100,000.

Some special measures that are not true rates deserve mention. Among them are the infant mortality rate (IMR) and maternal

mortality rate (MMR). The IMR is the number of children who die before their first birthday in a year divided by the number of live births in that year. The MMR indicates the risk of death from causes associated with childbirth. Deaths during pregnancy, labor and delivery, or postpartum in a year make up the numerator, and live births in the same year are the denominator. These measurements have been defined succinctly elsewhere.¹²

A life table employs ASDRs converted to probabilities of death for each age interval. Life table data describe the mortality or survival of a person or a group over a lifetime. Life table analysis addresses the question, "What would be the mortality experience and life expectancy of a group of people who had these probabilities of death at each age for the rest of their lives?" Using ASDRs for a specific period (usually 1 year) permits a current, or period, life table to be calculated for a synthetic cohort. Using ASDRs over the lifetime of a group born in the same year, or interval (often 5 years), permits the construction of a real (rather than synthetic) cohort life table. Cohort life tables are more often referred to as generation, or longitudinal, life tables.⁹

Migration

The measurement of migration is conceptually similar to that for fertility and mortality. Defining terms requires that a distinction be made between internal migration (movement by in-migrants and out-migrants across borders that are within a nation's bounds) and international migration (movement across international boundaries by immigrants and emigrants). The crude in-migration rate has the number of in-migrants or immigrants who enter a specified geographic area during a stated time interval in the numerator. This is divided by a denominator that is the population of the area at the midpoint of that interval. Similarly, the crude out-migration rate is the measure in which the number of out-migrants or emigrants is divided by the population of the area at the midpoint of the time interval. The crude net migration rate is one in which the difference between the number of in-migrants or immigrants and out-migrants or emigrants is the numerator divided by the population of the area. All these rates are multiplied by a constant, usually 1000. Rates constructed using age, gender, and national origin are appropriate for analyzing migration. These rates analyze changes caused by the movement of people in the same way as measures of fertility and mortality analyze changes related to birth and death.

Population Growth

Population growth is a function of births, deaths, and migration. Growth measured by births and deaths alone is referred to as natural increase, it is measured by the CRNI (Change in Rate, Natural Increase), such that:

$$\text{CRNI} = \text{CRB} - \text{CDR}$$

The equation that includes changes in population size resulting from migration as well as fertility and mortality is called the *demographic equation*. It states that the difference in population from time 1 to time 2 is equal to the births minus the deaths in the interval, plus in-migration minus out-migration in the interval.

$$P_1 - P_2 = B - D + \text{IM} - \text{OM}$$

Often, data are lacking for the migration component of this equation, and population growth is expressed only in terms of births and deaths, that is, natural increase.

Population Composition

Population composition is defined in terms of the distribution of people by specific characteristics at a particular point in time. The most important characteristics are demographic, social, or economic. This information, most commonly based on census data, may show, for

Figure 4-1. Population pyramids for Sweden (*upper panel*) and Mexico (*lower panel*) by age and sex. Vertical axis: Age. (Source: U.S. Bureau of the Census.)

example, the number or the percentage of the population in each age-sex group. A graph called a *population pyramid* is a useful way to display these data. Figure 4-1 contrasts the age-sex composition of a country with low fertility and a long life expectancy (*upper panel, Sweden*) with that of one with high fertility and a shorter life expectancy (*lower panel, Mexico*), showing them as population pyramids, for the year 2000.

A brief summary of demographic measures appears in Table 4-1.

► **FERTILITY**

Fertility is important to public health, population change, and the quality of human life. The role it plays in determining the size, composition, and growth of populations is a powerful factor governing the course of population change. In addition, fertility change influences the health of women, their offspring, their families, and, therefore, public health practice.

Fertility, in its most specific sense, refers to the actual birth of living offspring. Natality is often used synonymously for fertility. Additionally, the capacity to bear children is termed fecundity, and

TABLE 4-1. BASIC FERTILITY AND MORTALITY MEASURES

Measurement	Numerator	Denominator	Constant*
CBR	All births	Total population	1,000
GFR	All births	Women aged 15–44	1,000
ASFR	Birth in age group	Women in age group	1,000
CDR	All deaths	Total population	1,000
ASDR	Death in age group	Population in age group	100,000
IMR	Infant deaths in year	All births in same year	1,000
MMR	Maternal deaths in year	All births in same year	10,000 or 100,000

Abbreviations: CBR, crude birth rate; GFR, general fertility rate; ASFR, age-specific fertility rate; CDR, crude death rate; ASDR, age-specific death rate; IMR, infant mortality rate; MMR, maternal mortality rate.
 *The constants shown in this column are those used most often. Others may be used in special demographic or public health reports.

the probability of conceiving in a given month is called fecundability. Natural fertility describes the level of fertility found in populations that use neither contraception (temporary or permanent) nor induced abortion.

The determinants of fertility in a population are both biological and behavioral. They can be aggregated into a structure that permits a quantitative appraisal of the factors influencing fertility change in a population.

Biological Determinants

Menarche and Menopause

Menarche is the beginning of menstruation. It defines the youngest end of the age limit within which women begin to ovulate and are able to conceive. The age of menarche is becoming younger in developed countries. Menopause is the cessation of menstruation. It signals the end of the reproductive years. The age for menopause has increased slightly in recent decades in developed countries. Some societies have experienced a widened span of reproductive years that is caused by a decline in the age at menarche and an increase in the age of menopause. Since these are modernized societies that control fertility with contraception, abortion, and sterilization, changes in the age of menarche or of menopause are not important determinants of present-day fertility.

Ovulation

In demographic terms, ovulation influences fertility most by influencing waiting time until conception, or ovulatory interval. This interval is greatest at the extremes of the reproductive years, either when regular ovulation is not established or when it is waning. While this aspect of ovulation is not a consequential determinant of current fertility levels, the delay in ovulation after childbirth is. The length of postpartum anovulation may vary from 1.5 months to as long as 2 years depending on the frequency and duration of lactation.¹³

Age within Reproductive Span

Once intercourse is an established practice, natural fertility declines with age. Data from several societies with differing fertility levels confirm this observation. This is observed in populations with both high and low fertility rates.¹⁴

Spontaneous Intrauterine Mortality

The influence on fertility of spontaneous abortions, or miscarriages and stillbirths is difficult to assess because of the problems in ascertaining these events in a representative population. Nonetheless, current evidence indicates that the risk of spontaneous pregnancy loss is greatest early in pregnancy and declines steadily throughout. It is probably greatest among women in their later childbearing years. Since the evidence suggests little variation from community to community in this biological factor, it is not likely to be a major determinant of differing levels of fertility.

Involuntary Infertility

Involuntary infertility is also called sterility or infecundity. It is measured, in demographic terms, as the inability of a woman to bear a living child during the span of reproductive years. (Although involuntary infertility in males is a serious health concern, it does not influence fertility in a population.) Involuntary infertility in women has several causes. It may result from anatomical abnormalities of the reproductive tract or malfunction of ovulation. When ovaries malfunction, conception does not occur. Recurrent intrauterine loss of pregnancy, or specific diseases associated with infertility, such as gonorrhea and genital tuberculosis, also cause involuntary female infertility.¹⁵ The first three categories are presumed to occur to a similar extent in all populations, although the evidence for this is not entirely satisfactory. The last group, that is, specific diseases such as gonorrhea and tuberculosis, is presumed to account for the occurrence

of a high proportion of childlessness. This is especially true among groups in developing countries where fertility is otherwise quite high.¹⁶

Behavioral Determinants^{14,17}

Marriage or Sexual Union

Age at first marriage or consensual union is a principal determinant of the number of children a woman will bear. It marks the beginning of socially approved exposure to the probability of conception. The association between increase in the age at marriage and concurrent decline in fertility has been shown in several societies.

Frequency of Intercourse

Frequency of sexual intercourse is directly related to the capacity to bear children, assuming that the menstrual cycle is ovulatory and insemination occurs in mid cycle. Nonetheless, there are very few studies of the frequency of intercourse (not including abstinence) and probability of ovulation in a specific cycle. Therefore, evidence is insufficient to suggest that these factors account for differences in fertility levels from one population to another.

Abstinence, whether voluntary or involuntary, is an important determinant of fertility. In some cultures, abstinence is required during lactation. In others, lactation and religious beliefs are related, influencing the role an individual or group plays within a religion. In economic circumstances that require couples to separate because of employment, abstinence may result because of a work situation.

Contraception

Contraceptive use is one of the principal determinants of fertility. The prevalence of contraceptive use varies widely among nations, ranging from approximately 10% to more than 75%. Modern contraception is highly effective and safe. The variation in patterns of use by method among different countries is substantial. Surveys of China, for example, report a high prevalence of intrauterine device (IUD) use, while oral contraceptives are widely used in the United States and condoms play a particularly important role in Japan.¹⁸

Voluntary Sterilization

Voluntary surgical sterilization is an important determinant of fertility because it limits the span of years during which reproduction is possible. This approach to fertility regulation is highly effective and safe. Although some studies treat this method of fertility control as if it were a method of contraception, the fact that this method requires surgery makes it more appropriate to identify sterilization separately for health practitioners.

Induced Abortion

Induced abortion is one of the principal determinants of human fertility. In some countries abortion is legally prohibited, but often takes place, even if rarely acknowledged. Rates of induced abortion in developing countries are also affected by international funding availability, which has many political dimensions.¹⁹ Elsewhere abortion is permitted virtually on request, and women may experience on average between two and three during the reproductive years.²⁰

Breast-Feeding

Breast-feeding is an important determinant of fertility. Lactation, stimulated by a nursing infant, influences the duration of anovulation after childbirth. In the United States and other developed countries, the practice of breast-feeding has little influence on the level of fertility. However, in less developed areas, groups are found in which infants are breast-fed very frequently. Some infants are fed on demand because these nurslings have almost no other source of nutrition. Although the mothers of these babies use no other form of fertility control, they have fertility levels nearly the same as developed countries.

Table 4-2 lists the determinants of fertility.¹⁴

TABLE 4-2. DETERMINANTS OF FERTILITY**■ Biological**

Menarche
Menopause
Ovulation
Postpartum anovulation
Age within reproductive span
Intrauterine mortality
Involuntary infertility

■ Behavioral

Age at marriage or first union
Frequency of intercourse
Contraception
Voluntary sterilization
Induced abortion
Breast-feeding

► MORTALITY

Public health traditionally focuses on preventing death. Measures of mortality describe both the likelihood of dying in any specific time interval and the expectation of survival.

Determinants

The factors that determine differences and changes in the levels of mortality among populations are biological or behavioral.

Age

Age is a principal determinant of mortality. Starting at a high level in infancy, mortality declines precipitously in childhood, remains at a low level through adolescence and early adulthood, and then increases inexorably in adulthood and older ages. This pattern holds true for both males and females in both developed and developing countries.

Sex

In the modern era, perhaps even from conception, males have a higher risk of mortality than females in developed countries and most developing countries. For this reason, published life tables separate computations for each sex. Exceptions to this point exist under special circumstances, for example, in societies that may value the survival of male offspring over females, and situations of low levels of economic development, where childbearing increases the risk of mortality for women of reproductive age. Specific causes of death, as illustrated by breast cancer, may also carry greater risk for women than they do for men. Nonetheless, when all causes of death are considered together, the risk of mortality is less, the likelihood of survival is greater, and life expectancy is longer for females than for males.

Race/Ethnicity

Different racial and ethnic characteristics within a population are often associated with differences in mortality. These differences are recognized in population data from major regions of the world including Asia, Africa, and North America, and in large part are considered to be the result of social and economic differences between racial or ethnic groups in a population. In the United States, differences in the mortality for blacks and whites are sufficiently important that official life tables are published for all causes of death by race, as well as by sex, and official public health policy focuses on approaches to resolve these differences.

Region/Area

Mortality may differ by geographic region both within and across national boundaries. This can be most readily recognized by reviewing

United Nations publications, especially the World Mortality Report.²¹ Life tables that estimate mortality in areas where population data are incomplete reflect this fact by having four sets of models based on regional differences in the risk of death.²² In the United States, data published by region or state show differences in key parameters of mortality such as life expectancy. The reasons for these differences are presumably related to social, economic, and health service factors.

Cause of Death

Although the specific cause of death is important to each individual and often to a specific public health program, population changes are determined by the spectrum of disease causes prevalent in a community and whether the means are available to control such causes. Diarrheal diseases, for example, are an important cause of mortality in developing countries, while cardiovascular disease deaths are more prevalent in modernized nations. One important development is the global occurrence of human immunodeficiency virus (HIV) and other emerging infections. These viral infections are transmitted by a variety of mechanisms, such as sexual contact, blood products, and needles contaminated with blood from infected individuals. (The current status of this global epidemic is dealt with in detail in a separate chapter.) Patterns of causes of death and their influence on population change are discussed in more detail in the section, Determinants of Population Group: The Epidemiologic Transition.

Social and Economic Conditions

Economic development, measured by per capita national income and other indicators of economic advancement, is related to the increase in life expectancy in most parts of the world; moreover, this one factor explains an important part of the difference in life expectancy among countries.²³ The mortality decline of the nineteenth century has been ascribed to improvements in living standard, diet, sanitation, and improved working conditions.²⁴ However, in the future, this trend, which continued in the twentieth century, may be regionally mitigated by war, insurrection, and disease pandemics.

Public Health

Public health measures have played a leading role in reducing mortality through preventing the transmission of infection. Even before the discovery of specific microorganisms, epidemiologists identified the ways in which diseases, such as childbed fever and cholera, were transmitted and promoted measures for prevention. In recent decades, immunization has led to the worldwide eradication of smallpox²⁵ and brought about a substantial decline in measles in the United States.²⁶ Studies of tobacco use and its attendant health problems have led to a reduction in cigarette smoking.²⁷ Screening for cervical cancer has, in all likelihood, presumably led to a decline in mortality caused by this condition.²⁸ More recent improvements in mortality, the likely result of collective individual modifications in lifestyle, such as dietary improvements and exercise, have been aided by public health promotion efforts and clinical preventive interventions.

Trends in mortality in the United States can be found in the publications of the NCHS, a part of the Centers for Disease Control and Prevention. International mortality rates, in general and for specific countries and regions, can be found in the publications of the United Nations,²¹ the Population Reference Bureau, the World Bank, and other organizations.

► MIGRATION

Migration is an important component of population change. However, it is often neglected in calculations of population growth because of the difficulty in measuring and collecting accurate migration information. Migration may be defined as movement of people involving a change of residence between two clearly defined geographic units.

The definition of residence and the choice of geographic units vary, depending on the particular use of the migration data. Data on population migration can be obtained from the United Nations and other international organizations. The study of migration is divided into two subdisciplines: internal migration and international migration. Internal migration refers to changes of residence within national borders, and the movers are called in-migrants and out-migrants. International migration refers to residence changes across national boundaries, with movers termed immigrants and emigrants.

Migration has become an important factor in many national population estimates, both negative and positive. There is a substantial literature on why migration occurs, including economic forces, political oppression, environmental change (both natural and man-made), family movements, and war and other social conflicts. There are theoretical perspectives on migration, such as Lee's Push-Pull Theory,²⁹ theorizing that migration comes about as the result of individuals responding to negative or "push" factors at place of origin and positive or "pull" factors at place of destination. In addition to the positives and negatives at origin and destination, the decision of the potential migrant will also take into account "intervening obstacles," which are factors associated with the migration process itself, such as distance, financial or psychic costs of the move, immigration laws, etc.

It is clear that population migration has varied and has important effects on health status. Improved social and economic status achieved by some migrants may alter overall health status and specific conditions in complex ways, due to changing lifestyle practices and interactions with the health-care system,^{30,31} as well as by access to health services due to reasons of resources or lack of documentation. Migration also has an impact on the countries of origin (e.g., the "brain drain" of health professionals) and the use of health services in the host country (e.g., overwhelming local health resources).^{32,33}

► DETERMINANTS OF POPULATION GROWTH

The determinants of demographic change for the world's population, that is, fertility and mortality, have been the subject of theoretical concepts at least since Malthus published his first *Essay on the Principle of Population As It Affects the Future Improvement of Society* in 1798.³⁴ Subsequently, careful examination of population data have led to the formulation of other concepts of population change.

Theory of Demographic Transition

The original theory of the demographic transition describes the historical experience of population growth of Western countries that accompanied economic development.³⁵ The transition can be divided into three stages. During the first stage, birth and death rates both are high but at similar levels so that population growth is minimal. This stage is referred to as the *stage of high growth potential* because, if mortality were to decline without a concurrent decline in fertility, the size of the population would increase rapidly. The second stage is called the *transition stage* because it describes the transition from high to low birth and death rates that result from economic development. It is characterized by an initial decline in mortality while fertility remains high, followed by a decline in fertility, until both fertility and mortality meet at low levels. During the first part of this stage the high growth potential is realized, while at the latter part of this stage growth has tapered off. The third and final stage of the theory is called *incipient decline* and describes both birth and death rates at low and relatively stable levels, with fertility at times falling below death rates and thus at times producing a decline in population.

Although the classic theory of the demographic transition provides a perspective for interpreting the historical change in Western populations, it does not describe or explain patterns of population change in non-Western societies nor those in developing countries.^{36,37} Over the years, the theory has been examined and reexamined in light of new data and knowledge of variation in cultural conditions. Today,

reformulated versions of the theory that depend more on social structural explanations for changes in birth and death rates are being considered. The basic relationship between mortality decline, fertility decline, and population growth, however, is still used as a framework for comparing population trends.

Epidemiologic Transition

In 1971 the theory of epidemiologic transition was proposed, which built upon that of demographic transition. Accepting the assumption that mortality is a fundamental factor in population change, this theory identified three stages through which the causes of mortality evolved: the first was a period of widespread epidemics and famine; the second was a stage of receding epidemics associated with increasing population growth; and the third was a stage of degenerative diseases and those related to individual lifestyle. In terms of fertility, this concept identified a classic, or Western, model in which change is related to social factors, an accelerated model in which change is related to medical factors (including antibiotics, steroids, contraceptive pills, and induced abortion), and a delayed model in which mortality is influenced by the medical factors of the accelerated model, but fertility decline is delayed.²⁴

This theory is susceptible to some of the same criticisms as demographic transition theory because both have difficulty adapting to less developed countries and they ignore migration. Moreover, the epidemiologic transition model has not been subject to the detailed scholarly review given the theory of demographic transition. The concept of epidemiologic transition, however, is an important idea that builds appropriately on the theory of demographic transition. This concept provides one theoretical framework for comparing and contrasting secular trends in disease and death rates across countries. Population projections for the United States are available from the U.S. Bureau of the Census.³⁸

► CONSEQUENCES OF POPULATION GROWTH

Projecting Change

Projecting population growth in terms of size and composition is an important starting point in trying to determine the consequences of population change. Using age- and sex-specific probabilities of death, age-specific fertility probabilities and the sex ratio at birth, and reported or assumed migration rates permits demographers to project, but not to forecast, population into the future. The distinction between projecting and forecasting is important because a projection uses an explicit set of assumptions and is intended to be an illustrative calculation based on these assumptions. A forecast, on the other hand, includes an element of subjective judgment to set the levels of mortality, fertility, and migration for specific times in the future. Projections are usually made based on a single set of mortality probabilities. Fertility, on the other hand, because it varies over shorter intervals, is often projected using three or four different sets of assumed probabilities thereby generating different projections. Migration is based on current data and estimates; projections of migrants are usually assumed to remain stable unless specific changes in policy or other determinants of population mobility are known.

Population Growth and Economic Change

The role of population growth in relation to economic change is a central global concern, especially of bodies such as the World Bank and the United Nations Fund for Population Activities (UNFPA). The work of Coale and Hoover in 1958 was instrumental in pointing out that "A reduction in fertility would make the process of modernization more rapid and more certain. It would accelerate the growth in income, provide more rapidly the possibility of productive employment, ... make the attainment of universal education easier—and ... [provide] women of low-income countries some relief from constant pregnancy, parturition, and infant care."³⁹ Pursuing a course of lower

fertility would, according to these scholars, create this advantageous effect by reducing the number of dependent children, that is, those aged 15 years and younger, with only minor effects on the size of the labor force or its increase until 30 years later. Subsequently, this work has been debated and contradicted, and the relation between population growth and economic status remains complex.

Population, the Environment, Resources, and Food

Around the beginning of the nineteenth century, Malthus recorded his views on population growth and its consequences, specifically inadequate food supplies. In more recent years, others have emphasized and extended these observations, linking environmental degradation to uncontrolled population growth. Among the most important contributions to this debate was the publication of *The Limits to Growth* in 1972.⁴⁰ Supported by an informal group of international professionals who called themselves The Club of Rome, a research team at the Massachusetts Institute of Technology investigated the state of the world in terms of population growth, agricultural productivity, environmental pollution, industrial output, and nonrenewable resources. After determining the status of each factor and the trends of change from 1900 to 1970, they projected the effects of these trends into the future and reached the following conclusions: (a) if these trends persist unchanged, the limits to growth on the earth would be reached within the next 100 years; (b) the trends could all be altered so that economic and ecological stability might be reached and sustained; and (c) the sooner governments and citizens around the world undertake the measures to alter current trends in all five of these areas of social and ecological concern, the greater would be the chances of attaining global equilibrium. A flurry of criticism followed the publication of *The Limits to Growth*. Nonetheless, it heightened the intensity of debate over global issues important to the present and future of human well-being, and many of the issues, including continued population growth, remain important today.

Concern about the environment and its importance to humanity has rekindled awareness of population growth.¹ Ehrlich and colleagues have reemphasized the gravity of environmental degradation as a consequence of population growth. Specifically, they draw attention to the human impact on land use, desertification, deforestation of most tropical areas, and “anthropogenic climate change.”⁴¹ The relation between population and environment remains complex, but is the subject of continued inquiry.⁴²

► POPULATION CHANGE AND PUBLIC HEALTH

As this chapter shows, there are many areas of intersection between demographic change and the health of the public. In addition to the issues of migration and population and the environment, noted above, the following are some of the specific areas of intersection where demography and specific population health issues intersect.

Teenage Fertility

Teenage pregnancies are a profound population issue because children born to young women may lead to unanticipated momentum in population growth by increasing total family size over a lifetime and by shortening the time between generations of future children. Moreover, they are a serious public health problem because teenage pregnancies may be at high risk of preventable infant mortality, and pregnancies in very young women of reproductive age are often not intended. The health implications to the pregnant teen are also of great import.^{43,44}

Urbanization

The movement of people to cities (urbanization) was one of the dominant characteristics of population change of the twentieth century and is continuing. The growth of cities is determined by three factors: (a) migration; (b) natural increase, that is, the number of births in

excess of the number of deaths; and (c) the reclassification of areas from rural to urban as they rapidly become more populous. Urban growth at the global level has been 2.5% annually in recent years, or about 50% greater than that of the total population. Urbanization is most profound in developing countries.

The health problems of city life are not so directly caused by urban living as much as they are by the extent to which the infrastructure of society is overwhelmed by the size of the population. Rapid urban growth resulting primarily from rural to urban migration creates health problems related to the need for housing and sanitation, improved food supply, transportation within the city, and the distribution of preventive and curative health services. In many developing countries, the vast numbers of people leaving rural areas for urban places reside in the unsanitary conditions of shantytowns or squatter settlements on the fringe of the capital cities, where public health problems are exacerbated.^{45,46}

Refugees and Other Migrants

There are millions of refugees dispersed throughout the world. While most are in Africa and have come from other countries on that continent, refugees can be found in almost every nation. Although many such people leave their homelands because of civil conflict and other political reasons, others do so for reasons that have led some experts to identify them as “ecological refugees.” Jacobson cites food shortages and sharp increases in food prices, generally or for specific staples, as events that trigger ecological refugee movements. In other situations, migrants move to find better employment opportunities and an improved quality of life. Nonetheless, even in areas where people from other nations are welcome, or when migration takes place within a single country, the difficulties of geographic displacement may be augmented by occupational displacement, environmental change, social disruption, and economic hardship.

Refugee movements may bring with them serious public health problems, such as severe malnutrition, as is the case in Africa. In other instances, refugees and other migrants may carry infections to areas in which such diseases are under control, or where they have not previously existed, thereby necessitating new or intensified public health screening efforts followed by treatment or other control measures. In some areas, violence related to historical ethnic conflicts is a serious problem.

Health problems are also encountered by migrants as a consequence of their move to a new environment. Psychological stress and physical deprivation associated with living in an unfamiliar environment, such as a refugee camp or squatter settlement, can bring about high levels of violence, including suicide, homicide, and rape. Language and other cultural differences between refugees or migrants and their place of destination produce serious barriers to health-care information and services at the new location.^{47,48,49}

Aging

As the death rate declines in most parts of the world, life expectancy increases, and the number and ages of older people increase. This change is more characteristic in developed countries, where life expectancy often exceeds 70 years. A shift in the age of a population has important implications for the health problems a society must face and the health services that must be provided.^{50,51}

The spectrum of health problems facing the public with an aging population will change profoundly. Heart disease, cancer, and cerebrovascular disease, which account for most of the deaths in the United States, will continue to be prevalent. Degenerative conditions, such as Alzheimer’s disease, will increase as an important cause of mortality. The need to prevent disability and injury in the aging, intensified needs for long-term care, and other special health services has reached a new level of importance that will persist in the twenty-first century. Health measures, public policy on retirement, and the desire of the older members of the population to continue working will be important determinants of the quality of living in the future.

While research on genetics and disease causation, such as diabetes and Alzheimer's disease, holds great promise for the future, its impact is unlikely to be felt among older populations in both developing and developed countries equally.

The Need for Improved Population Health Measures

In addition to the important information that comes from vital records, there is a need for innovation in collecting demographically related measures of population health, since there are impediments related to conceptualization challenges, availability of resources, methodological inadequacies, and political resistance. Given the high levels of immigration in many countries, there is a need for better characterization of language distributions, literacy levels (general and health-related), and personal lifestyles and behaviors that may be intimate and difficult to report. Better understanding of levels of access to medical services, cultural beliefs and practices, and personal and family economic status are also critical for directing public health measures to populations and communities.

Public Health Informatics

David A. Ross • Alan R. Hinman

Information is a critical component of all public health activities. The purpose of public health informatics is to systematically apply “information and computer science and technology to public health practice, research, and learning.”¹ The definition of public health informatics posited by O’Carroll et al. implies a broad range of activities drawn together by a focus on populations, not merely on individuals, and on public health organizations that operate with legal mandates. Although O’Carroll described informatics as primarily an engineering discipline, we believe that it is evolving more into a discipline of logical and strategic thought and management.

Medical and clinical informatics focus on improving the processes of diagnosis, care, and treatment of individuals. In contrast, public health informatics supports the activities, programs, and needs of those entrusted with assessing and assuring that the health status of whole populations is protected and improves over time. Public health informatics concerns itself with supporting programmatic needs of agencies, improving the quality of population-based information upon which public health policy is based, and expanding the range of disease prevention, health promotion, and health threat assessment capability extant in every locale throughout the world.

This chapter examines the historical and governmental context that guides the current evolution of the emerging public health informatics discipline, and describes some of the issues relating to the abilities of the public health worker to use information systems, as well as the larger scale issues relating to developing and implementing integrated information systems at regional and national levels.

► HISTORICAL CONTEXT

John Snow conducted one of the first comprehensive epidemiological studies undertaken in response to the 1854 cholera outbreak in London. Snow investigated and mapped the locations of the homes of those who had died in the outbreak—one of the first geographic information applications in public health. By linking the locations of their homes to a single water pump on Broad Street in Soho, London, he established that cholera was a water-borne disease. Of the 89 people who died, only 10 lived closer to another pump. Within a week of the outbreak and armed with visual data, Snow convinced the authorities to remove the pump handle. Following that simple intervention, the number of infections and deaths fell rapidly.²

Over the past 30–50 years, public health programs have emerged around specific diseases (e.g., tuberculosis), behaviors (e.g., smoking), or technologies (e.g., immunization). Each of these new programs carried with it data and information needs and information systems were developed to meet these needs. Just as public health programs and their related information systems were evolving, so, too was technology. The technology changes associated with personal computing allowed for a more distributed approach to information system

development. The conjunction of distributed computing and categorical public health programs led to a proliferation of information systems supporting narrowly focused public health programs—“silo” systems.

Individual public health programs have typically developed (or acquired) information systems designed to suit their individual program needs (e.g., surveillance, tuberculosis prevention, and control), often in response to requirements of federal funding agencies. These systems have typically been incapable of communicating with other systems within the health agency or with systems outside the agency. A single federal agency may fund several state/local programs, each of which has its own required information system for providing information to the national level and each of which differs from the others, requiring that state/local health department workers who are involved in a number of programs learn a variety of different ways of entering and summarizing information.

Public health has lagged behind health-care delivery and other sectors of industry in adopting new information technologies, in part because public health is a public enterprise depending on funding action by legislative bodies (local, state, and federal). Additionally, adoption of new technologies requires significant effort to work through government procurement processes.

Beginning in the 1980s, the desirability of making the various systems congruent with one another and standardizing the way information is captured and transmitted has gained increasing attention in the public health arena. At the Centers for Disease Control and Prevention (CDC), a 1995 study reported that integrated information and surveillance systems “can join fragments of information by combining or linking together the data systems that hold such information. What holds these systems together are uniform data standards, communications networks, and policy-level agreements regarding confidentiality, data access, sharing, and reduction of the burden of collecting data.”³ In the late 1990s, it became apparent that public health must be more comprehensive in understanding disease and injury threats, necessitating a level of programmatic and supporting information system integration (see below). Combining data from disparate programmatic sources—for example, from surveillance systems covering different diseases or from a variety of service delivery systems—requires systems that connect seamlessly. Interoperability refers to data from various sources being brought together, collated in a common format, analyzed and interpreted without manual intervention. Interoperability requires an underlying architecture for data coding, vocabularies, message formats, message transmission packets, and system security. Interoperability implies connectedness among systems, which requires agreements that cover data standards, communications protocols, and sharing or use agreements. Interconnected, interoperable information systems in public health allow information systems to address larger aspects of the public health enterprise. The enterprise era of public health informatics rests on a

rigorous approach to solving semantics problems—interpretation, negotiation, and reasoning—that were once the domain of humans alone and will now be mediated by computers. Major advances in the quality, timeliness, and use of public health data will require a degree of machine intelligence not presently imbedded in public health information systems.⁴

The context in which informatics can contribute to public health progress is changing. New initiatives within public health and throughout the health-care industry portend changes in how data are captured, the breadth of data recorded, the speed with which data are exchanged, the number of parties involved in the exchange of data, and how results of analyses are shared.

► PUBLIC HEALTH SYSTEM NEEDS FOR INFORMATICS

In the future, public health informatics will have major impact on the three core public health functions: assessment, policy development, and assurance. Assessment will require that a public health official knows more about the dynamics of health within a jurisdiction, knows it sooner, and knows it with more precision. This will require greater breadth, precision, and timeliness in data capture and analysis, as well as an ability to detect important disparities in health. Policy development speaks to both micro-level (community) analysis and recommendations and also to macro-level (state and national) policy needs based on trends detected in assessment systems, relationships among forces impacting health status, and social determinants, such as insurance, employment, and other economic trends. Assurance activities complete the legal guarantee of services, such as screening every baby for heritable disorders and linking the child to a medical home that assures appropriate follow-up care, or assuring that preventive services reach every citizen. Assurance activities coupled with e-government initiatives guarantee more convenient access to government-mandated services, and assurance activities will become more aligned with continuous quality improvement, which implies an ability to measure against benchmarks on a timely basis.

The national security emphasis brought on by the events of September 11, 2001 and thereafter, points toward a cradle-to-grave approach to the management of health data. Biosurveillance has become a term meaningful to every lawmaker. Tracking personal health through personal health records (PHRs) is under serious consideration as a component of national health-care automation initiatives. Attention to injury prevention and other threats to health are leading community organizations to analyze data to adapt to spur legislative and regulatory actions at the local and state levels. Public health is now a key component of emergency response and recovery teams in every locality in the nation. All of these areas require timely information and communication.

In all segments of industry and government, the best applications of technology are those that clearly support critical missions. In public health, a field with vast responsibilities, it is even more important to carefully isolate the need for and purpose of information systems to assure that the investment in a system results in tangible support to health promotion, disease prevention, or health protection goals.

Experience with information technology (IT) projects in all industries has shown that IT projects are risky ventures prone to failure. General IT project success rates are poor—31% cancelled before completion, 53% challenged by cost and/or time overruns or changes in scope.⁵ For large-scale enterprise applications (e.g., commercial comprehensive business software solutions), similar data indicate about a 39% hard dollar return on investment.⁶ The investment house Morgan Stanley estimated that U.S. companies threw away \$130 billion on unneeded software and other technology in a 2-year period.⁷ These data demonstrate that neither government nor private industry is immune to ill-conceived, poorly executed IT projects.

► ENTERPRISE ARCHITECTURE AND DATA INTERCHANGE

Aligning informatics strategy to organizational goals is one of the most important contributions senior public health leaders can make in creating viable, sustainable information infrastructure. Aligning informatics strategy rests on at least two pillars. First, the organization must have goals and a plan of action to achieve those goals. Without these, informatics investments will most likely serve small, narrow, program-specific objectives rather than the larger organization. Second, a public health organization needs an enterprise architecture.

Public health endeavors are moving from isolated interventions toward a more coordinated systems view. Political leaders, policy makers, and public health professionals are taking an enterprise view to be more responsive to large-scale problems and to be more cost effective in their use of public funds. Adopting an enterprise view implies multiorganization cooperation and coordinated information systems planning, development, and deployment. Developing information systems that support multiple parties achieving multiple goals underscores the organizational and management aspects of public health informatics.

For public health agencies to become successful at conceiving, developing, and using enterprise-level information systems, careful attention must be applied to a series of activities corresponding to the life cycle of any information system project:

- Aligning organizational and IT strategies (a managerial informatics task)
- Establishing a clear rationale of benefits (business case)
- Justifying a long-term finance strategy
- Building a framework of process descriptions, tied to how supporting work processes actually create the data of interest
- Developing a comprehensive set of requirements or statements of what the system must be capable of doing
- Answering the “buy or build” question
- Managing the project development phase
- Training the many individuals who will play a role in operating or using the new information system(s)
- Guiding the implementation of the system and the accompanying change processes that will be required of the organizations affected by the system
- Evaluating the ultimate impact the system has on health outcomes

Enterprise architecture is a way to describe an agency’s business operations and processes, the performance outputs or measures used to achieve agency goals, the description of data and information related to lines of activity, categorizing the IT services and applications in use, and the technologies and standards used throughout all the applications. Developing and maintaining enterprise architecture is time consuming and can be complex, however, the benefits are extensive. The benefits include helping the agency align IT goals with agency-strategic direction, accommodate more rapidly to new requirements, improve system management due to more consistent components, lower support costs, and support interoperability within the agency and with external partners.

The need for an enterprise view and an enterprise architecture is not unique to public health. In 2004, the National Academies noted that “the success of the FBI’s information technology efforts will require the development of a close linkage between IT and a coherent view of the bureau’s mission and operational needs . . . the enterprise architecture. . . .”⁸

Data interchange technologies are changing how public health agencies can approach their need to capture and manipulate data to produce the information that is essential to protecting community health. Public health is moving from thinking about an IT solution for a specific problem (e.g., capturing case data on a specific disease) to thinking in terms of a class of similar challenges (e.g., data structures

that can be used for infectious disease surveillance). Data no longer need to exist as entities unto themselves. Using the concept of metadata—that is, a list of facts that describe the data and how they are used—data sources can be conceptually indexed, allowing anyone to understand which data are being captured by which system. Using Extensible Markup Language (XML) technology, data can be tagged in a manner that provides for convenient transfer and interpretation from one system to another. Thus, public health agencies need to adopt new data transfer technologies and simultaneously establish and manage enterprise architectures.

► PUBLIC HEALTH WORKER NEEDS

If they are not already at least minimally computer literate, public health workers will have to become so in order to be fully functional. This does not mean they will have to understand how to program computers. It does mean they will have to understand what computers can and cannot do and how to communicate effectively with systems engineers. The Council on Linkages between Academia and Public Health Practice has developed informatics competencies for public health professionals.⁹ Three categories of competencies have been developed for front-line staff, senior-level technical staff, and supervisory/management staff: effective use of information, effective use of IT, and effective management of IT projects. Table 5-1 lists the domains/topical areas within each of the categories.

Two of the most important skills needed by public health workers are:

1. The ability, and the willingness, to explicitly lay out the functional requirements of the information system
2. Active participation in all phases of conceptualization, development, design, implementation, and evaluation of the system

TABLE 5-1. INFORMATICS COMPETENCIES FOR PUBLIC HEALTH PROFESSIONALS

1. Effective use of information
 - a. Analytic assessment skills
 - b. Policy development/program planning
 - c. Communication skills
 - d. Community dimensions of practice
 - e. Basic public health sciences
 - f. Financial planning and management
 - g. Leadership and systems thinking
2. Effective use of IT
 - a. Digital literacy
 - b. Electronic communications
 - c. Selection and use of IT tools
 - d. On-line information utilization
 - e. Data and system protection
 - f. Distance learning
 - g. Strategic use of IT to promote health
 - h. Information and knowledge development
3. Effective management of IT projects
 - a. System development
 - b. Cross-disciplinary communication
 - c. Databases
 - d. Standards
 - e. Confidentiality and security systems
 - f. Project management
 - g. Human resources management
 - h. Procurement
 - i. Accountability
 - j. Research²²

► PUBLIC HEALTH INFORMATION SYSTEM NEEDS

In the area of childhood immunizations, a revolutionary approach was undertaken in the early 1990s to serve both medical care and public health needs by developing population-based immunization registries, which gather information from all providers of immunizations (whether private or public) and consolidate the information so that any provider can, at a glance, determine the complete immunization history of a child. This work was supported by CDC's National Immunization Program and by All Kids Count, a program funded by The Robert Wood Johnson Foundation.¹⁰ Although practice-based registries had been used for some years, this was the first attempt to capture information from all sources, private and public, and was particularly useful since more than 25% of U.S. children receive immunizations from more than one provider before they are 3 years of age. Registries can also generate reminder/recall notices, create official immunization records, and assess the immunization coverage in a given area or practice. Immunization registries have advanced further than other information systems seeking to bridge the public/private divide. Currently, more than 50% of U.S. children less than 6 years of age have at least two immunization doses recorded in a population-based registry, and there is a Healthy People 2010 goal of 95% participation by U.S. children less than 6 years of age.¹¹

Considerable effort has gone in to defining functional standards for registries (Table 5-2).¹² Agreement has been reached that Health Level 7 (HL7) packaging will be used for transferring information. A certification process for registries is in development. Although registries have proven their worth and are well advanced, very few are capable of communicating with other health information systems. Most are not yet capable of exchanging information with other registries and few integrate with information systems serving other program areas.

Emphasis in the public health community has now shifted to integration of information systems in order to share information. In our view, integration refers to the presentation of information to the end-user, not to the hardware or software behind it. Some information systems are developed as comprehensive (integrated) systems with different programmatic areas forming modules of the whole. More commonly, existing information systems may be linked together in a variety of ways to combine information and present it in an integrated way. In many ways, this is a bottom-up approach to developing enterprise systems.

An important, practical approach to integrating child health information systems has been undertaken by the Genetic Services Branch,

TABLE 5-2. IMMUNIZATION REGISTRY MINIMUM FUNCTIONAL STANDARDS

1. Electronically store data on all NVAC-approved data elements
2. Establish a registry record with 6 weeks of birth for each newborn child born in the catchment area
3. Enable access to and retrieval of immunization information in the registry at the time of encounter
4. Receive and process immunization information within one month of vaccine administration
5. Protect the confidentiality of health-care information
6. Ensure the security of health-care information
7. Exchange immunization records using HL7 standards
8. Automatically determine the routine childhood immunization(s) needed, in compliance with current ACIP recommendations, when an individual presents for a scheduled immunization
9. Automatically identify individuals due/late for immunization(s) to enable the production of reminder/recall notifications
10. Automatically produce immunization coverage reports by providers, age groups, and geographic areas
11. Produce official immunization records
12. Promote accuracy and completeness of registry data

Division of Services for Children with Special Health Care Needs, Maternal and Child Health Bureau, Health Resources and Services Administration (MCHB/HRSA). Since 1998, MCHB/HRSA has undertaken a series of grant initiatives to facilitate, among other things, the development of integrated child health information systems to include newborn-screening systems. All Kids Count (now a part of the Public Health Informatics Institute) has worked with MCHB/HRSA in this area since 2000. As a starting point, four programmatic areas were selected for integration of information systems—newborn dried blood spot (NDBS) screening for inherited and congenital disorders, early hearing detection and intervention (EHDI), immunizations, and vital registration. These four were selected because they are recommended for all infants/children, they are carried out (or begin) in the newborn period, they are time-sensitive (delay in carrying them out can lead to adverse outcome), and they are primarily delivered in the private sector but have a strong public sector component (e.g., public health agencies, federally qualified health centers). Additionally, most or all states mandate them.

Two activities to support integration have been the development of a sourcebook containing key elements for successful integrated health information systems¹³ and the development of principles and core functions of integrated child health information systems.¹⁴ The nine key elements identified were:

1. Leadership—project has an executive sponsor and a champion.
2. Project governance—project is guided by a steering committee representing all key stakeholders and uses outside facilitators.
3. Project management—formalized management strategies and methodologies are used. Project has adequate and appropriate staffing.
4. Stakeholder involvement—there is frequent interaction and high quality communication with stakeholders.
5. Organizational and technical strategy—strategy is based on local issues, aligned with national efforts, customer-focused, developed through a legitimate process, and based on business processes.
6. Technical support and coordination—centralized within the health department with technical staff working closely with program staff. Uses business analysts to coordinate between technical and program staff.
7. Financial support and management—funding is adequate, derived from multiple sources and managed by an oversight committee.
8. Policy support—legislation, regulation, and policy foster or are neutral to the integration of information systems.
9. Evaluation—regularly performs qualitative and/or quantitative monitoring or evaluation.

► MEDICAL CARE INFORMATION SYSTEM NEEDS

In the clinical care arena, one of the most exciting developments has been the continuing evolution of electronic medical records, which are now in use in a number of practice settings, both inpatient and outpatient. Many of these information systems are capable of bringing together information from a variety of different sources, including nursing, pharmacy, laboratory, radiology, and physician notes. Some of the sources themselves have dedicated information systems to meet their individual needs (e.g., pharmacy, laboratory). Traditionally, these systems are not designed to handle other facets of health care, such as reporting notifiable diseases to health departments or providing information directly to the patient. In 2003, only an estimated 5% of U.S. primary care users were using electronic medical records.¹⁵ The American Academy of Family Physicians has established the goal of having at least half of its members using electronic health records by 2006.¹⁶ The special requirements for electronic medical record systems in pediatrics have drawn attention.¹⁷ Some of

the important data needed in pediatric records that may not appear in adult electronic medical records include growth data, age-based normal ranges, information on dosage of medications, and immunizations.

► NATIONAL HEALTH INFORMATION SYSTEM INITIATIVES

In the late 1990s, CDC launched an initiative aimed at rethinking notifiable disease surveillance—National Electronic Disease Surveillance System (NEDSS). The NEDSS initiative leveraged developments in medical informatics (e.g., HL7, Logical Observation Identifiers Names and Codes [LOINC]) and new information communication technologies (e.g., pervasive Internet access, XML, etc.) to challenge existing disease-centric methods and approaches to handle information. NEDSS was built on the proposition that the process of notifiable disease surveillance could be described in a standard way—that is, as a business process core to public health practice—and could be standardized in a manner such that data captured in any jurisdiction could be transmitted through a network of computers to all layers of the public health system in need of the data. Following the events of September 11, 2001, CDC expanded the conceptions driving NEDSS to conceive a Public Health Information Network (PHIN) that would unify the disparate information and communications systems presently employed to meet the needs of many different public health programs.¹⁸ PHIN is a broad concept, built around the need to provide a crosscutting and unifying framework, to better monitor the disparate public health data streams for early detection of public health issues and emergencies. Through defined data and vocabulary standards and strong collaborative relationships, PHIN will enable consistent exchange of response-, health-, and disease-tracking data between public health partners. In conjunction with the PHIN vision, CDC and the HRSA have distributed significant grant funding intended to rapidly scale-up state and local public health information infrastructure.

Other federal funding agencies are promoting similar changes in the informatics structure of public health. HRSA has sponsored telemedicine and systems integration grants to states to spark development of systems that integrate child health information and extend health-care providers to remote and rural locations through telemedicine. The HRSA grants sponsor more than 20 states' efforts to integrate newborn dried blood spot screening results with other early child health information systems, such as newborn hearing screening and immunizations. The combination of funding for NEDSS, PHIN, terrorism and preparedness, and the HRSA integration projects has led to enterprise-level thinking within public health agencies. Public health information infrastructure will also benefit from fiscal year 2004 grants and contracts distributed by the Agency for Healthcare Research and Quality (AHRQ) that promote interconnection of health care and public health through use of electronic health records. In addition, public health informatics training is now a focus of the National Library of Medicine in a joint effort with The Robert Wood Johnson Foundation, through four grants to major academic centers who have joined medical informatics programs with schools of public health to build a cadre of doctoral and masters' level public health informaticists.

Several national initiatives that have major implications for the development of integrated health information systems are currently underway. These include the National Health Information Infrastructure (NHII) initiative, which addresses all aspects of health information systems, including clinical medicine and public health. NHII is "the set of technologies, standards, applications, systems, values, and laws that support all facets of individual health, health care, and public health". The broad goal of the NHII is to deliver information to individuals—consumers, patients, and professions—when and where they need it so they can use this information to make informed decisions about health and health care.¹⁹ CDC's PHIN initiative addresses the public health component of NHII. In addition, the Medicaid

Information Technology Architecture (MITA) initiative of the Centers for Medicare and Medicaid Services addresses information systems for the nation's largest payer of health care.²⁰

In 2004, the Office of the National Coordinator for Health Information Technology (ONC) was established within the Department of Health and Human Services to coordinate and oversee the range of activities in developing health information systems around the country. A Framework for Strategic Action was developed and released in July 2004.²¹ The framework describes a vision for consumer-centric and information-rich care with four goals:

1. Inform clinical practitioners to improve care and make health care delivery more efficient.
2. Interconnect clinicians to allow information to be portable and to move with consumers from one point of care to another.
3. Personalize care—consumer-centric information will help individuals manage their own wellness and assist with their personal health-care decisions.
4. Improve population health through the collection of timely, accurate, and detailed clinical information to allow for the evaluation of health care delivery and the reporting of critical findings to public health officials, clinical trials and other research, and feedback to clinicians.

The establishment of ONC sent the signal that information technologies must be deployed in a way that supports improvement in quality, safety, and efficiency of care. If agreements can be reached on the major information architectural standards (data, transmission, and security) and appropriate approaches to governance and viable business models can be demonstrated, then regional health information exchanges (RHIOs) will emerge across the nation to assist and transform how health care is delivered. Public health considerations should be central to this transformation, and public health informatics will be central to how public health agencies participate.

Some of the most important barriers to development of integrated information systems are the lack of agreement on standards for data exchange and the lack of clarity on developing statements of required functionality.

► LESSONS LEARNED IN DEVELOPING HEALTH INFORMATION SYSTEMS TO DATE

The All Kids Count project summarized 10 lessons learned for health information systems projects:

1. Involve stakeholders from the beginning—stakeholders, especially those who are the users and beneficiaries of information systems, need to be actively involved throughout the planning and implementation of health information systems.
2. Recognize the complexity of establishing a population-based information system—although clinical information systems may be quite complex, they essentially deal with transactions in a population that is quite selective (e.g., those admitted to a particular hospital). By contrast, population-based information systems must ensure that all people who live in a particular area are included, regardless of whether they make use of clinical or public health services or not.
3. Develop the policy/business/value case for information systems—a systematic and rigorous approach to developing the business of value case for integrated health information systems is needed to gain support from policy makers.
4. Define the requirements of the system to support users' needs—information systems are designed to support health care or public health functions. Too often, the users are not explicit in defining what the system must be able to do in order to support them appropriately. This leaves system developers with insufficient guidance. More emphasis is

needed on designing information systems that support the work processes of physicians and other health workers and on developing tools and techniques to help them overcome both perceived and real barriers to using information systems.

5. Develop information systems according to current standards—successful exchange of information between public health and clinical information systems will require public health agencies to support standards-based system as an essential investment in their infrastructure.
6. Address common problems collaboratively—although no two programs are the same, most public health programs face common challenges in developing and implementing information systems. By working collaboratively, it is possible to learn from one another and avoid making the same mistakes repeatedly. The Association of Public Health Laboratories (APHL) and the Public Health Informatics Institute collaborated with 16 states to define the business processes and functional requirements for public health laboratory information systems. As the states worked together, they discovered that they had more in common than they initially believed, although there were some areas that were unique to a given state (diversity within commonality).
7. Plan for change—the pace of evolution in information systems is dazzling and it is clear that there will continue to be rapid changes. We must develop change management plans to be able to accommodate to the changing environment.
8. Plan boldly, but build incrementally—it is important to have a grand view of the end product but it is also important to build the system incrementally. This allows demonstration of completed products and permits adaptation to the inevitable changes in environment and technology.
9. Develop a good communication strategy—a good communication strategy begins with listening to the various stakeholders to understand their concerns and needs before shaping informational messages. It ensures a message is repeated many times.
10. Use the information (even if not perfect)—one of the characteristics of those developing information systems is the desire to have everything perfect before rolling out the product or sharing information. This is a tendency that must be resisted. Providing information allows providers to verify it against records and subsequently update and correct inaccurate information. This feedback loop is an important ingredient of progress.⁴

► CHALLENGES FOR THE FUTURE—IMPLICATIONS FOR PUBLIC HEALTH INFORMATICS

The broad public health mission demands that the organized efforts of governmental agencies work in collaboration with multiple partners—medical care providers and provider organizations (hospitals, managed care organizations), first responders (fire, police), and many others depending on the circumstances. Because public health agencies are components of government, they are restricted in where they focus their efforts. Public health has evolved its mission through careful assessment of the causes of death and disability and translation of those findings into policy initiatives that bring about changes in law, which in turn increase the scope of the public health mission. Public health informatics should be central to this process because it is through information technologies that data are gathered, analyzed, and understood. Further, public health informatics can influence the services that public health agencies are legally mandated to assure. Information technologies support processes; public health drives numerous processes that support the delivery of primary care and population-based services. Public health also coordinates efforts from local communities to state authorities and eventually works in concert with federal agencies (e.g., DHHS, DHS, USDA, EPA, etc.). In every domain of the public health mission, informatics has and will

continue to have an impact on how services are organized and delivered, the scope of information made available for policymaking, and how policy makers, providers, and citizens at large are informed.

Technologies provoke policy change by creating new possibilities. For example, the invention of penicillin changed the treatment of communicable diseases like syphilis and changed the manner in which public health agencies organized efforts to treat infected individuals. In a similar manner, innovations in IT have provoked changes in public health practice. When a new technology presents a significant shift in capability, public health organizations are forced to respond. Thus, public health informatics is both a servant to program needs and an agent of mission change. The evolution of data coding (e.g., LOINC, SNOMED, etc.) and data transmission (e.g., HL7) make the capture and transmission of clinical information a feasible and cost-effective reality. Given that reality, public health agencies cannot ignore the potential to capture a more complete picture of current patterns of illness and patterns of care. The cycle of innovation provoking new forms of practice continues at an increasing pace. Public health informatics rests at the fulcrum of this change.

► OVERVIEW OF HEALTH DISPARITIES

Some health experts argue that we may have entered a third wave of health.¹ After combating communicable diseases in the first wave and chronic disease in the second, an era may emerge in which people are living longer with increasingly less disease burden, technological advances are promising to halt the encroachment of disease, and a growing number of people are considering themselves to be in good health.¹ At the same time, however, millions of people worldwide are suffering and dying from diseases and disabilities that are easily preventable or curable. Diseases such as polio, measles, and tuberculosis, are rare or nonexistent among populations with access to resources, but far too commonplace for those living in impoverished or disadvantaged conditions. In developing countries, one million children die each year from measles, infant mortality rates are seven times higher than in industrialized countries, and the AIDS virus threatens to undo any gains made in childhood survival rates.² Such statistics are not isolated to developing nations. In more developed regions of the world, such as North America and Europe, many people still receive substandard care or suffer from significantly higher rates of disease and lower levels of favorable health outcomes than others. Although by no means universally agreed upon, the concept of health disparities refers to differences in one or more health-related variables associated with membership in some population group or subgroup.

Initially, the United States may have lagged behind other nations in recognizing the health disparities concept, as well as in efforts to research and redress health disparities. The last 12–15 years, however, have witnessed increasingly strong governmental and philanthropic efforts in this area. A strategically important landmark in this regard was the setting of national health objectives embodied in the *Healthy People 2010* endeavor under the auspices of the U.S. Department of Health and Human Services (DHHS).³ Goals of *Healthy People 2010* include (a) increasing life expectancy and improving quality of life for all individuals and (b) eliminating disparities among population segments, including socioeconomic position, gender, race/ethnicity, disability, geographic location, or sexual orientation. These goals went beyond those of *Healthy People 2000* that were principally concerned with population groups that were believed to be at high risk for death, disease, or disability. Cascading from *Healthy People 2010* have been strong health disparity research and monitoring efforts emanating from other federal agencies, each conditioned by its particular

substantive focus. For instance, the Institute of Medicine's 2003 report, *Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care*⁴, concluded that after controlling for socioeconomic status (SES) and health insurance, African Americans and Latinos received inferior health care in part related to physicians' stereotypes of minority patients. The Institute of Medicine separates these issues of bias together with those of health-care system inequities from differences due purely to clinical considerations. Other government entities have also substantially contributed to the overall effort. These include various operations of the National Institutes of Health, the Health Research and Services Administration, and the National Center for Health Statistics (NCHS). In addition, acting collaboratively and independently, state health departments have initiated and sustained health disparity research, monitoring, and intervention initiatives.

Conceptualizing Health Disparities

At its core, the notion of health disparities relies on differences—differences in health attributable to membership in one population group versus another. A historically influential feature of the health disparity concept is its location in worldwide policy and scholarly debates about public health. It is important to understand that recognition of health disparities as a public health issue and subsequent elaboration of its definition and its relationship to other issues, such as health care and measurement of public health variables, took place under the auspices of international institutions such as the World Health Organization (WHO). In the United States there is generally firm adherence to the term disparity, while in the United Kingdom and European countries the terms “inequality” and “variations” are more typically employed. Regardless of the particular term invoked, the logic of health disparities is consistent and can be illustrated (Fig. 6-1.)

In this scheme, it is held that differences or variations, say, in race/ethnicity are conceptually part of disparities because they are facets of the implicit overarching public health or societal value of equity. It is generally held that group differences based on these variables are proximally or distally associated with differences in health, thereby establishing inequitable life situations, including differences in health care or health outcomes. Disparities in health exist between *groups* of people, not individuals. The chain of events set in motion by membership in a particular group emanates from differential

Figure 6-1. Conceptualizing health disparities.

environments, health status, or access to health care, and these are presumed to be underlying causes of health disparity. Therefore, group membership based on such factors as gender, race, and/or class inequalities may confer limits on one's access to adequate nutrition, safe living and working conditions, educational opportunities, and personal medical services, which in turn result in differential health outcomes. For example, differences between U.S. non-Hispanic whites and African Americans are found with infant mortality, with African Americans experiencing higher rates than non-Hispanic whites. The overarching value of equity highlights concerns of privilege inherent in social groupings, and it affects ways in which health disparities are conceptualized and measured.

In addition to this basic health disparities logic, additional considerations are consistent features of health disparities debates. These include individual versus structural influences on health and the extent to which health inequalities are avoidable and unjust. The first of these references the fundamental question of whether health disparities arise due to individual behavioral choices and cultural practices or externally imposed structural factors.^{5,6} Responsibility cannot be completely attributed to one or the other; rather, health disparities are generally thought to arise at the intersection of individual behavior or cultural constructions and the social structure.⁶ Populations that live in environments of high material and social disadvantage, that is, poverty, low social position, unemployment or underemployment, discrimination, lack of social capital, unsafe living and working environments, and powerlessness are thought to be at relative increased risk for disease.^{7,8}

Second, health disparities do not refer to *all* differences in health but to those that are potentially avoidable or that occur as the result of injustice. In a just system, the majority of care and health resources would be allocated to those in the most need, the most disadvantaged in society.⁹⁻¹² Therefore, much of the work regarding health disparities is particularly concerned with issues of social justice and human rights, one of which is health. This refers to both the right to obtain adequate health care and the right of everyone to enjoy the highest level of health. From the justice standpoint, structural constraints on adequate health and health care are a denial of one's fundamental human rights. In an equitable system, all would have the same opportunity to attain their full health potential. Resource allocation and health care access would also be based on and distributed according to the greatest need.⁹ However, the current health-care system often functions according to the *inverse care law* in which regions with the highest disease burden receive the fewest health resources.¹¹ Likewise, funding tends to flow away from these areas, not toward them. Although policy makers are aware of this discrepancy, it is often difficult to shift or reallocate resources. For example, in the United States from 1991 to 2000, medical advances in technology averted 176,633 deaths, but "equalizing the mortality rates of whites and African Americans would have averted 886,202 deaths."¹³ Far more

is spent on technology than on achieving equity in health care delivery. These data highlight the compelling nature of health disparity, and they bring to the foreground the ethical issue of what differences should be tolerated and redressed. The compound effects of social disadvantage and increased risk for disease can be thought of as a form of structural violence precipitated by social structures and institutions, which prevents individuals from achieving their full potential. As Paul Farmer¹⁰ asserts, "Structural violence is visited upon all those whose social status denies them access to the fruits of scientific and social progress."

International Context. The diverse vantage points for considerations of health disparities are located by how disparities are defined. Sorting out terms such as disparity, difference, inequality, and inequity is largely a matter of grasping the way in which definitions of disparity have emerged over time and in various contexts. One of the earliest and most influential definitions is attributed to Margaret Whitehead through work with the European Office of the WHO in the 1990s. As shown in two reviews,^{9,14} her definition explicitly references inequalities and inequities, where inequalities are defined as "differences in health which are not only unnecessary and avoidable but, in addition, are considered unfair and unjust," and "equity in health means that all persons have fair opportunities to attain their full health potential, to the extent possible." She went on to specify determinants of inequalities, including exposure to unhealthy environments, poor access to health care, and other individual-level variables such as natural selection and individual behaviors. These definitions are notable for distinguishing determinants from outcomes and for emphasizing the value of equity.

Subsequent WHO definitions are conceptually more inclusive and explicit, as well as more elaborate, in their focus on equity, and they introduce the need to consider measurement of health disparities, something that has emerged as a dominant concern in health disparities research and intervention. For instance, "Equity means that people's needs, rather than their social privileges, guide the distribution of opportunities for well-being. In virtually every society in the world, social privilege is reflected in differences in SES, gender, geographic location, ethnic/religious differences and age. Pursuing equity in health means trying to reduce avoidable gaps in health status and health services between groups with different levels of social privilege."¹⁵ Another international health organization, the International Society for Equity in Health, also invoked equity, "The absence of systematic and potentially remediable differences in one or more aspects of health across populations or population subgroups defined socially, economically, demographically, or geographically."¹⁶ Still another definition refers to "social determinants" and stresses inequalities, "systematic differences in health of groups and communities occupying unequal positions in society."¹⁷

The "unequal positions in society" aspect of the inequalities notion highlights another persistent and crucial context of the health disparities debate—differential access to health care. From logical, ethical, and policy standpoints, differential access to health care is a key issue with respect to health disparities because it may serve as a vehicle for reifying inequality inherent in group memberships as inequitable health outcomes. Access to health care necessarily entails access to health-care resources and attention to equitable distribution of resources by researchers and interventionists. A thorough treatment of equity in health care is beyond the scope of this chapter, but most definitions reference the fit between need and resources.¹⁸ Accordingly, *vertical equity* refers to the allotment of health resources based on differential need between groups.¹⁹ Perhaps owing to structural differences in health-care systems between the United States and many other developed nations, equitable access to health care, broadly conceived, is a key element of health disparities policy, research, and intervention in the United States.

United States Context. The U.S. Health Resources and Services Administration has been an integral part of the U.S. context in health disparities. As its name implies, this agency's definition explicitly

links health disparities to access to care, "... a population-specific difference in presence of disease, health outcomes, or access to care."²⁰ Similarly, one of the Institute of Medicine's foci is on the differential burden of disease based on differences in, say, cancer survival rates among population groups, including race/ethnicity or SES.²¹ Compared to Europe-located definitions above and owing in large part the *Healthy People 2000* and *Healthy People 2010* processes, this and other U.S. definitions of health disparities emphasize the word *differences*—differences in groups and differences in health outcomes. While the overarching value of equity is implicit in U.S. definitions, it is not often explicit. Nevertheless, equity is inherent in the *Healthy People 2010* goal of eliminating health disparities, "to eliminate health disparities among segments of the population . . ."²³

It should also be emphasized that this goal takes the affirmative stance of moving beyond mere concern for equity to setting the goal of *eliminating* disparities for specific groups. The impetus and coordination supplied by *Healthy People 2010* has resulted in adoption of generally compatible definitions across agencies responsible for different parts of the United States' health promotion and health care systems. Important U.S. legislation such as Public Law 106-525, the Minority Health and Health Disparities Research and Education Act of 2000, focuses attention on population differences. "A population is a health disparity population if . . . there is a significant disparity in the overall rate of disease incidence, prevalence, morbidity, mortality, or survival rates in the population as compared to the health status of the general population . . . populations for which there is a considerable disparity in the quality, outcomes, cost, or use of health care services or access to, or satisfaction with such services as compared to the general population."²²

It is important to consider how various entities within the U.S. government define health disparity, as their agencies' agendas for research and intervention are reflected in and determined by these definitions. Agencies such as the National Institutes of Health, the Centers for Disease Control and Prevention (CDC), and the entirety of the DHHS have adopted this definition: "Health disparities are differences in the incidence, prevalence, mortality and burden of disease and related adverse health conditions that exist among specific population groups in the United States . . . these population groups may be characterized by gender, age, ethnicity, education income, social class, disability, geographic location or sexual orientation."²³ Owing to its conceptual inclusivity, this definition sets an ambitious and far-reaching agenda that has tremendous implications for research and monitoring efforts, specifically with respect to measurement issues. Disparities that might be uncovered by a particular study or focused on as part of a community-based participatory research (CBPR) effort are dependent on the measure used. That is, each measure used reflects some meaning of disparity, and the choice of measure used depends on the goals of a particular study. Nevertheless, there is a customary collection of measurement strategies employed, and we provide an overview of these.

Measuring Health Disparities

To a great extent, the quality of interventions and research such as CBPR that aim to understand or redress health disparities depends on the quality of health disparity indicators. Measures of health disparity are part and parcel of research, intervention, and ethical concerns about what aspects of disparity are vital to address. Some measures are intended to gauge the grouping variables in Fig. 6-1 such as socioeconomic position, while others focus directly on measurement of health outcomes like infant mortality. Deciding which measure to use depends on the particular research question one is attempting to answer, and these questions are often intertwined with value questions such as fairness, different conceptions of health, and concerns about what is important to assess. There is an increasing array of measures and analytic techniques used by health disparity researchers,²³ and a full treatment of these is beyond the scope of this chapter. Nevertheless, all measurement situations are intended to clarify some feature of the relationship between group membership and health.

In the simplest form, measurement of health disparities takes place when a single disparities subgroup within, say, the race/ethnicity group is compared across a single health outcome. For instance, this type of measurement might entail comparing a sample of Hispanics to the total population on the incidence of Type II diabetes. Two subgroups might also be compared to one another, for example, males versus females or urban versus rural populations on one or more health outcomes. A yet more complex measurement situation involves comparison on some health disparity outcome across multiple subgroups within a disparities group, for example, several race/ethnicity categories or several socioeconomic categories. Additionally, more complex measurement situations would involve combining subgroups in order to make comparisons. For instance, low-SES Hispanics might be compared to high-SES non-Hispanic whites on the incidence of Type II diabetes.

Issues of research design should also be considered. Recently, the NCHS published a guide written by an expert group that details a set of six choice points linked to guidelines for measuring health disparities that is consistent with *Healthy People 2010* goals, four of which are recounted here.²⁴ For clarity and consistency, our treatment follows these recommendations. The reader is advised to consult this and other publications^{25,26} for a more complete view of important nuances involved in the choice point and guidelines.

When measuring disparities, it is customary to calculate a quantitative comparison on some health-related indicator between groups within a domain of interest. Domains are sets of groups defined by some variable, for example, gender, race/ethnicity, socioeconomic position. Although not universally achieved, it is methodologically important that groups be as mutually exclusive as possible, such that calculations of difference are made between males and females only on some health indicator. Some domains may be ordered from low to high, as in SES, while others, for example, race/ethnicity can not be ordered. Calculations can include rates, percentages, averages, and many other statistics. In the health disparities literature, the terms difference, risk, and disparity are often used interchangeably. Shown in Table 6-1 are selected choice points and guidelines from NCHS. Those selected represent common and important decisions regarding which disparity measures to use.

Reference Point. The choice of reference point is fundamental to measurement of health disparities. It refers to the question, "different compared to what?" and will indicate the size and direction of disparities. Because they are generally the most stable, total population rates are often used for comparison. The mean of the rates for each group may also be used. Other frequently used reference points are the *Healthy People 2010* target rates, and it is highly recommended that, in nearly all situations, rates for the healthiest or more favorable groups be employed as points of reference. For example, females generally have more favorable (lower) rates of hepatitis B than males, so the rate for females would be the required reference point. The choice of a specific reference point will also depend on the purpose of a given study; but in all cases, reference points are to be clearly identified.

Absolute versus Relative Disparity. When comparing two or more groups on some health indicator(s), the values for the indicator(s) may be expressed as absolute values or relative to a reference point. Absolute measures yield data on the size of disparities and are calculated by subtracting the value for a reference point from one or more group values. Relative measures are useful for making comparisons without regard to size and are expressed as ratios or fractions wherein the rate for a reference group is subtracted from the rate for given group, and that value is divided by the value of the reference point and then multiplied by 100 to yield a percentage difference. In some cases the two measures mean essentially the same thing, but comparisons across measures, time, population groups, or geographic areas may yield different conclusions. In order to generate a more complete view of disparities, the NCHS group recommends using both absolute and relative measures.

TABLE 6-1. CHOICE POINTS AND GUIDELINES FOR MEASURING HEALTH DISPARITIES

<i>Choice Point</i>	<i>NCHS Guideline</i>
Reference point: the specific rate, percentage, proportion, mean or other quantitative indicator from which a disparity is measured	<ul style="list-style-type: none"> Reference point(s) should be explicitly identified and rationale provided. In making comparisons between two groups, the more favorable group is to be used as the reference point.
Absolute versus relative disparity	<ul style="list-style-type: none"> Disparities should be measured in both absolute and relative terms in order to understand their magnitude, especially when comparisons are made over time or across geographic areas, populations, or indicators.
Measuring disparity in terms of adverse or favorable events	<ul style="list-style-type: none"> When relative measures of disparity are employed to compare disparities across different indicators of health, all indicators should be expressed in terms of adverse events.
Choosing whether to weight groups according to group size	<ul style="list-style-type: none"> The choice of whether to weight the component groups when summarizing disparity across a domain should take into consideration the reason for computing the summary measures. When assessing the impact of disparities, the size of the groups and the absolute number of persons affected in each group should be taken into account.

Measuring Disparity in Terms of Adverse versus Favorable Events. Although this choice refers only to relative measures of disparity, the ubiquity of relative measures makes it important. This choice point hinges on what it means to ameliorate disparity. In most cases the language is that of reducing or eliminating differences on some health indicator between a historically disadvantaged group and its comparator advantaged group. For example, the goal might be to reduce the relative difference in infant mortality rates between non-Hispanic blacks and non-Hispanic whites, the reference group. This entails reducing an adverse event. The intent of preferring adverse events is to increase consistency in reporting, especially across indicators to assess change over time. Additionally, measuring disparities in the same way facilitates comparisons of relative measures.

Choosing Whether to Weight Groups According to Group Size. Frequently, it is important to know the size of one social group's contribution to the domain under consideration and to weight group values accordingly. In these cases, group values may be statistically adjusted on some disparity measure to account for the size of a group's contribution to the domain. Depending on how they are applied, weighted measures may highlight the contribution of disparity to population health or they may obscure important health differences in relatively small populations. The choice of whether or not to weight measures should be made on the basis of the purpose of a particular study in the context of the accumulated literature, the size of groups, numbers of persons affected, and the reference point employed.

Identifying Determinants of Health Disparities

Members of non-white racial and ethnic groups tend to experience more ill health and disease than their white counterparts. On almost every health outcome variable, African Americans suffer more than European Americans.⁵ American Indians and Alaskan Natives (AIAN) experience significantly higher rates of dental caries, disability, diabetes, circulatory problems, arthritis, and death and are less likely to receive adequate care.^{27,28} Studies show that minorities often receive less care, less intensive treatment, and less follow-up care.^{4,29,30} Despite steady improvements in overall health status in the United States, racial and ethnic minorities experience a lower quality of health services, are less likely to receive routine medical procedures, and

have higher rates of morbidity and mortality than the majority population. These disparities in health care exist even when controlling for gender, condition, age, and SES. Due to strength and persistence of these effects, race/ethnicity has come into sharp focus as a key health disparity variable. Nevertheless, health researchers often do not define these terms and use them without questioning why such a discrepancy exists.^{13,29,31–33} Often the terms “race” and “ethnicity” are used interchangeably and without considerations of potentially important distinctions between the two.⁵

Dressler and colleagues⁵ recently described several models that attempt to explain health disparities. They describe a racial-genetic model, which emphasizes differences in the distribution of genetic variants between groups; a health-behavior model, which focuses on differences in the distribution of individual behaviors (e.g., tobacco use, physical activity) between groups; a socioeconomic model, which highlights the over-representation of groups within lower SES; a psychosocial stress model, which emphasizes the stresses associated with experiencing conditions such as racism; and a structural-constructivist model, which focuses on differences in morbidity and mortality due to both racially stratified structures and cultural construction of routine goals and aspirations.

Race is an especially problematic term. For many, race represents a biological reality. Increasingly, however, researchers have come to recognize that while human variation is biological, race itself is a cultural construction. As such, it is frequently used as a proxy for a variety of environmental, behavioral, and genetic factors, and consequently, “rigorous tests of the precise causal mechanisms involved are the exception, not the rule.”⁵ From this perspective, individuals are “racialized subjects.” They are only acknowledged in terms of their racial status, are therefore deprived of agency, relegated to being passive “victims” who lack knowledge, resource, and initiative.^{34,35} Additionally, “race/ethnicity” is frequently a code for black or African American, and research is primarily concerned with the health divide between European Americans and African Americans.^{5,13} Understanding the disparities between these two groups is essential to understanding health disparities in general. There are several explanations posited as to why such a discrepancy exists. The first explanation ascribes the poorer health of African Americans to their natural or genetic traits. This is an appealing explanation, because it fits with common ideologies regarding the biological reality of race, but actually, such claims are wholly unsubstantiated. Such suppositions

regarding genetic causes of racialized diseases have historically been used to manage and control black populations and make their higher propensity for disease seem natural and unproblematic.³⁶

One explanation attributes racial differences in disease to cultural or behavioral differences. In this view, suffering as a result of poverty or poor living conditions is explained as the result of a certain culture or lifestyle.¹² When culture is employed as an explanation for health, interventions are often misdirected toward individual behavior change. However, it is unreasonable to expect that behavior will change easily when so many other prohibitive social, cultural, and physical factors exist.³³ Notwithstanding behavior change adopted by some individuals, more will continue to enter the at-risk population because “we rarely identify and intervene on those forces in the community that cause the problem in the first place.”³⁷ A third explanation posits that the health gap between blacks and whites exists due to differences in economic status. However, SES, although a contributing factor, by itself cannot explain all racial and ethnic health disparities. Furthermore, this explanation assumes that all African Americans are of a lower economic status.

Yet another model attributes health disparities to psychosocial stress due to persistent racism and discrimination,⁵ wherein race is often treated as a proxy for racism, which is viewed as the determinant of disease.³¹ Nancy Krieger³⁸ identifies five pathways through which racism and discrimination harm health: (a) economic and social deprivation, (b) increased risk of exposure to toxic substances and hazardous conditions, (c) socially inflicted trauma, including perceived or anticipated racial discrimination, (d) targeted marketing of legal and illegal psychoactive substances, and (e) inadequate health care. These pathways implicate material, subjective, and institutional components of racism.

SES is one of the primary determinants of ill health.^{31,37} There is a clear link between socioeconomic status and health. SES influences virtually all major indicators of health status, including functional impairment, self-rated health, and disease-specific morbidity and mortality.³¹ However, disentangling effects of individual variables from the mass of SES definitions and variables employed in the research base is difficult. For instance, people living in economically deprived conditions may also be geographically isolated from necessary resources, such as health-care providers and grocery stores, and they often experience high rates of unemployment and are among those least likely to receive a high school diploma. Other SES-related variables to consider include lack of accumulated wealth among families, toxic environmental conditions, and low levels of social support or social capital. The effect of SES on health may be explained by psychobiological mechanisms. Specifically, long-term stress associated with low SES may result in chronically elevated cortisol levels.⁶ The Whitehall II study, for example, showed that decreased employment gradient position was linked to numerous stress-related conditions, including increasingly low control of work activities, lack of work variety, low job satisfaction, increased hostility, low social contact, distressing events, financial difficulties, and low control over health outcomes.³⁹ Individuals under such chronic stress have resulting chronic elevations of cortisol, as well as epinephrine and norepinephrine (catecholamines), which have been linked to decreased health status.⁶

Barriers to Reducing or Eliminating Disparities. Despite the recognition that issues of substandard or inadequate health care and access need to be addressed and remedied, numerous barriers stand in the way of efforts to reduce health disparities. First, racial and ethnic inequalities are overemphasized in health disparities research, while other differential aspects of health and health care are ignored. For example, the health needs of rural populations are less represented in the literature, and it is clearly an issue related to the overarching value of equity. In this regard, it may be asked whether it is fair that rural populations, in general, have higher mortality rates than urban dwellers.

More research is needed to uncover such potentially important findings as people living in nonmetropolitan areas are more likely to be uninsured (20% versus 17% in metropolitan areas) and are more

likely to participate in seasonal work and have lower incomes.⁴⁰ Therefore, rural inhabitants are at high risk for being both uninsured and living below the federal poverty level.⁴⁰ Second, interventions are not always effectively tailored to the target population. Medical care and health messages are targeted at a baseline, mainstream, unmarked audience. Campbell and Quintiliani⁴¹ argue that tailored messages are critical to eliminating health disparities, but they fail to recognize that messages are already tailored to the unmarked category, which is typically middle-class white male. Failure to target marked groups may lead to ineffective messages.

Finally, some contend that professional organizations impede efforts to reduce or eliminate health disparities. For example, New Zealand has had excellent success with a program that trains pediatric oral health therapists to provide basic dental care. Despite the proven effectiveness of this model, efforts to initiate this program in the United States to bring dental care to AIAN children have been stalled by the American Dental Association (ADA). The ADA is attempting to put legislation into place that would prevent non-dentists from making diagnoses or performing irreversible procedures such as treatment of caries or extractions, the most needed procedures among these children.²⁷ Due to this lobbying, scores of children and their families continue to suffer a lack of good dental hygiene.

One of the emerging trends in health disparities research is highlighting previously unrecognized underserved populations. For example, there is a small but growing body of literature regarding inequalities in the health status of elderly minority populations, which has resulted in more legislation to address this population.²⁸ Other developments focus on efforts to reduce/eliminate disparities. Empowerment is proposed as an effective strategy to facilitate efforts of people to gain control of their lives, meet new challenges, and create new, positive experiences.^{6,7} An extensive amount of recent work has focused on one empowerment-based strategy—CBPR as a way to reduce health disparities.^{33,37,42} In this approach, the reduction of health disparities is viewed as not only a matter of increasing access to services or reducing exposure to harmful agents, but also the rights of all people to participate as equal partners in policy and decision making, regardless of class, race, ethnicity, or national origin.⁴³

► OVERVIEW OF CBPR

Conceptualizing CBPR

CBPR represents an increasingly popular empowerment-based orientation to health research and practice that attempts to redress health disparities. CBPR occurs when professionals and community members work together as partners. The basic premise is that this partnership is equal. Each partner is viewed as bringing to the table different expertise at different points and time in the CBPR process. A widely cited definition for CBPR is that offered by the W.K. Kellogg Foundation’s Community Health Scholars Program.⁴⁴ CBPR is defined as a “collaborative approach to research that equitably involves all partners in the research process and recognizes the unique strengths that each bring. CBPR begins with a research topic of importance to the community with the aim of combining knowledge and action for social change to improve community health and eliminate health disparities.” As can be seen in this definition, CBPR emphasizes communities’ active engagement in the identification, implementation, and evaluation of solutions to problems confronting them. The construct of citizen empowerment, therefore, is a vital foundation of CBPR. Given the importance of the concept of empowerment in CBPR and other types of interventions concerned with health disparities, a brief review of the construct of empowerment is presented.

Empowerment. Empowerment refers to “a social action process by which individuals, communities, and organizations gain mastery over their lives in the context of changing their social and political environment to improve equity and quality of life.”⁴⁵ Empowerment occupies a central position in CBPR and other community-based health

promotion and disease prevention efforts, and is typically considered a mediator between health interventions and the achievement of crucial health outcomes.⁴⁶ Zimmerman's⁴⁷ theoretical framework has been an influential model of empowerment because it articulates processes and outcomes at individual, organizational, and community levels of analysis. Empowerment at the individual level may be labeled *psychological empowerment*, and may be conceptualized as including intrapersonal, interactional, and behavioral components. At the organizational level, *organizational empowerment* refers to organizational efforts that generate psychological empowerment among members and organizational effectiveness needed for goal achievement. Empowerment at the community level of analysis, *community empowerment*, refers to efforts that deter community threats, improve quality of life, and facilitate citizen participation. These empowerment concepts are useful because they may be used to evaluate the extent to which CBPR partnerships and initiatives are both empowering for citizens and empowered to create changes in environmental conditions that contribute to health disparities.

To address persistent public health challenges, researchers and practitioners have embraced participatory and empowerment-based strategies through various forms of community organization, such as coalitions or consortia, as well as CBPR partnerships. The principal advantage of community participation is that it may play a catalytic role in promoting individual development as well as system change, and its importance is emphasized in consensus statements of health promotion priorities by such institutions as the WHO. CBPR may be a particularly useful tool for addressing disparities in health for several reasons. One reason is that CBPR, at least conceptually, emphasizes reliance on community viewpoints in defining and developing solutions to health problems. This is in contrast to traditional expert-led processes, which often fail to create effective ways to address root causes of health disparities. In addition, CBPR may reduce health disparities through improved community capacity and empowerment. While it is generally held that community participation is a route to increasing capacity to confront the diversity of a community's health or social issues, much remains to be learned about how to tailor CBPR partnerships and initiatives to optimize their effects on health disparities. Because of the current popularity of CBPR as an empowerment-based strategy to redress health disparities, we will now turn to a critical analysis of published literature on CBPR initiatives.

Critique of CBPR Initiatives

In this section, we provide a critical analysis of published CBPR initiatives in rural contexts. To identify CBPR initiatives for our review, we conducted a computer database search that included PubMed, Cinahl Plus, PsycINFO, and Cochrane Database of Systematic Reviews. Both chapters and peer-reviewed journal articles were included in our search. Only projects that self-identified as CBPR were included in this review. Therefore, the phrase *community-based participatory research* was used to identify all CBPR projects. This phrase was combined, using an AND term, with the following keywords: *agriculture, agricultural, farmworker, migrant, rural, and village*. The inclusion criteria for the study included empirical studies, of rural populations, published in peer-reviewed journals or edited books between January 1995 and October 2005.

A total of 16 unique returns resulted from the database search. Of these, nine were considered ineligible upon review of the publications. Five were urban in location, and four were not empirical studies. The seven remaining publications represent ten different CBPR studies.^{43,48–53} One article reports on three studies, one article reports on two studies, and one study was reviewed in two different publications. The seven papers that met the inclusion criteria were coded according to the definition of CBPR as articulated by the W.K. Kellogg Foundation's Community Health Scholars Program, which was presented previously in this chapter. Two research assistants reviewed and coded each publication according to the CBPR definition criteria, and two different research assistants reviewed and coded each publication according to the content analysis tool. The lead authors

then discussed disagreements between the primary coders, and all discrepancies were resolved. The article was considered the unit of analysis for this review. Therefore, the two publications that represented one study were each coded separately, according to the information presented by the authors in the individual paper.

Of the articles and case studies reviewed which identified themselves as CBPR, only 20% clearly reported that the health problem was defined by the community. Conversely, the majority of articles appeared to indicate that the health problems of interest were defined primarily by university academics. Moreover, approximately 40% of the articles defined health problems using only empirical data. Unfortunately, few of the articles reported conducting community surveys or focus groups with community representatives to ascertain the community's health problem to be addressed. The majority of health problems were defined by university academics who had secured funding for a health problem.

The majority (57%) of the articles did not present information to represent the involvement of community partners in the research process. However, over 70% of the studies did present some unique strength of the partners during the process. There were no consistent presentations of the roles of each partner or specifically how they contributed to the partnership. Notably, only 10% of the articles reported the identification of any theory on which to base their work. Most articles (60%) used an observational design collecting information only at one point in time. Surveys were used 100% of the time for data collection, with some augmenting this information with archival or other data. Most of the information was collected via the interviews (80%); only 30% of the articles stated a testable hypothesis or research question to be investigated. The articles discussed here were by no means a comprehensive assessment of the complete body of CBPR literature. It does represent, however, articles during a specific time period, which stated using a CBPR approach to address a rural health issue.

What is self-evident is the lack of any standardized, accepted reporting policies based on agreed-upon definitions of CBPR. The articles lacked specificity on the roles of partners and their true collaborative nature. Overall, the research topics appeared to be initiated by researchers. Any assessment of the problem was only through empirical data for that area. While reasonable epidemiological approaches to public health exist, these approaches do not appear to fit directly into a CBPR approach to health because they were not based upon truly empowering processes that facilitated community control. It is clear that for CBPR studies to move forward and address health disparities, agreed-upon criteria by reviewers and editorial boards to assess the fidelity of CBPR partnerships and initiatives need to be developed. The assessment criteria could be based upon agreed-upon definitions through acceptable published literature.

Economic analyses of CBPR partnerships and initiatives may be especially needed to advance the health disparities agenda, but are currently absent from the published literature. Although there may be an inherent tension between issues of social justice and developing economic, profit-oriented justification and analyses, models for conducting economic analyses that may be applied to CBPR are found in disciplines such as health services research. The field of health services research has lived with the intriguing and at times frustrating reality that the utilization, costs, and outcomes of health and medical care services vary markedly by community.^{54,55} For a number of reasons, however, the field of health services research has not been able to fully capture the essence of community differences in its research. Part of the challenge has been that communities function, to some extent, as loosely coupled network forms of organization, and the research on such forms of organization is relatively young in its development.⁵⁶ This raises an important and challenging economic problem.

As many have recently argued, successful health initiatives of the future will be ones which can be supported by a clear "business case."^{57–59} How can we examine the "business case" for CBPR as a strategy to redress health disparities? Can proximal, intermediate, and distal outcomes be sufficiently measured and attributed to specific types of CBPR partnerships and interventions? Clearly, the challenge is different than, say, measuring the impact of a specific medical care

intervention and determining the extent to which the medical care intervention was responsible for observed changes in outcomes. This kind of analysis is the realm of standard intervention-based cost-effectiveness research.^{60,61}

CBPR may be relatively unique in that benefits accrue to the individuals who participate in CBPR partnerships, as well as to individuals for whom the interventions are intended and to the community as a whole. Evaluations of CBPR initiatives would appear to have limited their focus primarily to individuals for whom the interventions are intended. However, the benefits that accrue to partnership participants and the broader community in the form of enhanced skills and competencies, quality of life, and productivity at school and work may be equal to or greater than the sum of the individual benefits of the intervention. In other words, many CBPR initiatives may result in economic “spillovers” to the community, which in turn implies that any economic assessment or cost-effectiveness analysis of the CBPR initiatives would be incomplete without considering the secondary economic benefits to partnership participants as well as the community within which the intervention was employed.

► CONCLUDING REMARKS

A mounting body of research indicates that a disproportionate burden of morbidity and mortality exists among communities with few economic and social resources, and those of color. Researchers should continue developing concepts and measures of health disparities that reflect a comprehensive understanding of issues facing populations, subpopulations, and communities. These conceptual and measurement schemes should fit both the context of a population and a particular health concern. In addition, more work should be undertaken to understand and evaluate the increasingly popular empowerment-based approach of CBPR as a means to redress health disparities. The promise of CBPR to reframe the role of community in research is appealing, but researchers should be more systematic in applying and reporting explicit models and outcomes of community participation. Addressing these issues may be critical for researchers and practitioners to more effectively redress health disparities.

Genetic Determinants of Disease and Genetics in Public Health

Fred Lorey

Social policies, public health, and medicine, in that general descending order of importance, have improved human well-being and longevity in the twentieth century. Yet disease continues, in the form of sick populations and sick individuals,¹ and unhealthy longevity is a macroeconomic problem.² Naturally, there has been a response—one composed of social policies, public health, and medicine. In Canada, a major milestone in this response was the government document *A New Perspective on the Health of Canadians*,³ which outlined the Health Field Concept. Reasonable, thoughtful, and provocative, this document espoused a four-pronged attack on disease, and it welded ideas on lifestyle, environment, health care organization, and human biology into an approach to address disease more effectively. Considerable attention has been paid to the first three but rather less has been heard about the fourth component, namely, the biological basis of disease. This chapter addresses that particular theme. Our topic is genetic determinants of disease and examples of genetics and genetic disease in public health as illustrated by newborn and prenatal screening programs.

At least 5.3% of liveborn individuals in a large population of over a million consecutive births were found to have diseases with an important genetic component before age 25 years.⁴ If congenital anomalies (some of which have a genetic cause) are also included, then 7.9% of the population has been identified by age 25 as having a genetic disorder. A sampling of over 12,000 admissions to a pediatric hospital found that 11.1% were “genetic,” 18.5% were for congenital malformations, and 2% were “probably” genetic.⁵ These findings have been confirmed in other studies.^{6,7}

Health is a state of homeostasis, and it is maintained in the face of a changing and shifting environment. The central tendencies of metrical traits (mean values) are the quantitative measures of homeostasis (e.g., level of blood glucose, cholesterol, phosphorus, osmolarity, blood pressure, and so on).⁸ The polypeptide mediators of homeostasis (enzymes, transporters, channels, receptors, etc.) that are essential to this process of homeostasis are encoded by genes, descended to homo sapiens through the evolutionary process. Individuals retain health if experience does not overwhelm homeostasis or mutation does not undermine it.

In the conventional medical model, disease manifestations (symptoms and signs) are the product of a process (pathogenesis) that has an origin (cause). The manifestations of disease dominate the practice of medicine. Consideration of cause, incidence, and distribution of cases constitutes the public health focus. Public health in

genetics takes this a step further, by identifying and treating genetic disorders in large, universal populations of newborns, or providing earlier detection of birth defects in pregnant women.

Rather than thinking of the determinants of disease as outside ourselves, our genetic individuality should be seen as a potential ingredient in the origin of health. Because each individual has a different risk for disease, progress will be optimized if this fact is recognized, taken into account, and applied. Socioeconomic and environmental factors are important determinants of health, but, given a particular environmental factor, *who* gets sick may be determined by genotype. If environmental causes of disease are examined without taking genetic predisposition into account, we not only are getting an incomplete picture but also may be missing the chance to identify, and target with preventive programs, the most “vulnerable” groups.

In this chapter, we start with the premise that genetic causes of disease have implications for public health because they either explain cases or identify persons predisposed to disease under disadvantageous circumstances. Although most diseases have two histories, one biological and the other cultural, it is more likely that particular genes for genetic disease or predisposition exist differentially or in different frequencies in different populations because of the roles of natural selection, heterozygote advantage, or genetic drift and nonrandom mating. This means that in some populations the genes may have reached such a frequency that they may now exhibit “clustering” of related disease. When diseases have significant genetic determinants, there is an opportunity for prevention through counseling and treatment. To explain cases and thus understand why a particular person has a particular genetic disease at a certain time, we summarize the rules of inheritance. If diseases associated with inheritance of biological determinants reach particular high frequencies in a population, it is through one or several historical mechanisms: genetic drift (founder effect), selective advantage, high mutation rate, reproductive compensation, or several genes associated with a common, shared phenotype. These mechanisms are examined in this chapter because they are relevant to public health. They are helpful in our understanding of the impact and relevance of particular population screening programs to current and future disease incidence.

A completed human gene map (both genetic and physical) is an important resource in medicine and for public health; we therefore describe its relevance. Finally, medical screening is a conventional activity in public health; genetic screening is a new form of it. The rationales, principles, and practices of genetic screening are therefore examined as well. Because innovations on the horizon (e.g., DNA tests) will change the way health-care professionals view sick individuals and sick populations, we discuss the implications for public health and for society in general of the new genetic technology.

Note: This chapter was written for the 14th edition by Patricia A. Baird and Charles R. Scriver, and revised for the current edition by Fred Lorey.

► GENES IN POPULATIONS

Inheritance and Distribution

Since the beginning of Western medicine, it has been recognized that physical traits and some diseases are inherited. A conceptual basis for the mechanism of inheritance—the gene—has been richly borne out by a great deal of animal and plant experimental data as well as by empirical human data. However, time and research, much of it in public health, now tell us that the role genetics plays does not always fit the red, pink, white paradigm of Mendel's peas.

As a species we have a long evolutionary history, and natural selection has ensured that most genes we possess are useful and advantageous. However, deleterious genes certainly exist and cause major problems for their possessors. What determines the frequency of such genes? Will modern medical care for people with deleterious genes (relaxed selection) mean that as a species we will accumulate an increasing genetic load of such mutant genes? Take, for example, the prevalence of vision defects such as myopia. Look around you at the number of people who wear glasses or contact lenses (or in this day, have had remedial eye surgery). In our ancestors 50,000–100,000 years ago, such a handicap could be deadly, and that danger probably kept the frequency of these visual impairments low. Today, that natural selective force has been removed, and visual deficiencies are commonplace. Sickle cell disease increased in frequency only in malaria-infested areas because in the heterozygote state, it was resistant to malaria. Today, has the relaxation of that selective factor changed the frequency of sickle cell disease? The question of what determines the frequency of mutant genes is therefore an important one.

It has been estimated^{10–12} that a human being has between 50,000 and 100,000 structural genes. In general, except for those on the sex chromosomes in males, humans have two copies of every gene, and therefore each specific function in an individual is usually coded for by two genes—one from the mother, one from the father. If both copies in a gene pair code for fully functional gene products, the individual will have normal function. If both copies code for defective products that normally are essential for life, the individual will have in most cases, but not all, a lethal disease. If one member of the pair is normal and the other defective, the person's fate will depend on whether the normal gene has sufficient product to allow healthy function. Alternative forms of a given gene are called *alleles* of that gene. An individual who has identical alleles in a gene pair is said to be homozygous. If the alleles in a pair are different—that is, they code for different (although similar in structure) products—that individual is said to be heterozygous.

In thinking about the frequency of genes in a population, that population can be considered as a pool of genes, a pool from which any individual draws two alleles for each gene pair. Consider a population with random mating where a given gene may exist in the form of allele *A* or of allele *a*. The chance that a person will draw any one of three possible combinations (*AA*, *Aa*, *aa*) depends on the frequency of *A* compared with *a* in the gene pool.

If *p* is the frequency of *A*, and *q* is the frequency of *a*, then

$$p + q = 1$$

and

$$p = 1 - q$$

and the relative proportion of the three possible combinations will be

$$p^2(AA) + 2pq(Aa) + q^2(aa)$$

This formula for the distribution of genes in a population^{13,14} is known as the Hardy-Weinberg (H-W) equilibrium, since this

relationship holds only as long as there are no mitigating influences such as further mutation, natural selection, small population size, or positive or negative assortative mating (nonrandom mating).

However, when these H-W rules are violated, there can be a rise in the frequency of a particular phenotype caused by one or more of these factors:

1. Nonrandom Mating

If mating is random, the only thing determining the probability of a genotype's occurring is the relative frequency of the genes in the population pool. This condition may not be met if there is preferential mating due to traits wholly or partly genetically determined. Assortative mating (like with like) exists for several human traits.

2. Selection

A mutant allele that is harmful to the individual will be less likely to be passed on to the next generation, since its possessor is less likely to have children. In other words, it will be selected against and become less frequent. If the allele is *dominant* (i.e., just one copy of it is harmful), selection may be quite rapid, particularly if it means that all individuals with the gene are unable to reproduce; then no copies will be passed on to the next generation. In this situation, if the disorder occurs in the next generation, it does so by new mutation. Thus the proportion of cases of a dominant genetic disorder that are inherited depends on the effects of the gene on the likelihood of reproduction by its possessor. Selection against *recessive* alleles is much less effective, since most copies of the gene exist in carriers who are normal and able to pass the mutant gene on. Even if selection is completely against reproduction in the homozygote, it would take 10 generations (about 300 years) to reduce a gene frequency of 0.10 to 0.05. The less frequent the allele, the slower the decline in frequency. From a health policy point of view, it is important to note that going in the opposite direction—that is, removing selection—acts just as slowly. Successful therapy for phenylketonuria, for example, would take many generations to raise the frequency of the gene to any appreciable extent.

If an X-linked allele affects the male so that he does not reproduce, only the genes in female carriers are passed on to the next generation. Females carry about two-thirds of all such mutations. If affected males are able to have children, then a greater proportion of cases in the next generation are inherited. Treatment of males with hemophilia, for example, would be expected to cause some increase in the frequency of this condition in the absence of any other measure (such as prenatal diagnosis).

3. Mutation

A mutation is a change in the genetic material (DNA). The term can be used in a broad sense to encompass any change, including chromosomal deletions or rearrangements. However, it is usually used to mean a change in the DNA sequence of a gene so that the gene product is different (a point mutation), and that is how it is used here.

Mutations are the raw material of evolution and, in a changing environment, give a species the ability to adapt. However, most mutations cannot be expected to be beneficial, since they occur in an exquisitely coordinated system of genetic information that has taken eons to develop. A random change is not likely to be helpful. Many new dominant mutations are lethal either in utero or very early in life, so that the cases actually observed in human populations represent only a proportion of those that occur.

It is difficult to estimate with any accuracy¹⁵ the current mutation rate in humans. It is probably quite different for different gene loci. An "average" spontaneous mutation rate in humans would be about 1 in 100,000 per locus per gamete per generation. Since mutation is usually a stochastic event, the longer the time elapsed, the greater the likelihood that a mutation will have occurred. Thus it could be predicted that parents who are older at conception would have an increased risk for a child with a dominant mutation, and this in fact is borne out by data. There is increased paternal age in fathers

of children with dominant disorders (e.g., achondroplasia) that have never before occurred in the family.^{16,17}

4. Heterozygote Advantage

It is possible that a gene that is harmful in the homozygous state may be advantageous in the carrier. This is the case with the genes for thalassemia and sickle cell anemia, which in carriers may protect against malaria.¹⁸ The gene for Tay-Sachs disease is frequent in Ashkenazi Jews, and it has been suggested that under ghetto conditions¹⁹ it confers an advantage in the carrier. The occurrence of such genes in populations has importance in terms of health planning and in evaluating whether screening programs are appropriate for particular groups within the larger population.

5. Genetic Drift and Founder Effect

When people migrate to new regions, they may develop “new” diseases or express “old” disease at higher frequencies. This phenomenon reflects either new experiences or “old” genes expressed at altered frequencies in the settlers.²⁰ How many susceptible persons there are in the newly resident population after migration of the “founder” depends on the number of incoming mutant genes borne by the founders and on factors that favor their spread through the population (rates of natural increase, degree of consanguinity, and mode of inheritance). Accordingly, demographic history and structure of genetic variation may explain clustering of cases.

In the absence of any factor disturbing the equilibrium, the proportions of the genotypes will remain the same from generation to generation. Thus, if one knows how often a disease due to two defective alleles (a recessive disorder) occurs, it is possible to calculate the frequency of heterozygotes (or carriers) in the population. For example, if a given recessive disorder (*aa*) appears in 1 in 10,000 liveborn individuals, the frequency of carriers (*Aa*) in that population will be approximately 1 in 50.

However, as we discovered with Mendel’s peas, the reality with H-W is often different than the theory. Public health genetics, because of its universal and large population numbers, has often provided the evidence for this. In California, for example, where there is a significant Asian population, newborn screening for hemoglobin (Hb) E has shown that the frequency of carrier (heterozygotes) versus homozygous EE or E/beta-thalassemia does not conform to H-W.²¹ The most logical violator of the H-W rules in this case is probably that there is not random mating in this population. In this illustration, as with many mutations, there are far more copies of the gene in carriers than occur in affected individuals. In other words, based on the frequency of Hb E carriers, one would expect far more homozygous EE individuals in the population than are seen.

Methods of Measuring Mutation Rates

In theory, simply counting all individuals in a population of births who have a disease known to be due to a dominant gene, at the same time by family history evaluating how many are not inherited, should give the mutation rate for that locus. In practice, even with excellent population-based disease registries, this is extremely difficult to carry out in a large population. In addition to the logistical difficulties of collecting complete information on a large number of individuals, it is complicated by such factors as nonpaternity, mild cases that are missed, patients who die before ascertainment, and similar conditions that may be wrongly categorized. Indirect approaches to estimating the mutation rate for recessive disorders use the fact that the frequency of the recessive disease can be counted and that the reproductive *fitness* (the proportion of mutant to normal alleles passed on) can be measured in affected individuals. These are related as follows:

$$\text{Mutation} = (1 - \text{Fitness}) \times \text{Disease frequency}$$

These methods have yielded a range of estimates and may differ according to gene locus and sex.²² In any case, determining frequencies in humans is difficult.²³

► INCIDENCE AND PREVALENCE OF GENETIC DISEASE

Measuring the frequency of genetically determined diseases in a population, in the absence of public health programs, is also difficult. Onset may occur at any time in the life cycle, and there is a gradation from diseases due to genes that do not permit normal function in any environment to those in which genetic predisposition is expressed only in certain environments. Statistics are usually available on a population only for aspects such as mortality by categories of cause or hospital admissions for diseases coded to the International Classification of Disease (ICD). This classification does not allow the frequency of genetic disease to be estimated because it is not a classification by etiology.

However, population-based registries, most often obtained by public health genetics programs like newborn screening, prenatal screening, or birth defects monitoring, offer a mechanism for counting the occurrence of various disorders that may answer this question. Registries provide the basic information on disease incidence and prevalence necessary for planning health and other special programs and facilities such as health professional and other personnel needs. If a registry receives information from multiple sources over individuals’ lifetimes (especially if this can be linked into sibship and family groupings), some classification of disease in a population by etiology is possible. Additional coding for classification of cases by etiology is needed. With this approach it is possible to get some estimate of the relative importance of genetics to health.^{4,24} Some estimates on the role of genes at different stages of life are provided:

Conception to Birth

Between 50 and 70%²⁵ of pregnancies in healthy women fail to produce liveborn babies. Genetic causes are a major factor in failed pregnancies, especially those during the first trimester. Chromosomal abnormalities are found in half of early spontaneous abortions.²⁶

From Infancy to Young Adulthood

The relative contribution of genetic disorders to all causes of disease in our population has likely increased markedly in this century for many conditions. As environmental causes of death and disease have declined, such as for infant mortality,²⁷ genetic causes assume more prominence. As the nutritional causes of rickets have declined, the proportion due to genetic defects in vitamin D metabolism has increased,²⁸ and the heritability of the conditions has increased. This is but one example of several thousand different genetic diseases,²⁹ many of which are likely to have also increased in heritability as the environment has changed.

From Middle to Late Adulthood

We have very limited knowledge about the effects of genetic factors on the overall health of people after 25 years of age. The incidence of multifactorial disorders of late onset may be up to 60% if such conditions as diabetes, hypertension, myocardial infarction, ulcers, and thyrotoxicosis are included.³⁰ Including certain cancers makes this figure even higher.

If age-specific mortality rates are examined, a characteristic “U-shaped” mortality curve is obtained, with rates highest at each end of the age spectrum. The causes of death composing the two arms of the curve are not the same.³¹ Those in early life are characterized by abnormal development and difficulty in adaptation to life after birth. Mendelian disorders are characteristically diseases of prereproductive life,³² with over 90% being apparent by the end of puberty. They reduce the life span and usually cause psychosocial handicaps. Those in the other “limb” of the curve are mainly diseases associated with specific environments, patterns of living, particular occupations, and advancing senescence.

Several predictions follow from the assumption that heritability of disease declines with increasing age³¹:

1. Persons with early onset are more likely to have severe disease and to have affected first-degree relatives.
2. Age-at-onset should reach a peak and then decline, since by some age most of those with the relevant genes will already have the disease.
3. There should be multigenic diseases that do not require a specific environment.
4. Migration, socioeconomic status, and other environmental change may change age-at-onset and the likelihood of the disease's clustering in families.
5. If one sex is less often affected, early onset, severity, and increased incidence in affected relatives should characterize it.
6. Concordance in monozygotic twins should be greatest when disease onset is early.
7. Patients with late onset have milder disease that is more responsive to prevention and treatment.

For disease categories with a wide range of age of onset, monogenic forms are more likely to be found among the early-onset cases, multifactorial subtypes should characterize adult and middle age, and in the very old, the disease should likely be due to environmental determinants. Single-gene disorders of early onset carry heavier burdens than those of later life and are relatively resistant to treatment.³³ There may be an irreducible minimum of genetic contribution to disease and death that feasible environmental manipulation cannot prevent, and the genetic variation in the population may determine the limits to what can be achieved by any environmental measures. However, with the advent of a greater understanding of genetic pathophysiology, it may become possible to tailor "microenvironments" to fit particular genotypes.

Determining the role of genetics in disease will require better methods of classifying disease and processing health data. Computerized record linkage will be increasingly important, not only to build longitudinal health histories on individuals but to link these into sibships and family groupings. Administrative and other health data sets that already exist can be combined to evaluate if familial clustering occurs. If familial clustering is found, then various methodologies may be used to untangle whether this is due to genetic or shared environmental factors or, more likely, an interaction between the two.

► CATEGORIES OF GENETIC DISEASE

Given that genetic disease has a substantial impact on health, it is of interest to examine the various categories of genetic disease that occur in humans, their frequencies, and the strategies currently available to deal with them. Several categories may be used when thinking about genetic disease, although at some level these are artifactual and imposed to organize the reality, which is a continuum.

Chromosomal Disorders

One in 200 liveborn infants has a chromosomal error, making this a common category of disorder. All are potentially detectable by prenatal diagnosis, but since only those subgroups of women identified as being at higher risk (because of age or family history) are screened prenatally, there is the opportunity to avoid only a proportion of such conditions at present. Errors may occur in the number of chromosomes (too many or too few) or in their structure (deletions or duplications of parts of chromosomes). Two texts cover this topic in depth.^{34,35} Many of these errors are incompatible with survival to term; for example, almost half of all recognized spontaneous abortions in the first trimester have chromosomal abnormalities.³⁶ The proportion of stillborn infants with chromosomal errors is about 6%.^{37,38}

Autosomal Chromosome Disorders

If an extra chromosome occurs for a given pair, this is called trisomy. Trisomy has not been observed in living infants for most chromosomes,

although it is compatible with life for the sex chromosomes and chromosomes 13, 18, and 21. The latter, Down syndrome, is the most frequent trisomy in liveborn humans. It occurs approximately once in 1000 births, but large-scale screening in public health programs has indicated the prevalence rate in second trimester is closer to 1/700. So the exact frequency depends on the age composition of reproducing women in the population and whether prenatal diagnostic programs for its detection are in place. It is the most common recognizable cause for mental retardation in Western populations and is thus of relevance to public health and planning. Its occurrence is very strongly related to maternal age;³⁹ prenatal diagnostic programs are usually offered to detect chromosomal abnormalities in pregnant women over 35 years of age. Even though these programs are shown to be cost-effective in terms of health resources, they can reduce the birth incidence of Down syndrome only to a limited degree.⁴⁰ This is because, even though young women have a much lower risk individually, they contribute a far greater number of births than women over 35, so that most Down syndrome infants are born to young women. However with universal or nearly universal prenatal screening for under 35 women, the birth incidence can be reduced. It is important that couples with an increased recurrence risk are made aware of the option of prenatal diagnosis in future pregnancies. It used to be thought that survival to adulthood in Down syndrome was very poor, but recent data^{41,42} show that over 70% of afflicted individuals survive to their thirties and about half to their late fifties. This obviously has implications for programs planning to integrate affected individuals into community, educational, vocational, and residential settings.

The other autosomal trisomies (13 and 18) are less frequent (1 in 11,000 and 1 in 6000 livebirths, respectively [California Birth Defects Monitoring 2005]) and result in infants with multiple congenital anomalies who often fail to thrive and die relatively young. It is important to make the diagnosis so that the parents may be counseled regarding the etiology, prognosis, and recurrence risk. Deletions (or duplications) may occur in any chromosome and occur anywhere along the chromosome. The size will vary among patients and give rise to a whole array of abnormal conditions. Some correlations of particular chromosomal abnormalities with particular clinical pictures have been made, for instance, deletion of part of the short arm of chromosome 5 with the cri-du-chat syndrome. Such chromosomal abnormalities explain why many infants and children are retarded, fail to thrive, and have birth defects.

Sex Chromosome Disorders

Recognition of sex chromosome disorders is important so that there is opportunity for avoidance of abnormal offspring and so that the affected individual can receive proper management to avoid known complications. Turner's syndrome was described in 1938⁴³ in girls who were short and sexually immature. It was later⁴⁴ discovered that this clinical picture was found in girls missing the second X chromosome in at least some of their cells. This condition occurs once in 5000 livebirths and does not occur more frequently in the offspring of older mothers; the recurrence risk is negligible. Klinefelter's syndrome occurs in newborn surveys in about 1 in 500 males. This term is used to refer to males who have at least one extra X in at least some of their cells. The classic case has an XXY constitution, but there are other variants. The more Xs present, the more likely are mental retardation and additional physical stigmata. If Klinefelter's syndrome is not detected during childhood, afflicted males may learn that they have the syndrome when they attend an infertility clinic as an adult.

The XYY syndrome probably occurs about 1 in 500 males. This condition was sensationalized in the lay press for a time because of a theory that the extra Y made these males taller, aggressive, and anti-social. A study in the Danish population of army inductees⁴⁵ with this condition showed that crimes of violence against another person were not higher, although the total rate of criminal convictions was greater. The intelligence and educational level of XYY individuals was lower than control subjects, and it is possible that they may not commit crimes more often but get caught more often. The triple X female has been given the misnomer "superfemale" by some; however, retardation and

infertility are increased in these women, although most are probably never diagnosed. If the diagnosis is made, prenatal diagnosis should be offered, since they are at increased risk for bearing XXY and XXX offspring.

Autosomal Dominant Disorders

This is the first of four categories that fall into the “single gene” or Mendelian disorder group. It is important to understand the mechanism of their transmission, so that opportunities for prevention can be incorporated into planning and that the differing impact of preventive programs on the future frequency of these disorders be understood. In total, by 1997, over 5000 Mendelian disorders had been documented, with another 3000 conditions thought to be in this category. Most of the identified loci (4917) were on autosomes with less than 300 being X linked.⁴⁶ Although individually each is uncommon, there are so many that they have in toto a substantial impact on the health-care system.

If an allele is always expressed, whether that person is homozygous or heterozygous at that locus, it is said to be dominantly inherited. If a gene is expressed in the phenotype only when it is homozygous, that trait is said to be recessively inherited. This distinction between dominant and recessive inheritance is an operational one for convenience in many ways. As better techniques are found, more recessive genes in the heterozygote can be detected. Thus, the line between dominance and recessiveness is an artificial, albeit useful, concept in practice.

What sorts of disease are inherited in an autosomal dominant fashion? Included in this category are such entities as Huntington’s disease, neurofibromatosis, achondroplasia, tuberous sclerosis, and Marfan syndrome. If the affected person reproduces, the abnormal gene will be passed on average to half his or her children, who will also be affected. If a person does not receive the gene, then that branch of the family is “in the clear” from then on. Dominant disorders can change frequency rapidly in the population with intervention, making genetic diagnosis and counseling crucial.

Variable expressivity must also be considered before counseling is given. Each dominantly inherited disorder has a recognized profile; one disorder may have a very narrow range clinically with little variation in expression, whereas another may typically differ between persons even within a family. If an individual has the gene for a disorder where variable expressivity is not a feature, it is safe to reassure the apparently normal sibling that his or her children will not be at increased risk. However, for dominant disorders where there is great variation in severity, such as osteogenesis imperfecta, this reassurance must be tempered with caution. If a couple asks advice about risk for children when this disorder is segregating in their family, a detailed and sophisticated examination is indicated.

Another recently identified factor is *imprinting*, which is imposed on the genetic information during gametogenesis.^{47–50} This imprinting persists in a stable fashion throughout DNA replication and cell division in an individual, to be erased in the germ line and then be differentially established once more in the sperm (or egg) genomes of that individual. It has the consequence that expression of a given disease gene can depend on whether it is inherited from the mother or the father. Other factors to consider are *reduced penetrance* (where some individuals with the gene will show no clinical effect) and variation in age of onset. All genetic disease is not congenital. Many genetic disorders do not become clinically evident until adulthood or midlife. Genetic heterogeneity is a common phenomenon that must be taken into account, not just for dominant disorders but for all categories of genetic disease. A genetic disorder that appears to be the same in different families may in fact be due to different lesions in the same gene or to a different mutation at another locus that affects the same pathway, and therefore, leads to a similar clinical endpoint. When a case is sporadic and no other individual in the family is affected, the clinical endpoint observed may have been reached by other means than a single gene mechanism, such as an environmental insult in development.

Autosomal Recessive Disorders

Most recessive disorders are individually rare, each with a birth prevalence of 1 in 15,000 to 100,000. However, since there are so many, they have a considerable impact, with more than 1 in 500 live-born individuals being identified as having one of these disorders before age 25 years. They often have their onset in early life, and there are population screening programs at birth for several of them, based on biochemical testing. Rapid advances in DNA technology will make it possible to offer population screening programs in a public health context for some of these disorders. Examples include phenylketonuria (which results in retardation and seizures, but can be treated by diet) and a whole host of other metabolic disorders all detectable by a single methodology called tandem mass spectrometry (ms/ms), adenosine deaminase deficiency (which results in severe immune deficiency and early death), and cystic fibrosis, which is one of the most common recessive disorders in white populations (approximately 1 in 22 people carry this gene).

Since genes segregate in families, the rarer the particular recessive allele for a disorder, the more likely that consanguinity is observed in the parents of an affected child case or that the individual will be born into a religious or geographical isolate. An allele for a particular recessive disorder may be so common in some subgroups that an appreciably increased risk of affected offspring occurs. It is therefore desirable to offer carrier or prenatal testing to these groups (e.g., Tay-Sachs disease in Ashkenazi Jews; thalassemia testing for populations of Mediterranean or Asian descent). For disorders with a very high carrier rate in the population (such as hemochromatosis, which has a carrier rate of about 1 in 10 people),⁵¹ cases may appear in succeeding generations, a feature not usually observed for recessive disorders.

Just as with dominant disorders, genetic heterogeneity may occur. For example, a couple, both deaf because of being homozygous for a recessive gene that causes hearing loss may have normal children if the genetic lesion in one parent is not allelic to that in the other. There is also variability seen in recessive disorders, just as in dominantly inherited disorders. This may be because of molecular heterogeneity—that is, the lesion in the gene is different on the two chromosomes—or because the recessive genes act on different backgrounds of other genes.

In an increasing number of recessive disorders, prenatal detection is now possible. Unfortunately, a particular couple usually does not realize the need for prenatal detection until they have had one affected child; however, they may wish to have the opportunity to avoid having another affected child. In some disorders that cause severe shortness of stature or particular morphological abnormalities, x-ray or ultrasound studies may be diagnostic. In others with a known biochemical defect, enzyme activity or other metabolites can be measured either directly in the amniotic fluid or in cultured fetal cells. In yet others, DNA diagnosis is possible. An enzyme deficiency has already been demonstrated in about a third of the known recessive disorders in humans.²⁹ Two alternatives that should be mentioned to couples who do not wish to take the one in four risk of an affected child and for whom prenatal diagnosis is not possible are adoption and gamete donation.

X-linked Recessive Disorders

Some examples of X-linked single-gene disorders are hemophilia and Duchenne’s muscular dystrophy. In X-linked recessive disorders, the problem gene is located on the X chromosome. Since females have two Xs, if one is normal, that female will be healthy. Since males only have one X, if this has the X-linked disease gene, the male will be affected. In these families, therefore, females may be healthy, unaffected carriers of the gene, but half of their sons will have the disease. Carrier detection tests for the female relatives of male patients are very important in giving them the option to avoid having affected sons, and prenatal diagnosis is becoming available for an increasing number.

X-linked Dominant Disorders

There are fewer disorders in this category, with some examples being familial (XL) hypophosphatemia with rickets, and Alport's syndrome (hereditary nephropathy and deafness). X-linked dominant disorders occur in females as well as in males, and an affected female transmits the gene to half her daughters and half her sons, whereas an affected male transmits it only to his daughters, all of whom will have the gene. There is no male-to-male transmission.

Mitochondrial Disorders

The mitochondria in human cells have circular chromosomes that contain genes that code for proteins involved in oxidative phosphorylation, providing the cell with energy. Since the mitochondria are cytoplasmic organelles, these are always inherited from the mother. A characteristic of cytoplasmic inheritance is that segregation ratios characteristic of Mendelian disorders are not observed, but many offspring in the maternal line are affected. By 1997, 37 mitochondrial loci had been identified.⁴⁶ Some clinical entities identified with mitochondrial mutations are Leber's optic atrophy, infantile bilateral striatal neurosis, and Kearns-Sayre syndrome. The situation is complex in that a wide range of abnormality is possible, depending on the numbers of abnormal mitochondria included in the egg and the differential multiplication of these organelles in different tissues.⁵² They may explain some errors of development and congenital malformations, as well as later-onset disorders.⁵³

Multifactorial Disorders

In this group, interactions between environmental factors and the genes of an individual cause disease in ways only partly understood. Some examples are common congenital malformations, such as neural tube defects (spina bifida and anencephaly), congenital dislocated hips, and some adult-onset disorders such as atherosclerosis, hypertension, schizophrenia, and some cancers. It is likely that most chronic diseases of adult onset with a major impact on health care and social systems fall into this group. This is by far the largest category of disease where genetics plays a role; it appears that even by age 25 at least 1 in 20 individuals in the population is affected by multifactorial disorders; over a lifetime, probably a much greater number are affected.⁴ The situation is not simple, and at the population level a given disease category is likely to consist of individuals who have reached that endpoint by a variety of genetic "routes," some interacting with environmental factors.

It is likely that many individuals with a common disease such as Alzheimer's disease, atherosclerosis, manic depression, or diabetes have a gene that determines whether external influences will result in illness. In the future, the use of DNA markers may give the opportunity to prevent expression of the disease. For example, 1–2% of the population has a single gene type of hyperlipidemia. These individuals constitute over a quarter of individuals with heart attack at less than 60 years.³⁸ Such individuals may avoid this by early detection, followed by diet and medication. Since genes underlying predisposition to these "multifactorial" conditions cluster in families, there is an opportunity to identify and pull out of the larger group subsets of individuals (and members of their families) who are identifiable as being at increased risk.

► THE HUMAN GENE MAP AND GENE SEQUENCING

A detailed knowledge of the structures of genes would open the door to diagnosis and treatment of human genetic disease. A collaborative project—the Human Genome Project¹²—to obtain such knowledge for all human genes, by determining the sequence of the DNA in all 23 different human chromosomes, has been undertaken by human and molecular geneticists worldwide.

Several remarkable technological developments have made it possible to determine the human sequence and to "map" the location

of any gene. The first is *molecular cloning*, the insertion of a stretch of DNA of interest from one source into another DNA molecule that can reproduce itself independently in special strains of laboratory bacteria. This allows the collection of purified DNA molecules in very large amounts that could not be obtained from their original sources. Another is *DNA sequencing*, the ability to determine the order of the bases for any stretch of DNA that has been cloned, and automation of that sequencing.

Several complementary and useful approaches to developing the human gene map include somatic cell hybridization, in situ hybridization, cell sorting, deletion and duplication mapping, linkage development of yeast artificial chromosomes, and sequence scanning.¹² These methods are even more powerful and informative when used in a complementary way.

► EVIDENCE FOR CLUSTERING IN FAMILIES

Obviously, if a disease is common, it may occur in more than one member of a family simply by chance. Several features, if present, provide evidence that the familial clustering is nonrandom:

1. Healthy individuals who have a family history of the disorder when followed over time develop that condition more often than other comparable individuals without any family history.
2. The relatives of afflicted individuals have a greater frequency of the disorder than comparable control subjects.
3. The relatives of afflicted individuals have a greater frequency of the disorder than is found in the general population.
4. If the trait can be quantitatively measured (e.g., blood pressure), there is a positive correlation between pairs of related individuals.

It is essential that the endpoint or disease being evaluated for familial clustering is as homogeneous as possible. If the disease being evaluated is actually a clinical picture that can be reached in several different ways (some with a genetic determinant, others where an environmental factor is the main determinant), then a very confused picture may result, with some studies finding familial clustering and others not.

There are many common diseases in adults that by the foregoing criteria have been shown to aggregate in families. For example, coronary heart disease shows familial clustering even after all known risk factors have been adjusted for (e.g., smoking, weight, serum lipids, blood pressure, diabetes, behavior pattern). There is also evidence for familial clustering of each of these risk factors.⁵⁴ Several birth defects, neurological and behavioral disorders, and cancers also cluster in families by the usual criteria. Identification of this clustering is the first step in untangling the complex web to elucidate the genetic components that determine a disease. Clustering in families may be due not to sharing of genes but to sharing of a common environment or cultural transmission of disease determinants. Even showing that the correlation in the disease frequency is greater the closer the genetic relationship is not sufficient, since shared environmental and cultural factors may also increase as the relationship gets closer.

Methods to Elucidate Cause of Familial Clustering

Usually several methods are used because they are complementary.

Twin Studies

Monozygotic (MZ) twins are genetically identical; they result from the splitting of one fertilized ovum. Dizygotic (DZ) twins are only as genetically alike as any two siblings. This allows comparison of genetically identical and genetically different individuals who are usually raised in a similar environment. It therefore makes possible an estimation of the degree of genetic influence on the disease. It is

also possible to look at identical twins reared apart and together to help estimate the effect of environmental factors.

If a disease were completely determined by gene(s), then the concordance rate in MZ twins should be 100% and the concordance in DZ twins should be the same as in the other siblings of a proband. Studies in MZ and DZ twins for many common adult disorders show much higher concordance in MZ than in DZ pairs. This is true for schizophrenia, multiple sclerosis, alcoholism, affective disorders, epilepsy, the neuroses, non-insulin-dependent diabetes mellitus, and allergies, clearly demonstrating a genetic contribution. However, the concordance rate in these studies in MZ twins is less than 100%, demonstrating that an environmental component is also present. Interestingly, the concordance rate for DZ twins in these studies is often greater than that shown between twin probands and their other siblings, which could reflect a greater similarity in environment of DZ twins compared with other siblings or could reflect some selection bias.

Heritability Studies

Heritability (h^2) in the narrow sense is defined as the contribution of additive genes to the phenotype of interest. It will be the proportion of variance in a population for the trait contributed by additive genes (V_A) compared with the total population variance for the phenotype (V_p).

$$h^2 = V_A/V_p$$

In genetic aspects of human disease this definition of heritability is usually broadened to

$$h^2 = VG/V_p$$

where VG refers to the total genotypic variance including nonadditive interactions, such as dominance or epistasis, between genes. (Epistasis is the synergistic effect of genes at different loci.) Estimates of heritability of a trait relate to the particular conditions under which it is measured. For example, if the environment changes, it is no longer valid. Estimates of heritability have been made for many quantitative human traits. They should be interpreted only as indicators of whether the role of genes is relatively large or small in the population and of the circumstances in which the condition is measured.⁵⁵

Analysis of Familial Common Environmental Exposures

Familial clustering may be due to clustering of culturally transmitted behaviors or family practices that result in particular exposures (e.g., dietary or smoking habits).⁵⁶ Kuru, for example, was a disease thought to be genetic but in reality is due to an infection perpetuated by ritual cannibalism. It is likely that diseases such as lung cancer or alcoholism involve cultural inheritance of exposure behavior as well as genetically inherited determinants.

Associations Between Genotype and Susceptibility

Humans differ in an identifiable way in their human leukocyte antigen (HLA) system and their ABO blood group systems, thus allowing evaluation of existing genotypes in these systems. Different genotypes within these systems are associated with the occurrence of any one of a variety of diseases. Increasingly, recombinant DNA polymorphisms will be evaluated and correlated with a variety of disease outcomes in the same way. There are now a number of well-documented examples where having a particular identifiable genotype is associated with disease susceptibility (or resistance).

Methods for Determining Mode of Inheritance

Most common diseases that cluster in families do not show simple Mendelian inheritance, since they result from an interaction of both genes and environmental factors. A number of methods elucidate the mode of inheritance of the genetic susceptibility.

Multifactorial Model Analysis

The genetic component to determination of a disease with a multifactorial etiology could be equal to additive effects of many genes or a few or one gene of large effect. Either model explains why individuals could be put over a threshold in the continuum of liability and thus show disease.

The introduction of methods to detect single genes (HLA typing, DNA polymorphisms, sophisticated statistical pedigree analysis) has, in recent years, shown that it is likely that one or a very few genes of major effect are involved in the multifactorial pathway.⁵⁷ This finding is relevant to diabetes mellitus, rheumatoid arthritis, and some hyperlipidemias. Increasingly there will be opportunities to identify predisposed individuals, and the study of families (particularly those of early-onset cases) may give the opportunity to target clusters of higher risk individuals. The model where many genes of small effect are relevant (polygenic) may apply to pyloric stenosis.

Segregation Analysis

If a single gene has a major effect on disease susceptibility, it is essential to clarify how it is inherited—autosomal dominant, autosomal recessive, or X-linked. These alternative modes of inheritance give different disease risks for different classes of relatives (e.g., 50% of children are affected if dominant, compared with a low risk for the children of an individual with a recessive disorder). By comparing the observed disease incidence in each class with that expected based on alternative genetic models, it is possible to see how well these agree.

Analysis of Maternal Effects

As discussed previously, the DNA of the mitochondria is inherited only from the mother. This means that diseases that appear to affect both males and females but are transmitted only by the mother are candidates for this mechanism of inheritance,⁵² and data may be analyzed with this hypothesis in mind.

Linkage Analysis

If segregation analysis shows that inheritance of a single gene may be responsible for disease susceptibility, it is possible to look at whether a wide variety of genetic markers (including DNA polymorphisms) segregate along with the disease susceptibility. Already this approach has indicated that a dominant susceptibility allele may exist in linkage to particular DNA markers in certain families for Alzheimer's disease,⁵⁸ manic depression,^{59,60} and breast cancer.⁶¹

Sibling Pair Methods

These are particularly relevant where data on genetic haplotype (usually for the HLA region) is available in siblings. On the hypothesis that there is a disease susceptibility gene close (linked) to the HLA region, this gene should usually be inherited along with a particular haplotype. Thus, siblings who share this HLA haplotype are more likely to have also both inherited the susceptibility allele. This method evaluates coinheritance of HLA haplotype and disease. Siblings who are both affected with the disease would be expected to share the same haplotype more often. With sufficient data on affected sibling pairs, it is possible to evaluate the mode of inheritance of the disease-predisposing allele.⁶²

Particular genes occur in higher frequency in a number of subgroups. One such gene is that for Tay-Sachs disease in Ashkenazi Jews. Between 1970 and 1980, over 300,000 Jewish adults were voluntarily screened.⁶³ Screening for carrier detection for cystic fibrosis, now that the gene has been located,⁶⁴ is likely to develop rapidly. This disorder is common (1 in 2000 to 2500 births) in individuals of northern European extraction. Thalassemia screening is offered to people from southeast Asia and China, since the frequency of this gene is similar to that of the cystic fibrosis gene in northern Europeans. Populations of Mediterranean origin may be screened for beta-thalassemia.⁶⁵ Congenital hypothyroidism, though in most cases not genetic in nature, can vary from 1:1900 in Hispanics to 1:10,000 in African Americans, and is twice as frequent in females as males.^{66,67}

Genetic methods are increasingly allowing us to identify genetically susceptible individuals. Tools from classic epidemiology can then be profitably used to compare environmental factors in affected and unaffected genetically susceptible individuals. Conversely, the other approach to disentangling the interaction is first to identify those individuals who have the environmental factor present and then compare the unaffected and affected in that group, looking for particular genetic subgroups. The new molecular genetic techniques now allow particular DNA sequences to be evaluated in patients and in control subjects and hold out the hope of more fruitful progress.

► SCREENING

Let us now return to the field of public health genetics. Genetic screening may serve several objectives. A program may exist to identify individuals with a particular genotype so they may receive an intervention or treatment. Newborn screening programs are of this category. A program may exist to identify individuals who are at risk of having children affected by a genetic disease. Examples of such programs are Tay-Sachs screening in Ashkenazi Jews and amniocentesis for prenatal karyotyping in women over 35 years of age. Or, in some cases, public health provides a universally available prenatal screening program that is performed routinely, and assigns a risk for certain chromosomal abnormalities such as Down syndrome, and neural tube defects, such as spina bifida or anencephaly. A screening program may also exist to gather needed epidemiological information. Useful reviews of this topic are contained in a report of a Workshop on Population Screening⁶⁸ and a report of the Office of Technology Assessment.⁶⁹

Newborn Screening Programs

Newborn screening exists in all 50 states and most countries worldwide. It is probably the best example of a public health genetics program, and provides the only real example of population-based screening. Virtually all newborn screening programs are both mandatory and universal (not targeted to certain groups). What was once screening for phenylketonuria and congenital hypothyroidism has grown rapidly in recent years to include as many as 75 disorders, including over 30 metabolic diseases detectable by one test. Newborn screening uses a small dried blood spot obtained by heel stick of the newborn at a few days of age. Many of these programs are mandated by law, and appropriate resources must be provided to ensure that follow-up study and counseling are available as necessary and also to ensure laboratory quality and accuracy.⁷⁰ An abnormal screening test is not diagnostic but is the signal for rapid and appropriate medical and biochemical evaluation as well as parental counseling.

The expansion from a few isolated disorders in the 1960s and 1970s took a quantum leap with the addition of screening for sickle cell disease in the 1980s, in a variety of ways. First, although the addition was facilitated by research indicating daily oral penicillin could prevent most of the deaths due to infection, which was most often the cause of death in young children, it was the first time a newborn screening did not completely fit with all the cardinal rules of newborn screening: most importantly, the treatment was not a “magic bullet” such as a dietary treatment or a daily dose of thyroxine. The prevention was more subtle, because it couldn’t prevent many of the symptoms of sickle cell disease. It did, however, reduce the number of deaths.⁷¹ It was also a leap because some of the screening methodologies, particularly high pressure liquid chromatography (HPLC), detected many more types of hemoglobinopathy variants such as Hb C, D, and E, and some types of thalassemia. So, although sickle cell disease was the impetus, programs were in a sense obligated to include several more hemoglobin disorders in the newborn screening results, because the information was presented to them in the testing, and it was not considered ethical not to inform. Sickle cell disease also introduced the concept of carrier status and counseling for the first time. Again because of the nature of the test, carriers of the Hb

S trait who did not have the disease, were detected. It is important to provide adequate counseling, not only for the newborn’s information, but because it could indicate that the parents might be at risk for having a child with disease in a subsequent pregnancy. Therefore parent testing was included in many states.

The most recent technological change is the addition of tandem mass spectrometry. This methodology can detect over 30 different metabolic disorders by a single test. Like sickle cell disease, many of these disorders were not good candidates for screening because there was not a good treatment available, or they were very rare. But because the methodology provided the information, programs were obligated to report the results. This quandary has actually led to some important benefits to be discussed in the following section.

Benefits of Newborn Screening in the Public Health Sector

The problems and controversies posed by the increase in disorders screened as a result of new technology, ironically, has led to some important benefits beyond the normal prevention of serious health consequences. First, because children are now being screened for very rare disorders of unknown or not well-known etiologies, it is contributing to the knowledge of these disorders. With universal screening in such large numbers, researchers and specialists will now have much better ideas of the prevalence rate of these disorders. Also, identifying them at birth before the serious clinical consequences have occurred provides at least the possibility of developing new interventions even in diseases thought not to be treatable. At the very least, it gets them into medical care at the very beginning. A good example of how this concept has evolved is the example of cystic fibrosis. This very common genetic disorder was never a candidate for newborn screening because it was felt that the outcome could not be prevented by early detection. But after important research at the University of Wisconsin and the Wisconsin Department of Health was conducted, it was found that indeed there were significant advantages of early detection. Growth rates could be normalized for example, and possibly even deaths are prevented. As a result of this and continuing research, cystic fibrosis is now part of the newborn screening program in 12 states, with more being added each year. Another advantage is that early detection, even when there is not the “magic bullet,” can prevent the nightmare to parents known as the *diagnostic odyssey*. Many children with cystic fibrosis, as well as many other rare metabolic disorders, have gone for months or even years of severe symptoms and incorrect diagnoses until the correct one was found. This is all avoided with newborn screening.

Disadvantages of Newborn Screening

Few people today describe serious disadvantages of newborn screening when compared to the benefits, but they exist. Again we turn to the example of cystic fibrosis. Since the testing methodology is usually mutation analysis, not all cases will be detected because of rare mutations. Conversely, because of newborn screening and the initial protein screen, cases of cystic fibrosis with benign or partially benign mutations will be detected. This may cause a great deal of anxiety for the patient, family, and health-care professionals. Attempts are now being made to limit the types of mutations screened, so that nonclinical cases are not detected in newborn screening.

► PRENATAL DIAGNOSIS

Prenatal diagnostic techniques are used to diagnose genetic disorders and birth defects that result in marked disability or death early in life. Although one option that it permits is termination of the affected fetus, in a few disorders diagnosis permits therapy in utero or special management during pregnancy and delivery to minimize further damage to a vulnerable infant. For example, for a fetus with methylmalonic acidemia, the mother will be given vitamin B₁₂; for a galactosemic infant, the mother may receive a low-galactose diet.

Furthermore, chromosomal anomalies such as Down syndrome often involve significant health issues such as heart defects, and the outcome is much better when health-care professionals and parents are expecting the result at birth and can be ready for treatment.

There are a number of indications for prenatal diagnosis. Sometimes the test that is done prenatally is targeted specifically to the indication for prenatal testing. For example, a mother with a previous child with Tay-Sachs disease will have hexosaminidase A measured in the amniotic fluid sample, whereas a woman who is at risk because of increased age will have chromosome analysis of the fetal cells obtained at sampling. The following is a breakdown of indications for prenatal testing on an individual basis.

Increased Maternal Age

As maternal age increases, so does the risk of Down syndrome,⁷² and this is also true for the other trisomies. For this reason, many jurisdictions offer prenatal diagnosis to pregnant women 35 years and over. Such testing can decrease the birth incidence of Down syndrome by approximately 25% in most North American populations.⁷³

Neural Tube Defects

These birth defects, anencephaly and spina bifida, are relatively common, occurring in approximately 1 in 700 births in many North American populations.⁷⁴ Once a couple has had an affected child, the recurrence risk in subsequent pregnancies is about 2%.⁷⁵ Other close relatives may be at increased risk.⁷⁴

Family History of Specific Disorders

A previous child may have had a Mendelian disorder, chromosome anomaly, or birth defect. Also, the family history may indicate that the woman may be a carrier for an X-linked disorder. If a test is available (biochemical, cytogenetic, or DNA) or it is possible to evaluate for abnormal morphological findings (e.g., short limbs), then this testing is offered. For example, maternal exposure to a known teratogen (e.g., valproic acid) or a maternal disorder (diabetes mellitus) may justify offering prenatal diagnosis in some cases.

Public Health-Based Prenatal Screening

Because some disorders are common and inexpensive to test for once a sample is obtained, they are done on any pregnant woman who is already being subject to sampling, whether or not they have an indication for prenatal testing or a family history. This had led to public health-based prenatal screening programs. In California and Iowa, all pregnant women are given the option of a prenatal screening test called the triple marker or quadruple marker test. This screening test on the mother's serum can detect increased risk for Down syndrome, trisomy 18, and several types of neural tube defects. Many women choose to have this test even though there is a significant risk of a false positive or false negative, because they would rather base a decision on a risk from an easy test than have an invasive procedure such as amniocentesis, which in rare instances cause a spontaneous termination. The screening and follow-up data collection on such a large number of women in a very representative population (75% of women elect to have the test) has, like newborn screening, led to a wealth of knowledge on prevalence rates, pregnancy success rates, and outcomes of pregnancy. The California Program, in cooperation with the California Birth Defects Monitoring Program, another Public Health Agency involved with genetics, has resulted in a great deal of published research on neural tube defects and Down syndrome.

► GENETIC SERVICES

Genetic services, both diagnosis and counseling, are offered only to those who have been identified as in need, by their physicians or by themselves. There are two main avenues for service receipt: by having had an individual in the family with a genetic disorder or being identified as "at risk" by a population screening program.

Genetic service programs usually have arisen in association with a university or teaching hospital, fostering a research-service interaction. All provinces and states have at least one center, often many. However, the availability and expertise differs from one region to another. There is a useful directory of such programs published by the March of Dimes Birth Defects Foundation.⁷⁵ Many university centers also have associated training programs.⁶³

The process of genetic consultation and counseling is complex and time consuming and has not yet been well integrated into the clinical practice of medicine. Funding mechanisms for provision of this service are not satisfactory in many jurisdictions and differ from place to place, having grown in an "ad hoc" fashion. If the rapidly escalating new insights into human diseases being made in genetics are to be brought to practical use, we will need a cadre of trained individuals to deliver these services in the coming decades. Already it is not possible to offer on a population level many beneficial genetic programs (e.g., DNA diagnosis for a variety of Mendelian disorders).¹⁷

An important principle in genetic medicine is the need for diagnostic accuracy and precision. Genetic heterogeneity is a complicating issue in many disorders. Accuracy of diagnosis may be especially difficult to achieve in the sporadic case, when the possibilities of new dominant mutations or phenocopies exist, or more commonly, when rare mutations are not clearly visible by testing. Paternity is an issue that must be borne in mind, since in a significant proportion of cases (which will differ with the particular population) the husband cannot be assumed to be the father. This needs sensitive and empathetic handling. If the genetic mechanism leading to the particular condition diagnosed is known, it is possible to quantitate risk precisely for different relatives. If the genetic mechanism is not clear, as is the case for many "multifactorial" conditions (e.g., congenital malformations, mental retardation, schizophrenia), then if a thorough evaluation of the family history, pregnancy history, medical history, and physical findings reveals no specific etiology, empirical risk figures can be given regarding recurrence risk. These should be employed with caution, and communication of their meaning and limitations is not a simple process.

► OPPORTUNITY AND DANGER: SOME SOCIAL AND ETHICAL IMPLICATIONS

We have known for a long time that many common diseases are familial, but the genetic aspects have been ill-defined. It is clear that most common diseases are genetically heterogeneous, but susceptibility is due to major genes in many cases. Genotypes relatively unusual in the population may come to make up a large proportion of those with common diseases. Individuals at risk may soon be identified by DNA testing for intervention, and there may be ample time to intervene. For example, the immunological process in diabetes can precede onset of symptoms by many years; carcinogenesis also takes many years. The phenotype of disease, what we observe clinically, is somewhat removed from the primary action of the particular gene. This means that there may be considerable modulation possible. Rather than ignore the internal genetic component of disease causation, we should evaluate the genetic input and then attempt to tailor preventive or therapeutic programs to take it into account. If the new molecular genetic capability is incorporated into health care planning, it could allow public health to enter a new era of prevention. Through this new technology, rather than exposing the whole population to the same preventive medical programs, they could be directed to those individuals at risk, with relevant health messages focused to particular individuals.

The path to planning how the new capabilities in genetic risk identification might best be used in prevention and treatment is not simple. Although it has the potential to better the human condition, it is essential that enthusiasm for this approach be tempered with the realization that it is possible to cause great harm because we have not carefully weighed the pitfalls, ramifications, and dangers of this approach.^{64,65}

Well-designed research projects should be undertaken before there is any implementation at the population level.⁷² These should address aspects such as psychological and family impact, confidentiality, long-term outcome, compliance, safety, cost benefits, and appropriate laboratory quality control procedures. It is also important that genetic risk identification not be offered before the personnel and facilities to provide appropriate counseling and follow-up study are identified and funded.

The new capabilities raise many questions that will require scrutiny, relating, for example, to ownership of the information on genetic makeup.⁷³ With regard to confidentiality, policies and procedures must be put in place on who should have access to genetic test results so that the values of personal privacy and autonomy are respected. There may be potential situations where the public good may override the value of personal confidentiality, but these must be thoroughly considered before inclusion in policy.

As we become capable of identifying individuals in whom the disease outcome is less clear because of unpredictable gene-environment interactions, we may need guidelines to evaluate whether such programs should be offered. We might cause harm by identifying individuals as having a genetic vulnerability. Much of illness is perception and attitude, and it is important to avoid harm by causing identified individuals to view themselves as ill. In addition to stringent guidelines regarding data confidentiality, policies to avoid possible discrimination against identified individuals are also needed.

All of us are genetically unique, and all of us have weaknesses and strengths. This realization has the potential to break down the current generally held perception of the distinction between the majority “normal” population and the small minority with “genetic diseases.” A better perception—that everyone is vulnerable in his or her own way—would weaken or remove any basis for stigmatization of those with “genetic diseases.” However, genetic identification could also be negative if it created a population each of whose members was aware of and continuously concerned about a particular genetic predisposition and the likelihood of becoming ill. In the case of newborn screening, however, these issues are generally outweighed by the benefit of early detection and prevention of serious birth defects, mental retardation, and death.

Some specific issues of legal and social consequence raised by DNA testing are discussed below. DNA testing can identify each individual (except for identical twins) uniquely. It can also be used to identify genetic relationships with unprecedented accuracy. These new abilities raise issues in several areas.

Paternity

The paternity tests that were previously available could disprove paternity when a child had a genetic factor that wasn't present either in the mother or in the putative father. It could not usually prove that a particular man was the father. The new DNA testing can achieve levels of probability that establish beyond any reasonable doubt (1 in 100 million) the real father, if the tests are of high quality. This has been accepted as evidence in a number of courts. At the same time, it means that quality control of laboratory tests and procedures to safeguard against human error, such as mislabeled samples, are also necessary.

Workplace Testing

DNA testing can also be used to identify persons at risk in situations where costs may be incurred, for example, by an employer or an insurance carrier. DNA testing could show predisposition to cancer, emphysema, hemolysis, ischemic artery disease, hypertension, and so on with implications for both the employer's cost and the insurance carrier's profits. For many U.S. companies, offering health benefits adds substantially to the costs of production, and this added cost is becoming important in an increasingly competitive global market. Employers may, therefore, wish to screen potential employees so that their medical and life insurance plan costs will be lower. Appropriate safeguards against discrimination and misuse must be put in place.

Insurance

Laws may be needed to address how the new genetic knowledge should be limited in its application by the insurance industry as well as by employers. Guidelines or legislation may be required for medical and life insurance companies concerning genetic testing before coverage. It is possible that insurance companies could require testing before coverage and then charge higher premiums or refuse coverage to those at higher risk because of their genotype. Because the principle of insurance is to spread risk over many individuals, it seems unjust to disadvantage individuals who through no fault of their own are likely to become ill. Legislation to ban insurance discrimination based on genetic status was recently passed overwhelmingly in the U.S. Senate, but has languished in the Republican-led House of Representatives for reasons that are not clear. This is not as dramatic a problem in Canada, which has a universal health-care system, but it could be a very important problem in the United States. If the U.S. insurance industry is not regulated in this regard in some way, it may be necessary for government to set aside funding for health care of such noninsurable individuals.

► SUMMARY AND CONCLUSIONS

It is evident that the role of genetics in society and public health is growing as fast as the new genetic discoveries. New DNA technology will affect many areas of our society and will pose often difficult choices. It presents an opportunity and a useful tool if it is used wisely and humanely, but it is also a danger if the implications for social justice of its use are not thought through. Screening programs, in particular, if applied prematurely may cause harm and waste resources. However, if done well and with fully informed communication, they could decrease disease and better the human condition. The new DNA technology opens up questions that have wide-ranging social, ethical, and legal ramifications. Our new abilities with the technology often highlight the difficulty of balancing the individual's and the group's rights.^{74,75} These issues require ongoing discussion by scientists, public health practitioners, lawyers, politicians, and the public.^{78,79}

Control of Communicable Diseases

Overview

Richard P. Wenzel

The most important function of public health in its broadest sense is to seek an optimal harmony between groups of people in society and their environment. This goal can be achieved in three ways: (a) by methods to improve host resistance of populations to environmental hazards; (b) by effective plans to improve the safety of the environment; and (c) by improving health-care systems designed to increase the likelihood, efficiency, and effectiveness of the first two goals. With respect to infectious diseases there are special elements within each of the three categories (Table 8-1). One might then view communicable diseases as an imbalance in the relationship of people and their environment which favors microbial dominance in populations.

It is argued that improved host resistance is the purview of clinical medicine and that both environmental safety and public health systems are public health efforts. However, improved resistance in populations cannot be divorced from necessary educational and effective health delivery systems. For that reason it may be considered an essential component of public health. In this schema of public health, the infectious agent is considered not as a separate focus but as one important component of the environment. This organization is designed to integrate the schema with a concept of health, and of public health in particular. The implication is that the organism is a necessary but not sufficient cause of ill health; it is only one of many risk factors. Moreover, humans constantly encounter myriads of potential microbial pathogens, and removing all such organisms is untenable. It seems more fruitful to develop effective barriers between humans and problematic environmental microbes or at the very least to create pathways for peaceful coexistence. In addition, to many authors it has seemed that public health has focused excessively on environmental controls and too little on the health-care system. Yet all of these categories are interrelated: a change in any aspect of the three areas perturbs the entire system and has a direct effect on public health.

With respect to improved host resistance, McKeown¹ has argued that improved nutrition, personal hygiene, and public sanitation have more to do with the control of infectious diseases than vaccines and health care. There is no question, however, that vaccines and new antibiotics have greatly reduced morbidity and mortality from infectious diseases.² For example, with respect to smallpox, the vaccine—in concert with a public health system for identifying and isolating cases and contacts—was essential for its eradication.³

In the last two decades, it has been proposed that exercise may improve both mental and physical health^{4,5} and that there may be important interactions between psychological factors and immunity.⁶ Furthermore, with the explosion of activities in the field of molecular biology and the cloning of the human genome,⁷ it is not far-fetched to think that within a few decades genetic alteration of cells will enable us to enhance host resistance to adverse environmental challenges.⁸

The environment has long been a primary focus of public health, with efforts to improve the cleanliness of food and water, upgrade

public sanitation, and clean the air of toxic pollutants. Efforts to remove infectious agents by reducing animal reservoirs and vectors have been another focus for public health in general and in veterinary medicine in particular. Recently, many have postulated that adequate personal space is important for prevention of many urban problems. It has long been recognized that control of streptococcal infections in the military could be minimized by increasing space between the bunks of recruits and that crowding is a major risk factor.⁹ In addition, since large droplets are known to be important for many viral respiratory agents,¹⁰ it is generally accepted that spatial considerations are important for the prevention and control of communicable diseases.

A third method for public health control of infectious diseases involves the systems approach or management aspects. The social, economic, legal, and administrative forces important for health must operate in the interest of the public. Progress toward such goals must begin with access not only to health care but also to preventive health services and to health education. To that end, resources must be made available and important public health problems given sufficient priority—usually a political process—to demand necessary resources. Proper management at federal, state, and local levels needs to be operative for efficiency, effectiveness, and cost-effective delivery of care and education. Moreover, surveillance needs to be developed and maintained to detect new problems, new epidemics, and the efficacy of control measures.¹¹

► MAJOR PROBLEMS

There is always risk in attempting to prioritize the most important infectious agents, and readers may construct a different list from that of the author (Table 8-2). Nevertheless, the agents listed are important and serve as a focus for discussion of public health issues. An example of how one might apply the proposed schema to a communicable disease is discussed below with the example of acquired immunodeficiency syndrome (AIDS).

There is no question that AIDS—caused by the human immunodeficiency viruses 1 and 2 (HIV-1 and HIV-2)—remains the principal viral problem today. It is a global epidemic that affects the young in our society—not only as victims but also as orphaned children of victims. Though therapy is evolving, there is no cure in sight and it involves the strongest of human emotions. The interaction of host, virus and the environment is writ large in sub-Saharan Africa and Asia, where the majority of the 40 million HIV-infected people live.¹² The poor nutrition in these resource-limited geographic areas has a huge impact on both morbidity and mortality.

As to a preventive approach, it has been suggested that an effective global intervention program targeting sexual transmission and intravenous drug use transmission begun immediately could avert 28 million new HIV infections in the next ten years.¹³ In the analysis,

 Laws
 Measurement of problems and of the efficiency and effectiveness of control

such efforts would affect over 50% of the etiological fraction and cost \$3900 to prevent a new infection.

An approach to control via vaccination is ideal, but so far it has eluded scientists in the field. Experts who follow the genetic diversity within strains of HIV viruses report increases over time and space, with great relevance to vaccine development.¹⁴ It has been recognized furthermore that variations in HIV-1 clades affect both host immune responses and drug resistance. The point is that an increasing partnership of public health and molecular geneticists will be beneficial and probably essential for disease control. The current lack of understanding of the molecular biology of HIV infection and prevention is highlighted by the fact that only three candidate vaccines have made it to phase III clinical trials.¹⁵

With respect to improved environmental safety, the office of the surgeon general of the United States in 1988 had recommended barrier protection, that is, safer sexual practices, and the Centers for Disease Control then recommended universal precautions for health-care workers to minimize transmission in hospitals and clinics.¹⁶ However, the use of condoms—despite their value in preventing infections—has become a political issue in some countries, and a social issue in still others; both issues need continual attention with a focus on science in the AIDS era.

From a public health systems point of view, a great deal of discussion has occurred regarding access to medical care for AIDS victims, and in December 2005, the UN General Assembly called for

universal access to antivirals by 2010.¹⁷ This is a timely resolution since it has recently been shown that providing treatment free of charge in low income settings was associated with lower mortality.¹⁸ One can apply the proposed paradigm (Table 8-1) to HIV infection and understand not only the illness but also the disease in populations as a function of the three components of public health control.

Other illnesses needing special attention in the next decade (Table 8-2) are discussed elsewhere in this text.

► A NEW ROLE FOR PUBLIC HEALTH

With the spiraling costs of medical care and the corresponding interest in cost containment and accountability,¹⁹ it is reasonable to avoid duplications. We need a closer link of clinical and public health disciplines and activities. A recent example of the control of a new epidemic by the collaborative efforts of the World Health Organization (WHO), basic scientists and clinicians followed the outbreak of SARS—Severe Acute Respiratory Syndrome.²⁰ WHO forcefully assumed international leadership, coordinated scientific investigations, and quickly reported all new advances from the laboratory and field epidemiological studies to clinicians. In medical schools it is propitious for these disciplines jointly to develop curricula and research projects.

In the health service arena, closer ties between clinicians and public health officials will be efficient and effective for the good of the population. A special role for public health officials could be to “translate” important epidemiological data for clinicians giving primary care. This could be particularly important and useful in enhancing prevention. Examples of useful data would be the risk ratios for becoming an alcohol abuser for persons with and without a family history of abuse; cigarette smoking for the smoker, those nearby, and the unborn fetus; and for fatal versus nonfatal injury in persons driving with and without a seat belt. In the field of communicable diseases it is useful to know the risk of AIDS in those practicing intravenous drug abuse or unprotected sexual activities, the relative risk of Lyme disease in those using effective insect repellents versus those not using such agents, and the relative risk of hepatitis B in health-care workers who have received the vaccine and those who have not. In 2006, a key role for a public health-clinicians partnership is the continual education of the public about the real risks of avian (H5N1) influenza and the progress toward its prevention and control.²¹

An epidemiological approach to community-wide education about local health risks, perhaps with a well-designed periodical, would further link the clinician and public health official. The Centers for Disease Control and Prevention (CDC) has done this successfully with *Morbidity and Mortality Weekly Report*. A community-wide modification for consumption by local practitioners would be helpful. Such networking is feasible and desirable.

Networking with schools, businesses, health clubs, and senior citizen groups might increase compliance with behavior designed to enhance resistance to environmental hazards. Fundamentals of general and dental hygiene, nutrition, exercise, and stress control would be essential components. It would be reasonable to reinforce such basic principles as maintaining immunizations and proper use of antibiotics. In summary, we need a proactive and integrative role in education, one that involves networking with clinicians and the public directly.

Improving environmental safety has been the focus and strength of public health. Essentially, the goal has been to reduce the microbial hazards to humans. For the most part, this is carried out by systematic measurement or a series of inspections of the environment. Good general sanitation and safe air, water, and food are hallmarks of public health. Environmental activist groups have heightened interest in environmental safety. This is an opportune time to build a coalition between informed public health officials and interested and energetic activists genuinely concerned with improving the environment.

From infectious diseases point of view, an important goal would be to reduce the degree of exposure while preserving the vitality of the ecosystem. The government of Brazil was reported to have instituted a \$200 million program to control malaria in the Amazon region by spraying dichlorodiphenyltrichloroethane (DDT) in thousands of

TABLE 8-2. CHIEF INFECTIOUS DISEASES IN THE LATE 2000s

Bacterium	Staphylococci – Especially methicillin- resistant strains	<i>S. pneumoniae</i> <i>S. pyogenes</i> Nosocomial pathogens
Parasite	Malaria	Leishmania Onchocerciasis

rain forest huts. As McCoy²² pointed out, however, the chemical has been banned in over 40 countries because of its lethal effect on birds and fish. Moreover, in India, although it had a remarkable short-term effect initially (75 million annual cases of malaria reduced in the 1950s to 50,000), the number of cases rose to 65 million by 1976, the result of resistance in mosquito vectors. Moreover, bottled milk sampled in India in April 1990 had 10 times the permissible limit of DDT. DDT is fat soluble and has been carried in food chains to countries all over the world.²³ The lesson we have learned from the Russian nuclear accident at Chernobyl, the AIDS epidemic, and the DDT experience and the SARS epidemic is that radiation, viruses, and pollutants respect no national borders.

The response to such lessons needs to be an enhanced commitment by individuals, communities, and nations to solve the problems of others and to view the world as a global village. Limiting the survival of important infection agents, their animal reservoirs, or hosts requires careful examination of the implications of such approaches in collaboration with veterinarians, entomologists, and toxicologists.

► PUBLIC HEALTH SYSTEMS

Of the proposed public health systems important for control of communicable disease (Table 8-1), containment, contact tracing for prophylaxis and therapy, education, and measurement (surveillance) have been the mainstay of public health. Public health should become more involved with the rest as well.

CDC has taken the lead by suggesting an epidemiological approach to priorities, listing adjusted mortality rates for various conditions and years of productive life lost (YPLL) for leading causes of death.^{23,24} Ideally there would also be separate measures of morbidity and economic burdens so that in a country with limited resources leaders of the public health system could make more informed decisions and have the general community “buy into” their decisions.

It would seem prudent and desirable to have public health become more visible in terms of medical care access and efficiency of care. Great optimism can be appreciated, however, by the effort of the CDC to show the real risk of AIDS and the low (but not zero) probability of incurring an infection while taking care of an AIDS patient. Surely this contributes to the access of AIDS victims to the health-care system.

With respect to efficiency of care, it has primarily been a function of the individual physician and more recently of hospitals interested in cost containment. Such activities are often subsumed

under the umbrella term “quality assurance.” Accrediting agencies in the United States such as the Joint Commission for Accreditation of Healthcare Organizations (JCAHO) also are interested in the efficiency of health-care services. It is not unreasonable to expect that public health officials, working with hospital epidemiologists and staff of “managed care” systems, would lend their expertise to this aspect of quality care of populations.

The legal process is paying attention to epidemiological data. Public health workers may need to “translate” public health findings that may have an impact on the legal system in a beneficial way for the population. Finally, social forces are often more effective than education alone in beneficially modifying health-related behavior. The facts on the hazards of smoking have been available for decades, but only in the last 20 years have substantial numbers of the population in the United States avoided smoking. It has become socially unacceptable in many situations to smoke. In addition, lucrative business enterprises have made healthy behavior and exercise fashionable. These social forces need to be exploited and tested for use in control of infectious diseases. Patients in hospitals could be advised to request that all their health-care providers wash their hands before touching them. This would reduce nosocomial infection rates, especially those due to staphylococci. It is not far-fetched to imagine safer sex as a result of social pressure to ask a partner to use barrier protection. Similar social pressures are operating when both passengers and drivers use their seat belts or when friends drive an intoxicated friend home after a party. Such social forces are powerful.

A corollary would be a suggestion for marketing good public health. An effective marketing campaign was carried out by former surgeon general of the United States C. Everett Koop. He was perceived as caring, knowledgeable, and honest. An expanded approach to increasing the acceptance of vaccines, avoiding unsafe travel, and avoiding unsafe sex could be promoted just as consumer products are promoted—by use of effective peer groups and role models. This is a testable hypothesis for the twenty-first century.

In summary, a unified approach to public health is suggested involving clinicians, public health officials, basic scientists, and interested members and groups in the community. Networking, clarity in the presentation of epidemiologically important data, and a sense of the global community at risk with its environment are important. A sensitivity for the side effects of public health measures is essential and the use of effective education, social forces, and marketing practices may be the new tools of public health.

Emerging Microbial Threats to Health and Security

Stephen M. Ostroff • James M. Hughes

► INTRODUCTION

Our relationship to infectious pathogens is part of an evolutionary drama.

Joshua Lederberg

Traditionally, the world learns prevention the day after the epidemic.

Today, we have the responsibility of preparing for the prevention and control

not only of known but also unknown conditions

William H. Foege

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Despite great progress in the prevention and management of infectious diseases, microbial threats continue to evolve, proliferate, and result in human infection—the consequence of social and ecologic changes associated with a globalized society. The far-reaching effects of the 2003 outbreak of severe acute respiratory syndrome (SARS) highlight the ability of a previously unrecognized agent to appear unexpectedly, spread rapidly in the absence of diagnostics and effective disease prevention strategies, and cause widespread suffering as well as political, economic, and social turmoil. The emergence of SARS, a single example among many in recent years (Table 8-3), also illustrates the potential dangers of infectious agents and underscores the importance of preparedness for the unexpected. Previously known infectious diseases also continue to present new challenges. Some such as West Nile virus infection and Rift Valley fever have recently jumped to new continents, whereas others such as dengue are showing renewed intensity. Many established diseases, such as malaria and tuberculosis, continue to exact a high burden,

TABLE 8-3. SELECTED INFECTIOUS DISEASE CHALLENGES, 1993–2004

1993	Hantavirus pulmonary syndrome (United States)
1994	Plague (India)
1995	Ebola fever (Democratic Republic of Congo [former Zaire])
1996	New variant Creutzfeldt-Jakob disease (United Kingdom)
1997	H5N1 influenza (Hong Kong); vancomycin-intermediate <i>Staphylococcus aureus</i> (Japan, United States)
1998	Nipah virus encephalitis (Malaysia, Singapore)
1999	West Nile virus encephalitis (Russia, United States)
2000	Rift Valley fever (Kenya, Saudi Arabia, Yemen); Ebola fever (Uganda)
2001	Anthrax (United States); foot-and-mouth disease (United Kingdom)
2002	Vancomycin-resistant <i>Staphylococcus aureus</i> (United States)
2003	Severe acute respiratory syndrome (SARS) (multiple countries); monkeypox (United States)
2004	H5N1 influenza (Southeast Asia)

fueled in part by antimicrobial resistance. Moreover, incidents such as the 2001 anthrax attacks in the United States have heightened concerns about the use of microbial pathogens for bioterrorism.

In 1992, the Institute of Medicine (IOM) published a report¹ describing the increasing public health challenges posed by new, reemerging, and drug-resistant infections and calling for improvements in the nation's public health infrastructure. The report identified six factors underlying infectious disease emergence (Box 8-1) and described their impact on diseases that had emerged in the United States in the last two decades. In 2003, this report was updated² with expanded emphasis on the global impact of infectious disease threats and the international collaborative response needed to address them. In addition to the six underlying factors outlined in the first report, the new report cited seven other factors that contribute to the emergence of global microbial threats (Box 8-1). Combined, these 13 factors can be broadly categorized into four domains: genetic and biologic factors; physical environmental factors; ecologic factors; and social, political, and economic factors. These factors and their associated domains greatly affect the interaction of humans and microbes and can converge to produce an emerging global microbial threat.

BOX 8-1. FACTORS CONTRIBUTING TO THE EMERGENCE OF INFECTIOUS DISEASES

<ul style="list-style-type: none"> • Human demographics and behavior • Technology and industry • Economic development and land use • International travel and commerce • Microbial adaptation and change • Breakdown of public health measures 	<div style="border: 1px solid black; padding: 5px; width: fit-content; margin: 0 auto;"> <p>1992 Institute of medicine report</p> </div>

Institute of Medicine. *Microbial Threats to Health: Emergence, Detection, and Response*. Washington, DC: National Academy Press; 2003.

This chapter describes recent infectious diseases that present particular public health concerns, either because of the significance of their emergence or their continued or potential impact. The increasing problem of antimicrobial resistance—a major factor contributing to the impact of these diseases—is also discussed.

► EMERGING ZONOTIC INFECTIOUS DISEASES

Microbes that originate in animals and are transmitted to humans, either via direct transfer (zoonotic diseases) or through an intermediate vector (vector-borne diseases), are the source of a growing number of emerging infectious diseases.³ Aided by a complex mix of social, technological, ecologic, and viral changes, zoonotic agents are increasingly crossing the barriers that once limited their geographic or host range and igniting the emergence, reemergence, and spread of infectious diseases. Many of the new diseases that have appeared in recent years, as well as the established diseases that are increasing in incidence or expanding their range, are caused by zoonotic agents with wildlife reservoirs.^{4,5} Wild mammals and birds provide a potentially rich pool of disease agents and hosts that can come into contact with humans either naturally or, more likely, because of disruption or destabilization of their natural ecosystems. For example, hantavirus pulmonary syndrome appeared in the U.S. Southwest in 1993 when the deer mouse population increased rapidly due to climate-related food surpluses and spilled into nearby human habitations. The mice were carrying a previously unrecognized subtype of hantavirus that was transmitted to humans by direct contact with rodents or their excretions or by inhalation of aerosolized infectious material (e.g., contaminated dust arising from disruption of rodent nests).^{6,7}

More recently, the highly lethal Nipah virus appeared after changes in agricultural practices and land use created first an emerging disease in livestock and then a health crisis in humans. The virus naturally infects *Pteropus* fruit bats, which are widely distributed in Asia and likely serve as the reservoir for the disease agent.⁸ Nipah virus was discovered in Malaysia in 1998–1999 during an outbreak of encephalitis that killed 105 persons, most of whom had occupational exposure to ill pigs.^{9,10} Changes from traditional to modern animal husbandry practices had increased the size and density of pig farms in the area, extending their reach into nearby orchards that harbored fruit bats whose natural habitats had been destroyed. Aerosolization of virus-containing bat droppings caused infection of the pigs, overcrowded conditions led to efficient pig-to-pig transmission, and close contact with ill animals led to infection in pig handlers.¹¹ The virus has since appeared in Bangladesh, causing a series of limited but deadly outbreaks that appear to have been caused by children who had direct contact with bat-contaminated fruit.¹² Genetic analysis showed Nipah virus to be closely related to Hendra virus, which was discovered in Australia as the cause of a fatal outbreak that killed 14 racehorses and 2 humans and also is maintained in pteropid hosts. The viruses constitute a new genus in the paramyxovirus family.¹³

International travel and trade also provide opportunities for the amplification and penetration of zoonotic microbes, as evidenced by the U.S. outbreak of monkeypox associated with the exotic pet trade and the epidemic of SARS that spread globally by travelers. In 2003, monkeypox, a rare viral disease that occurs mainly in the rainforest countries of central and West Africa, was reported among prairie dogs and humans in the midwestern United States, the first such outbreak recognized in the Western hemisphere.^{14,15} Traceback investigations implicated a shipment of animals from Ghana as the probable source of introduction of monkeypox into the United States. The shipment contained approximately 800 small mammals of nine different species, including six genera of African rodents, imported to the United States as pets. Laboratory testing of animals from this shipment found evidence of monkeypox virus in several species, including one Gambian giant rat, three dormice, and two rope squirrels. Prairie dogs became infected by contact with the Gambian rats during their transport and warehousing for distribution as exotic pets.¹⁶ Human infection occurred from contact with ill prairie dogs that were

being kept or sold as pets. In total, 72 cases, 37 of which were laboratory confirmed, were reported from six midwestern states.

The respiratory illness later designated SARS was first reported in late 2002 from the southern Chinese province of Guangdong.¹⁷ In February 2003, the disease spread beyond China when several international travelers staying in a hotel in Hong Kong became infected as a result of contact with an ill physician visiting from Guangdong.^{18,19} These persons returned to their home countries, where some seeded multiple chains of transmission that, over the course of only four months, led to more than 8000 cases of SARS and nearly 800 deaths in 29 countries or areas and generated widespread panic, paralyzed travel, and threatened the global economy.^{20,21} Genetic analysis of the previously unknown SARS-associated coronavirus (SARS-CoV) determined that it was unlike other known members of the coronavirus family.^{22–25} Retrospective analyses of banked respiratory and serologic specimens detected no evidence of human infection before the explosive outbreak was recognized in China in late 2002. Surveys in south China found potential zoonotic reservoirs for the virus in live wild animals sold for food in open markets and serologic evidence of human infections in persons working in these markets.^{25,26}

Among the characteristics that distinguish SARS-CoV from many other zoonotic agents is its ability to spread not only from animals to people but also from person to person.²⁷ After crossing the species barrier to humans, the virus was transmitted from clinically ill persons to household members, health-care workers, and other close contacts, raising fears of possible pandemic spread. Fortunately, despite the occurrence of several so-called “superspreading events” in which certain infected persons were linked to large numbers of subsequent cases,^{18,28–30} SARS proved to be less transmissible than most respiratory infections and was controlled relatively quickly by use of infection control and community containment measures.³¹ Concerns about a possible recurrence of SARS remain, but, to date, only a few sporadic cases have been reported since the original outbreak; most of these cases were directly or indirectly linked to inadvertent laboratory exposures.^{32–35}

In the wake of the SARS outbreak, public health officials are increasingly concerned about the pandemic potential of avian influenza, another zoonotic agent with a wildlife reservoir. Avian influenza is an infectious disease of birds caused by type A strains of the influenza virus.³⁶ Infection causes a wide spectrum of symptoms in birds, ranging from mild illness to rapidly fatal disease. To date, all human outbreaks of the highly pathogenic form have been caused by influenza A viruses of subtypes H5 and H7. Of these, H5N1 is of particular concern because of its ability to mutate rapidly and exchange genes with viruses from other species. Migratory waterfowl, the natural reservoir of avian influenza viruses, are the most resistant to infection, whereas domestic poultry are particularly susceptible to fatal disease. Direct or indirect contact of domestic flocks with wild migratory waterfowl has been implicated as a cause of epidemics.^{37,38}

In recent years, sporadic human infections with avian influenza viruses have raised concerns that currently circulating avian influenza viruses will adapt to humans through genetic mutation or reassortment with human influenza strains and evolve into a pandemic strain.^{39,40} Avian influenza viruses were first shown to cross the species barrier and cause respiratory disease and death in humans in 1997, when highly pathogenic influenza A (H5N1) spread directly from infected chickens to humans in Hong Kong and killed 6 of 18 infected persons.^{41,42} Culling of nearly 2 million chickens in Hong Kong’s markets and farms successfully contained the outbreak. Since that time, outbreaks of different subtypes of avian influenza have caused disease in poultry, with secondary but mild infections reported in pigs and human. In January 2004, another H5N1 strain spawned disease outbreaks in poultry in several Asian countries, ultimately leading to the culling of more than 100 million birds in an effort to control the spread of the virus. Unprecedented in geographic scale and impact, the outbreaks have caused more than 50 human cases and more than 40 deaths among persons in Cambodia, Thailand, and Vietnam through early 2005.⁴³

To date, human infections with avian influenza viruses detected since 1997 have not resulted in sustained human-to-human transmission.

However, virulent avian influenza A (H5N1) viruses have become endemic in eastern Asia, posing an immediate risk of transmission to humans and increasing opportunities for human coinfection with avian and human influenza viruses.³⁶ In addition, recent studies have yielded evidence of continued evolution of the virus, with increased pathogenicity and an expansion of its host range.^{44–47} Given the close living conditions of humans and poultry in parts of Asia, such factors increase the possibility that an avian-human reassortant virus may emerge and give rise to a pandemic.^{39,44}

► EMERGING VECTOR-BORNE INFECTIOUS DISEASES

Viruses with a zoonotic origin that are spread by arthropod vectors have posed particular challenges, both in tropical areas where many previously controlled diseases have resurfaced and throughout the world as endemic diseases have appeared in new areas. One example is Rift Valley fever, an enzootic infection of domestic cattle, sheep, goats, and camels caused by a mosquito-borne phlebovirus.⁴⁸ Originally confined to parts of the African continent where it has caused major epizootic outbreaks with occasional cross-infection to humans, it spread for the first time in 2000 into southwest Saudi Arabia and Yemen, probably by infected imported livestock or windborne infected mosquitoes.^{49–51} By mid-2001, the infection had killed several thousand animals and more than 230 people.

West Nile virus (WNV) provides another example of a vector-borne disease that has spread swiftly into new areas. WNV is a mosquito-borne flavivirus that is maintained in a cycle primarily involving bird-feeding mosquitoes, with wild birds as the principal amplifying hosts. The virus has been found to be particularly lethal among American crows (*Corvus brachyrhynchos*)⁵². It is occasionally transmitted to humans, horses, and other mammals in which disease may occur. The virus was first isolated in the West Nile district of Uganda in 1937⁵³ but was not encountered in the Western hemisphere until 1999, when it was identified as the cause of an epidemic of aseptic meningitis and encephalitis in New York City.^{52,54} After its introduction into North America by an unknown vector, the virus spread rapidly across the continent, causing an estimated 940,000 infections and 190,000 illnesses through mid-October 2004.^{55,56} (Fig. 8-1). Based on data reported through this date to ArboNet, an electronic surveillance system used by the Centers for Disease Control and Prevention (CDC) and state and local health departments to track WNV infections, the virus has caused nearly 7000 cases of severe neuroinvasive disease and more than 600 deaths among U.S. residents and has been reported in more than 50 mosquito and nearly 300 bird species.⁵⁶ In addition to an unusual proportion of severe cases, the U.S. epidemic beginning in 2002 revealed several new clinical syndromes and five new modes of spread, including transmission to recipients of transplanted organs and transfused blood.^{52,57,58} The virus has also spread to both Canada and Mexico,^{59,60} and evidence of transmission has been documented in the Caribbean and Central America.^{61,62}

Although West Nile virus is now a major epidemiologic concern in the developed world, dengue viruses have become the most important human arboviral pathogens to emerge globally. Dengue is endemic in Africa, the tropical Americas, and parts of the Middle East, Asia, and the Western Pacific.⁶³ The frequency of dengue and its more severe complications, dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS), has increased dramatically since 1980, with an estimated 50 million infections recorded annually.⁶³ Dengue is caused by four closely related flaviviruses transmitted by mosquitoes, primarily by domestic, day-biting *Aedes aegypti*. This mosquito was historically found in Africa but spread through the world’s tropical regions over the past two centuries through international commerce. A global pandemic of dengue began in Southeast Asia after World War II and has since intensified, with more frequent and progressively larger epidemics associated with severe disease.⁶⁴ The resurgence and spread of dengue and DHF have been most dramatic in Asia and Latin America, where the uncontrolled

Figure 8-1. Spread of West Nile virus in mosquitoes, birds, horses, other animals, and humans in the United States, 1999–2004. The incidence of human neuroinvasive disease (meningitis, encephalitis, and acute flaccid paralysis) is indicated according to county. Data for 2004 are reported cases as of October 15. growth of urban shantytowns with poor sanitation and unreliable water systems has led to the proliferation of the *Aedes aegypti* mosquito vector in open water pools.⁶⁴

► EMERGING FOODBORNE AND WATERBORNE DISEASES

Despite improvements in the treatment of diarrheal diseases, an estimated 2.5 million people worldwide still die annually from diarrhea caused mainly by contaminated food and water.⁶⁵ Although the vast majority of diarrhea-associated mortality occurs in less developed countries, the problem is also significant in more developed settings. In the United States, foodborne infections cause an estimated

76 million illnesses and 5000 deaths each year, although many more infections likely go undiagnosed and unreported.⁶⁶ The epidemiology of foodborne illness continues to evolve as changes in food production, distribution, and consumption create opportunities for new pathogens to emerge, well-recognized pathogens to increase in prevalence or become associated with new food vehicles, and widespread outbreaks to occur.⁶⁷ Recently identified foodborne pathogens, many of which are zoonotic in origin, include bacteria (*Escherichia coli* O157:H7, *Listeria monocytogenes*, *Campylobacter jejuni*, *Yersinia enterocolitica*), parasites (*Cryptosporidium*, *Cyclospora*), and viruses (noroviruses). In addition, prions have been discovered to cause fatal neurodegenerative conditions (transmissible spongiform encephalopathies) in animals and humans.

First recognized as a human pathogen in 1982, *E. coli* O157:H7 has rapidly become a major cause of hemorrhagic colitis and

hemolytic uremic syndrome.⁶⁸ In the United States, *E. coli* O157:H7 is estimated to cause more than 73,000 cases of illness and approximately 60 deaths per year.⁶⁹ A zoonotic agent, *E. coli* O157:H7 colonizes the intestinal tract of agricultural animals, most often cattle,^{70–72} and is transmitted to humans through fecally contaminated food, milk, or water and through direct animal contact. Foodborne transmission is believed to account for 85% of the 73,000 estimated cases of *E. coli* O157:H7 cases per year in the United States.⁶⁶ Outbreaks have also been reported in Australia, Canada, Japan, various European countries, and southern Africa. Although most foodborne outbreaks were initially associated with consumption of undercooked ground beef,⁷³ more recent outbreaks have been linked to other food vehicles, including unpasteurized fruit juice, lettuce, alfalfa sprouts, and game meat.^{74–79}

A significant proportion of reported foodborne outbreaks is traced to fresh produce. Globalization of the food supply and centralization of food production have increased the volume of fresh produce grown in the developing world for export to other countries. Added to increases in U.S. consumption of “heart-healthy” and “cancer-preventing” fruits and vegetables and a growing demand for organic, exotic, and out-of-season produce, these factors have increased opportunities for the introduction of foodborne pathogens into susceptible populations.⁸⁰ As a result, U.S. foodborne outbreaks associated with fresh produce have increased in absolute numbers and as a proportion of all reported foodborne outbreaks, rising from 0.7% in the 1970s to 6% in the 1990s.⁸⁰ In the United States from 1973 through 1997, 32 states reported 190 produce-related outbreaks, associated with 16,058 illnesses, 598 hospitalizations, and 8 deaths. The produce items most frequently implicated include salads, lettuce, juice, melon, sprouts, and berries. In addition to *E. coli* O157:H7, major pathogens associated with produce-related outbreaks are *Salmonella* spp, *Shigella sonnei*, *Cyclospora cayetanensis*, and hepatitis A.^{81–83}

Viruses are associated with an estimated two thirds of the foodborne illnesses caused by known pathogens.⁶⁶ The *Caliciviridae* family, known as Norwalk-like or noroviruses, account for the overwhelming majority of these illnesses and have emerged as the leading cause of acute viral gastroenteritis worldwide.^{66,84,85} Noroviruses are transmitted most commonly by direct contamination of food (e.g., salads, sandwiches, bakery products) by infected foodhandlers,⁸⁶ but also via foods contaminated at their sources, such as oysters and raspberries. Transmission is facilitated by the high prevalence of these viruses in the community, their stability in the environment, their low infectious dose, and the prolonged duration of viral shedding among asymptomatic persons.⁸⁶ These factors presumably account for both the frequency of noroviruses as an important cause of epidemic gastroenteritis in nursing homes, hospitals, schools, and cruise ships and the difficulty in controlling norovirus outbreaks.^{84,87,88}

Changes in agricultural practices are the basis for the recognition of a new class of foodborne pathogen, the prion. Although prion diseases in animals have been long recognized, the emergence in 1996 of a new variant form of Creutzfeldt-Jakob disease (vCJD) brought these agents to international attention. The etiologic agent proved to be indistinguishable from that of bovine spongiform encephalopathy (BSE), a fatal neurodegenerative disease of cattle that caused a large-scale bovine epidemic in Great Britain beginning in 1986.⁸⁹ Cattle in Britain had presumably been exposed to the BSE agent since about 1982, when changes in the rendering process allowed contamination of cattle feed with infected tissues from previously slaughtered cows. Consumption of BSE-infected feed allowed the agent to recirculate within the cattle population and subsequently enter the human food chain via contaminated meat products.^{89–91}

Since 1986, BSE has been confirmed in Japan, Israel, Canada, the United States, and 20 European countries;⁹² most BSE cases outside of Britain have been traced to the importation of British cattle. BSE transmission to humans has led to more than 150 cases of invariably fatal vCJD, the vast majority occurring in Britain. Compared with the extent and speed of transmission of BSE in cattle, vCJD cases have increased very slowly. However, a likely long interval between exposure and development of symptoms raises concerns about the future appearance of additional cases as well as the risk of bloodborne transmission.^{89,93,94}

Infections are also emerging through the waterborne route, i.e., from ingestion of contaminated drinking water or through immersion in contaminated water.⁹⁵ Increases in recreational water-associated outbreaks have also been reported, from both treated and fresh water sources.⁹⁶ The commonly recognized waterborne pathogens include several groups of enteric bacteria, protozoa, and viruses. For example, contaminated drinking water has been implicated in outbreaks of campylobacteriosis,^{97,98} and *E. coli* O157:H7 has been transmitted via recreational water, well water, and contaminated municipal water.^{99–103} In 1992, *Vibrio cholerae* O139, a novel strain, was first detected in South Asia and quickly spread to many regions of India and Bangladesh.^{104–108} Since then, its impact has fluctuated throughout South Asia.^{109,110} The most important parasitic protozoa associated with waterborne transmission are *Giardia lamblia* and chlorine-resistant *Cryptosporidium parvum*, the latter of which caused a municipal water outbreak of cryptosporidiosis that affected more than 400,000 people in Milwaukee, Wisconsin, in 1993, and motivated authorities to reassess the adequacy of water-quality protections.^{111,112} Although waterborne outbreaks of norovirus gastroenteritis are far less common than foodborne outbreaks, norovirus outbreaks have been associated with contaminated municipal water, well water, stream water, commercial ice, lake water, and swimming pool water.⁸⁶

► HUMAN IMMUNODEFICIENCY VIRUS, TUBERCULOSIS, AND MALARIA

Despite the steady emergence of new pathogens with significant public health, economic, and geopolitical impact, three well-known but poorly contained diseases—HIV/AIDS, tuberculosis, and malaria—persist in contributing to more than half the global burden of infectious disease mortality. These diseases seriously affect health and constrain economic growth and development in many of the world’s poorest nations. They also continue to affect developed countries, often related to factors such as immigration, international travel, and poverty.

The appearance and rapid global dissemination of HIV is the most vivid example of the ability of an infectious agent to suddenly emerge and proliferate with long-lasting impact. Studies of the origin of AIDS suggest that humans first became infected with HIV in the early to the mid-twentieth century from contact with nonhuman primates in Africa.^{113,114} After crossing over to humans, HIV spread rapidly around the world due to a convergence of social, behavioral, and economic changes that interacted to facilitate viral adaptation and transmission.^{11,115} Despite advances in prevention and treatment and declining incidence in some population groups, the HIV/AIDS epidemic continues to expand and evolve. Current global estimates include approximately 28 million deaths from HIV/AIDS, nearly 40 million persons living with the disease, and more than 14 million children orphaned.^{116,117} In 2004 alone, it is estimated that approximately 3 million people died from AIDS and that almost 5 million people, including 700,000 children, became newly infected. HIV/AIDS is the fourth leading cause of death worldwide. Increasing mortality over the past five years is attributed to both the nature of the epidemic and the low coverage of antiretroviral therapy in developing countries.^{117,118}

Nearly two thirds (65%) of all persons living with HIV/AIDS and 75% of all women living with HIV/AIDS reside in Sub-Saharan Africa, the worst affected region.^{117,118} However, new epidemics are igniting in other parts of the world—primarily Eastern Europe and central Asia, where the number of persons living with HIV/AIDS increased by more than nine-fold in less than a decade.¹¹⁷ HIV has spread to all of China’s provinces, several of which are experiencing rapidly expanding epidemics, and serious outbreaks are underway in some areas of India. Injecting drug use is a major driver of HIV transmission in these regions, where large populations and adverse socioeconomic conditions provide the potential for explosive spread.¹¹⁶ Although the epidemic appears to have stabilized or decreased in much of the developed world, increasing rates have been observed in some populations, including men who have sex with men and racial and ethnic minorities in the United States.¹¹⁷

Unlike HIV, *Mycobacterium tuberculosis* has a history spanning thousands of years.¹¹⁹ Nonetheless, its impact continues into the present, with one third of the world's population currently infected.¹²⁰ Although not all of these persons will become ill, those who develop active tuberculosis will infect an estimated 10 to 15 other people each year.¹²⁰ In 2002, approximately 2 million people, most (98%) from developing countries, died as a result of tuberculosis, and 8–9 million became ill, many with strains of *M. tuberculosis* resistant to antituberculosis drugs.¹²⁰

In most countries, tuberculosis incidence has been increasing by approximately 0.4–3% per year.^{2,121} However, much higher rates of increase have been reported in areas such as Eastern Europe and sub-Saharan Africa, and the largest number of cases occurs in southeast Asia.¹²⁰ After more than a decade of falling rates attributed to implementation of directly observed therapy, the rate of decline in the United States is also slowing (Fig. 8-2). From 2000 to 2001, reported cases dropped by only 2%, with 50% of the 15,990 annual cases occurring in foreign-born persons.^{122,123} HIV infection is an important risk factor for the progression of tuberculosis infection to active disease.¹²⁴ In areas of the world with dual epidemics, the impact on the occurrence of active tuberculosis has been dramatic.¹²⁵ Tuberculosis is now one of the most common infections complicating HIV/AIDS in subtropical Africa and a major contributor to death. War, poverty, overcrowding, mass migration, and declining medical and public health infrastructure due to lack of political will are also important factors in the development, transmission, and spread of tuberculosis.

In addition to HIV and tuberculosis, malaria remains a major threat to global health and development, causing as many as 500 million cases and 3 million deaths each year, most of which occur among young children in sub-Saharan Africa.^{126,127} Four species of *Plasmodium* are capable of producing malaria in humans: *P. falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*. All are transmitted to humans by *Anopheles* species mosquitoes. *P. falciparum* and *P. vivax* cause the majority of malaria cases in humans, but *falciparum* malaria is considered the greater public health concern due to its more severe clinical manifestations and higher mortality.

Although treatable and preventable, malaria is endemic in more than 90 countries, placing approximately 50% of the world's population at risk.^{126,128} The disease is transmitted primarily in tropical and subtropical regions in sub-Saharan Africa, Central and South America, Hispaniola, the Middle East, India, Southeast Asia, and Oceania. Within these areas, the risk of transmission is highly variable, affected largely by climate.¹²⁹ Although most malaria transmission occurs in rural areas, explosive population growth has contributed to increased transmission in many urban areas, and weakening public health infrastructures have triggered large-scale epidemics in countries of the former Soviet Union and elsewhere during the last decade.^{126,130}

▶ ANTIMICROBIAL DRUG RESISTANCE

Added to the health impact and challenges of emerging infections is the growing resistance of infectious agents to antimicrobial drugs.^{131,132} Not only are antimicrobial-resistant organisms increasing in number, but they are also expanding their geographic range, increasing the breadth of their resistance, and spreading from health-care settings into the community.¹³¹ Drug-resistant organisms include all major groups of disease-causing agents: strains of HIV and other viruses; bacteria such as staphylococci, enterococci, and gram-negative bacilli, which cause serious infections in hospitalized patients; bacteria that cause respiratory diseases such as pneumonia and tuberculosis; foodborne pathogens such as *Salmonella* and *Campylobacter*; sexually transmitted organisms such as *Neisseria gonorrhoeae*; *Candida* and other fungi; and parasites such as *P. falciparum*.

Staphylococcus aureus is one of the most common causes of hospital- and community-acquired infections.¹³³ Methicillin-resistant *S. aureus* (MRSA) was first recognized as a nosocomial pathogen in 1961, shortly after the introduction of methicillin. By 2000, approximately half of all nosocomial *S. aureus* isolates in the United States were methicillin-resistant.¹³⁴ Risk factors for health-care-associated MRSA infection include recent hospitalization, residence in a long-term care facility, dialysis, and indwelling percutaneous medical devices and catheters. In recent years, MRSA infections have started to spread from the health-care setting and into the community, where outbreaks are occurring among persons with no prior hospital exposure.^{135–137} Transmission has occurred by close physical contact in situations involving children in day care centers, children and adults on Indian reservations, athletes, military personnel, inmates in correctional facilities, and men who have sex with men.^{138–145} Available data suggest that community-associated strains are more likely than health-care-derived isolates to carry virulence factors associated with pneumonia in children and skin and soft tissue infections in adults.¹³⁵

A steadily increasing proportion of MRSA also shows low-level resistance to vancomycin, currently considered the treatment of last resort.¹⁴⁶ In 1996, the first appearance of intermediate resistance to vancomycin in *S. aureus* with minimum inhibitory concentrations (MICs) of 8 ug/mL was reported from Japan,¹⁴⁷ and additional cases were subsequently found in other countries.¹⁴⁸ By the end of 2004, 12 infections with vancomycin-intermediate *S. aureus* (VISA) had been confirmed in the United States. The first two confirmed clinical infections caused by *S. aureus* isolates with complete resistance to vancomycin (VRSA) occurred in the United States in 2002, both in outpatient settings.^{149,150} These strains reportedly acquired the resistance trait from vancomycin-resistant enterococci (VRE), which were first documented in 1986¹⁵¹ and are now endemic in many hospitals.¹⁵² A third documented clinical isolate of VRSA from a U.S. patient was reported in 2004.¹⁵³

Figure 8-2. U.S. tuberculosis cases, 1983–2003 (Source: Reported tuberculosis in the United States, 2003. Atlanta, GA: U.S. Department of Health and Human Services, CDC; September 2004.)

Driven in large part by the use of antibiotics in livestock and poultry, antimicrobial resistance among foodborne bacterial pathogens is making the health impact of foodborne infections even more serious.^{67,154} For example, fluoroquinolone-resistant *Campylobacter* infections emerged in the United States in the early 1990s, coincident with the licensing of fluoroquinolones for treatment of respiratory disease in poultry. Similarly, the emergence of *Salmonella* strains resistant to ceftriaxone is thought to be associated with the widespread use of third-generation cephalosporins in cattle.^{67,155} Multidrug-resistant definitive phage type (DT) 104 strains of *S. Typhimurium* increased in prevalence from 0.6% in 1979–1980 to 34% in 1996, after spreading first among food animals.^{154,156}

Multidrug resistance has also expanded rapidly to other pathogens, fueled by antimicrobial use and misuse as well as economic decline and failing health infrastructures in many parts of the world.¹³¹ Since the early 1990s, resistance of *Streptococcus pneumoniae* to penicillin and other antimicrobial agents has spread,^{157,158} and an increasing trend of invasive pneumococci resistant to three or more drug classes threatens the treatment of pneumonia and ear infections, especially in children.^{159,160} The frequency of fluoroquinolone-resistant *E. coli* has reached 70% in parts of Southeast Asia and China and nearly 10% in some industrialized countries, including the United States, and some strains of *E. coli* are resistant to as many as six drug classes.^{131,132,161,162} Strains of *N. gonorrhoeae* have been widely resistant to both penicillin and tetracycline since the 1980s.¹⁶³ The more recent appearance of fluoroquinolone-resistant strains is severely limiting therapeutic options for gonorrhea, the second most frequently reported communicable disease in the United States.^{163,164}

In many countries, the failure to treat all patients properly is leading to the emergence of *M. tuberculosis* strains that are resistant to increasing numbers of antituberculosis drugs and undermining disease elimination efforts.¹⁶⁵ Of the estimated 300,000 new cases of drug-resistant tuberculosis occurring globally each year, 79% are resistant to three of the four first-line drugs.¹⁶⁶ *M. tuberculosis* strains resistant to at least isoniazid and rifampin (MDR TB) are currently ten times more frequent in eastern Europe and central Asia than elsewhere in the world, although incomplete reporting precludes a true measure of the burden in all areas.¹⁶⁷ A WHO survey of 77 locations showed that, in 1999–2002, the prevalence of resistance to at least one antituberculosis drug ranged from 0% in some western European countries to 57% in Kazakhstan. In the United States, the incidence of drug resistance in new cases of tuberculosis is highest in foreign-born persons (1.2%).¹²³ The increased costs of treatment associated with the more expensive second-line drugs pose a major barrier to completion of treatment and increase the risk of progressive disease and death.¹²⁹

Globally, drug resistance has also become one of the greatest challenges to malaria control. Drug resistance has been associated with the spread of malaria to new areas, the reemergence of malaria in previously affected locales, and the occurrence and spread of epidemics.¹³⁰ Resistance to chloroquine, the main affordable and available antimalarial treatment, is now widespread in 80% of the 92 countries where malaria continues to be a major killer,¹⁶⁸ and resistance to newer antimalarial drugs is widespread and growing. The diminished efficacy of chloroquine represents a tremendous setback for malaria control, leading to a resurgence of malaria-related morbidity and mortality in Africa.¹⁶⁹

► BIOTERRORISM THREATS

Any consideration of new infections arising unexpectedly from nature must include the possibility of the deliberate release of infectious agents by dissident individuals or terrorist groups. Biological agents are attractive instruments of terror because they are relatively easy to produce, capable of causing mass casualties, difficult to detect, and likely to generate widespread panic and civil disruption. The dissemination of *Bacillus anthracis* through the U.S. postal system in 2001¹⁷⁰ demonstrated the vulnerability of the United States and

the world to the unleashing of any of a host of dangerous microbes and accelerated research and preparedness activities. The six pathogens identified by experts as having highest potential for bioterrorism—designated Category A agents—are: *B. anthracis* (anthrax), *Clostridium botulinum* toxin (botulism), *Yersinia pestis* (plague), variola virus (smallpox), *Francisella tularensis* (tularemia), and viral hemorrhagic fever viruses.^{171,172} A more lengthy list of Category B agents and diseases that are thought to pose the next highest level of risk includes brucellosis, viral encephalitis, and food and water safety threats. Category C includes emerging infectious diseases such as Nipah and hantaviruses. Further information on these categories and the designated threat agents is available at <http://www.bt.cdc.gov/agent/agentlist.asp>.

All six of the Category A agents can be effectively introduced through aerosol dissemination, considered the likeliest route for intentional dissemination of a biologic agent. However, other dispersion methods are also possible. Increasing centralization of food processing and distribution has heightened the risk of a serious strike against the food supply.¹⁷³ Deliberate mass contamination of a widely consumed food item could sicken millions of citizens and cripple national agriculture and food industries. Food safety threats include *Salmonella* species, *E. coli* O157:H7, and *Shigella*. Water treatment and distribution facilities are also potential targets for contamination with agents such as *V. cholerae* and *C. parvum*.¹⁷⁴ A biologic attack against crops or livestock could have devastating consequences.¹⁷⁵ Examples of animal diseases that could possibly be spread intentionally are avian influenza, food and mouth disease, BSE, and African swine fever.

► STRATEGIES FOR ADDRESSING EMERGING INFECTIOUS DISEASES

Since earliest history, human populations have struggled against an evolving array of infectious diseases. However, the unprecedented succession of recent infectious disease emergencies—and the threat of more to come—bring new challenges that require novel solutions.¹⁷⁶ Unlike previous eras of infectious disease, the scale is global and changes are occurring on many fronts, requiring the readiness of a coordinated international response.

The mainstay of infectious disease control continues to be public health surveillance and response systems that can rapidly detect unusual, unexpected, or unexplained disease patterns; track and exchange information on these occurrences in real time; manage a response effort that can quickly become global in scope; and contain transmission swiftly and decisively. The surveillance methods, investigational skills, diagnostic techniques, and physical resources needed to detect an unusual biologic event are similar, whether a seasonal influenza epidemic, a contaminated food in interstate commerce, or the intentional release of a deadly microorganism.

Internationally, the World Health Organization (WHO) coordinates these efforts through the Global Outbreak Alert and Response Network (GOARN), which was launched in 2000 as a mechanism for combating international disease outbreaks, ensuring the rapid deployment of technical assistance to affected areas, and contributing to long-term epidemic preparedness and capacity building.¹⁷⁷ The importance of such a network was demonstrated during the SARS epidemic, when WHO effectively coordinated disease surveillance, investigation, pathogen identification, laboratory diagnostics, and information dissemination.^{178,179}

In the United States, CDC works with state and local health departments and other agencies to detect and monitor microbial threats. Surveillance for notifiable diseases is conducted by state and local health departments, which receive reports from clinicians and laboratorians at the clinical front lines. To supplement routine public health surveillance functions, CDC funds and coordinates 11 Emerging Infections Program (EIP) sites (Fig. 8-3) in collaboration with state and local health departments, public health laboratories, and clinical and academic organizations. These sites form a national

Figure 8-3. Emerging infections program (EIP) sites.

network for population-based studies on emerging infectious diseases of public health importance. Two International Emerging Infections Program (IEIP) sites have been established in Thailand and Kenya through collaborations with the ministries of health and other partners in those countries; plans for other IEIP sites are underway. CDC also works in partnership with sentinel specialists in infectious diseases, emergency medicine, and travel medicine to track conditions that are likely to be seen by clinicians but that may be missed by traditional surveillance approaches. Much-needed collaborations with veterinary partners are improving the detection and monitoring of zoonotic agents.¹⁸⁰

Increased security concerns since 2001 have placed a new focus on the importance of identifying unusual health events and responding rapidly to prevent large-scale devastation. A special strategic challenge is how to integrate bioterrorism preparedness into overall infectious disease preparedness in ways that are synergistic and cost-effective. One example of such “dual-use” capability is the Laboratory Response Network (LRN), a multi-level network of more than 120 laboratories that links U.S. public health agencies to advanced-capacity diagnostic facilities and provides laboratory support during responses to naturally occurring as well as intentionally caused outbreaks.¹⁸¹ Operational since 1999, the LRN builds on the nationwide system of public health and affiliated laboratories that conduct routine disease surveillance and are needed to combat the threat of emerging diseases. Between 2001 and 2003, LRN member laboratories helped detect and monitor cases of SARS, West Nile virus infection, and monkeypox, as well as intentionally caused anthrax.

Control of foodborne illnesses provides added challenges due to the size and complexity of the food industry, the rapid changes that have occurred in its organization, products, and workforce, and the difficulty in tracking and monitoring these diseases. Prevention-based regulatory approaches that address the entire food supply chain are needed to ensure the safety of every food product “from farm to table.”¹⁸² Global food supplies and large distribution networks also demand strengthened capacity for disease surveillance and response to outbreaks that can quickly cross local, national, and international borders.⁸¹ To address these needs, laboratory-based surveillance and molecular epidemiology tools have been developed to improve the understanding of the scope and source of

foodborne outbreaks and direct investigative and research efforts. These include FoodNet, an active surveillance system designed to determine the frequency and severity of foodborne diseases in the United States, monitor trends, and determine the proportion of disease attributable to specific foods,¹⁸³ and PulseNET, a national molecular subtyping network for foodborne bacteria that facilitates rapid identification of and faster responses to outbreaks of foodborne disease.¹⁸⁴

New technologies are stimulating the development of other innovative public health tools that are invigorating disease surveillance and response systems. Internet-based information technologies are being used to improve national and international disease reporting, as well as facilitate emergency communications and the dissemination of public health information. Data from the Human Genome Project provide the foundation for public health genomics, a field that holds great promise for understanding the role of human genetic factors in susceptibility to disease, disease progression, and host responses to vaccines and other interventions.^{185,186} As the genomic sequences of microbial pathogens become available, discoveries in microbial genetics are suggesting new methods for disease detection, control, and prevention.¹⁸⁷ Scientific advances are also facilitating the development of improved diagnostic techniques and new vaccines to prevent infection by emerging microbial agents such as HIV, West Nile virus, dengue virus, and H5N1 avian influenza virus. Sophisticated geographic imaging systems are being used to monitor environmental changes that might influence disease emergence and transmission.¹¹ Other novel technologies, although less sophisticated, nonetheless provide hope for the control of some persistent diseases. For example, the CDC Safe Water System uses point-of-use disinfection and safe water storage to prevent waterborne diseases in developing countries.^{188,189} In rural Africa, insecticide-impregnated bednets have proven highly effective in reducing morbidity and mortality from malaria.^{190–192}

Important as each of these strategies is, however, none can succeed in the long-term without the political will and actions to address the root causes of infectious diseases. As demonstrated by many of the examples cited above, infectious diseases do not exist in a social vacuum.¹⁹³ Ultimately, disease transmission may be affected less by the features of the etiologic agent than by factors

such as poverty, overcrowding, poor nutrition, social inequities, inaccessibility of health care, workforce shortages, economic instability, and social and ecologic disturbances. In the midst of rapid global change, persistent health disparities, and increasingly vulnerable populations, governments need to supplement scientific and technologic breakthroughs with long-term actions that recognize the complex social context of disease emergence and that focus on underlying health, development, and sociopolitical determinants.

► CONCLUSION

Microbes share our biosphere and possess the intrinsic genetic capacity to adapt, shift, and gain new hosts. Despite advances in science, technology, and medicine that have improved disease prevention and management, endemic and emerging infectious diseases continue to pose a threat to domestic and global health. The ever-increasing speed

and volume of international travel, migration, and trade create new opportunities for microbial spread, increases in the world's most vulnerable populations, and the prospect of a deliberate release of pathogenic microbes underscore the importance of preparedness to address the unexpected.

The best defense against these pathogens is a multifactorial solution characterized by international collaboration and communication; coordinated, well-prepared, and well-equipped public health systems; improved infrastructure and methods for detection and surveillance; effective preventive and therapeutic technologies; and strengthened response capacity. Partnerships among clinicians, laboratorians, and local public health agencies,¹⁹⁴ as well as linkages between human health and veterinary organizations and professionals,¹⁸⁰ are also essential components in preparedness and response efforts. Above all, political commitment and adequate resources are needed to address the underlying social and economic factors that increase the vulnerability of human populations to infectious microbes.

Health Advice for International Travel

Christie M. Reed • Stefanie Steele • Jay S. Keystone

According to the World Tourism Organization (WTO), in 1999 an estimated 80 million travelers from industrialized countries (US/Canada, Europe, Japan, and Australia/New Zealand) visited developing areas of the world, where the risk for infectious diseases, many of them vaccine-preventable, has increased.¹ Each year millions of U.S. citizens travel internationally in search of exotic vacation destinations or to conduct business, government, or humanitarian activities in remote areas of the world. Studies show that 35–64% of short-term travelers report some health impairment, usually caused by an infectious agent.^{2–4} Although infectious diseases are the major contributors to illness associated with travel, they account for only 1–4% of deaths among travelers.⁵ Cardiovascular disease and injuries are the most frequent causes of death, accounting for approximately 50% and 22% of deaths, respectively. While mortality due to cardiovascular disease in adults is similar to that in non-travelers, deaths from injury, mostly from motor vehicle accidents, drowning, and aircraft accidents, are several times higher among travelers.⁶

Most travel-related illnesses are preventable by immunizations, prophylactic medications, or pretravel health education. Included in health education should be mention of the role of hand hygiene in reducing the transmission of pathogenic organisms. If hand washing with soap and water is not feasible and hands are not visibly soiled, alcohol-based hand gels may be considered for use by travelers to reduce travel-related infections. In a recent study, hand gels containing 60% alcohol were shown to reduce respiratory illness transmission in the home.⁷

Health recommendations for international travel are based primarily on individual risk assessment and any requirements mandated by public health authorities of the countries the traveler plans to visit.⁸ The risk for acquiring illness depends on the area of the world visited, the length of stay, activities and location of travel within these areas,

and the underlying health of the traveler. A health advisor should know the travel itinerary and the sequence in which countries will be visited and transited; the length of stay in each country; whether travel will be rural or urban; the style of travel (first-class hotels vs. local homes); the reason for travel; whether the traveler has any underlying health problems, allergies, or previous immunizations; and, in the case of a female traveler, whether she is planning pregnancy or is pregnant or breast-feeding.

Travelers may also be at risk for infectious diseases when they travel by cruise ship. The unique environment of a cruise ship, in which large groups of people from different regions of the world congregate, has been a factor in several influenza and norovirus outbreaks.^{9,10} Cruise ship passengers may also be exposed to infectious diseases when they disembark at ports of call, although such risks are difficult to quantify.

► IMMUNIZATIONS

Immunizations for international travel can be categorized as

1. Routine: childhood and adult vaccinations (e.g., diphtheria/tetanus, polio/MMR)
2. Required: those needed to cross international borders as required by international health regulations (e.g., yellow fever and meningococcal disease)
3. Recommended: according to risk of infection (e.g., typhoid, hepatitis A, rabies)

Routine Immunizations

Travel is an excellent opportunity for the practitioner to update an individual's "childhood" or adult immunizations, such as diphtheria/tetanus, measles, mumps, polio, rubella, *Haemophilus influenzae* type b (infants and children), hepatitis B, varicella, and influenza. These immunizations are discussed in the guide for adult immunization and

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

the recommendations of the Advisory Committee for Immunization Practices (ACIP).^{11,12}

Required Immunizations

Each year the World Health Organization (WHO) updates a list of required immunizations by country. "Health Information for International Travel," published biennially by the Centers for Disease Control and Prevention (CDC), combines data from this list with information obtained directly from ministries of health.¹³ In accordance with the International Health Regulations, required vaccinations must be recorded in the document "International Certificate of Vaccination" and validated by a stamp issued by state health departments. Yellow fever is the only vaccination designated by WHO as required for entry into specific countries. WHO also recognizes the Saudi Arabian requirement for meningococcal vaccine for pilgrims visiting Mecca for Hajj or Umrah. These travelers must show documentation of vaccination against meningococcal meningitis A,C,Y,W-135 when applying for a visa for Hajj or Umrah. Documentation must also be shown to the Saudi Arabian passport authority upon entry to the country. Countries requiring immunization against either of the above infections could refuse the right of entry to travelers who do not have a recorded valid immunization or a written statement by a physician (on the physician's letterhead) indicating why immunization was not given. WHO eliminated the requirement for cholera vaccine for travelers in 1988; however, there are occasional reports that health officials at international borders may still seek evidence of immunization. No vaccinations are required for entry into the United States.

Yellow Fever

Yellow fever, which occurs only in tropical Africa, certain countries in South America, Panama, and Trinidad and Tobago, can be prevented by a single subcutaneous injection of a live attenuated virus vaccine. A certificate of yellow fever vaccination is valid for 10 years after a 10-day waiting period, although protection probably lasts longer.¹⁴ The vaccine is not recommended for infants less than nine months of age. Like all other live virus vaccines, yellow fever vaccine should not be administered to immunocompromised patients and should be avoided during pregnancy. However, pregnant women and HIV-positive individuals with CD4 counts greater than 200 should discuss immunization with their health-care provider if they are at high risk of infection.

Because the vaccine is grown in chick embryos, it should not be given to persons who have egg allergies. Rare, serious adverse events, including fatalities, have been documented, primarily in persons over 60 years of age who receive yellow fever vaccine for the first time.¹⁵ A history of thymic dysfunction may also be an independent risk factor for yellow fever vaccine-associated viscerotropic disease, a disease that clinically and pathologically resembles naturally acquired yellow fever.¹⁶ Before administering yellow fever vaccine, health-care providers should ascertain the traveler will be going to an area of risk and ask about any history of thymus disorder or dysfunction (i.e., myasthenia gravis, thymoma, thymectomy, or DiGeorge syndrome), regardless of the age of the traveler. Patients who cannot be immunized safely should receive a physician's letter on the physician's letterhead, stating that the immunization is contraindicated and that the traveler has been counseled about measures to prevent mosquito bites, such as the use of insect repellent and insecticide treated bednets.

Meningococcal Meningitis

Vaccination against meningococcal meningitis is required for entry to Saudi Arabia for those attending the annual Hajj (see Meningococcal disease below under recommended immunizations).

Recommended Immunizations

Tetanus

Serosurveys in the United States indicate that prevalence of immunity to tetanus declined with increasing age. Only 45% of men and 21%

of women aged >70 years had protective levels of tetanus antibodies. These same studies show that prevalence of immunity to diphtheria progressively decreased with age from 91% at age 6–11 years to approximately 30% by age 60–69 years.

Tetanus immunization must be kept up-to-date; it is protective for at least 10 years. Because diphtheria is endemic in many countries and became a widespread problem several years ago in eastern Europe, tetanus immunization should be given in combination with diphtheria vaccine, either as tetanus and diphtheria (Td) for adults or as diphtheria-tetanus-acellular pertussis (DTaP) vaccine for children less than seven years of age. Adults aged 19–64 years should receive a single dose of diphtheria-tetanus-acellular pertussis (Tdap) to replace a single dose of Td for active booster vaccination against pertussis to reduce the morbidity associated with pertussis in adults. Some physicians vaccinate adult travelers at 5- to 10-year intervals to avoid the need for a booster or tetanus immune globulin if a person has a tetanus-prone wound within five years. This approach reduces the traveler's likelihood of receiving an injection in a developing country where the sterility of needles may be in question.¹⁷

Poliomyelitis

All travelers to countries where polio is or has recently been endemic should be immunized adequately. Although poliomyelitis has been eliminated from the Western hemisphere, it remains endemic in India, Pakistan, Nigeria, Egypt, and Afghanistan. Beginning in 2003, cases of poliomyelitis have been reported from several countries in sub-Saharan Africa and more recently, Indonesia and Yemen, where polio had recently been eliminated through global efforts. These cases have been linked to outbreaks in northern Nigeria, where eradication efforts were interrupted. Individuals who have written documentation of having completed the primary series of at least three doses require only one lifetime booster dose of enhanced-potency inactivated polio vaccine or oral live attenuated vaccine. The live vaccine is no longer available in the United States.

Measles

Indigenous transmission of measles has been interrupted in the Western Hemisphere. Recent cases in the United States have been imported or epidemiologically linked to international travel. Half of these cases were in returning residents and the other half in foreign visitors, including adoptees. Measles remains a common infection outside the Western Hemisphere, particularly in developing countries. All international travelers, including those who are infected with HIV (except those who are severely immunosuppressed) should have documented measles immunity. The vaccine is recommended for all persons traveling abroad born after 1956 who do not have documentation of physician-diagnosed laboratory evidence of measles immunity, or documented evidence of two prior doses of live measles virus vaccine. Children may be immunized as early as six months of age. In such cases, they should receive measles-mumps-rubella (MMR) vaccine at 12–15 months and again at entry to kindergarten or first grade. A dose of MMR vaccine can be considered for persons born in 1956 or earlier whose history of measles disease is uncertain. Pregnant women and immunocompromised patients other than HIV-infected individuals (e.g., those on chemotherapy for cancer) should not be given MMR vaccine.

Hepatitis A

Hepatitis A is one of the most frequently reported vaccine-preventable infections of travelers. Although most infants and young children are asymptomatic when infected, they do pose a health risk to others because of the ease of fecal-oral spread of this virus. Mortality from hepatitis A increases with age and reaches 1.2% in patients over the age of 60.¹⁸ The risk of hepatitis A infection among travelers from industrialized countries to developing countries has been estimated to be 3–6 per 1000 persons per month for the average non-immune traveler or business traveler, increasing to 20 per 1000 per month for the traveler who ventured off the usual tourist routes prior to widespread use of vaccines.¹⁹ More recent estimates indicate 14–24% of Canadian travelers are immunized prior to departure and that the risk of acquiring Hepatitis A during one month of travel in the developing world

among unimmunized Canadian travelers may be lower: 1 case per 3000.²⁰ Hepatitis A vaccination is recommended for all travelers to the developing world, as even in major tourist destinations the purity of water and the cleanliness of food and food preparation cannot be guaranteed. Two well-tolerated parenteral hepatitis A vaccines are highly efficacious, with seroconversion rates of almost 100% by the second dose.²¹ These inactivated hepatitis A vaccines require two doses 6–12 months apart. Within two weeks of the first dose, 70–85% of vaccinees will have protective antibodies. Studies of antibody decline suggest that these vaccines will provide protection for 25 years or more in adults and 14–20 years in children.²² ACIP recommends that persons traveling to a high-risk area less than four weeks after the initial dose should also be administered immune globulin (0.02 mL/kg) at a different anatomic injection site, because protection might not be complete until four weeks after vaccination.²² However, in view of the rapidity of vaccine-induced seroconversion and the several-week incubation period for hepatitis A, travel advisors in most countries do not recommend simultaneous administration of immune serum globulin even for imminent travel. A combined hepatitis A and hepatitis B vaccine is also available (see below).

Hepatitis B

Persons working in areas of high or intermediate hepatitis B virus (HBV) endemicity for six months or longer have infection rates of 2–5% per year.²³ Short-term travelers are also at risk for infection if they engage in unprotected sexual contact or injection drug use with residents of these areas; receive medical care that involves parenteral exposures, such as might occur after a traffic accident; or are exposed to blood, such as might occur while engaging in medical procedures or disaster relief activities.²⁴

Currently available recombinant vaccines are highly effective and may provide lifetime protection. ACIP recommends hepatitis B immunization for unvaccinated adults and children who plan to travel to areas that have intermediate to high rates of HBV infection. Regardless of destination, all persons who might engage in practices that might put them at risk for HBV infection during travel should receive hepatitis B vaccination if previously unvaccinated.²⁵ Many travel health experts advise that all travelers receive this vaccine, as it is virtually impossible to predict who may be involved in an accident leading to injury that would require needle insertion or who may engage in risk-taking behaviors. Low-risk areas for hepatitis B include Western Europe and parts of Central and South America.

Primary immunization with monovalent hepatitis B vaccine consists of three doses, given on a 0-, 1-, and 6-month schedule. At present, no booster dose is recommended after the primary series.

A combination hepatitis A and hepatitis B vaccine, approved for persons aged 18 years and older, has been found to be of equivalent immunogenicity to the monovalent hepatitis vaccines.²⁶ Primary immunization consists of three doses, given on a 0-, 1-, and 6-month schedule, the same schedule as that used for single-antigen hepatitis B vaccine. Clinicians may choose to use an accelerated schedule (for either the monovalent B or combined hepatitis A and B vaccine) (i.e., doses at days 0, 7, and 21). The FDA has approved the accelerated schedule for the combined hepatitis A and B vaccine, but not for the monovalent hepatitis B vaccine. Persons who receive a vaccination on an accelerated schedule should also receive a booster dose at one year after the start of the series to promote long-term immunity.

Typhoid Fever

More than half of the approximately 400 cases of typhoid fever reported each year in the United States are acquired during foreign travel.²⁷ The typhoid fever infection rate among travelers (residents and nonresidents) arriving in the United States from typhoid-endemic regions (i.e., all countries except Canada, Japan, and countries in Europe and Oceania) was found to be 0.93 cases per 100,000. For countries for which data were available, individual rates for U.S. resident travelers ranged from 0.30 per 100,000 (Mexico) to 16.7 per 100,000 (India).²⁸ In a recent CDC study, unvaccinated travelers to

areas where typhoid fever is prevalent were found to be at risk for the disease even when their visits were less than two weeks. Risk was particularly high for travelers returning to their homeland to visit and stay with relatives and friends (VFR) in six countries: India, Pakistan, Mexico, Bangladesh, the Philippines, and Haiti.²⁹ Typhoid vaccination is highly recommended for those traveling off usual tourist routes, VFR travelers, and those who plan to stay abroad short- or long-term, even in highly developed urban centers.

The typhoid vaccines available are the live, attenuated multidose oral vaccine developed from the Ty21a strain of *Salmonella* Typhi and the Vi capsular polysaccharide vaccine (ViCPS) administered intramuscularly in a single dose. Both vaccines have demonstrated efficacy in preventing infections; however, they differ in duration of induced immunity.³⁰ The oral vaccine is administered as one capsule on alternate days for four doses. The regimen should be completed at least one week before travel. A booster is required after 5–7 years. The oral vaccine should not be given concurrently with antibiotics. Because oral vaccine is self-administered, there may be associated compliance problems. The parenteral, polysaccharide vaccine is administered at least two weeks before departure in a single dose, with a booster at two-year intervals.

Meningococcal Meningitis

Meningococcal meningitis poses a sporadic or epidemic risk—most notably to pilgrims to Saudi Arabia during the Hajj, and travelers to sub-Saharan Africa. Although the risk for meningococcal disease has not been quantified, it appears to be greatest among travelers who have direct close contact with indigenous populations in overcrowded conditions in high-risk areas.

Because of the lack of established surveillance and timely reporting from many of these countries, travelers to the meningitis belt during the dry season should be advised to receive meningococcal vaccine, especially if prolonged contact with the local population is likely. Vaccination against meningococcal disease is not a requirement for entry into any country, except Saudi Arabia, for travelers to Mecca during the annual Hajj.

A single dose of quadrivalent polysaccharide A/C/Y/W-135 vaccine is protective for 3–5 years in adults and older children.³¹ The polysaccharide vaccine is not effective in children younger than 2–3 years of age. A quadrivalent conjugate vaccine for the prevention of meningococcal disease Groups A, C, Y, and W-135 was recently licensed in the United States for use in adolescents and adults aged 11–55 years.³²

Rabies

Few cases of rabies have been reported in travelers, but no data are available on the risk of infection. However, 33% of the 36 rabies cases in the United States since 1980 were presumed to have been acquired abroad.³³ Pre-exposure rabies vaccine is appropriate for adults and children planning extended stays in much of the developing world (or for those anticipating shorter stays, but who may be at increased risk due to activities such as bicycle riding) and for persons who might be at occupational or avocational risk for exposure (e.g., veterinarians, cavers) in areas where rabies is a significant threat. Children may be at particular risk of rabies because of their stature, usual carefree attitude toward petting stray animals and the fact that they do not typically report that they have been bitten. Modern cell culture vaccines, such as the human diploid and purified chick embryo cell vaccines are inactivated products that are more immunogenic and less reactogenic than earlier neural tissue rabies vaccines, and are given on days 0, 7, and 21 or 28 for preexposure vaccination. Since the three-dose series almost always yields a satisfactory antibody level, routine measurement of titers is no longer recommended after the third vaccine dose. Travelers should be advised that pre-exposure vaccine eliminates the need for rabies immune globulin (RIG) after rabies exposure, but does not eliminate the need for additional postexposure rabies vaccinations. Unavailability of RIG in many developing countries is a problem that can necessitate repatriation for an unvaccinated traveler if bitten. Revaccination is not needed for unexposed travelers. Evaluation for

booster vaccination is only recommended for persons in high-risk categories, such as veterinarians and rabies laboratory workers. In addition, travelers should be counseled to avoid animals, particularly dogs, and to clean animal bite wounds promptly and thoroughly.

Japanese Encephalitis

The estimated risk of Japanese encephalitis (JE) in highly endemic areas during the transmission season can reach 1 per 5000 persons per month.³⁴ The infection was reported in 24 U.S. travelers over the 15-year period from 1978 through 1992 and one additional U.S. traveler in 2004.^{34,35} Although most infections are asymptomatic, among patients who develop clinical disease the case-fatality rate may be as high as 30%, with severe neurologic sequelae in 50% of survivors. The vaccine should be reserved for those traveling in endemic areas, especially when there is rural exposure in rice and pig farming areas during summer months. The primary series consists of three injections on days 0, 7 and 30; the last dose should be administered at least 10 days before departure. If risk continues, a booster dose at 24 months or more is recommended. An abbreviated schedule of two doses (on days 0 and 7) has been shown to provide seroconversion in 80% of vaccinees.³⁴

Because serious adverse reactions to the vaccine (generalized itching, respiratory distress, angioedema, and anaphylaxis) can occur in some individuals up to one week after vaccination and adequate immune response is not achieved for several days, if possible, travelers should receive the last dose of vaccine 10 days before departure.

Influenza

The risk for exposure to influenza viruses can occur throughout the year in tropical and subtropical areas. The attack rate for infection was found to be 1.2–2.8% in travelers of all age groups, making influenza the most common vaccine-preventable disease affecting travelers.³⁶ ACIP recommends influenza vaccination before travel for persons at high risk for complications of influenza if they travel to the tropics, with large groups at any time of the year, or to the Southern Hemisphere from April through September. Because vaccine may not be available in the summer in North America, vaccine for travel should be administered in the spring if possible.³⁷ Some health-care providers recommend vaccination for all travelers if vaccine is available.

An inactivated parenteral vaccine and a live, attenuated influenza vaccine (LAIV), administered by nasal spray, are currently available in the United States. LAIV is approved for use only in healthy persons aged 5–49 years.

Typhus

Since typhus is rarely seen in travelers, routine immunization is not recommended. Typhus vaccine is not available in the United States.

Tuberculosis

Tuberculosis (TB) has now become the number one killer infectious disease globally. Each year, approximately nine million persons become ill from TB; of these, two million die.³⁸ Persons who will live for prolonged periods in developing countries and those who will have close contact with local residents are at increased risk of exposure. Recent prospective studies in the Netherlands showed that the risk of TB infection was approximately 3% per year of travel in a high endemic area and 10% among those traveling to the Hajj in Saudi Arabia.^{39,40} The efficacy of Bacille-Calmette-Guerin (BCG), a live vaccine derived from a strain of *Mycobacterium bovis*, is still debated in the United States, where the incidence of the disease is low. In developing countries, BCG appears to be most effective in preventing severe complications of tuberculosis in children. Most European countries recommend BCG vaccine for persons with a negative tuberculin skin test who are planning an extensive stay in a developing country. However, in Canada and the United States, under these same conditions, travel medicine practitioners will occasionally recommend BCG only for infants to reduce the risk of TB meningitis and disseminated disease. Side effects, ranging from draining abscesses

at the site of immunization (common) to disseminated infection (rare), must be weighed against the risk of exposure to active tuberculosis for the traveler—a risk that varies directly with the intimacy and duration of contact with the indigenous population. BCG vaccine is very rarely used in the United States because it can negate the utility of the tuberculin skin test used for early detection of latent TB infection, as well as use of an effective intervention (isoniazid) for treatment. It is recommended that travelers who will stay longer than six months should have a baseline tuberculin skin test placed before travel and repeated at 1- to 2-year intervals if risk continues.

Cholera

Cholera has continued to remain an important cause of severe diarrheal disease globally, especially with its recent spread in the 1990s into Central and South America. Cholera among European and North American travelers is extremely rare (0.2 per 100,000 travelers).⁴¹ However, in 1991 the rate among Japanese travelers was 13 per 100,000 travelers in those returning from Indonesia.⁴² The standard phenol-killed whole cell cholera vaccine requires two injections and confers a maximum protection of only 50% for 3–6 months. It is no longer available in the United States and is generally no longer recommended because of the brief and incomplete immunity it confers. New oral vaccines, not yet available in the United States, provide 60–80% protection for about six months to one year, but are not effective against the new serotype O139, which spread rapidly through Asia in the mid-1990s.⁴³

► TIMING OF VACCINES

Many travelers visit a physician only a short time before their anticipated date of departure. When necessary, inactivated vaccines may be administered simultaneously at separate sites with separate syringes. Theoretically, live vaccines should be administered 30 days apart because of possible impairment of the immune response. However, this restriction does not apply to oral polio virus (OPV), MMR, and varicella, which may be given together.⁴⁴ Ideally, immunoglobulin administration should be delayed until after the administration of certain live attenuated vaccines because of the possible reduction in antibody response. This caveat does not apply to OPV or yellow fever vaccines but does apply to MMR and its component vaccines. Killed or inactivated vaccines usually pose no danger to the immunocompromised host, although the immune response to these vaccines may be suboptimal; also, these vaccines are not usually contraindicated during pregnancy. Regardless of how long a vaccination schedule has been interrupted, there is no need to restart a primary series of immunizations. It is sufficient to continue where the series was interrupted. Finally, all immunizations should be recorded in the international certificate of vaccination booklet and carried with the passport.

► MALARIA PROTECTION

More than 30,000 North American and European travelers develop malaria each year.⁴⁵ Although malaria is a reportable disease in most industrialized countries, reliable estimates of the true number of imported cases are difficult to obtain because of underreporting; TropNet Europe (with 46 collaborating centers in 15 European countries) reported 976 cases in 2003 but estimates that the average number of cases in the European Union is closer to 11,000 a year.^{46,47} The most recent national data available from Canada reveal 369 cases in 2004, 1089 imported cases in the United States in 2004, and 1747 in the United Kingdom in 2006.^{48–50} The risk of malaria per month of stay without prophylaxis is highest in sub-Saharan Africa and Oceania (1:50 to 1:1000), intermediate (1:1000 to 1:12,000) for travelers to Haiti and the Indian subcontinent, and low (less than 1:50,000) for travelers to Southeast Asia and to Central and South America.⁵¹ Sub-Saharan Africa is also the most common region of acquisition reported among travelers in the surveillance systems cited above and

via the GeoSentinel Surveillance Network, a global sentinel surveillance network through the International Society for Travel Medicine and CDC, with 30 sites on six continents.⁵² Travel for the purpose of visiting friends and relatives accounted for most of the cases in all five surveillance systems cited above^{48–50,52} and represented an eightfold relative risk compared with tourists among the cases reported to GeoSentinel (personal communication, David Freedman, January 2005). With the worldwide increase in chloroquine and multidrug-resistant *Plasmodium falciparum* malaria, decisions about chemoprophylaxis have become more difficult. In addition, the spread of malaria due to both primaquine-tolerant and chloroquine-resistant *P. vivax* has added further complexity to the issue of malaria prevention and treatment. Compliance with antimalarial chemoprophylaxis regimens and use of personal protection measures to prevent mosquito bites are keys to prevention of malaria. Travelers, particularly VFRs, must be educated about the risk of malaria, personal protection measures against mosquito bites, appropriate chemoprophylaxis, symptoms of the disease, and measures to be taken in case of suspected malaria during and after travel. To make the above determinations, travel medicine advisors must conduct a careful review of the itinerary, whether urban and/or rural areas will be visited, the length of stay, style of travel, and medical history, including allergies and the likelihood of pregnancy. Current information on malaria transmission by country is provided by WHO at www.who.int/ith/en and by CDC in the United States at www.cdc.gov/malaria.

Detailed recommendations for the prevention of malaria are available from CDC 24 hours a day from the voice information service (1-877-FYI-TRIP; 1-877-394-8747), or on the Internet at <http://www.cdc.gov/travel>.

Health-care professionals who require assistance with the diagnosis or treatment of malaria should call the CDC Malaria Hotline (770-488-7788) from 8:00 a.m. to 4:30 p.m. Eastern time. After hours or on weekends and holidays, health-care providers requiring assistance should call the CDC Emergency Operation Center at 770-488-7100 and ask the operator to page the person on call for the malaria branch. Information on diagnosis and treatment are available on the internet at www.cdc.gov/malaria.

Personal Protection Measures

Anopheles mosquitoes, the vectors of malaria, are exclusively nocturnal in their feeding habits; protection from mosquito bites from dusk to dawn is highly effective in reducing infection. When practical, travelers should wear protective clothing, such as long-sleeved shirts and long pants when outside during evening hours. Combining a pesticide such as permethrin on clothing with an insect repellent containing DEET (N,N-diethyl-m-toluamide) applied to exposed skin is highly efficacious at protecting against mosquito bites. DEET is the most effective and best-studied insect repellent currently on the market. When used in concentrations less than 50%, it has a remarkable safety profile after 40 years of worldwide use. Toxic reactions can occur, but usually when the product has been misused (e.g., ingestion). DEET has not been associated with an increase in adverse pregnancy outcomes. Thirty percent DEET is recommended for use in children older than two months of age. Plant-based repellents are generally less effective than DEET-based products.^{53,54} Where possible, travelers who cannot stay in air-conditioned quarters should use a bed net impregnated with permethrin, which has an efficacy of up to 80% in the prevention of malaria.⁵⁵ Permethrin may also be sprayed on or soaked into clothing for added protection. A pyrethroid-based flying insect spray should be used to clear the bed net and room of mosquitoes.

Chemoprophylaxis

Personal protection measures greatly reduce but do not eliminate risk of malaria. Most antimalarials are only suppressives, acting on the erythrocytic stage of the parasite beyond the liver phase, thereby preventing the clinical symptoms of disease but not infection. No drug guarantees protection against malaria. For this reason, travelers must

be informed that any febrile illness that occurs during or up to one year after travel to a malaria-endemic area should be evaluated immediately by a health-care professional. Because health-care providers may not always ask about a patient's travel history, it is incumbent upon febrile returned travelers to inform their health-care provider of their travel to malarious areas and the need to rule out malaria, regardless of the prophylactic used.

Chemoprophylaxis with mefloquine or chloroquine should be started 1–2 weeks prior to entry into a malarious area, during exposure, and for four weeks after departure from a malarious area. Prophylaxis with atovaquone/proguanil or primaquine can begin 1–2 days before travel, during exposure, and for seven days after departure from a malarious area. Similarly, prophylaxis with doxycycline can begin 1–2 days prior to travel and can be used during travel; however, it must be continued for four weeks after departure from the malarious area. Beginning antimalarials early allows the drug to be in the blood before travel and enables travelers to switch to alternative drugs should adverse effects occur. The postexposure period of prophylaxis is particularly important to enable the antimalarial to eradicate any organisms that have been released from the liver into the bloodstream after departure from a malarious area.

Atovaquone/proguanil may be used in all malarious areas. It should be taken with food or milk to reduce the rare incidence of gastrointestinal side effects and to increase absorption. Atovaquone/proguanil is administered daily as a single tablet containing 250 mg atovaquone and 100 mg proguanil hydrochloride. Atovaquone/proguanil is contraindicated in persons with severe renal impairment (creatinine clearance <30) and is not recommended for pregnant women or women breast-feeding infants weighing less than 5 kg. Pediatric dosages are available for prophylaxis of children weighing greater than 5 kg.

Chloroquine is still recommended for travelers to Central America north of the Panama Canal, Haiti, and parts of the Middle East. However, the global spread of chloroquine-resistant *falciparum* malaria has necessitated the use of alternative regimens for most areas of the world. Chloroquine should be taken with meals to reduce gastrointestinal side effects. Chloroquine can be given safely to children and pregnant women. However, since the difference between a prophylactic dose and a potentially fatal toxic dose is relatively small, the tablets and pediatric elixir should be kept in closed, childproof containers. Non-allergic, intense pruritus is well documented, almost exclusively in black Africans. The dose of chloroquine for adults is 300 mg base or 500 mg salt taken weekly.

Doxycycline may be used for all malarious areas, and given its low cost and low rate of side effects, it is increasingly used for adults. The side effects of gastrointestinal upset, exaggerated sunburn, and vaginal candidiasis can be reduced or managed by taking the drug with food, using a sunscreen containing a ultraviolet A (UVA) blocker, and carrying an antifungal medication for self-treatment. The drug is contraindicated during pregnancy and in children less than 8 years of age. The adult dose is a 100-mg tablet taken daily.

Mefloquine may be used for travel to all malarious areas, with the exception of the Thai-Cambodian and Burmese (Myanmar) borders, in the western provinces of Cambodia, in the eastern states of Burma (Myanmar), and recently on the border between Burma and China, in Laos along the borders of Laos and Burma, the adjacent parts of the Thailand-Cambodia border, as well as in southern Vietnam. Gastrointestinal side effects can be reduced by taking the drug with food. Mefloquine is contraindicated in persons allergic to mefloquine or related compounds (e.g., quinine and quinidine). It should be used with caution in persons with psychiatric disturbances, or a previous history of depression, and it is not recommended for persons with cardiac conduction abnormalities. Despite limited data, CDC recommends mefloquine for young children weighing less than 5 kg if they are at high risk. Mefloquine is administered to adults as a 250-mg tablet taken weekly. The pediatric dose is as follows: for children weighing ≤9 kg: 4.6 mg/kg base (5 mg/kg salt) orally, once/week; 10–19 kg: 1/4 tablet once/week; 20–30 kg: 1/2 tablet once/week; 31–45 kg: 3/4 tablet once/week; and ≥46 kg: 1 tablet once/week.

Primaquine, which has in the past been used to prevent relapses of *P. vivax* malaria, has recently been shown to be a very effective antimalarial when taken daily.^{56,57} It is an option in special circumstances and should be used in consultation with malaria experts. It is contraindicated in persons with G6PD deficiency, so the patient's G6PD status must be known before this medication is prescribed. It is therefore also contraindicated during pregnancy and lactation, unless the infant being breast-fed has a documented normal G6PD level. Primaquine is administered to adults as two tablets of 15-mg base, taken daily. The pediatric dose is 0.6 mg/kg base (1.0 mg/kg salt) up to the oral adult dose, taken daily.

Regardless of the chemoprophylactic regimen recommended, it is important for travel health advisors to tell the traveler that (a) globally there is no uniformity concerning malaria chemoprophylaxis recommendations and (b) they are likely to meet other travelers and health-care providers overseas who give conflicting advice as to the optimal regimen for malaria chemoprophylaxis. Persons who are unable to obtain medical care in less than 48 hours may consider carrying a self-treatment regimen. Unfortunately, however, evidence suggests that those who carry self-treatment regimens often use them inappropriately. The drugs used for self-treatment are no different from the agents used for malaria treatment (quinine plus doxycycline, mefloquine, atovaquone plus proguanil). CDC now recommends only atovaquone/proguanil for standby therapy. The global spread of drug-resistant malaria has stimulated the search for new approaches to prevention and treatment of malaria. Tafenoquine is currently the only major alternative prophylactic agent in the clinical trial stage.

▶ TRAVELERS' DIARRHEA

Diarrhea is the most frequent health impairment among travelers, with a risk of 7% of travelers to the developed countries and risks of 0–90% of travelers to some parts of the developing world.^{58–60} The most common symptoms, in addition to diarrhea and fecal urgency are abdominal cramps, nausea, vomiting, and general malaise, often resulting in incapacitation for more than 10% of the international excursion.⁶¹ The most frequent etiologic agents at most destinations are enterotoxigenic *Escherichia coli* (ETEC), and enteroaggregative *E. coli* (EAEC).⁶² The most common causes of travelers' diarrhea, in addition to *E. coli*, are *Shigella* spp., *Salmonella* spp., *Campylobacter* spp. *Vibrio parahaemolyticus* (in Asia), rotavirus (in Latin America), and protozoa (*Giardia*, *Cryptosporidium*, and *Cyclospora* spp., and *Entamoeba histolytica*), but no pathogen is identified in over half of patients.⁶³ Noroviruses, which cause the majority of acute viral gastroenteritis cases worldwide, are increasingly being recognized as a cause of outbreaks and illness among travelers.^{10,64} When counseling travelers about diarrhea, health-care providers must consider several issues: food and water precautions, hand hygiene, chemoprophylaxis, self-treatment of illness, and immunization.

Food and Water Precautions

Unpeeled fruits, uncooked vegetables, food that has been cooked or stored at insufficient temperatures, unpurified water, and ice cubes made from it are believed to be the main sources of enteric pathogens for the traveler. Tap water and ice cubes should be avoided unless there are strong assurances of proper treatment. Tea or coffee is safe when consumed hot; commercially bottled, carbonated beverages are highly recommended; and unpasteurized milk and milk products should be avoided. If safe beverages are not available, travelers may need to disinfect water by bringing it to a boil, using chemical disinfection (iodine or chlorine) by means of commercial tablets or iodine crystals, or using purification devices. Raw foods other than vegetables and fruits (e.g., bananas and avocados) that can be peeled by the traveler should be avoided, and cooked foods should be eaten only when served hot.

Chemoprophylaxis/Self-Treatment

The standard food and water precautions outlined above are not always easy to follow, particularly among vacationers who, wanting to relax and indulge in local cuisine, are more likely to be noncompliant with food precautions.^{65,66} For this reason, the concepts of chemoprophylaxis and self-treatment have gained popularity in recent years. Since bacterial pathogens account for most episodes of travelers' diarrhea, antibiotics and bismuth subsalicylate have been the focus of testing for both treatment and prevention.⁶⁷ The overriding principle in the management of travelers' diarrhea is the maintenance of adequate food and electrolyte balance. Fluids can be replenished with bottled soft drinks, juices or electrolyte-containing oral rehydration solutions. Because of damage to the intestinal lactase-producing cells by enteric pathogens, dairy products should be avoided during illness.

Most travel advisors recommend that travelers should carry an antimotility agent (such as imodium or lomotil) and an antibiotic for self-treatment of diarrhea occurring during travel.⁶⁸ Many studies have shown that antimicrobial therapy leads to symptomatic improvement and reduction in the duration of illness, particularly among those infected with ETEC and *Shigella*. Widespread resistance of enteric pathogens to trimethoprim-sulfamethoxazole, ampicillin, and doxycycline have, for the most part, rendered these drugs ineffective. The drugs of choice for treatment of travelers' diarrhea are the quinolone antibiotics. Standard therapy with ciprofloxacin (500 mg), norfloxacin (400 mg), and ofloxacin (300 mg) consists of one dose twice a day for three days. Single-dose therapy with ciprofloxacin (500 mg to 1 gram), and norfloxacin (800 mg), with or without an antimotility agent, can be as effective as the standard 3-day course of treatment.^{69,70} Travelers should be cautioned that antibiotic resistance is on the rise globally, as indicated by a recent study in Thailand in which *Campylobacter* isolates in U.S. troops with diarrhea showed 70% and 30% resistance to ciprofloxacin and azithromycin, respectively.^{71,72}

Bismuth subsalicylate (Pepto-Bismol), two tablets four times a day, has shown a protective effect of up to 65%. Antibiotic agents, on the other hand, have shown up to 90% efficacy in protecting against travelers' diarrhea, particularly a single daily dose of ciprofloxacin (500 mg), norfloxacin (400 mg), or ofloxacin (300 mg).^{73,74} However, prophylactic antimicrobials are generally not recommended because of their potential for increasing antibiotic resistance and the risk of untoward drug reactions or superinfection with other, more pathogenic microorganisms. In addition, antimicrobial prophylaxis may engender a false sense of security that puts the traveler at increased risk, as it does not protect travelers from other foodborne or waterborne infections with viral agents (e.g., norovirus, hepatitis A and E), or any of the parasitic agents. Some authors recommend prophylactic therapy with bismuth subsalicylate or a quinolone antibiotic in specific circumstances for travel of less than three weeks' duration for travelers who repeatedly develop diarrhea during travel; have diminished protective gastric acidity; cannot afford incapacity for even one day (e.g., athletes, military personnel); or would poorly tolerate travelers' diarrhea due to an underlying medical condition (e.g., inflammatory bowel disease, brittle insulin-dependent diabetes mellitus, chronic renal failure, or AIDS). Rifaximin is a new antibiotic that is FDA-approved for use against toxigenic *E. coli*. Some experts use it as a first-line treatment (or self-treatment) for travelers to Mexico or the Caribbean.⁷⁵ Studies are ongoing to assess its use in the prophylaxis of travelers' diarrhea.

Recent studies have shown that the oral cholera B subunit whole-cell vaccine provides short-lived protective efficacy against the ETEC bacteria responsible for most travelers' diarrhea and other vaccines against ETEC have been studied. On the horizon are new antibacterial vaccines against ETEC, *Salmonella*, and *Shigella* species.

► VECTOR-BORNE DISEASES

Although malaria is the most important vector-borne infection in travelers, others also require attention. Of these, dengue is an increasing problem, as noted by a dramatic rise in the infection globally, particularly in the Caribbean, Central and South America, and Southeast Asia. Dengue is transmitted by the *Aedes* mosquito, which prefers an urban and often indoor habitat. This mosquito bites during the day, particularly in the early morning and late afternoon. Therefore, it is important to take insect precautions during the day, in addition to those required between dusk and dawn for malaria.

Tick-borne encephalitis is acquired by the bite of an infected tick or rarely, by ingesting unpasteurized dairy products in endemic foci between latitude 39° and 65°. The risk for travelers to urban or nonforested areas who do not consume unpasteurized dairy products is thought to be negligible. Travelers with occupational exposure (e.g., forestry) and unprotected exposure (e.g., camping in endemic areas) might be at high risk even if the visit is brief. Two effective vaccines are available in Europe; however, protection lasting three years requires three doses (the first two separated by 4–12 weeks and the last at least nine months after the second). An accelerated schedule is used by some physicians. Travelers anticipating high-risk exposure, expatriates, or those planning to live in endemic countries for an extended period of time may need special consideration.

In addition to insect precautions, some vector-borne diseases can be prevented by prophylactic medication. For example, loiasis can be prevented by taking 300 mg (adult dose) of diethylcarbamazine once each week while in a very heavily infested area such as Central or West Africa. Tick- and mite-borne typhus, relapsing fever, bartonellosis, and plague can be prevented by using doxycycline prophylaxis, 100 mg daily, during exposure. For the most part, prophylaxis of these latter infections is not recommended except for a very select group of individuals at high risk for infection.

► SEXUALLY TRANSMITTED DISEASE

During international travel, individuals often feel a sense of anonymity, may be less sexually inhibited, and may therefore put themselves at greater risk for the acquisition of sexually transmitted disease. The risk is increased by exposure to multiple or professional partners. Safer sexual practices, including the use of condoms throughout intimacy, are particularly important in the era of HIV/AIDS. Immunization against hepatitis B is a must for those who may engage in casual sex while abroad.

► SOIL- AND WATERBORNE DISEASE

Schistosomiasis, a helminthic disease that infects over 200 million people in parts of South America, the Caribbean, Africa, the Middle East and Southeast Asia, can be avoided by advising travelers to stay out of slow-moving, fresh water in developing countries in these areas of the world. Swimming in the ocean or freshwater pools without snails is safe. Barefoot walking exposes the traveler to a variety of hazards, including tungiasis (sandflea), snake bites, cutaneous larva migrans from dog and cat hookworms, human hookworm infection, and strongyloidiasis. Sandals provide only partial protection; closed footwear should be fully protective.

► ADAPTATION TO THE ENVIRONMENT

Excessive sun exposure can cause erythema and sunburn, chemical hypersensitivity, eye damage, bleaching of the skin, and predisposition toward skin cancers, including malignant melanoma. The least potent sunscreen that should be used is one with a sun protection

factor (SPF) of 15, offering 93% protection. Adaptation to a hot climate can take from one to several weeks, depending on the ambient temperatures and humidity. Clothing should be made of natural fibers such as cotton and linen to allow air to circulate. Light colors reflect light and are preferable to dark fabrics. Since sweat contains both water and salt, it is important to replace salt by eating salty foods or adding extra salt to food. In hot weather and in the absence of strenuous exercise, the average person must replace at least 1½ liters of fluid per day.

► SPECIAL RISK TRAVELERS

It is beyond the scope of this review to cover health issues related to pregnant and infant travelers and to chronically ill or HIV-infected individuals. However, excellent reviews are available on these subjects.^{76–82}

► ILLNESS AFTER RETURN

It is more the exception than the rule that physicians ask “Where have you been?” of travelers who become ill after their return. Therefore, before departure travelers should be warned that if they become ill on return, regardless of how carefully they have followed recommended precautions, they should immediately inform their physicians that they have traveled recently. This advice is particularly important for febrile travelers, since no antimalarial drug guarantees protection against malaria.

Diseases Controlled Primarily by Vaccination

Measles

Walter A. Orenstein • Mark Papania • Peter Strebel

► INTRODUCTION

Measles has been recognized as a distinct clinical disease for more than 10 centuries and in the developing world is associated with high mortality rates in early childhood. The epidemiology of measles is markedly affected by population size, density, movement, and social behavior. In the absence of vaccination, the disease infects essentially everyone at some time during life except in isolated populations. Beginning in 1963 the availability and increasing use of live attenuated measles vaccines have made prevention possible. Countries in the Americas, Europe, and the Eastern Mediterranean have undertaken the interruption of measles transmission.^{1,2} Measles has not been endemic in the United States since 1997.³ Indigenous transmission of measles was interrupted in the Americas in 2002.⁴

Measles is one of the most contagious of infectious diseases. Mathematical models suggest that in a totally susceptible population the average case of measles may result in transmission of measles to 12–18 persons.⁵ Thus it is estimated that the immunity level needed to interrupt transmission is on the order of 94% or higher. Contact rates vary substantially by age group and affect the age-specific level of immunity needed to prevent transmission. Although high levels of immunity substantially reduce the likelihood that susceptible persons within a population will be exposed to disease, there is no level of immunity short of 100% that will absolutely guarantee absence of transmission.

Clinical Characteristics

Following an incubation period averaging 10–12 days (range 8–16 days), the patient typically has fever and malaise, followed shortly thereafter by cough, coryza, and conjunctivitis.⁶ An enanthem, characterized by small bluish white spots on a red background (Koplik's spots), may be seen on the buccal mucosa within the two days before and after the onset of rash. The characteristic maculopapular rash of measles usually appears an average of 14 days after infection begins and typically 2–4 days after the onset of the prodromal symptoms. The exanthem

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

classically starts on the face and hairline and then spreads to the trunk and extremities. The patient's temperature usually peaks 1–3 days following the onset of rash. The rash, areas of which fade in order of appearance, typically lasts 5–7 days, and the illness is entirely gone by 10–14 days after the onset of symptoms. There are few clinically inapparent primary infections.

The patient is infectious during the prodromal period and for the first few days of rash. The infectious period is usually considered to stretch from four days before to four days after the onset of rash. Measles is usually transmitted in large respiratory droplets, requiring close contact between patients and susceptible persons. However, measles virus can survive for at least two hours in fine droplets, and airborne spread has been documented.^{7,8} Neither a long-term infectious carrier state nor an animal reservoir is known.

Complications

The risk of complications and death is highest in young children and adults. In the United States, the most common complications of measles are otitis media and pneumonia, which occur in 2–14% and in 2–9% of cases, respectively.⁶ In developing countries, complications and case fatality rates may be higher. Pneumonia, the most common cause of death, may be caused by the measles virus itself or by secondary bacterial infection.^{6,9} These complications frequently require specific antibiotic therapy. Secondary viral infections may play a prominent role in measles pneumonia-related deaths in the developing world.¹⁰ Severe diarrhea and malnutrition may result from measles infection, particularly in the developing world.¹¹ A substantial proportion of patients in less developed countries who survive during the first month after measles succumb during the ensuing year.¹²

Measles encephalitis, which occurs typically 4–7 days after the onset of rash (range generally 1–15 days), is reported approximately once in every 1000 cases of measles.^{6,13} Approximately 15% of patients with measles encephalitis die, and another 25–35% have permanent neurologic residua. Less common complications include bronchiolitis, sinusitis, mastoiditis, myocarditis, keratoconjunctivitis, mesenteric adenitis, hepatitis, and thrombocytopenic purpura. In the United States, the reported death to case ratio has been 1 to 3 deaths per 1000 cases.⁶ In contrast, the death-case ratio in the developing world, particularly where malnutrition and crowding are common, frequently ranges from 5–10% and in some situations is even higher.¹⁴

Atypical measles syndrome, characterized by high fever, pneumonia, pleural effusions, edema of the hands and feet, hepatic abnormalities, and an unusual rash, is a rare manifestation of measles infection sometimes seen in persons who received killed measles vaccine in the past and who were subsequently exposed to measles virus. An estimated 600,000 to 900,000 persons in the United States received the killed vaccine between 1963 and 1967.¹⁵

Measles infection during pregnancy is associated with spontaneous abortion and with delivery of low birth weight infants.¹⁶ Although there have been rare reports of congenital malformations associated with measles infection during the first trimester, there is no good evidence for the existence of a congenital measles syndrome.

In addition to the acute complications noted above, measles virus can cause a degenerative disorder of the central nervous system known as subacute sclerosing panencephalitis (SSPE).¹⁷ The reported risk of SSPE ranges from 1 case per 100,000 measles cases in persons infected after four years of age to 18 cases per 100,000 measles cases in persons infected in infancy.¹⁷ A recent study in the U.S. noted a rate of 22 cases of SSPE per 100,000 reported measles cases.^{17A} This illness begins insidiously an average of seven years following the initial infection and is characterized by progressively severe personality changes, myoclonic seizures, motor impairment, coma, and death over the course of several months to years.

Before the introduction and widespread use of measles vaccine, measles infection was essentially universal in the United States. Approximately 95% of persons living in urban areas were infected by age 15 years.^{18,19} The disease typically appeared in cycles with major peaks every 2–3 years. A marked seasonal pattern was apparent with peaks during the late spring months. The highest reported age-specific incidence rates were in children 5–9 years old. In the decade from 1950–1959, an annual average of more than 500,000 cases was reported. The true number of infections was estimated to be nearly 10 times as high. During the same period, nearly 500 measles deaths were recorded each year.

Etiological Agent, Immunology, and Diagnosis

Measles is caused by a single-stranded RNA virus of the paramyxovirus group. It is very sensitive to acid conditions, drying, and light, but can survive in aerosolized droplets. Three membrane proteins appear to play critical roles in the pathogenesis. The hemagglutinin protein (H), which projects from the virion, attaches to cell surfaces. The fusion (F) protein allows cell-to-cell spread. Finally, the matrix (M) protein, associated with the inner surface of the viral envelope, appears important for successful generation of intact viral particles.²⁰ Abnormalities in the synthesis of these proteins have been postulated to play an important role in the pathogenesis of SSPE.²¹

Laboratory confirmation of suspected measles cases is a critical component of measles surveillance and a Global Measles Laboratory Network with more than 700 laboratories has been formed to support measles control activities.²² Measles virus infection with either wild type measles or live virus vaccine induces the production of a variety of antibodies. Immunoglobulin M (IgM) antibodies are detectable in approximately 80% of cases within the first 72 hours after rash onset and in nearly 100% of cases thereafter.²³ Because IgM antibodies decline to undetectable levels within 1–2 months, they provide evidence of recent infection. Testing a single specimen for measles IgM antibody is the preferred method for evaluating suspected measles in most countries.²⁴

IgG antibodies appear shortly after rash onset, and peak 2–4 weeks later and appear to last a lifetime. Therefore single serum IgG antibody tests are typically used to assess immunity to measles. A significant rise in total antibody (IgG and IgM) in paired titers, with acute serum drawn shortly after rash onset and convalescent serum two weeks later, provides laboratory confirmation of acute measles infection. Although testing of paired sera is less convenient and takes longer than IgM testing, it is more accurate and may help to validate IgM results in some situations. Serologic tests cannot distinguish between antibody produced by wild type infection and that resulting from live measles virus vaccination.

Because of the widespread availability and ease of use, enzyme linked immunosorbent assays (ELISA) tests are the most commonly used method to measure measles IgM and IgG antibodies. Several commercial ELISA kits have been shown to be sensitive and specific.^{25,26} Plaque reduction neutralization (PRN) assays are considered the gold standard for antibody testing because they provide a quantitative measure of the antibodies' ability to prevent measles virus pathology. However, PRN testing is laborious and generally confined to research settings. In addition to the humoral immunity represented by the antibodies, cellular immunity is also critical in protection against measles. However, there are no standardized tests for cellular immunity to measles.

Measles virus can be cultured from respiratory secretions, urine or whole blood or detected by reverse transcriptase polymerase chain reaction (RT-PCR) in these specimens. These tests can support the laboratory diagnosis of measles but they do not currently serve as frontline diagnostic tools because they take too much time to provide results and the sensitivity of the tests is highly dependent on the timing and quality of the specimen collection and on proper shipping. However, testing of viral specimens by culture and RT-PCR allows determination of the genotype of the virus, which enhances the ability to identify sources of infection and track chains of transmission.²⁷ Obtaining respiratory (nasal or throat swabs), urine, or whole blood specimens for viral isolation from each isolated measles case and each chain of transmission is highly recommended.

Antibody testing is usually conducted with serum samples while virus isolation and RT-PCR use clinical specimens as described above. Both serologic and virologic specimens require a cold chain for storage and transport. Methods are currently being developed to allow both serologic and virologic testing from a single specimen and to limit the invasiveness of the collection method and the need for a cold chain. The two most promising are oral fluid collection and filter paper blood spots. Oral fluids specimens have been used successfully without cold chain in the United Kingdom for measles surveillance since the mid-1990s, initially with a radioimmunoassay and more recently with ELISA tests with reasonably high sensitivity and specificity.^{28,29} However, these tests are not currently commercially available. Oral fluids have also been used to detect and identify measles viruses.³⁰ Filter paper blood spots have been shown to have high sensitivity and specificity compared to serum for IgM and IgG antibodies^{31,32} and have been used to detect and identify measles viruses by RT-PCR.³³

Immunization

Passive Immunity. Passive immunity against measles disease can be induced by the administration of commercially prepared immune globulin (IG) (formerly called immune serum globulin [ISG]), which typically has a high measles antibody titer. Administration of 0.25 mL of IG per kilogram (maximum dose 15 mL) can modify or prevent the development of measles in the exposed person.³⁴ The IG preparation is most effective if administered within six days of exposure, preferably as soon after the exposure as possible. IG is particularly indicated for susceptible household contacts, especially those who are immunocompromised. Persons in the latter groups are at greatest risk of complications from measles.

Almost all infants acquire passive immunity against measles from the transfer of maternal antibodies across the placenta. Such infants are usually immune to measles for at least the first six months of life. Immunity gradually wanes thereafter, and by 12–15 months essentially 100% of infants are susceptible. Children born to mothers who have vaccine induced antibodies tend to become seronegative earlier than infants born to mothers who have had measles disease.³⁵ Measles disease induces higher levels of antibodies than measles vaccination.

“Modified” measles is a mild form of illness occasionally seen in persons with passively acquired antibody. The incubation period may be prolonged up to 20 days. Immunity after modified measles is believed to be permanent.

Active Immunity. In 1963, two types of measles vaccine were licensed in the United States. One was a vaccine prepared from live-attenuated virus grown in chick embryo tissue culture (Edmonston B strain). Because there was a high rate of reactions to this vaccine, including fever, rash, and catarrhal symptoms, the concomitant administration of IG was recommended.³⁶

A second vaccine used the same virus, but the virus had been inactivated (killed) by formaldehyde. Immunity to the killed measles virus vaccine (KMV), or to KMV followed by live measles vaccine within three months, was short lived and induced hypersensitivity to measles virus in some persons, resulting in atypical measles syndrome (see above).

Beginning in 1965, vaccines prepared from further-attenuated strains of measles virus and not requiring the concomitant administration of IG became available and quickly became the most common vaccines in use in the United States (Schwarz strain licensed in 1965 and Moraten strain licensed in 1968). From 1965–1989, when one dose of measles vaccine was recommended, more than 172 million doses of measles containing vaccines were distributed in the United States. Following the recommendation of a routine two-dose schedule in late 1989 (see below), more than 213 million doses were distributed from 1990 to 2005.

The age at which measles vaccine is administered represents a balance between the ability of the vaccinee to respond to vaccination and the risk of measles. The proportion of vaccine recipients who developed antibodies to measles virus increases with increasing age at administration up to 12–15 months of age, presumably because of the persistence of passively acquired maternal antibodies in the infant and young child.³⁷ When measles vaccine was first introduced in the United States, it was administered at nine months of age because of the high risk of measles, even though seroconversion rates were not optimal. As the risk of measles declined, the age at administration was raised to 12 months (1965) and 15 months (1976) to assure maximal seroconversion rates. Recent studies, performed when an increasing proportion of infants are born to mothers with vaccine-induced immunity, indicate seroconversion rates at 12 months are comparable to rates at 15 months.^{35,38} Thus, in 1994 the Advisory Committee for Immunization Practices (ACIP) recommended that the first dose of measles vaccine as part of measles-mumps-rubella (MMR) vaccine could be administered any time between 12 and 15 months of age.³⁹ Administration of further-attenuated live measles vaccine to children at 12–15 months of age or older can be expected to produce measurable circulating antibodies in 95% or more of recipients.³⁸ During measles outbreaks, vaccine can be given to children as young as six months of age with subsequent revaccination.³⁴ The vast majority of persons with seroconversion have long-term, probably lifelong immunity, although waning immunity may occur in a small percentage.^{40,41}

Measles vaccine is indicated for all persons without contraindications who are at least 12 months of age, who were born after 1956, and who lack documented proof of the receipt of at least one dose of live measles vaccine or after the first birthday, proof of physician-diagnosed measles, or laboratory evidence of immunity.³⁴ Whenever such proof is lacking, persons should be vaccinated. The risk of adverse events following vaccination is not increased among persons who have previously been vaccinated.⁴²

Because measles transmission had been documented among the 2–5% of persons who did not respond to a first dose of measles vaccine, in 1989, both the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP) and the ACIP recommended a change from a one-dose schedule to a routine two-dose schedule for measles vaccination.^{43,44} The second dose recommendation focused on school children. States and localities generally implemented second dose vaccination for one school grade cohort at a time, although some elected to vaccinate multiple grade cohorts to achieve more rapidly the goal of vaccinating school children with two doses. By 2001, 82% of school children in the United States were in grades for which their states had a requirement for two doses of measles vaccine.⁴⁵ In addition to routine revaccination at entry to kindergarten or first grade, all children should be checked at the adolescent visit at

11–12 years of age to assure they have received a second dose.³⁴ Both recommended doses should be combined MMR vaccine. The primary purpose of the second dose is to induce immunity in persons who failed to mount an adequate immune response to the first dose. Waning of vaccine-induced immunity, while documented, appears to play only a limited role in sustaining measles transmission among vaccine failures.⁴⁰ Approximately 95% of persons who failed to respond to the first dose make a primary immune response, characterized by IgM antibody, following a second dose.⁴⁶

In addition to school age children, other groups of people are at increased risk of exposure to measles including persons who work in health-care facilities, students in post high school institutions and international travelers. Persons in these groups should receive two doses of measles vaccine if they do not have other evidence of measles immunity (i.e., documented prior physician diagnosed measles or laboratory evidence of immunity). Because almost half of imported measles cases occur in United States residents returning from overseas trips, infants 6–11 months of age traveling internationally should receive a dose of measles vaccine before departure and persons over 13 months of age should receive the second dose of measles vaccine before departure, given at least 28 days after the first dose.^{34,47,48}

Fever higher than 103°F (39.4°C) and fleeting rash are reported in 5–15% of recipients of measles vaccine.³⁴ Encephalitis has been reported after the use of measles vaccine. Comparing the number of cases reported to have occurred within the 30 days after immunization to the number of doses distributed in the United States yields an estimate of approximately one case of encephalitis per million doses of vaccine distributed.⁴⁹ This rate is similar to that of reported encephalitis of unknown cause seen in a comparable period in the general population in the same age group. The Institute of Medicine has concluded that available evidence is not sufficient to prove that vaccination causes encephalopathy or encephalitis.⁵⁰ SSPE has been reported in recipients of measles vaccine, but the incidence rate is approximately 5% of that following natural illness. Genotyping of specimens from persons with SSPE consistently demonstrates wild type virus rather than vaccine strains, even among persons who have a history of measles vaccination, but no history of measles disease.^{17,51} The risk of SSPE has fallen following the decrease in measles resulting from vaccination programs.¹⁷

Some have raised concerns that MMR vaccine can cause autism. However, an exhaustive review by the Institute of Medicine of at least 13 studies that addressed the question concluded that the evidence favors rejection of a causal relationship between MMR and autism.⁵² Children with anaphylactic reactions to egg ingestion may be vaccinated without prior skin testing.⁵³ They should be observed for 30 minutes before releasing to assure they do not develop severe allergic reactions. Persons with a history of anaphylactic hypersensitivity to neomycin or gelatin should not be vaccinated because measles vaccine contains neomycin and gelatin. On theoretical grounds, vaccine should not be administered to a woman known to be pregnant.³⁴

Measles vaccine is contraindicated in persons with immunodeficiency or immunosuppression. However, it should be administered to persons with asymptomatic human immunodeficiency virus (HIV) infection since measles disease may be severe or fatal in such persons. One 20-year-old man with hemophilia and HIV infection was reported to have been hospitalized with giant cell pneumonia, determined to be caused by the vaccine strain of measles virus. He had been vaccinated 11 months before this episode of pneumonia and had a CD4 T-lymphocyte cell count of “too few to enumerate.” These data suggest that severely immunocompromised persons with HIV infection should not be vaccinated.^{34,54} Severe immunosuppression is defined as (a) CD4+ T lymphocyte counts less than 750 for children younger than 12 months, less than 500 for children 1–5 years, or less than 200 for persons 6 years old or older; or (b) CD4+ T lymphocytes less than 15% of total lymphocytes for children younger than 13 years or less than 14% for persons 13 years old or older.³⁴

MMR vaccination causes clinically evident thrombocytopenia in 1:30,000 to 1:40,000 vaccinations.⁵⁰ Because persons with a history

of idiopathic thrombocytopenic purpura (ITP) may be at increased risk for thrombocytopenia following measles vaccination, a history of ITP is a contraindication to measles vaccination.^{34,55}

Vaccination of persons who received IG, whole blood, or other antibody-containing blood products should be postponed for 3–7 months or longer depending on the product and dose received to avoid potential interference with seroconversion.^{34,39} Vaccination should be postponed in persons with severe febrile illnesses. Persons with mild illnesses such as upper respiratory tract infections may be vaccinated.^{34,56}

Impact of Vaccination on Disease. The licensure and widespread use of live virus vaccine, beginning in 1963, have brought about both a dramatic reduction in the reported occurrence of measles and a substantial alteration in its epidemiological characteristics. By 1968, the reported level in the U.S. dropped by 95%, reaching a low of 22,231 cases (Fig. 9-1). Between 1968 and 1978 the reported occurrences varied from a low of 22,094 cases to a high of 75,290 cases. In 1978, an effort began to eliminate indigenous measles in the United States. Between 1981 and 1988, reported measles incidence averaged about 3100 cases annually, ranging from a low of 1497 cases in 1983 to a high of 6282 in 1986.⁵⁷ Between 1989 and 1991, the United States experienced a resurgence of measles peaking in 1990 with 27,786 cases and 64 deaths. During the 3-year period, 55,622 cases, 11,252 hospitalizations, and 123 deaths were reported. The epidemic disproportionately affected members of racial and ethnic minority groups and children living in inner cities.⁵⁸ The major cause was failure to achieve high levels of immunization coverage during the second year of life with measles coverage in two-year-old children in some cities as low as 52%.^{58,59}

After 1991, reported measles incidence declined dramatically with fewer than 1000 cases annually since 1993 and 120 or fewer cases annually since 1998. Based on provisional reports, a record low of 37 cases was set in 2004. The vast majority of measles cases in the United States since 1997 are internationally imported or linked to importation.⁶⁰ Further analysis of the gene sequences of the hemagglutinin (H) and nucleoprotein (N) genes of measles viruses isolated in the United States since 1993 documented they are significantly different from strains circulating between 1989 and 1992 and that they are related to strains isolated elsewhere in the world.²⁷ None of the recently detected genotypes occur in a repeating pattern that would suggest a new endemic genotype has been established.⁶¹ All measles in the United States since 1997 are believed to be due to international importation with very limited local transmission.^{61A}

Absence of Endemic Measles in the United States

The United States has made three attempts to eliminate indigenous measles transmission beginning in 1966. The current elimination strategy has four components: (a) maximizing population immunity by achieving and maintaining high immunization levels, (b) ensuring adequate surveillance, (c) aggressive outbreak control, and (d) working to improve the global control of measles. The most important component is maintaining high immunization levels with both recommended doses of measles vaccine. The enactment and enforcement of comprehensive school immunization laws covering all students, from kindergarten through high school, have been instrumental in achieving high two-dose coverage levels.⁴⁵ To ensure adequate surveillance a national case definition has been instituted. A probable case of measles is defined as an illness with (a) fever equal to or higher than 101°F (38.3°C), if measured); (b) generalized rash of three days or more duration; and (c) either cough, coryza, or conjunctivitis. A confirmed case is any case with laboratory confirmation, or one that meets the clinical definition given above and that is epidemiologically linked to a laboratory confirmed case. The consistent detection of imported measles cases is evidence of adequate surveillance for measles in the United States. Aggressive outbreak control consists of rapidly identifying contacts of measles cases and vaccinating those who are not immune. Historically, in school-based outbreaks, exclusion of students lacking proof of immunity played a key role in terminating transmission.⁴⁹ Two-dose immunization requirements for school students have made school-based outbreaks extremely rare in the United States.⁶²

In 2000, an expert panel concluded that measles is no longer endemic in the United States. The basic evidence supporting this conclusion is the continued low annual incidence level since 1997 (< 1 case/million people), the predominance of imported cases among the few cases that do occur, the absence of an endemic genotype, and the high levels of population immunity documented through immunization coverage estimates and serological surveys.³ Further decreases in measles incidence have been reported since 2000, demonstrating a continued lack of endemic transmission.⁶² Sustained elimination will require continued high coverage with the first dose in preschool populations and second dose for all school age children, continued adequate surveillance for measles, and aggressive response to cases. The fourth component of the strategy—to improve the global control of measles—is needed because all measles today in the United States is believed to be due to recent importations. Efforts to improve measles control in other countries are necessary to sustain elimination in the United States.

Figure 9-1. Reported measles cases, United States, 1950–2003.

Worldwide Control and Elimination

Measles poses a substantial health problem in both the developing and the developed world. Factors predisposing infected persons to complications and death are young age, crowding, malnutrition, infection with human immunodeficiency virus, and coincident respiratory or gastrointestinal illness. Before immunization, almost 2.5 million children died from measles or measles-related complications annually.⁶³ Worldwide in 2000, there were still an estimated 777,000 measles deaths, of which 58% were in sub-Saharan Africa.⁶⁴ In the developed world, two doses of measles vaccine are usually recommended; the first dose during the second year of life, typically at 12, 15, or 18 months of age, and the second dose before entry into school, depending on the country. In contrast, in the developing world, measles vaccine is generally administered in a single dose at nine months of age. This younger age was chosen for two reasons. First, measles attack and complication rates are often high during the first year of life in the developing world. Waiting until the second year would result in substantial morbidity and mortality. Second, seroconversion rates after measles vaccination at nine months of age are higher in developing countries than in developed countries. Since the mid-1990s, an increasing number of developing countries have begun offering a second opportunity for measles immunization through regular supplementary immunization activities. This serves to protect children who either missed their nine month vaccination or did not develop immunity from the vaccination.⁶⁵

In developing countries, it is particularly important to vaccinate sick children. Often, they are at greatest risk of measles complications, and nosocomial spread of disease is common.

In 1994, the 24th Pan American Sanitary Conference established a goal of eliminating indigenous measles from the Western Hemisphere by the year 2000.⁶⁶ Available epidemiologic and virologic evidence indicate that this goal may have been achieved in late 2002 and maintained through end the 2005.^{4,65,66} The strategy used by Pan American Health Organisation (PAHO) member countries to stop endemic transmission of measles consists of a one-time, nationwide, mass vaccination of children 9 months–14 years of age regardless of prior vaccination status, high routine immunization coverage, periodic (every 3–4 years) mass vaccination campaigns targeting children aged 1–4 years of age, and careful surveillance. The success of the PAHO strategy for measles elimination has led to it being adopted by other countries and regions. Seven southern African countries have implemented this strategy and by 2000, zero measles deaths were reported in these countries.⁶⁷ In 2003, the World Health Assembly resolved to reduce measles deaths by 50% by 2005 compared with 1999 levels. Between 1999 and 2005, global measles mortality was reduced by an estimated 60% suggesting that this target may be achieved on schedule.^{65,68}

Although measles meets the criteria for disease eradication, a target date for global eradication has not yet been established. Lack of political commitment, weak routine immunization systems, densely populated mega cities, and the HIV pandemic remain as significant barriers to eradication.⁶⁹

MUMPS

Francisco Averhoff • Melinda Wharton

In the fifth century BC, Hippocrates described a distinct illness characterized by unilateral or bilateral swelling of the cheeks occasionally associated with inflammation of the testes in males. In eighteenth-century England, Hamilton described a similar entity and reported that it was called “mumps” by the “common people” of England.¹ Hamilton also described the presence of central nervous system (CNS) symptoms in some patients and orchitis in adult males. The etiologic agent was identified as a virus in 1934 by Johnson and Goodpasture who demonstrated transmission to rhesus monkeys;² propagation of the virus ultimately led to the development of vaccines.³ Mumps vaccine has led to dramatic decreases in the incidence and associated morbidity in the United States and other countries that have introduced the vaccine routinely for children.

Etiologic Agent, Immunology, and Diagnosis

Mumps is caused by a ribonucleic acid (RNA) virus in the family Paramyxoviridae. Transmission occurs by contact with an infected person or by droplet spread. The incubation period averages 18 days but can range from 14–21 days. The infectious period, when virus is excreted, ranges from seven days before to nine days following the onset of disease. Man is the only known natural reservoir. Immunity following infection is long lasting, although reinfections

may occur. Most reinfections result in an asymptomatic rise in antibody titer, however reinfections can occasionally cause a mild illness. Reports of more severe reinfections have lacked adequate documentation.

The diagnosis of mumps has historically been made on clinical grounds, although there are other known causes of parotitis. With increased control of mumps due to vaccination in the United States, it is increasingly likely that sporadic cases of parotitis encountered are caused by agents other than mumps virus.⁴ Therefore, it is necessary to confirm the clinical diagnosis with laboratory testing. Laboratory diagnosis of mumps is made by viral isolation, serologic testing, or by molecular techniques such as reverse transcriptase polymerase chain reaction (RT-PCR). The presence of IgM antibodies indicates acute (recent) mumps virus infection although an IgM response may not occur in vaccinated persons. IgM antibodies are detectable within the first few days of illness, may peak at seven days following onset of illness, and remain elevated for several weeks to months. Paired sera of total or IgG mumps antibody using various assays may also be used in the diagnosis; the acute (initial) serum should be obtained as close to onset of symptoms as possible and the convalescent serum 4–6 weeks later. Mumps virus may be isolated from the Stensen’s duct, saliva, urine, or cerebral spinal fluid (CSF) during the first five days of illness. Reverse transcription polymerase chain reaction (RT-PCR) has also been used to detect virus in the same fluids and wild virus can be distinguished from vaccine virus. Laboratory confirmation in previously vaccinated persons may be problematic due to absence of IgM response, lower viral load, and shorter duration of viral excretion.

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Clinical Description

Mumps is a generalized viral infection that may cause a prodrome characterized by fever, headache, malaise, myalgias, anorexia, and fatigue followed by parotitis that occurs in up to 70% of infections.⁵ Inflammation of the submandibular or sublingual glands may occur alone or in combination with parotitis. Uncomplicated mumps illness resolves typically within 10 days. Mumps is the only infectious agent known to cause epidemic parotitis.

Complications

Complications associated with mumps infection are more severe in adults than children.^{5,6} Epididymo-orchitis may occur in 25–38% of postpubertal men and oophoritis in 5% of postpubertal women; no clear association with sterility has been documented. CNS involvement occurs in 4–6% of clinical cases; aseptic meningitis is the most common CNS complication and is typically mild. Encephalitis is a rare, serious complication that may result in death in 1–2% of cases but does not usually result in permanent sequelae. Although the overall mortality rate is low, death due to mumps infection is more likely to occur in adults. Sensorineural deafness associated with mumps infection can occur in up to 4% cases and may result in permanent hearing loss. Pancreatitis occurs in up to 4% of cases and is usually mild. An association with diabetes mellitus has been suggested, but further research is necessary to determine a causal link. Mumps infection during pregnancy has not been associated with congenital malformations but first trimester infections may result in spontaneous abortion.⁷

Immunization

Passive immunization with either immune globulin or mumps immune globulin has not been shown to be effective for post-exposure prophylaxis or for the prevention of complications. Maternal antibody crosses the placenta and provides for protection during the first year of life.

An inactivated virus vaccine was developed in 1948 but did not provide lasting protection and was withdrawn. In 1967, the Jeryl Lynn strain of live attenuated vaccine was licensed in the United States.⁸ The vaccine is available in combination with measles and rubella vaccine and is the only mumps vaccine licensed in the United States. Several strains of mumps vaccine are in use throughout the world and the World Health Organization (WHO) reports that 118 member countries include mumps in their routine vaccination program.⁹

The Jeryl Lynn vaccine induces seroconversion in more than 95% of vaccine recipients⁸ and studies have found long-term persistence of vaccine-induced antibody.¹⁰ Although the protective efficacy of the vaccine in controlled clinical trials has been found to be more than 95%,⁸ field studies of vaccine effectiveness following licensure have found the vaccine to be 75–91% effective in preventing disease.^{11–13} Vaccine virus cannot be isolated from blood, urine, or saliva of vaccinated individuals and is not transmitted to susceptible contacts.

There is no evidence that the vaccine provides protection when administered following infection with mumps. Non-immune persons who were exposed but not infected may be protected from subsequent infection and should be vaccinated; the vaccine does not increase the severity of disease when administered following exposure.

In the United States, mumps vaccine is usually administered in combination with measles and rubella vaccine as measles-mumps-rubella (MMR).¹⁴ The first dose of MMR is recommended at 12–15 months of age and a second dose at 4–6 years. Two doses for MMR vaccine are recommended for school-aged children, students in high-school, educational facilities, health care workers born in and after 1957, and international travellers.^{14A}

Persons in the United States can be considered immune to mumps if they (*a*) have documentary evidence of age-appropriate

vaccination documentation (*b*) have laboratory evidence of mumps immunity, (*c*) were born before 1957, or (*d*) have a history of physician-diagnosed mumps.

Contraindications to vaccination include pregnancy because of the theoretical risk to the fetus of a live vaccine. Vaccine should not be administered within three months of the receipt of immune globulin (IG); the response to measles and rubella vaccine is known to be inhibited by IG and, although the effect of IG on mumps vaccine is unknown, it should not be considered effective. In addition, persons with altered immunity, severe febrile illness, and a history of prior hypersensitivity reaction to MMR vaccine or components such as gelatin and neomycin should not receive these vaccines. Persons with human immunodeficiency virus (HIV) infection who are not severely immunosuppressed may receive MMR vaccine. Persons with a history of anaphylactic reaction associated with egg ingestion were previously considered at risk of serious reaction following administration of MMR; research has shown this not to be the case and allergy to eggs is no longer considered a contraindication to vaccination nor is skin testing prior to vaccination recommended.¹⁴ Persons with a history of thrombocytopenia or thrombocytopenia purpura may be at increased risk of developing clinically significant thrombocytopenia following MMR vaccination, and the decision to vaccinate should be based on weighing the benefits of the derived immunity compared to the risk of developing a recurrence of thrombocytopenia.

In the United States, the most common adverse reactions to mumps vaccination are parotitis and low grade fever; parotitis occurs in 0.5–2% of vaccine recipients. Aseptic meningitis has not been associated with the Jeryl Lynn strain of mumps vaccine. The Urabe strain of mumps vaccine, which is widely available globally, has been associated with reports of aseptic meningitis following administration. Because most of the mumps vaccine administered in the United States is MMR, adverse reactions following receipt administration of MMR may be caused by any of the three components of the vaccine (measles, mumps or rubella vaccine).

In addition to the Jeryl Lynn strain, several strains of live attenuated mumps vaccine have been developed and are in use globally.¹⁵ The RIT 4385 strain which is derived from the Jeryl Lynn strain, the Urabe strain, the Leningrad-3 strain and the Leningrad-Zagreb strain, derived from the Leningrad-3 strain are the most widely used. Other strains have more limited distribution and use. The immunogenicity, efficacy, and adverse events associated with different vaccine strains may vary substantially.

Occurrence

Mumps occurs worldwide. Seroprevalence data from the prevaccine era suggests that although age of infection can vary, most infections occur during childhood. In the United States, prior to the introduction of vaccine, incidence was highest among children aged 5–9 years and there appeared to be no geographic differences.¹⁶ Cases followed a seasonal pattern with peak incidence during winter and spring. Incidence in the United States began to decrease following vaccine introduction in 1967 and recommendations for routine vaccination of children in 1977.¹⁷ Vaccine introduction caused in a change epidemiology of the disease with the highest attack rates shifting from children 5–9 years of age to those 10–14 years of age and outbreaks occurring in high schools and on college campuses.^{11,18} There was a relative resurgence of mumps during the period 1985–1987¹⁸ that was felt to be largely attributable to the under-immunized cohort of children born after vaccine introduction, between 1967 and 1977.¹⁹ Outbreaks also occurred among highly immunized population, suggesting primary vaccine failure; one dose vaccine effectiveness has been estimated to be between 75% and 91%^{11–13} Secondary vaccine failure may occur, but does not appear to be of epidemiologic importance.^{12,20}

Since the 1990s there has been a further large decrease in the reported incidence of mumps in the United States (Fig. 9-2). This is attributable to both higher first coverage attained and the implementation of the recommendation for a second dose of MMR in response to the

X-axis= Year

Figure 9-2. Reported mumps incidence per 100,000, United States, 1968–2004.

The mumps vaccine was licensed in 1967. Since the introduction and wide vaccine uptake, the number of reported mumps cases have steadily decreased by more than 99% from 88 cases per 100,000 persons in 1968 to 0.07 cases per 100,000 persons in 2003.

measles resurgence of the late 1980s; the second dose of MMR likely provides protection against mumps to some persons who did not respond to the first dose.²¹

In the United States, mumps vaccine coverage among children enrolled in kindergarten is estimated to be 96%²² while two dose MMR vaccine coverage among children aged 13–15 years is estimated to be 92% (CDC, unpublished data). High MMR coverage has contributed to the elimination of both measles²³ and rubella (Rubella and CRS Elimination Meeting, Atlanta, October 29, 2004) in the United States. Mumps incidence has decreased from a greater than 100 per 100,000 persons annually during the prevaccine era (prior to 1968) to less than 0.1 per 100,000 persons annually during 2001–2004, a reduction of greater than 99.9%. However, in 2006, a large multi-state outbreak occurred among college-age adults in the United States.^{21A}

Globally, mumps epidemiology varies greatly; many countries have not introduced mumps vaccine while Finland, which introduced a two-dose MMR schedule in 1982, has reported elimination of indigenous transmission,²⁴ the first country to do so. The United Kingdom,

which introduced mumps vaccination in 1988, reported a resurgence of mumps cases during 2004 and 2005.^{25,26} Most cases associated with this outbreak are occurring among young adults born before 1988, the year immunization against mumps was introduced in the United Kingdom.

Although further research may be needed, it appears that sustained declines in mumps incidence can be achieved by maintaining high immunization levels in infants and ensuring that children receive two doses of mumps containing vaccine. The experience from Finland demonstrates that high 2-dose mumps vaccination coverage can result in the elimination of mumps.²⁴ Measles and rubella have both been eliminated in the United States,^{27–29} suggesting the possibility of mumps elimination since MMR vaccine is used almost exclusively. Population immunity and high vaccination coverage play key roles in elimination of vaccine preventable infectious diseases. With the high rates of seroconversion (> 95%) among vaccinees receiving mumps vaccine and the high vaccination coverage attained, it is possible that indigenous transmission of mumps can be interrupted as well.

Rubella

Susan E. Reef

In 1941, an epidemic of congenital cataracts in Australia was observed in the wake of a large outbreak of rubella.¹ A usually mild and self-limited illness assumed new importance because of its ability to induce congenital defects in infants of women who acquire rubella during pregnancy. Subsequent success in developing and making available an effective vaccine to prevent rubella has been a major public health achievement. Even though several rubella vaccines became available in 1969, until recently the use of rubella-containing vaccine has focused mainly on developed countries. World Health Organization (WHO) conducts surveys to document the number of member countries that have introduced rubella-containing vaccine into their national immunization programs. In 1996, 78 (33%) countries/territories were using rubella vaccine in their national immunization programs,² but by August 2006, 117 (61%) countries reported using rubella-containing vaccine into their national programs.³

Etiological Agent, Immunology, and Diagnosis

Rubella (German or 3-day measles) is caused by an RNA virus of the togavirus family. Other agents in this family include eastern and western equine encephalitis viruses. Man is the only known reservoir. Rubella is a highly communicable but less so than measles or varicella. Virus is transmitted by the respiratory route, and infection usually occurs as a result of contact with nasopharyngeal secretions of infected persons by droplet spread. Primary rubella infection induces lifelong immunity. Reinfections of rubella have occurred in persons with natural or vaccine-induced immunity, but are usually asymptomatic and recognized only by serological testing. Reinfections in pregnant women apparently pose minimal risk to the unborn fetus.⁴

Clinical diagnosis is often unreliable because symptoms, including rash, are absent in up to one half of persons infected with rubella. A history of exposure to rubella may be helpful in the absence of the full complement of clinical signs and symptoms. Culture of virus is difficult and not widely available. Serologic confirmation remains the definitive means of diagnosing rubella. Antibodies to the virus (initially, both IgM and IgG) appear shortly after the onset of rash illness. IgM antibodies generally do not persist more than 8–12 weeks after the onset of illness, while IgG antibodies usually persist for the lifetime of the patient. Many rubella antibody assay methods are available.

Approximately 90% of all neonates with congenital rubella infection have virus in most of their accessible extravascular fluids (e.g., pharyngeal secretions, cerebrospinal fluid, tears, urine).⁵ Because IgM antibody normally does not cross the placenta, the presence of rubella specific IgM antibody in cord blood is evidence of congenital infection. The presence and persistence of rubella-specific IgG at higher-than-expected levels postpartum (the half-life of maternal antibodies is one month) are also suggestive of intrauterine infection.

Clinical Characteristics

Postnatal Infection. Rubella is an acute, mild disease in children and young adults. The first symptoms occur after an incubation period ranging from 14 to 21 days. Communicability may begin as early as seven days before onset of rash and persists to seven days

after rash onset. The cardinal manifestations of the disease are a non-specific maculopapular rash lasting three days or less (hence the term “3-day measles”) and generalized lymphadenopathy, particularly of the postauricular, suboccipital, and posterior cervical lymph nodes. However, asymptomatic infections are common: up to 50% of infections occur without rash. The rash, which is often the first sign of illness, appears first on the face and then spreads downward rapidly to the neck, arms, trunk, and extremities; pruritus is not unusual. In adolescents or adults, the rash may be preceded by a one- to five-day prodrome of low-grade fever, headache, malaise, anorexia, mild conjunctivitis, coryza, sore throat, and lymphadenopathy. The manifestations rapidly subside after the first day of the rash. Exanthems comparable to that observed with rubella infection have been described in infections with *echovirus* and *coxsackievirus* and other enteroviral infections, fifth disease (Parvovirus), and mild measles; these infections, however, are not commonly associated with postauricular or suboccipital adenopathy.

Prenatal Infection. The major disease burden of rubella virus is congenital infection. Primary rubella infection during pregnancy, whether clinical or subclinical, carries a significant risk of fetal infection. Congenital rubella is often associated with a disseminated and chronic infection that may persist throughout fetal life and for many months after birth. Spontaneous abortion, stillbirth, or congenital rubella syndrome (CRS) can result from chronic infection and the inhibition of cell multiplication in the developing fetus. Disrupted organogenesis and hypoplastic organ development lead to the characteristic structural defects; Table 9-1 lists manifestations associated with congenital rubella infection. Transplacental infection is not always reflected by immediately apparent disease; up to 50–70% of infants with congenital rubella infection may appear normal at birth. Deafness/hearing impairment is commonly diagnosed later when it is the sole manifestation. Other, relatively less frequent effects, including delayed developmental milestones to learning, and speech, behavioral, and psychiatric disorders, have been described.⁶ Autism has been reported to occur at a rate of 6%. Endocrinopathies such as thyroiditis with hypothyroidism or hyperthyroidism, diabetes mellitus, and Addison’s disease have also been occasionally reported to be late sequelae.

Congenital infection is not inevitable, however, and the fetal response to infection is not uniform; the gestational age of the conceptus at the time of primary maternal infection is the principal factor influencing the outcome of pregnancy. The risk of CRS as a consequence of maternal infection in the first 10 weeks of pregnancy may be as high as 90%,⁷ but the risk decreases sharply after the 11th week and is absent after the 20th week of gestation.

Complications

Although rubella is a mild disease in children, it may be more significant with complications in adults.⁸ Arthralgia and arthritis may occur in adults, particularly women, at a reported rate as high as 70%. Joint involvement usually occurs after the rash fades and typically lasts 5–10 days. Rare complications include optic neuritis, thrombocytopenic purpura, and myocarditis. Postinfectious encephalitis of short duration may occur 1–6 days after the appearance of rash; its incidence rate is estimated at 1 in 1600⁹ to 1 in 5000 cases.

Occurrence

In temperate climates, rubella is endemic year-round, with a regular seasonal peak during springtime. Before the advent of rubella vaccination, major epidemics of rubella in the United States tended

to occur at six- to nine-year intervals. The last major epidemic of rubella in the United States occurred in 1964 and 1965, and resulted in an estimated 12,500,000 cases of rubella and an estimated 20,000 cases of congenital rubella syndrome and 11,250 fetal death or therapeutic abortion. In 1969, live attenuated vaccines were first licensed in the United States. The goal of vaccination program was to prevent the congenital rubella infections. Initially, children from one year to puberty were targeted. During 1969–1977 (Fig. 9-3) the number of reported rubella cases declined by 78% from 57,686 cases in 1969 to 12,491 in 1977. As anticipated the greatest decreases in rubella occurred among persons aged less than 15 years; however,

**Figure 9-3.** Reported rubella and CRS, United States, 1966–2004.

incidence declined in all age groups, including adults. In the late 1970s, a resurgence of rubella occurred mainly among adolescents and young adults. In 1978, ACIP recommendations were changed to include vaccination for susceptible postpubertal females, adolescents, persons in military service, and college students. By the late 1980s, rubella and CRS were at record low levels in the United States. In 1989, there was an increase in rubella cases that continued into 1991. Of the 117 CRS cases reported between 1990 and 1999, 66 (56%) were born in 1990 and 1991. Most of the rubella cases were associated with outbreaks that occurred in settings where unvaccinated adults congregated, including colleges, workplaces, prisons, and in religious communities that did not accept vaccination. Before mid-1990s, rubella occurred among non-Hispanic children; however, after the mid-1990s, rubella occurred mainly in Hispanic adults. Beginning in 1998, data on country of origin were collected for rubella cases.¹⁰ Between 1998–2000, of the cases with known country of origin, 77% (404 per 533) were born outside the United States. Of these, 93% were from the Western Hemisphere, of which over 50% were born in Mexico. Since 2001, the annual numbers of rubella cases have been the lowest ever recorded in the United States: less than 25 cases annually. Approximately half of these cases have occurred among persons born outside the United States. This was also seen with the significant decrease in CRS cases. During 1998 through 2004, 27 CRS cases were reported, of which 23 CRS cases were born between 1998 and 2000.

Strategy for Prevention

Since licensure of live attenuated rubella virus vaccines in 1969, efforts to control rubella in the United States have been directed primarily at preschool and elementary schoolchildren of both sexes. It was reasoned that, in addition to protection of children, circulation of the virus would be greatly reduced or interrupted, and susceptible pregnant women would be protected indirectly by virtually eliminating the risk of exposure. As noted above, although this strategy substantially reduced the incidence of rubella and congenital rubella infection in the United States, this program did not reduce susceptibility among persons less than 15 years old. In 1978, the Advisory Committee on Immunization Practices (ACIP) recommendations were modified to include the vaccination of susceptible postpubertal females and high risk groups such as military recruits and university students. With combined routine childhood vaccination and vaccination of women of childbearing age, cases of rubella and CRS are at a record low in the United States. Another approach initially implemented elsewhere (e.g., in the United Kingdom) prescribed immunization of young adolescent girls at approximately 11–14 years of age, accompanied by vaccination of all susceptible adult women of childbearing age. It was anticipated that this approach would not reduce the total number of cases of rubella but would have a direct protective effect as these girls enter their childbearing years. Indeed, there was little change in the reported occurrence of rubella and CRS in the United Kingdom through the mid-1980s, and major epidemics occurred in 1978, 1979, 1982, and 1983. Nonetheless, serological evidence indicates that the proportion of young adult women who are susceptible has declined in recent years. However, because the vaccine is less than 100% efficacious and immunization coverage is lower than 100% in girls, cases of rubella in women of childbearing age do occur with subsequent CRS.¹¹ With the improvement of coverage and adequate surveillance, MMR vaccine was introduced in 1988 as part of the routine childhood immunization schedule, resulting in gradual decline in the number of cases of rubella.¹² However, in 1993, a resurgence of rubella occurred among young adult males. To prevent a measles epidemic, in November 1994, a national vaccination campaign was offered to all children aged 5–16 years of age using measles vaccine to which rubella vaccine was added. Since 1996, there have been no large outbreaks of rubella reported.¹³

In 1969, three rubella vaccines were licensed for use in the United States: the HPV-77 strain, prepared in duck embryo cell culture; the HPV-77 prepared in dog kidney cell culture; and the Cendehill strain, prepared in rabbit kidney cell culture. In 1979, the RA 27/3 strain,

which is prepared in human diploid cells, was introduced and has since been the only rubella vaccine that is distributed in the United States. In at least 95% of vaccinees, all these vaccines induce antibodies that have been shown to persist for more than 16 years,¹⁴ indicating that immunity is durable and probably lifelong. However, two studies have documented that there may be waning of rubella antibodies in adolescents that were vaccinated with rubella vaccine 9–14 years earlier.¹⁶ In recent years, outbreaks of rubella have occurred in young adults, but few cases were observed among persons with documented previous vaccination. This suggests that waning of antibody levels is not associated with loss of protection. Most of those persons who lack detectable antibody by standard tests have been shown to have antibody by more sensitive tests. When exposed to either natural disease or revaccination, such persons typically do not develop an IgM response and do not have detectable viremia.

In the United States, rubella vaccine is recommended for all susceptible persons 12 months of age and older, unless vaccination is contraindicated.¹⁷ Rubella vaccination is most cost-effective when offered as MMR vaccine. Persons should be considered susceptible to rubella unless they have documentation of (a) adequate immunization with rubella virus vaccine on or after their first birthday, (b) laboratory evidence of immunity, or (c) born before 1957 (except women who could become pregnant). Persons who are unsure of their rubella disease or vaccination history or both should be vaccinated. Adults born before 1957 may receive MMR vaccine, unless otherwise contraindicated.

Rubella vaccine given after exposure may not provide protection, but there is no contraindication to its use. The vaccine has not been observed to increase the severity of disease, and if the exposure did not result in infection, it should induce protection against subsequent infection. Immune globulin (IG) given after exposure to rubella will not reliably prevent infection or viremia but may only modify or suppress symptoms. Infants with congenital rubella have been born to women given IG shortly after exposure. The routine use of IG for postexposure prophylaxis of rubella in early pregnancy is not recommended unless termination would not be considered under any circumstances.

Adverse events following vaccination include low-grade fever, rash, and lymphadenopathy. As many as 40% of vaccinees in large-scale field trials had joint pain, usually of the small peripheral joints, but frank arthritis has generally been reported in fewer than 2% of subjects. As with natural disease, vaccine-associated arthralgia and transient arthritis occur more frequently and tend to be more severe in women than in men or children. As many as 3% of susceptible children have been reported to have arthralgia, and arthritis has been reported only rarely in these vaccinees; in contrast, 10–15% of susceptible female vaccinees have been reported to have arthritis-like symptoms. With both natural and vaccine-associated disease, these symptoms usually have not caused disruption of activities and most often have not persisted. However, rubella infection in adults is associated with a higher incidence, greater severity, and more prolonged duration of joint manifestations than are seen after rubella immunization.

During the mid-1980s, investigators from one institution reported persistent or chronic arthropathy in 5–11% of adult females following rubella vaccination.¹⁸ In 1991, Institute of Medicine concluded that, "Evidence is consistent with a causal relation between the currently used rubella vaccine strain (RA 27/3) and chronic arthritis in adult women, although the evidence is limited in scope and confined to reports from one institution."¹⁹ A placebo-controlled prospective study was conducted. Not surprisingly, acute arthropathy and arthritis were more common in the vaccinees. To be evaluated for persistent arthropathy, a woman had to experience acute arthropathy or arthritis. The frequency of chronic arthropathy was 15% in the placebo group and 22% in the vaccine arm. However, 72% of the women in the vaccine group with acute arthropathy later developed chronic arthropathy, which was not significantly different from the 75% of the women in the placebo arm.²⁰ However, data from studies in the United States and experience from other countries using the

RA 27/3 strain rubella vaccine have not supported this finding, suggesting that such occurrences are rare and may not be causally related to administration of rubella-containing vaccines.^{21–23}

Transient peripheral neuritic complaints, such as paresthesias and pain in the arms and legs, have also very rarely occurred. Reactions such as these usually occur only in susceptible vaccinees; persons who are already immune to rubella, either due to previous rubella vaccination or natural infection, are not at increased risk of local or systemic reactions following the receipt of rubella vaccine.

Although use of rubella vaccine is contraindicated in pregnant women or women planning pregnancy within four weeks, inadvertent administration of the vaccine to pregnant women does occur. Prior to November 2001, women were advised to wait for three months after vaccination. The recommendation was changed to one month based on data reviewed for 680 live births to susceptible women who were inadvertently vaccinated three months before or during pregnancy with one of three rubella vaccines (HPV-77, Cendehill, or RA 27/3). None of the infants was born with CRS. However, a small theoretical risk of 0.5% (upper bound of 95% confidence limit=0.05%) cannot be ruled out. Limiting the analysis to the 293 infants born to susceptible mothers vaccinated 1–2 weeks before to 4–6 weeks after conception, the maximum theoretical risk is 1.3%. This risk is substantially less than the more than 20% risk for CRS associated with maternal infection during the first 20 weeks of pregnancy.

In view of the importance of protecting women of childbearing age from rubella, reasonable practices for avoiding vaccination of pregnant women in a rubella immunization program should include (a) asking women if they are pregnant, (b) excluding from the program those who say they are, and (c) explaining the theoretical risks to the others before vaccinating. The vaccine should also not be given to those with immunodeficiency diseases or compromised immune systems as a result of disease or treatment because of the theoretical possibility that replication of the vaccine virus can be potentiated. Other contraindications to vaccination are recent administration of IG, and severe febrile illness.

The goal of elimination of indigenous rubella and congenital rubella syndrome in the United States was established for the year 2010. In October 2004, a panel of experts reviewed data indicating that less than 25 reported rubella cases had occurred yearly since 2001 (Fig. 9-3), more than 95% vaccination coverage was documented among school-age children, more than 91% population immunity was present, adequate surveillance was in place to detect outbreaks of two or more cases, and the pattern of virus genotypes was consistent with the conclusion that cases in the United States are caused by virus originating in other parts of the world. Based on these available data, panel members concluded unanimously that rubella was no longer endemic in the United States.

With the elimination of endemic chains of rubella transmission in the United States, future patterns of rubella in the United States will most likely reflect global disease epidemiology. Since 2000, most non-U.S.-born cases of rubella reported in the United States have occurred among people born in Asia, the Middle East, or elsewhere in countries that have not implemented rubella vaccination or just recently implemented a vaccination program. According to a survey of the member countries in the World Health Organization, the number of countries that have incorporated rubella-containing vaccine into their routine national program increased from 78 (33%) in 1996 to 117 (61%) in 2006. However, rubella continues to be endemic in many parts of the world. While rubella circulates anywhere in the world, the United States must continue its vigilance on three fronts to prevent the reestablishment of rubella transmission and the occurrence of CRS: maintaining high vaccination rates among children; assuring immunity among women of childbearing age, with particular attention by health-care providers to those women born outside the United States; and continuing to conduct surveillance for both rubella and CRS.

Pertussis

Margaret Mary Cortese • Kristine M. Bisgard

Pertussis is a highly communicable respiratory illness caused by the bacterium *Bordetella pertussis*. It is typically manifested by paroxysms of severe coughing that can persist for many weeks and are often associated with inspiratory whooping and post-tussive vomiting. In the prevaccine era, pertussis was a significant cause of morbidity and mortality among infants and children in the United States, with an average of more than 160,000 cases and more than 5000 deaths reported annually in the 1920s and 1930s (Fig. 9-4).¹⁻²

Clinical Characteristics

The main clinical feature of classic pertussis is paroxysmal coughing (i.e., the sudden onset of repeated violent coughs without intervening respirations).³ The onset of illness is insidious. During the first one or two weeks of illness, coryza is accompanied by shallow, irritating, nonproductive coughing, which gradually changes into spasms of paroxysmal coughing. The patient generally remains well and free from cough between paroxysms. In classic pertussis, the coughing attacks become more severe and are commonly followed by inspiratory whooping or vomiting. After a few weeks of paroxysmal coughing, the disease peaks in severity and begins to subside, although convalescence (manifested by diminished but continuing cough) is protracted and can last over three months. In young unvaccinated children, leukocytosis and lymphocytosis are often present during the early paroxysmal stage of the disease. Classic pertussis can occur in a person at any age. Mild or atypical pertussis (without severe paroxysms or whooping) can occur in vaccinated children and in adolescents and adults whose protection from childhood vaccination or previous natural exposure has waned. A diagnosis of pertussis may be suggested in such patients by a history of persistent cough and exposure to a known or suspected case. In infants, serious apnea may follow coughing paroxysms. Very young infants (i.e., infants aged ≤ 3 months) may present with apnea and/or bradycardia with relatively minimal cough or respiratory distress and pertussis may not be initially suspected.⁴⁻⁵ In a recent study of infants admitted to UK pediatric intensive care units with respiratory failure, an acute life-threatening event, or apnea/bradycardia, pertussis was initially suspected in only 28% (7/25) of those ultimately diagnosed with pertussis.⁶ Although boosting of antibodies is not uncommon in exposed household contacts who do not develop symptoms, asymptomatic infection with isolation of *B. pertussis* occurs only in a small minority of household contacts.^{7,8} Long-term carriage is thought not to occur. Whooping cough may also be caused infrequently by *Bordetella parapertussis* and by the animal pathogen, *Bordetella bronchiseptica*. Infection with adenoviruses, *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* should be included in the differential diagnosis.

Complications

The major complications, including hypoxia, pneumonia, malnutrition, seizures, and encephalopathy, are most common in young unimmunized children. Of the 18,500 cases reported in U.S. infants aged less than 12 months from 1990–1999, 67% were hospitalized and 0.5% died.² Of the 90% or more with information provided on

the following complications, 56% had apnea, 1.9% had seizures, and 0.3% had encephalopathy. Radiograph-confirmed pneumonia was reported for 22% of those infants with data provided (63% of infant cases had data, for a minimum pneumonia incidence of 14% in infected infants). Approximately 76% of infants aged less than four months with reported pertussis were hospitalized compared with 48% of infants 4–11 months of age. These older infants, unlike the younger infants, were eligible to have received at least two doses of vaccine. It is likely that infants hospitalized with pertussis are more likely to be reported to the surveillance system than those treated as outpatients. Because a large proportion of infants reported to the system were indeed hospitalized, the complication rates described above likely represent those infants with more severe disease. For children in developing countries, additional nutritional deficits from poor feeding and post-tussive vomiting are a serious complication of pertussis.

In developed countries, deaths from pertussis are almost always in infants, with the majority occurring in infants too young to have received three pertussis vaccinations.^{5,9} Of the 77 pertussis deaths reported in the United States from 1990–1999, 61 were among infants aged less than 12 months (average annual pertussis mortality rate among infants: 2.4 deaths per million), and 49 (80%) of the 61 fatal infant cases were in infants aged less than four months.⁵ Among these deceased infants, refractory pulmonary hypertension was a common, severe complication that contributed to death. Twelve percent of infants who died in 1980–1999 were reported to have encephalopathy. The term pertussis encephalopathy has generally been used to describe neurologic complications associated with pertussis, including seizures and coma. The pathophysiologic mechanisms for these complications are not clear; pathologic examination from previous reports of patients who died with pertussis encephalopathy generally had evidence of hypoxic damage or hemorrhage without inflammation in the brain.^{10,11}

Adolescents and adults can also develop complications from pertussis. Hospitalization rates were 0.8% and 3% for 1679 adolescents and 936 adults, respectively, with confirmed pertussis studied in Massachusetts during 1998–2000, and pneumonia was diagnosed in 2% of each group.¹² The most common complications reported in another Massachusetts cohort of 203 adults with pertussis were weight loss (33%), urinary incontinence (28%), loss of consciousness (6%), and rib fractures from severe coughing (4%).

Bacteriology and Pathogenesis

B. pertussis is a small, fastidious, gram-negative coccobacillus that was first isolated by Bordet and Gengou in 1906. Isolation requires a complex medium that contains blood or charcoal or both, on which the bacilli appear as small, pearly colonies. Pathologically, pertussis is a superficial respiratory infection, primarily of the subglottic respiratory tract. *B. pertussis* can be found attached to mucosal cells and inside alveolar macrophages. Systemic invasion does not occur. Pathological specimens from patients demonstrate local bronchial epithelial necrosis and inflammation. Pertussis appears to be a toxin-mediated disease resulting from local infection.^{13,14} The products or *B. pertussis* antigens that may be responsible for the local or systemic pathophysiological events, or both, include pertussis toxin (PT), endotoxin, dermatonecrotic toxin, tracheal cytotoxin, adenylate cyclase toxin, filamentous hemagglutinin (FHA), fimbriae 2,3 (FIM) and pertactin (PRN). PT is an ADP-ribosyl transferase (modulates host G proteins) and is considered responsible for the lymphocytosis and hypoglycemia that may be seen in whooping cough. PT and adenylate cyclase toxin are considered important mediators of altered

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Figure 9-4. Reported pertussis cases—U.S., 1922–2003.

immunological and phagocytic function. FHA, FIM, and PRN may mediate attachment to respiratory epithelial cells.

Characterization of *B. pertussis* isolates using molecular methods (e.g., pulsed-field gel electrophoresis) may be a useful tool in epidemiologic investigations and in the study of the bacterial genome itself.¹⁵

Diagnosis

Laboratory confirmation of the clinical diagnosis can be difficult. Culture specimens are obtained either by nasopharyngeal aspiration or by passing a fine wire tipped with Dacron or calcium alginate through the patient's nose to the posterior portion of the nasopharynx. The nasopharyngeal swabs are streaked on Bordet-Gengou, Regan-Lowe, or other appropriate agar medium. A selective antimicrobial agent, such as cephalaxin, greatly enhances recognition of pertussis colonies by suppressing the overgrowth of normal flora. The plates must be incubated for at least 5–7 days and preferably up to 12–14 days.

Recovery of *B. pertussis* from patients is affected by the patient's age, prior vaccination, antimicrobial therapy, and by the stage of illness.¹⁶ If nasopharyngeal specimens are collected from children within 2 weeks of cough onset and cultured on proper media, *B. pertussis* can be isolated in an experienced laboratory in up to 80% of patients with clinical disease who have had no prior vaccination or antimicrobial therapy. The yield of culture, however, is reduced in older patients and patients who have been vaccinated so that less than 50% may be positive. Additionally, the frequency of positive cultures diminishes rapidly after onset of paroxysmal cough. Cultures obtained 21 or more days after cough onset are almost always negative.

In vaccine efficacy trials, increases in immunoglobulin (Ig) A and G to *B. pertussis* antigens between acute and convalescent serologic samples were used as one method of diagnosing pertussis. Practical application is limited, however, because the first serum specimen must be collected very soon after cough onset for a significant antibody increase to be detected.¹⁷ In persons who have not been recently vaccinated (e.g., >3 years from the last pertussis vaccination), the anti-PT IgG titer in a single serum sample (measured by enzyme-linked immunosorbent assay [ELISA] using standardized, validated methodology) taken 2–8 weeks after cough onset can be used to diagnose pertussis.^{18–19} Although not all *B. pertussis*-infected individuals will have increased anti-PT IgG, this test is useful in adolescents and adults to document pertussis in suspected outbreaks, and to help assess the extent of the outbreak.

Polymerase chain reaction (PCR) methods have been developed for *B. pertussis* and are being increasingly used in research and for routine diagnosis. Compared with culture, PCR testing is more rapid and

could be more sensitive. However, this assay has not been well standardized, and there are concerns about false-positive test results.^{20,21} In addition, PCR does not provide a bacterial isolate that can be used for antimicrobial sensitivity testing or molecular characterization. During a suspected pertussis outbreak, the inability to culture *B. pertussis* from appropriately timed and handled specimens of at least several PCR positive persons can indicate the PCR results are falsely positive. Another test, direct fluorescence antibody (DFA) staining of mucous smears from nasopharyngeal swabs, has also been used for laboratory diagnosis. However, rates of false-positive and false-negative results can be high and DFA should not be used to diagnose pertussis.^{22,23}

Immunity

The mechanism of immunity in pertussis is not well understood. After natural infection, a rise in serum antibody level in most patients can be observed by ELISA measurement of class-specific antibodies to PT, FHA, FIM, and/or PRN. The timing of the appearance of IgG and IgA antibody corresponds roughly to the disappearance of culturable organisms from the nasopharynx (i.e., ≥ 2 weeks after cough onset). Studies in mice support a role for cell-mediated immunity in protection against pertussis. Immunity against clinical whooping cough induced by natural infection is believed to be long lasting; however, frequent exposure and infection with *B. pertussis* ("boosting") during an individual's life time may be required to maintain protection against clinical illness. Neonates are apparently generally susceptible to pertussis, suggesting levels of maternal antibodies are too low to provide protection.

The components of *B. pertussis* that induce protective antibody in humans have not been precisely identified. The protective effect of the whole-cell pertussis vaccine in humans, as measured by its effect on the secondary attack rate in household contacts, correlates moderately well with its potency in protecting mice against intracerebral challenge with the organism.²⁴ In the mouse potency test, mice are inoculated intraperitoneally with dilutions of the vaccine being tested or with the U.S. standard pertussis vaccine. Fourteen days later the mice are challenged intracerebrally with live pertussis bacteria and then observed for 14 days. Protection is determined by comparing the survival rates in recipients of the test vaccine and of the standard vaccine. Experience gained in field trials of different acellular pertussis vaccines in the 1990s provided new information regarding immunity to pertussis.^{25–26} Inactivated pertussis toxin is an essential component of all acellular pertussis vaccines tested and, in vaccines with sufficient quantity, may account for most of their efficacy. The addition of one or more attachment factors such as FHA, FIM, and PRN to the acellular pertussis vaccine seems to result in increased efficacy compared to PT alone.

Transmission

Pertussis is spread from person to person by large respiratory droplets generated by an infected person or by direct contact with secretions from the respiratory tract. Humans are the only reservoir for *B. pertussis* and the bacterium does not survive outside the host. Pertussis is highly contagious with secondary attack rates in unimmunized susceptible household contacts as high as 90%. The incubation period is usually 7–10 days (range 4–21 days). A person is considered most infectious during the early (catarrhal) stages of the disease. The likelihood of isolating *B. pertussis* declines rapidly by three weeks after onset of coughing.

Occurrence

Pertussis is endemic worldwide. The World Health Organization (WHO) estimates a global total of 48.5 million cases of pertussis per year, with 295,000–390,000 deaths.²⁷ In countries without an immunization program, WHO estimates that 80% of surviving newborn infants acquire pertussis in the first five years of life; case-fatality rates are estimated at 3.7% for infected infants and 1% for children aged 1–4 years. In communities with high vaccination levels, the reported number of cases of severe disease and deaths attributable to pertussis are substantially reduced, usually by more than 95%, compared with the prevaccine era.

Before the introduction of pertussis vaccines in the late 1940s in the United States, morbidity and mortality rates for pertussis had already begun to decline, indicating that other factors (e.g., household crowding) may affect the occurrence of pertussis. With the introduction and widespread use of infant/childhood vaccines, the age-specific incidence and clinical manifestations of reported pertussis in the United States have changed: the incidence of disease is now highest in infants too young to receive adequate immunization (i.e., at least 3 doses), and cases among adolescents and adults are increasingly reported (Fig. 9-5).^{28,29} Epidemic pertussis has a 3–5 year periodicity. During the period from 1997 to 2000, an average of 7400 cases were reported annually.³⁰ Of patients whose age was reported, 29% were less than 1 year of age, 12% were aged 1–4 years, 10% were aged 5–9 years, 29% were aged 10–19 years, and 20% were aged at least 20 years. The proportion of reported pertussis cases aged at least 10 years has increased from 19% during 1980 to 1989 to 49% during 1997 to 2000. This increase has been most marked in states with improved surveillance. Massachusetts, in particular, contributes a substantial proportion of the total reported adolescent and adult cases due to the availability in Massachusetts of a serologic test for diagnosis in these age groups.¹⁸ Vaccine-induced protection against clinical disease wanes over approximately 6–12 years. Studies of

selected populations suggest that pertussis is an important cause of acute cough illness of more than seven days duration in adolescents and adults, with as many as 12–26% of such patients who sought medical care having serologic evidence of recent infection with *B. pertussis*.^{31–32} In a cohort of 2781 adolescents and adults followed prospectively for two years in an acellular pertussis vaccine trial, 1–7% of cough illness episodes were attributed to pertussis.³³ In addition, outbreaks in middle schools, high schools, and among health-care workers in hospitals highlight the important role that older children and adults play in transmission. Better recognition, diagnosis, and reporting of pertussis in adolescents (including from school outbreaks) is responsible in large part for the greater number of cases reported in this age group; precisely how much of the increase reflects an actual change in the burden of disease is unclear. Nonetheless, the true burden of disease in adolescents and adults (estimated in two studies to be 450–507 cases per 100,000 person-years^{33,34}) is greatly underestimated by passive surveillance data systems because the pertussis cough is not pathognomonic, many persons do not seek medical care for a cough illness, and there is limited availability of reliable diagnostic tests in many states (Fig. 9-5).

Strategy for Prevention and Control

Active Immunization. Active immunization is the most effective method for preventing pertussis. The first generation of pertussis vaccines were developed and tested in the 1940s and consist of formaldehyde-treated whole-cell preparations of *B. pertussis* combined with diphtheria and tetanus toxoids (DTP). These vaccines have been used worldwide since the 1950s and have substantially reduced pertussis morbidity and mortality. Concerns about the safety of whole-cell pertussis vaccines led to the development of acellular vaccines which contain purified antigenic components of *B. pertussis* combined with diphtheria and tetanus toxoids (DTaP) and are much less likely to provoke common adverse events. Acellular pertussis vaccines have been in use in Japan since the early 1980s and were initially administered to children two years of age and older. In 1991, acellular pertussis vaccines were licensed in the United States for use as the fourth and fifth doses of the pertussis vaccination series; they were approved for use in the infant 3-dose series in 1996 when efficacy data became available.

Eight different acellular pertussis vaccines and four whole-cell vaccines were evaluated in large field studies in the 1990s for safety and efficacy when administered to infants.^{25,35,43} Because of differences in study design, clinical case definition, and laboratory methods used to confirm the diagnosis, comparison of efficacy estimates from

Figure 9-5. Age distribution of reported pertussis cases—U.S., 2003.

these studies should be made with caution. The protective efficacy of the acellular vaccines against moderately severe pertussis disease ranged from 59% to 85%. Vaccine efficacy for the four whole-cell vaccines ranged from 36% to 98%. One lot of whole-cell pertussis vaccine, manufactured and distributed in the United States, had unexpectedly low vaccine efficacy when used as a three-dose series in studies conducted in Sweden and Italy. In these trials, all the acellular vaccines evaluated were associated with fewer local (pain, redness, and swelling at the site of injection) and systemic (fever and fussiness) adverse reactions than whole-cell vaccines. Additionally, in a randomized double-blinded study ($n = 2200$ infants) of the adverse reactions following administration of 13 different acellular pertussis vaccines and one whole-cell vaccine at 2, 4, and 6 months of age, all the acellular vaccines were associated with substantially fewer local and systemic reactions than the whole-cell vaccine.³⁶

The efficacy of immunization with whole-cell pertussis vaccines for preventing classical pertussis is good initially (70–90%) but begins to wane over several years.^{37,38} One community study showed efficacy to be 79% in the first 3 years, 53% after 4–7 years, 35% after 8–11 years and essentially nil 12 years after immunization.³⁹ Follow-up studies of children in the acellular vaccine efficacy trials (with differences in follow-up study designs, case definitions for pertussis, and original vaccination schedules) have not detected reduction in efficacy during follow-up periods of up to six years.^{40,41} When pertussis does occur in recently immunized persons, it tends to be milder, with cough of shorter duration than in unimmunized persons.⁴²

Although pertussis vaccines are less immunogenic in younger infants compared with older infants, it is recommended that immunization begin at 6–8 weeks of age because the disease is most often life-threatening in young infants. Three or more doses of DTP or DTaP vaccine are required to reliably confer protection; two doses may provide protection against hospitalization and death.^{2,5} WHO recommends three doses of diphtheria and tetanus toxoids combined with whole-cell pertussis vaccine (DTP) at 6, 10, and 14 weeks of age. The added value of booster doses in the second year of life or at school entry depends upon the epidemiology of diphtheria, tetanus, and pertussis in the country, the coverage achieved with the first three recommended doses, and the resources available. In the United States, five doses of diphtheria, tetanus, and acellular pertussis vaccine are recommended: three primary doses at 2, 4, and 6 months of age, a booster dose in the second year of life (15–18 months) and a second booster dose at school entry (4–6 years).⁴³ During pertussis outbreaks in the United States, the first three doses may be given at 6, 10, and 14 weeks of age to provide protection as early in life as possible.

Treatment and Chemoprophylaxis. Pertussis symptoms may be ameliorated when effective antimicrobial therapy is started during the catarrhal stage or within two weeks of cough onset. Once the paroxysmal stage has begun, antimicrobial therapy has no clear effect on the course of illness. The major role for antimicrobial agents in pertussis is to decrease communicability. The preferred antimicrobial agents for treatment and prophylaxis of pertussis are macrolide antibiotics: erythromycin, clarithromycin, or azithromycin. Providers should consider safety, evaluation of concurrent medications for potential interactions, adherence to the prescribed regimen, and cost when choosing a macrolide or alternative agent for any patient.⁴⁴ Erythromycin has long been the drug of choice for treatment of pertussis (children: 40–50 mg/kg per day in four divided doses; adults: 1–2 g/day) and recommended duration to prevent bacteriologic relapse is 14 days. Recent guidelines from some countries have reduced recommended duration of treatment with erythromycin to 7 days.^{45,46} Newer antimicrobials (e.g., azithromycin and clarithromycin) are being increasingly used for treatment of pertussis because of reduced gastrointestinal side effects and simpler dosing regimens:^{47,48,49} azithromycin in adults: 500 mg once day 1250 mg once

daily days 2–5; children aged *more than* 6 months: 10 mg/kg/day as single dose on day 1, then 5mg/kg/day on days 2–5; infants aged less than 6 months: 10 mg/kg/day as single daily dose for five days; clarithromycin in adults 500 mg twice daily for seven days; children aged *at least* 1 month: 15 mg/kg/day in two divided doses (maximum 500 mg/dose) for seven days. Trimethoprim-sulfamethoxazole (adults: trimethoprim 320 mg per day, sulfamethoxazole 1600 mg per day in two divided doses; children: trimethoprim 8 mg/kg per day, sulfamethoxazole 40 mg/kg per day in two divided doses) is an alternative for patients who do not tolerate macrolides. Infantile hypertrophic pyloric stenosis (IHPS) in neonates (i.e., age ≤ 28 days) has been reported following the use of erythromycin.^{50,51} The high case-fatality ratio of pertussis in neonates emphasizes the need to prevent pertussis in this age group, but unnecessary prophylaxis in neonates should be avoided. Physicians who prescribe macrolides to neonates should inform parents about the possible risks for IHPS and counsel them about signs of developing IHPS.

Untreated children may return to school 21 or more days after cough onset; children treated with effective antimicrobial agents become noninfectious after five days of therapy. Health-care workers symptomatic with pertussis should be excluded from patient contact for five days while on effective antimicrobial treatment.⁵²

In general, chemoprophylaxis is recommended for close contacts of a pertussis case and especially if the contact is an unvaccinated child or is known to have contact with infants. Because household transmission or natural boosting has often occurred by the time the first case is diagnosed in a household, some countries have focused prophylaxis efforts on families where an infant (or other high risk individual, e.g., a pregnant woman in third trimester) resides, and have recommended only early detection and treatment for symptomatic persons in households without high-risk individuals.^{45,46}

Antimicrobial Resistance. The first known case of pertussis caused by a strain of *B. pertussis* resistant to high concentrations of erythromycin was reported in the United States in 1994; the isolate was sensitive to trimethoprim-sulfamethoxazole and the infected infant responded well to this therapy.⁵³ Other erythromycin-resistant isolates have been reported only very rarely. Outside of surveillance activities, susceptibility testing is recommended only when there is therapeutic failure.

New and Future Perspectives

Acellular pertussis vaccines (combined with tetanus and diphtheria toxoids) for adolescents and adults have recently been licensed in several countries, including Canada, Australia, and France, and licensure is expected in 2005 in the United States.⁵⁴ Some countries have made universal recommendations for one dose in adolescence, and some countries have additionally recommended this vaccine for health-care workers, and/or parents and other adults in close contact with newborns (“cocoon strategy”). Uptake has been variable and there are no data available yet on the impact of these recommendations on the burden of disease or any resultant changes in the epidemiology of pertussis. Importantly, it is not clear to what degree such strategies can reduce disease burden in the population most vulnerable for severe outcomes: infants too young to be fully vaccinated. In order to provide earlier protection for this critical group, additional vaccination strategies are being studied (e.g., maternal vaccination to boost antibodies passively transferred to the newborn, neonatal vaccination).^{55,56,57}

In developing countries, routine infant immunization with whole-cell pertussis vaccine and early diagnosis and treatment of clinical cases with erythromycin will likely remain the primary tools for pertussis control in the early twenty-first century.

Tetanus

Katrina Kretsinger • John S. Moran • Martha H. Roper

► INTRODUCTION

Tetanus is the only vaccine-preventable disease that is not communicable. The causative agent is ubiquitous, the disease has a high case-fatality ratio, and through immunization, is almost completely preventable. Following the introduction and widespread use of tetanus toxoid, a safe and effective vaccine, tetanus has become uncommon in developed countries. Nonetheless, it remains common in developing countries, particularly among neonates.¹

Etiological Agent, Pathogenesis, and Diagnosis

Clostridium tetani is an anaerobic, gram-positive rod that exists in both vegetative and sporulated forms. Tetanus spores can survive for years. They are highly resistant to heat and chemical agents, and can only be destroyed by rigorous sterilization procedures. As a result, spores are widespread in nature and are found in soil, dust, animal and human feces, and on human skin. Tetanus spores germinate, multiply, and elaborate toxin when inoculated into oxygen-poor sites, such as necrotic tissue, pus accumulations, and deep puncture wounds.

The *C. tetani* bacillus produces an exotoxin, tetanospasmin, a potent neurotoxin responsible for clinical tetanus. Tetanospasmin diffuses locally from wounds to adjacent muscle, and systemically through the bloodstream and lymphatics. The toxin does not cross the blood-brain barrier; entry and spread through the central nervous system is by retrograde intra-axonal transport. The quantity of toxin sufficient to cause disease is generally insufficient to induce an immune response. Consequently, tetanus infection does not confer immunity.

The diagnosis of tetanus depends on clinical signs and symptoms rather than laboratory confirmation. Isolation of *C. tetani* from infected wounds is neither sensitive nor specific; tetanus bacilli are infrequently recovered from contaminated wounds, and may be isolated from patients who do not have tetanus disease. Serum collected before tetanus immune globulin (TIG) is administered can demonstrate susceptibility to the disease if anti-tetanospasmin antibody levels are low; however, a level in the protective range does not rule out the diagnosis. The following clinical case definition is recommended by the Council for State and Territorial Epidemiologists (CSTE): “Acute onset of hypertonia and/or painful muscular contractions (usually of the muscles of the jaw and neck) and generalized muscle spasms without other apparent medical cause (as reported by a health professional).”²

Clinical Characteristics

The incubation period from spore inoculation to the onset of clinical manifestations is variable, ranging from 2 days to 3 weeks or longer, but is generally from 6 to 8 days. The severity of symptoms is inversely related to incubation period.³ Generalized tetanus is the most common clinical form. The earliest sign of tetanus often is spasm of the jaw muscles (trismus, or lockjaw). Progression results in spasm of other muscles of the neck, thorax, back, abdomen, and extremities, sometimes with generalized spasms of large muscle groups resulting in opisthotonos. Some patients manifest risus sardonicus, a characteristic grimacing facial expression. With severe

disease, tonic seizure-like activity (tetanospasm) also occurs. External stimuli aggravate spasms and should be minimized. Instability of the autonomic nervous system is a relatively common complication. Recovery from the acute episode of tetanus may require several weeks and can be complicated by conditions associated with generalized debility and poor nutrition, such as pneumonia and decubitus ulcers. In general, the risk of death is related not only to the quality of supportive care provided but also to the patient’s age and immunization status.⁴ Tetanus neonatorum is a form of generalized tetanus occurring in newborn infants.

Localized tetanus is an uncommon form of tetanus characterized by stiffness and rigidity around the site of injury due to muscle spasm. Localized tetanus usually resolves without sequelae, but can progress to generalized tetanus. Cephalic tetanus is a rare manifestation of the disease that is generally associated with lesions of the head or face. In contrast to the other forms of tetanus, cephalic tetanus is associated with atonic cranial nerve palsies.

Occurrence

Tetanus can occur as a complication both of acute wounds and chronic infections, including puncture wounds, compound fractures, abrasions, avulsions, burns, crush injuries, animal bites or scratches, surgery, injections, dental and ear infections, chronic skin ulceration, abscesses, gangrene, abortions, childbirth, and infections of the umbilical stump. Acute trauma accounted for 73% of 129 cases of non-neonatal tetanus in the United States between 1998 and 2000.⁴ Puncture and deep wounds, especially those associated with devitalized tissue, are more prone to tetanus infection than superficial abrasions. However, tetanus has also occurred after innocent-appearing wounds and in instances where no wound could be recalled.

Tetanus-associated mortality in the United States has declined at a relatively constant rate since the early 1900s.³ When case reporting began in the late 1940s, the annual incidence of reported cases was 4 per million population and the case-fatality ratio was 91%. The average annual incidence had dropped to 0.16 per million in 1998–2000 with a case-fatality ratio of 18% among the 113 patients with known outcomes.⁴ A total of 129 cases were reported with onset during this time period, an average of 43 cases per year.

Immunization status is inversely correlated with risk for disease and mortality from tetanus. Among the 129 cases from 1998 to 2000, complete immunization status was known for 50 (38%) of the cases.⁴ Among them, 20 (41%; 15% of all cases) were reported to have received three or more doses of tetanus toxoid; only eight (16%) were reported to have received their most recent dose of tetanus toxoid within the previous 10 years. Only one death occurred among those who reported having received at least a primary 3-dose series (6%). The remaining 19 deaths occurred in 95 patients with known outcome who reported either fewer than three previous doses, or did not know their immunization status (20%). Tetanus fatalities among patients who have received at least three tetanus toxoid doses are very rare. Only four such cases have been reported in the United States since 1972 (CDC, unpublished data).

The risk of tetanus increases with increasing age. In the United States, from 1998 to 2000, the average annual incidence was 0.05 per million among persons less than 20 years of age, 0.16 per million among persons 20–59 years of age, and 0.35 per million among persons 60 years of age or older.⁴ Older adults also have a higher case-fatality ratio. From 1998 to 2000, 40% of tetanus patients 60 years of age or older died, compared with 8% of patients 20–59 years of age and no patients less than 20 years.⁴

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Data obtained from a national population-based serosurvey conducted in the United States from 1988 to 1994 indicate that the prevalence of immunity to tetanus, defined as an antibody concentration of *minimum* 0.15 IU/mL, declines with increasing age. Thirty-one percent of persons 70 years of age were immune, compared to more than 90% of persons aged 6–11 years.⁶ The lower prevalence in older age groups likely reflects a combination of a lower likelihood of having completed a primary series of tetanus vaccination (birth before initiation of routine childhood immunization with tetanus toxoid), noncompliance with recommended decennial tetanus toxoid booster doses, and waning immunity with time since last dose. Overall, 17% more men than women had protective levels of antibody to tetanus, likely due to immunization received as part of military service or employment, or in conjunction with wound care. Finally, the seroprevalence of protective levels of tetanus antibody is lower among persons born outside of the United States.^{6,7}

Diabetes and intravenous drug use are independent risk factors for tetanus. Diabetic patients have a particularly elevated incidence of tetanus: 0.26 per million among persons 20–59 years of age and 0.70 per million among those 60 years and older. Intravenous drug users accounted for 15% of the tetanus cases from 1998–2000.

Tetanus is very rare among children and associated with failure to vaccinate. A review of 15 reported cases of non-neonatal tetanus among children less than 15 years of age from 1992 to 2000 in the United States found that 85% of the children were unprotected due to religious or philosophic objection to vaccination.⁵

Neonatal tetanus occurs during the month following delivery, usually as the result of *C. tetani* infection of the umbilical stump of a child born to a mother who did not possess sufficient antitoxin to provide passive protection by transplacental antibody transfer. Contamination of the umbilical stump occurs most often following deliveries unattended by trained personnel, especially when clean birthing surfaces and equipment for cutting the umbilical cord and dressing the cord stump are unavailable. Neonatal tetanus is a leading cause of death in many parts of the world. In 1988, an estimated 787,000 neonatal deaths (6.5 per 1000 live births) were attributed to neonatal tetanus;⁸ that number had dropped to approximately 200,000 in 2000,¹ a 75% decline. In the United States, neonatal tetanus is exceedingly rare. Only four cases have been reported since 1984, each in an infant born to a mother who was inadequately vaccinated due either to foreign birth or vaccine objection.^{9–11}

Prevention and Treatment

Preexposure Vaccination. Preexposure active immunization with tetanus toxoid offers the best and most efficient method of preventing tetanus. The results of active immunization of U.S. Army personnel during World War II demonstrated the effectiveness of the toxoid. Only 12 cases occurred among 2.73 million wounded or injured personnel (4.4 per million) compared with 70 cases among 0.52 million wounded or injured during World War I (134 per million).¹²

In the United States, tetanus toxoid is available as an aluminum phosphate adsorbed preparation, either as a single antigen (TT), or as combination pediatric vaccine with either diphtheria toxoid (DT) or diphtheria toxoid and acellular pertussis vaccine (DTaP), or as a combination reduced diphtheria toxoid (Td) for adolescents and adults.^{13,14}

In the United States, five doses of DTaP are recommended for routine childhood vaccination.^{14,15} The primary series is composed of three doses of DTaP at 2, 4, and 6 months of age. A booster dose is recommended in the second year of life (15–18 months), and a second booster dose at school entry (4–6 years). Children with contraindications to receipt of the pertussis component of DTaP should receive the child formulation of diphtheria and tetanus toxoids (DT) instead.¹⁶

Unimmunized persons aged seven to nine years should receive a 3-dose primary series with Td, and those over the age of nine years should receive a single dose of Tdap and 2 doses of Td. The first two doses are given at an interval of 4–8 weeks; the third 6–12 months

later. There is no need to restart a primary series regardless of the time elapsed between doses. DTaP and DT are not routinely recommended for persons seven years of age or older due to the increasing frequency and severity of reactions to diphtheria toxoid with increasing age.¹³

After complete primary tetanus immunization, boosters are recommended for routine pre-exposure prophylaxis every 10 years in the United States.¹³ A single booster dose of Tdap is recommended, and subsequent boosters should be with Td. The need for decennial boosters throughout adulthood has been questioned and alternative booster schedules proposed, based on the arguments that few cases of tetanus, and fewer tetanus deaths, occur among adults with a documented primary tetanus toxoid series despite poor adherence to adult booster recommendations, and that decennial boosters in adults are not cost-effective.^{17–20} The 10-year booster remains the recommended public health strategy for tetanus prevention to attempt to ensure protection in a high proportion of the adult population. The first booster dose is given at ages 11–12 years at the time of the adolescent immunization visit. An adult assessment visit at age 50 years also is recommended by the Advisory Committee on Immunization Practices in the United States to review past vaccination history and determine the need for all recommended vaccines.

Mild local reactions, such as pain, erythema and mild swelling at the injection site are relatively common following receipt of tetanus toxoid. Severe systemic reactions are very rare. In patients with a history of possible anaphylactic reaction to tetanus toxoid, skin testing with appropriately diluted toxoid should be performed before a decision is made to discontinue further tetanus toxoid immunization.^{3,21} Severe local swelling following tetanus toxoid (Arthus reaction) is rare and usually occurs in those who have received multiple doses of tetanus booster and have high preexisting antitoxin levels.^{22,23} Neurologic reactions after tetanus toxoid are rare but can occur. In a 1994 review, the U.S. Institute of Medicine concluded that a causal link existed between tetanus toxoid and brachial plexus neuropathy, but that insufficient evidence exists to assign causality to the association with Guillain-Barré syndrome.²⁴ A subsequent study also failed to find an association between tetanus toxoid and Guillain-Barré syndrome.²⁵

Wound Management. The management of wounds includes adequate wound cleaning and débridement, and evaluation of immunization status.¹³ The need for tetanus toxoid (active immunization) with or without TIG (passive immunization) depends on both the condition of the wound and the patient's vaccination history (Table 9-2). A careful attempt should be made to determine how many doses of toxoid a person has received previously. Patients with unknown or uncertain previous immunization histories should be considered to have received no previous tetanus toxoid.

If the patient sustains a wound that is judged to be clean and minor, administration of tetanus toxoid is necessary if the patient either has not yet completed a primary series, or has not received a booster dose within the preceding 10 years. In the case of a wound judged to be other than clean and minor, a booster dose is required if the primary series has not been completed, or if the patient has not received a booster dose within the preceding five years. Passive immunization with tetanus immunoglobulin (TIG) is indicated at the time of wound treatment in patients with contaminated or major wounds (Table 9-2) who have had fewer than three known previous doses of toxoid. All inadequately immunized patients should subsequently complete a 3-dose primary series.¹³

When passive tetanus prophylaxis is indicated, 250 units of TIG should be given intramuscularly. Tetanus toxoid and TIG can be given simultaneously, but should be administered at separate sites. Protection from TIG can be expected to last about four weeks. The use of equine antitoxin has serious disadvantages compared with the use of the human product, including short-lived protection, serum sickness, and occasionally anaphylaxis. Since the TIG of human origin has become widely available, there is little rationale for the use of equine antitoxin for postexposure prophylaxis and treatment except in countries where human TIG is not available.

TABLE 9-2. SUMMARY GUIDE TO TETANUS PROPHYLAXIS IN ROUTINE WOUND MANAGEMENT, 1994

History of Adsorbed Tetanus Toxoid (Doses)	Clean Minor Wounds		All Other Wounds ^a	
	Td ^b	TIG	Td ^b	TIG
Unknown or <three	Yes	No	Yes	Yes
≥ three ^c	No ^d	No	No ^e	No

^aSuch as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

^bFor children <7 years old, DTaP or DTP (DT, if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. For persons ≥ 7 years of age, Td is preferred to tetanus toxoid alone.

^cIf only three doses of fluid toxoid have been received, then a fourth dose of toxoid, preferably an adsorbed toxoid, should be given.

^dYes, if >10 years since the last dose.

^eYes, if >5 years since the last dose. (More frequent boosters are not needed and can accentuate side effects.)

Treatment

The treatment of tetanus includes antimicrobial therapy and appropriate wound care to help eliminate the organism and thereby prevent further toxin elaboration. TIG should also be given, in a single intramuscular dose to neutralize unbound tetanus toxin. The optimum therapeutic dose has not been established. Some experts recommend 500 units while others recommend 3000–6000 units.^{3,26,27} Treatment to control muscle spasm and autonomic dysfunction and to maintain adequate respiration are critical. In addition, intensive supportive care is essential to patient survival. Because tetanus disease does not induce immunity to tetanus, all persons with tetanus should complete a primary series or receive a booster dose of TT, as indicated.

Neonatal Tetanus Prevention

In 1989, the World Health Assembly adopted the goal of global elimination of neonatal tetanus (NT), defined as less than one NT cases per 1000 live births at the district level.^{1,28} In 1999, this goal was reaffirmed and extended to the elimination of maternal tetanus as well (MNT).²⁹ The key strategies in countries where MNT is still a public health problem are: achievement and maintenance of high TT vaccination coverage levels among women of childbearing age in high-risk

areas and promotion of clean delivery and cord care practices. Active immunization of unimmunized pregnant women with two doses of appropriately timed toxoid prevents MNT for that pregnancy; additional doses can be given with each subsequent pregnancy or at intervals of one year or more. The five TT doses recommended by WHO for previously unimmunized women of childbearing age are likely to provide protection throughout reproductive life.³⁰ A modified schedule taking childhood DTP doses into account is recommended in countries where high DTP3 coverage has been maintained for many years.³¹ The rarity of neonatal tetanus in developed countries is a consequence of the high proportion of institutional births attended by trained personnel, clean delivery practices, and the high proportion of mothers adequately vaccinated against tetanus.

Summary

Tetanus is a serious and preventable disease. All persons should receive an age-appropriate series of primary tetanus toxoid doses followed by recommended boosters. Health-care providers should use every patient encounter to evaluate immunization status and administer needed immunizations.

Diphtheria

Tejpratap S.P. Tiwari

During the twentieth century, diphtheria evolved from being a major childhood killer to a clinical curiosity in developed countries because of the development and widespread use of an effective and safe toxoid vaccine. However, a massive diphtheria epidemic in the countries of the former Soviet Union during the 1990s illustrated the potential for this vaccine-preventable disease to reemerge following decades of good control. Diphtheria continues to be an endemic disease and an important cause of morbidity and death in developing countries that do not have adequate childhood vaccine coverage.

Etiological Agent, Pathogenesis, and Diagnosis

Corynebacterium diphtheriae is a gram-positive, nonmotile, nonsporulating bacillus first described as the etiologic agent of diphtheria by Loeffler in 1884. The organism is killed if held at 60°C for 20 minutes but survives freezing and desiccation for months when enclosed in proteinaceous materials. There are four biotypes of *C. diphtheriae* (gravis, mitis, intermedius, and belfanti). Some strains produce a powerful toxin. Diphtheria toxin is composed of two polypeptide fragments, A and B, linked by a disulphide bond. Before *C. diphtheriae* becomes toxigenic it must be infected by a particular bacteriophage. The process is called lysogenic conversion. The bacteriophage carries the structural gene for the toxin, *tox*. Toxin-producing strains of all biotypes produce an identical exotoxin, and no consistent difference in pathogenicity or severity of disease has been demonstrated among the biotypes.

Respiratory diphtheria is a distinct clinical syndrome caused by the phage-induced toxin; infections with non-toxin-producing strains

Note: The findings and conclusions in this chapter are those of the author and do not necessarily represent the views of the Centers for Disease Control and Prevention.

of *C. diphtheriae* are not associated with respiratory diphtheria but can cause pharyngitis, localized inflammation (e.g. cutaneous infections) and, rarely, other disease syndromes.¹ Respiratory diphtheria is initiated by a superficial infection and toxin production by *C. diphtheriae* usually on pharyngeal mucosa or other respiratory mucosa. The toxin binds to a wide range of mammalian cells, including epithelial, nerve, and muscle cells, interfering with protein synthesis leading to cell damage and death. Local effects include severe tissue inflammation and the formation of a pseudomembrane composed of necrotic debris, exudate, and bacteria. Progressively greater systemic absorption of the toxin occurs as the pseudomembrane enlarges and local inflammation increases.

Transmission of *C. diphtheriae* is generally by droplet spread from either cases or carriers, or via fomites. Untreated, a patient usually remains infectious for two weeks or less. Chronic carriage may occasionally occur, and rarely occurs even after antimicrobial therapy. Transmission from cutaneous infections can be a result of environmental contamination with *C. diphtheriae* or of direct skin contact with infected skin lesions.

Respiratory diphtheria is usually suspected in the presence of a gray pseudomembrane in a patient with a febrile pharyngitis. Specific diagnosis depends on the recovery of toxigenic *C. diphtheriae* from the throat or respiratory tract. Specimens from the majority of cases are positive if taken before administration of antibiotics. If clinical specimens cannot be immediately transported to the laboratory, they should be sent in a transport medium or, if a long delay is anticipated, in silica gel. Specimen culture optimally requires the use of a tellurite-containing medium. Identification of *C. diphtheriae* and its biotypes is made from colony morphology (black colonies with a surrounding halo) and from biochemical tests. Toxigenicity of *C. diphtheriae* can be determined by *in vivo* (guinea pig) or *in vitro* (Elek) testing. Polymerase chain reaction (PCR) tests for gene coding for the A and B fragments of the exotoxin can confirm the presence of toxigenic organisms but not toxin. This PCR test is most useful in specimens taken from patients after administration of antibiotics. However, it is currently available only at some reference laboratories.² Molecular subtyping of *C. diphtheriae* strains shows considerable promise in aiding epidemiologic investigations and is available at some reference laboratories.^{3,4}

Clinical Characteristics

Respiratory diphtheria develops insidiously over 1–2 days after an incubation period of 1–5 days from infection of the respiratory tract, or, rarely, after infection of the skin or other mucosal sites (such as the eye, ear, or genitalia). Respiratory diphtheria usually presents as a febrile, pharyngitis with a pharyngeal, tonsillar, or nasal exudate or membrane and is associated with signs of systemic toxicity including weakness, tachycardia, and agitation disproportionate to the degree of fever, which is usually mild throughout the illness. In severe cases, patients may present with or progress to have neck edema, airway obstruction, myocarditis, or polyneuritis.

The anatomic sites of respiratory diphtheria commonly include the mucous membrane of the pharynx and/or tonsils, or larynx and/or trachea, or nose, either singly or in combination. Patients with pharyngotonsillar diphtheria usually have a sore throat, difficulty in swallowing, and low-grade fever at presentation. Examination of the throat may show only mild erythema, localized exudate, or a pseudomembrane. The membrane can be localized to a patch of the posterior pharynx or tonsil, cover the entire tonsil, or, less frequently, spread to cover the soft and hard palates and the posterior portion of the pharynx. In the early stage of the infection, or in patients who have been partially or fully immunized, a membrane can be whitish and wipe off easily. The membrane can extend and become thick, blue-white to gray-black, and adherent in inadequately immunized patients. Attempts to remove the membrane result in bleeding. Marked mucosal erythema surrounds and underlies the membrane. Patients with severe disease have marked edema of the submandibular areas and the anterior portion of the neck which, along

with lymphadenopathy, gives a characteristic “bullneck” appearance. Other infections that can present with pseudomembranes or exudate include infectious mononucleosis, viral pharyngitis (rarely), and streptococcal or monilial pharyngitis and immunocompromised conditions including the chronic use of steroids.

Laryngotracheal diphtheria is the most severe form of respiratory diphtheria. It is most often preceded by pharyngotonsillar disease, is usually associated with hoarseness and a croupy cough at presentation, and results when the infection extends into the bronchial tree. Initially, laryngeal diphtheria may be clinically indistinguishable from viral croup or epiglottitis. Nasal diphtheria generally is the mildest form of respiratory diphtheria. It is usually localized to the septum or turbinates of one side of the nose. Occasionally, a membrane extends into the pharynx.

Cutaneous infection with toxigenic *C. diphtheriae* is common in tropical areas; in temperate zones, cutaneous diphtherial infections are infrequent except in association with poor hygiene. The presenting lesion, often an ulcer, can be surrounded by erythema and covered with a membrane. Its appearance can be confused with streptococcal impetigo. Cutaneous infections often result from a secondary infection of a previous skin abrasion or infection. The clinical syndrome of severe diphtheria rarely results from isolated cutaneous infections, even in inadequately immunized individuals.

Complications

With the exception of airway obstruction, the serious complications of respiratory diphtheria result from the systemic effects of toxin absorption. Mechanical airway obstruction and myocarditis are the major causes of death. Airway obstruction can result from extension or sudden displacement of the membrane into the larynx and the bronchial tree. Myocarditis begins in the first through the sixth week of clinical illness. Electrocardiographic changes are present in as many as one-fourth of the patients; clinically evident cardiac impairment or congestive heart failure is present in a smaller proportion. Recovery is usually complete, but cardiac abnormalities can persist. Other complications include polyneuritis and, rarely, renal failure, thrombocytopenia, or shock with disseminated intravascular coagulation. Cranial or peripheral neuritis, primarily involving motor loss, usually develops 1–8 weeks or longer after onset of untreated disease, although isolated paralysis of the soft palate can be present at disease onset. Loss of visual accommodation, diplopia, nasal-sounding voice, and difficulty in swallowing are the most frequent manifestations of cranial nerve involvement. Complete recovery of neurologic impairment is the rule in patients who survive.

Occurrence

Developed Countries. The occurrence of respiratory diphtheria in the United States has fallen dramatically from 147,000 cases in 1920 to an annual average of two reported cases from 1990 through 2003. Eighteen of the 27 cases (69%) reported in the United States during 1990 through 2003 were among affected persons 20 years of age or older. Serosurveys during the 1980s and 1990s in the United States indicated that protective levels of antibodies against diphtheria decreased with increasing age; less than 40% of adults had protective levels by age 60.⁵ A similar pattern has been seen in other developed countries where vaccination programs have drastically reduced circulation of toxigenic *C. diphtheriae* and adults do not receive routine booster immunizations.^{6,7}

Diphtheria Resurgence in the Newly Independent States of the Former Soviet Union (NIS). A gap in adult immunity was a major factor in the diphtheria epidemic in the NIS, where diphtheria had been reduced to very low levels since the early 1960s. More than 125,000 cases and 4000 deaths, primarily among adults, were reported in this epidemic between 1990 and 1995.⁸

Additional factors that may have contributed to the resurgence include lowered childhood immunization rates due to misperceptions

among the general population and among physicians of the relative risks and benefits of vaccination, increased population movement due to the breakup of the Soviet Union, and socioeconomic hardships.⁹ A change in the *C. diphtheriae* organisms circulating, as manifested by the appearance of an epidemic clone of gravis strains in Russia, could have contributed to the epidemic;⁴ however, large outbreaks of the mitis strains also occurred during this epidemic suggesting that human population factors played a major role.

Effective control of the NIS epidemic was accomplished by raising childhood vaccination levels and achieving unprecedented high adult vaccination coverage.¹⁰ Control strategies included decreasing the resistance to vaccination among physicians and the population, and organizing mass vaccination campaigns for adults and infants. An international coalition of public health donors, led by the World Health Organization, mobilized the large amount of vaccine and other supplies needed by the NIS. Very few imported cases and no secondary outbreaks were reported by neighboring European countries. In 2002, more than 95% of cases from the European region were reported from the NIS.¹¹

Developing Countries. In developing countries, a steady decrease in diphtheria occurred after the introduction of diphtheria toxoid into the WHO Expanded Programme on Immunization in the late 1970s. In 2002, countries of the South East Asia, Eastern Mediterranean, and African regions of WHO contributed more than 82% of 9235 cases reported globally.¹¹

Even before the introduction of immunization programs, developing countries rarely experienced large outbreaks of diphtheria, although they reported many cases of diphtheria among very young children. The lack of outbreaks is thought to result from widespread natural immunity from high rates of skin infections with *C. diphtheriae* in early childhood. Outbreaks of diphtheria that have occurred in developing countries with effective childhood immunization programs for at least 5–10 years, typically show a shift in the affected age groups to older children and young adults. The introduction of routine booster doses may be needed to prevent outbreaks in these age groups.

Treatment

The mainstay of treatment of respiratory diphtheria is diphtheria antitoxin. The antitoxin neutralizes free, circulating toxin. Diphtheria antitoxin therapy has significantly reduced the rates of complications and death which are directly related to the delay before antitoxin treatment and the extent of the local pseudomembrane involvement lesion (although even mild illness can occasionally produce complications) and inversely related to the adequacy of previous vaccination. Treatment should not be delayed for bacteriological confirmation of the diagnosis; increasing intervals between onset of illness and treatment correlate with higher rates of complications and death.¹² The dosage of antitoxin depends on the interval since onset of the illness and the severity of disease. Doses range between 20,000 and 100,000 units. A diphtheria antitoxin licensed in Brazil (Instituto Butantan, San Paulo, Brazil) is available on a case-by-case basis through the Centers for Disease Control and Prevention (CDC) under an Investigational New Drug protocol with the FDA to treat suspected diphtheria cases.¹³ No U.S. licensed diphtheria antitoxin is available.

All commercially available diphtheria antitoxin products are produced from serum obtained from hyperimmunized horses and can produce severe reactions or fatal anaphylaxis in sensitized individuals. Treatment of suspected diphtheria with diphtheria antitoxin should be started as soon as possible after testing for hypersensitivity to horse serum; desensitization can be done if necessary.

In addition to anaphylaxis, adverse effects of antitoxin treatment include febrile reactions shortly after administration, and serum sickness, which occurs in approximately 5% of patients receiving antitoxin, usually 7–14 days after treatment. The risk of febrile reactions and serum sickness is not predicted by hypersensitivity testing.

Although antibiotics are not a substitute for diphtheria antitoxin, penicillin or erythromycin is also given to stop toxin production by

eliminating the organism and to prevent transmission. Patients should also receive diphtheria toxoid vaccine to complete a primary series or to bring booster doses up-to-date.

Management of Contacts of Patients With Suspected Disease. Nasal and throat swabs for diphtheria culture should be obtained from all household and other close contacts. After specimens are taken for culture, prophylactic antibiotic therapy with a single dose of intramuscular benzathine penicillin (600,000 units for persons less than six years old and 1.2 million units for persons six years and older), or a 7- to 10-day course of oral erythromycin (40–50 mg/kg, maximum 2 gm/day) is recommended for all persons exposed to diphtheria, regardless of vaccination status. Persons found to be carriers of *C. diphtheriae* should have cultures repeated a minimum of two weeks after completion of antibiotics; if colonization persists, carriers should receive an additional 7- to 10-day course of oral erythromycin. Vaccination with an age-appropriate diphtheria toxoid-containing vaccine should be done if more than five years have elapsed since completion of a primary series or the last booster dose.¹⁴ A primary immunization series with an age-appropriate diphtheria toxoid-containing vaccine should be started in previously non-vaccinated contacts.

Prevention and Control

In 1918, New York City initiated an immunization program for children using a mixture of antitoxin and toxin; the results provided the first large scale demonstration that such a program could decrease diphtheria incidence and mortality. Subsequent improvements in the efficacy and safety of immunization from the introduction of toxoid (formalin-treated toxin) by Ramon in 1923, and from alum-precipitated toxoid in 1931 contributed to the establishment of programs for childhood vaccination against diphtheria in the United States and many other developed countries in the 1930s and 1940s.¹⁵

Active Immunization. Active immunization provides individual protection by inducing circulating antitoxin. These levels will limit the extent of local invasion of the organism and neutralize unbound absorbed toxin, thus preventing life-threatening systemic complications. A 3-dose series of diphtheria toxoid is highly immunogenic in all age groups and significantly reduces both the risk of diphtheria and the severity of the illness. In addition to individual protection, high levels of population vaccination appear to have decreased diphtheria transmission in the United States and other developed countries, even though toxoid is not thought to prevent carriage of the organism in the pharynx or on the skin. Booster doses of diphtheria toxoid are required to maintain immunity in the absence of “natural” boosting from circulating diphtheria, as vaccine-induced antibody levels wane over time. The duration of immunity depends on multiple factors including the timing and antigenic content of the primary series.⁶

The global WHO recommendations for diphtheria immunization are for a primary series (three doses of a high antigenic-content preparation) in infancy, and maintenance of immunity with booster doses of diphtheria toxoid throughout life. Strategies vary by country depending on the capacity of immunization services and the epidemiological pattern of diphtheria.¹⁶ Few developing countries provide routine boosters to older children or adults. Global coverage with a primary series of three doses of diphtheria toxoid has exceeded 80% for children during the 1990s, but dropped below this level during 2001–2002; coverage rates are high in most developing countries outside of Africa.¹¹

The number of recommended doses of diphtheria toxoid-containing vaccine in the recommended vaccine schedule in the United States has remained constant although the licensure of new combination vaccines has created a greater choice of preparations, and licensure of additional combination vaccines is expected. Diphtheria toxoid is available in combination with pertussis vaccine (whole cell or acellular) or tetanus toxoid or both as DTP, DTaP, and DT for use in children less than seven years of age; the antigenic content of these preparations ranges from 6.7 to 15 limit of flocculation (Lf) units. Because the frequency and severity of local reactions increase with

increasing age, a lower (≤ 2) Lf content preparation, Td, is designed for use in older children and adults.

The childhood and adolescent schedule in the United States recommends three doses of diphtheria toxoid-containing vaccine (DTaP, DTP, or DT) at four- to eight-week intervals beginning at two months of age. A fourth dose is recommended at 15–18 months and may be administered as early as 12 months of age provided that 6 months have elapsed since the third dose and that the child is unlikely to return at the recommended age. A fifth dose is administered at 4–6 years of age.¹⁷ An adolescent booster dose with Td is recommended at 11–12 years of age and every 10 years thereafter. Unimmunized individuals seven years of age or older receive a primary series with Td; a primary series consists of three doses, the first two doses are given at an

interval of 4–8 weeks and the third 6–12 months later. Booster doses are recommended at 10-year intervals. There is no need to restart a primary series regardless of the time elapsed between doses.

Conclusion

Routine diphtheria vaccination has been highly successful in reducing the once devastating burden of disease. The recent diphtheria epidemic in the former Soviet Union underlines the importance to maintain high levels of immunization in both children and adults to provide both individual protection and high population immunity. Health-care providers can use every patient encounter to review and administer any needed vaccination. Whenever tetanus toxoid is indicated, administration of Td vaccine is preferred to TT.

Influenza

Mark Katz

Influenza is a highly contagious, acute febrile respiratory illness caused by influenza A and B viruses.¹ These viruses cause annual or near annual epidemics of febrile respiratory disease in regions with moderate climates, and less regular epidemics in the tropics. Influenza viruses infect people of all age groups.¹ Emergence of a new influenza A subtype among humans can cause a worldwide outbreak, known as a pandemic, leading to larger than usual numbers of deaths as well as societal disruption.

Although most cases of influenza are self-limited, young children, elderly individuals, and people with underlying medical conditions have an elevated risk of serious morbidity or mortality from influenza infection.^{2,3} Because of the very large number of influenza infections and their associated complications, the public health impact of influenza is considerable.¹ Vaccination is an effective method for reducing influenza-related morbidity and mortality. However, vaccination coverage for influenza is relatively low throughout the world, and influenza remains an uncontrolled disease. Eradication of influenza is unlikely because influenza A viruses circulate among several animal species, especially wild aquatic birds, which form the primary reservoir for all influenza A virus subtypes.

History

Influenza viruses were first identified in 1933, but outbreaks of rapidly spreading febrile respiratory diseases consistent with influenza have been documented as early as the twelfth century. The term “influenza” was first used in the 14th century, when Buonissequi described an epidemic as the “grande influenza.”⁴ The Italian word for “influence” was used as a collective term for various causes of widespread epidemics. Cold weather, or “influenza di freddo,” was considered a causal factor for many years.⁵

The first clearly described pandemic consistent with influenza occurred in 1580; 31 pandemics subsequently have been described.⁴ The “Spanish flu” pandemic of 1918–1919 is estimated to have caused 40 million deaths worldwide, including nearly 700,000 in the United States.⁶ Deaths occurred mainly among healthy 20- to 40-year-olds, in contrast to the usual pattern in interpandemic influenza seasons, in which most deaths occur among the elderly.⁵ In the era of HIV and AIDS, it is often forgotten that influenza caused the most deadly pandemic in recorded history.

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

During the twentieth century, a series of important discoveries led to the modern understanding of the virus and its epidemiology. The first influenza virus isolated was a type A virus cultured from ferrets in 1933 by Smith et al. In 1936, Burnet showed that the virus could be grown in embryonated chicken’s eggs. This discovery facilitated the study of viral characteristics and the development of inactivated vaccines.⁴ Influenza B was first isolated in 1940 by Francis.⁵ Hirst’s discovery of the hemagglutination protein on the virus’ surface in 1941 led to better characterization of these viruses and improved detection of antibodies to influenza. Public health control measures, in particular the widespread use of inactivated vaccines, began in the 1950s. Since then, targeted vaccination of selected segments of the population, especially those considered at risk for serious complications, has been the basis for reducing the health impact of influenza. Influenza antiviral agents for therapy and chemoprophylaxis first became available in the United States in 1966.⁴

Epidemiology

General Characteristics. Patterns of influenza epidemics vary by climate and region. In temperate climate zones such as North America, seasonal epidemics of influenza usually begin in the late fall to winter months and peak in mid to late winter.⁷ However, sporadic cases and institutional outbreaks can occur in any season. In tropical regions, influenza activity can occur throughout the year and increase during cooler months. Within communities in temperate climates, epidemics usually last six to eight weeks.

The beginning, peak, duration, and health impact of individual influenza seasons vary considerably from year to year. The pattern of influenza epidemics reflects several factors: the extent of the antigenic variation; virulence and transmissibility of the virus; the extent of immunity in the population; the specific population groups that are affected; and seasonal factors that remain poorly understood.⁷

Influenza A (H1N1), A (H3N2), and B viruses all currently circulate worldwide, and every year a representative virus from each group is selected for inclusion in the vaccine. The predominant influenza virus in circulation may vary temporally and geographically in any given year.⁷ Since 1968, influenza A (H3N2) viruses have caused the greatest aggregate morbidity and mortality.⁸

During influenza seasons, 10–20% of the U.S. population may become infected by influenza, but attack rates of 40–50% within institutions have been described.^{1,7,8} In communities, influenza cases often appear first among school-age children, who generally have the highest attack rates. However, the burden of serious disease remains

greatest among the elderly, the very young, and individuals with underlying medical conditions.¹ Every year influenza causes increases in the number of acute respiratory illnesses, absenteeism in schools and the workplace, patient visits to physicians, hospitalizations, and deaths.⁷ Influenza-related visits may overwhelm hospitals, clinics, and emergency rooms during the influenza season.⁹

Since the mid-nineteenth century, studies have attempted to quantify influenza-related mortality in terms of “excess” deaths: the number of observed deaths beyond the number of expected deaths if influenza viruses were not circulating.¹⁰ Recent studies have estimated annual mean numbers of influenza-attributable deaths and hospitalizations in the United States at 36,000 and more than 200,000, respectively.^{11,12} The statistical models in these studies used mortality data from the National Center for Health Statistics, hospitalization data from the National Hospital Discharge Survey (NHDS), and national influenza virus surveillance data. The recent morbidity and mortality estimates for influenza are larger than those in previous studies, and reflect an increasing elderly population with its higher risk of serious disease and death¹¹ and the predominance of influenza A (H3N2) viruses during the 1990s.

Pandemics. Influenza pandemics occur when a novel influenza A virus subtype emerges and spreads among people. Pandemics can be associated with significant worldwide increases in morbidity and mortality. Three pandemics were documented in the last century: the “Spanish flu” of 1918, associated with influenza A (H1N1) viruses;¹³ the “Asian flu” of 1957 (influenza A [H2N2]); and the “Hong Kong flu” of 1968 (Influenza A [H3N2]).

The ability of pandemic influenza to spread rapidly was well documented in 1957. The Asian influenza pandemic of 1957 began in February of that year in southern China. By April it had spread to Hong Kong and Singapore. In May, the causative agent, an influenza A (H2N2) virus, was isolated in Japan.¹⁴ The virus spread rapidly through the South Pacific, Southeast Asia, and the Middle East by June, and into Europe and North America by midsummer. By the end of 1957, the new subtype had spread worldwide. In the United States, the pandemic of 1957 resulted in an estimated 70,000 deaths.⁴

Although some pandemics have caused dramatic increases in morbidity and mortality, the cumulative numbers of deaths from seasonal epidemic influenza since the 1968 pandemic actually exceeds the total number of influenza-related deaths in the United States during the 1918 pandemic.

Etiologic Agent

Influenza is a medium-sized virus (80–120 nm) of the family Orthomyxoviridae. The virus consists of single-stranded segments of negative sense ribonucleic acid (RNA) enclosed in a helical protein shell, or nucleocapsid. The virus is covered by a lipid envelope with protruding surface proteins consisting of hemagglutinin (HA) and neuraminidase (NA). Influenza viruses are classified on the basis of their ribonucleoprotein (RNP) into three distinct types, A, B, and C. Only types A and B cause widespread epidemics in humans.⁸ Influenza C viruses often have been associated with a mild, upper respiratory illness, but can also cause outbreaks.^{1,15} Influenza A viruses have been isolated from humans, horses, dogs, swine, seals, ferrets, mink, whales, tigers, and avian species. Wild aquatic birds serve as the natural reservoir for all known influenza A viruses. Types B and C are almost exclusively recovered from humans but have been isolated from seals and pigs, respectively.^{16,17}

Influenza A viruses are subtyped based on their surface proteins, hemagglutinin (HA) and neuraminidase (NA). The HA and NA surface proteins are highly antigenic and are the target for the humoral immune response to influenza virus infection. HA is named for its ability to cause agglutination of erythrocytes (hemagglutination) *in vitro*. The attachment site for the virus to bind host cell receptors is located on the HA protein. NA functions as an enzyme that cleaves neuraminic acid from mucoproteins, allowing newly formed viruses to be released from the host cell surface.

Currently, 16 HA and 9 NA subtypes are known to exist, all of which have been isolated from birds.¹⁸ By contrast, only three HA subtypes (H1, H2, and H3) and two NA subtypes (N1 and N2) are known to have circulated widely among humans.¹⁹ H2 viruses have not been in circulation since 1968.

The nomenclature for influenza viruses includes the virus type, geographical origin, laboratory reference number, and year of isolation. For example, the first type B strain isolated by a laboratory in Oregon in 1965 would be designated B/Oregon/1/65. Among influenza A viruses, a description of the HA and NA subtypes follows the strain designation, for example: A/Mississippi/1/85 (H3N2).

Antigenic Variation

Antigenic Drift. Because the antigenicity of the virus changes frequently through antigenic drift, levels of immunity among human populations vary from year to year.²⁰ In antigenic drift, point mutations in the viral RNA genomes of both influenza A and B viruses can result in immunologically significant alterations to HA and NA. Drift results in more frequent antigenic changes of influenza A viruses than in influenza B viruses.¹ Predominant antigenic variants often circulate for a few years before being supplanted by a new predominant influenza strain.

Antigenic Shift. Antigenic shift occurs only among influenza A viruses. It is a more radical change and is defined by the emergence among people of an influenza A virus bearing a novel HA or a combination of both a novel HA and NA. Antigenic shift can occur in two ways. In the first, influenza A viruses of two different subtypes simultaneously infect the same host, allowing “reassortment,” or exchange of viral RNA segments in the host’s cells, resulting in a hybrid virus containing genes from both subtypes. For example, pigs have been considered effective “mixing vessels” because they contain receptors for both avian and human viruses. Pigs may be coinfecting with human and avian influenza A viruses, and a new “reassorted” virus may emerge that contains genetic material from both parental viruses. If such a virus were to infect people and spread easily, the human population would be immunologically naïve and therefore unprotected against the new subtype. This mechanism likely created the viruses that were responsible for the pandemics of 1957 (H2N2) and 1968 (H3N2).²¹

The second possible mechanism for antigenic shift involves the direct transmission of influenza virus from avian or other animal species to humans with subsequent adaptation by mutation to the new human host.⁷ Direct infections of humans with avian influenza viruses of A (H5N1),²² A (H9N2),²³ A (H7N7),²⁴ A (H7N2),^{25,26} and A (H7N3)²⁷ subtypes have occurred in the past decade, but no sustained human-to-human transmission of avian influenza A viruses has occurred.

Influenza Surveillance

Although influenza A or B viruses circulate virtually every winter in temperate zones of the Northern and Southern hemispheres, surveillance for influenza remains challenging. Influenza testing occurs infrequently in both the outpatient and inpatient settings, leading to missed cases and underreporting in discharge summaries and death certificates—sources routinely used to conduct surveillance. Most of influenza surveillance rely upon indirect markers of influenza infection, such as influenza-like illness and pneumonia and influenza mortality data.

In the United States, the Centers for Disease Control and Prevention (CDC) currently use seven systems for national influenza surveillance. Collaborating laboratories of the World Health Organization (WHO) and the National Respiratory and Enteric Virus Surveillance System (NREVSS) report the numbers of types and subtypes of influenza A viruses detected throughout the year. A network of sentinel health-care providers reports patient visits for influenza-like illness. Mortality attributed to influenza and pneumonia are reported

weekly from 122 cities. State health departments report an overall assessment of influenza activity in their respective states. Recently two surveillance systems were initiated to document hospitalizations associated with laboratory-confirmed influenza infections in children. For the 2004–2005 influenza season, national surveillance for influenza-related pediatric deaths was started.²⁸

Clinical Characteristics

Influenza spreads primarily from person-to-person when an infected individual coughs or sneezes and produces virus-laden droplets.²⁰ Transmission occurs predominantly through large droplets, although aerosol transmission may occur. The incubation period for the virus is 1–4 days.²⁹ Individuals can shed virus from approximately one day before symptoms begin through five days after illness onset. Children, in particular young infants, can shed virus for longer periods. Severely immunocompromised people can shed virus for weeks to months.^{30–33}

Uncomplicated primary influenza illness often begins abruptly with fever, chills, fatigue, headache, myalgias, anorexia, and nonproductive cough. Fever usually ranges from 38°C to 40°C but may be higher. In some elderly, people fever may be absent. In infants, influenza may present as a sepsis-like illness, and in children, high fevers can be associated with febrile seizures.¹ Influenza illness usually resolves within one week, but cough and malaise can persist for several weeks.²

Immunity. Development of antibodies primarily to the HA, but also to the NA, is the most important protective immune response to influenza virus infection or vaccination.³⁴ Most people infected with influenza develop specific antibodies within two weeks. Antibodies against a specific influenza A virus strain provide variable protection against another strain, depending on the degree of antigenic similarity.³⁵

Complications

The risk of complications, including hospitalizations, from influenza is elevated among people 65 years and older, young children, and individuals of any age with underlying chronic medical conditions.^{5,11,13,36–41} Pregnant women and immunosuppressed individuals are also at increased risk for complications from influenza infection.^{3,5,42–45} The elderly have a higher risk than any other group of death from influenza.^{2,11}

Common serious complications of influenza illness include the exacerbation of underlying chronic cardiopulmonary diseases and the development of secondary bacterial pneumonia. Patients with chronic obstructive lung disease, asthma, and congestive heart failure can experience worsening disease with influenza infection.¹³ Superimposed bacterial pneumonia is much more common than secondary viral pneumonia.⁴⁶ Primary viral pneumonia occurs infrequently but is often fatal.⁷ Additional respiratory complications such as bacterial sinusitis, croup, and otitis media can occur as well.¹

Reye's syndrome, which is characterized by acute encephalopathy and fatty degeneration of the liver,⁵ has been reported mainly in children with influenza who have been treated with salicylates, most common aspirin, for controlling fever.^{47,48} Since the 1980s the incidence of Reye's syndrome has decreased dramatically in the United States following warnings regarding the use of aspirin to treat children.¹

Recent reports, predominantly from Japan, have described an association between influenza infection and a severe and sometimes fatal acute encephalopathy, mainly in children less than five years old. While mean annual incidence of influenza-related encephalopathy has been estimated to be less than 1 per 100,000 in Japan, mortality among individuals with influenza-related encephalopathy can be as high as 32–37%.^{49,50} Additional neurological complications—encephalitis, transverse myelitis and Guillain-Barré syndrome—have been reported in association with influenza, but a causal relationship remains unclear.¹ Myocarditis and pericarditis were reported in association with influenza during the 1918 pandemic, but since then they have been documented infrequently.

Diagnosis

While diagnosis of influenza is often made on clinical grounds alone during periods of widespread influenza activity, laboratory confirmation of influenza can aid in clinical management when the incidence of influenza is low. When influenza is circulating within the community, the combined symptoms of fever and cough suggest a significantly increased likelihood of influenza among the elderly.⁵¹ Institutional outbreaks of respiratory illness should be evaluated by testing to document the etiology so that appropriate control measures can be initiated.

Several laboratory tests for influenza are available: viral culture, immunofluorescence (direct and indirect), rapid diagnosis, detection of viral nucleic acid (RNA), and serology. Specimens for testing include throat swabs, nasopharyngeal swabs and aspirates, nasal swabs, nasal washes, and sputum. The appropriate specimens depend on the test employed. Viral culture is generally considered the gold standard for laboratory diagnosis of influenza. It provides information on virus type and influenza A virus subtype and allows for additional antigenic and genetic characterization. However, isolation results are not usually available quickly enough for treatment decisions.²⁹ Detection of viral nucleic acid (RNA) can be done by reverse transcription (RT) of viral RNA from respiratory specimens followed by polymerase chain reaction (PCR).⁵² Rapid tests, most of which detect viral antigen, have lower sensitivity and specificity compared to viral culture but offer the advantage of fast results (<30 minutes).⁵³ Rapid tests are the most commonly used tests in clinical settings. Serologic tests require paired acute and convalescent serum samples to demonstrate a significant (four-fold or higher) increase in antibody level, and are not useful for acute clinical diagnosis and treatment of patients, but are often used in epidemiological studies.

Prevention and Treatment

The antigenic variability of influenza, combined with its rapid spread, short incubation period, and limited vaccine coverage in many populations, complicate efforts to control influenza. Influenza vaccination is the most effective approach to disease prevention. Antiviral medications are an adjunct to influenza vaccine for treatment and chemoprophylaxis of influenza.

Influenza Vaccines. The first influenza vaccine was commercially approved in 1945 following successful efficacy studies in military recruits using whole-virus inactivated influenza. Whole virus vaccines are no longer being sold in the United States. Most inactivated vaccines today consist of subvirion preparations, which retain the immunogenic properties of the viral proteins but are associated with fewer adverse reactions.^{54–58}

In the United States, two kinds of vaccine are currently available: inactivated (i.e., killed virus) influenza vaccine and live, attenuated influenza vaccine (LAIV). Inactivated influenza vaccine is approved for healthy people and people with chronic medical conditions aged at least 6 months. Currently LAIV is approved only for healthy individuals aged 5–49 years.

Influenza viruses for both inactivated and live attenuated vaccine are initially grown in embryonic hens' eggs. In the United States, inactivated vaccine is currently only approved for intramuscular administration. LAIV is administered intranasally. Both vaccines are trivalent, containing contemporary circulating strains of influenza A (H1N1), influenza A (H3N2), and influenza B virus.

Thimerosal is a mercury-containing preservative used in inactive influenza vaccine to prevent bacterial contamination. In 2001, a committee was convened by the Institute of Medicine of the National Academy of Sciences to examine whether the use of thimerosal-containing vaccines was associated with neurodevelopmental disorders. The committee concluded that the evidence was "inadequate to accept or reject a causal relationship" between thimerosal exposures from childhood vaccines and neurodevelopmental disorders.⁵⁹ Nonetheless, efforts have been made in the United States to reduce the amount of thimerosal in inactivated influenza vaccine, and preservative-free formulations of inactivated vaccine are available.^{60–62}

Global recommendations for the antigenic composition of the influenza vaccine are made twice a year based on antigenic and genetic characterization of viruses from both the Northern and Southern hemispheres. In the Northern Hemisphere, vaccine strains are selected between January and March to allow for adequate production time prior to the start of the next influenza season. The optimal time for vaccination is usually during October–November, but vaccination of high-risk persons should continue throughout the influenza season.²

Efficacy and Effectiveness of Influenza Vaccine. Efficacy and effectiveness of influenza reflects, in part, the antigenic similarity between circulating influenza viruses strains in the influenza vaccine, and the immunocompetence of the vaccine recipient.

Studies have shown that inactivated influenza vaccine can reduce influenza by 70–90 % among healthy adults aged 65 years or younger when the virus strains in the vaccine match the circulating strains in the community.^{63–66} Even during years when the match between viruses in circulation and vaccine strains is not optimal, vaccine can still be effective. For example, during the 2003–2004 influenza season, the circulating influenza strains and the vaccine strains were not matched optimally, but one study estimated that vaccine effectiveness in preventing influenza-like illness and pneumonia among 50–64 year-olds in Colorado was 52%.⁶⁷

Randomized studies using a variety of outcome measures (seroconversion, culture-confirmed influenza, clinically diagnosed disease) have also shown inactivated vaccine to be effective in preventing infection in children and the elderly.² Although some studies have found inactivated vaccine can decrease influenza-related complications in children, such as otitis media, by as much as 30%, other studies have not shown such an effect.^{68,69} Inactivated vaccine can also prevent hospitalizations by 28–65 % and death from all causes by 27–30% in the elderly.⁷⁰

In healthy, working adults vaccination has been shown to decrease work absenteeism by 29–43% and reduce physician visits by 42–44% when the influenza vaccine composition matched the predominant influenza strain in the community.^{63,64,71}

Recent randomized, double-blinded, placebo-controlled studies have evaluated the efficacy of LAIV. One study of healthy children found LAIV to be 92% efficacious in preventing culture-confirmed influenza during two influenza seasons.^{72,73} Another study of healthy working adults aged 18–64 showed reductions in numbers of severe febrile illness, duration of illness, and days of work lost among vaccine recipients.⁷⁴

Influenza vaccination can reduce health-care costs and productivity losses associated with influenza infection.² Studies focusing on people aged 65 years or older have shown an association between inactivated influenza vaccine and reduction of both direct and indirect medical costs.² Cost-effectiveness studies of influenza vaccination in healthy, working adults have reported conflicting results: one large study demonstrated a net savings of \$46.85 per healthy adult worker vaccinated,⁷¹ while another reported a net societal cost of \$11.17 per person vaccinated.⁶⁴

Vaccine Adverse Effects. The most frequent side effect associated with inactivated influenza vaccine is soreness at the vaccination site, lasting less than two days.² Fever, malaise, and myalgia do not occur more often among inactivated influenza vaccine recipients than controls.^{64,75–77} Acute allergic reactions, including anaphylaxis, can occur infrequently after administration of inactivated influenza vaccine in people who have anaphylactic reactions to eggs or documented immunoglobulin E (IgE)-mediated hypersensitivity to eggs. Protocols have been created to allow administration of influenza vaccine to persons with egg allergies.^{78–80}

The 1976–1977 swine influenza vaccine was associated with 1 additional case of Guillain-Barré syndrome (GBS) per 100,000 persons vaccinated above the background rate of GBS.⁸¹ From 1978–1988, no increased incidence of GBS was reported with influenza vaccine, but evaluation of the 1992–1993 and 1993–1994 influenza seasons found slightly more than one additional case of GBS per million persons

vaccinated with inactivated influenza.^{82–84} The estimated risk for vaccine-related GBS is substantially less than the risk of severe influenza in people at high risk, and the potential benefits of influenza vaccination in preventing serious complications and death in this group outweigh the possible risk for developing vaccine-associated GBS.²

Randomized, placebo-controlled safety trials have not shown an association between LAIV and adverse events such as pneumonia or CNS complications compared to placebo in healthy persons aged 5–49 years.² In studies involving children and adults, vaccine recipients reported runny nose, nasal congestion, and headache more often than placebo recipients.²

Current Vaccination Recommendations. The Advisory Committee on Immunization Practices (ACIP) is a group of 15 experts in immunization-related fields who have been selected by the secretary of the US Department of Health and Human Services to provide guidance to the Secretary, the Assistant Secretary for Health, and the CDC on the most effective means to control vaccine-preventable diseases.⁸⁵ ACIP makes annual recommendations for influenza prevention and control in the United States, which target young children, the elderly, pregnant women, and all persons with high-risk conditions for influenza vaccination. Additionally, health-care workers and close contacts of high-risk individuals are advised to receive the vaccine to reduce transmission to high-risk individuals. Current recommendations can be found in Table 9–3.

Vaccine Supply and Future Directions. In the United States, influenza vaccine use has increased considerably since the early 1990s, in part because of a Medicare program authorizing federal reimbursement for influenza vaccination of the elderly that began in 1993.⁸⁶ However, use of influenza vaccine among ACIP target groups continues to be highly variable. Between 1989 and 1999, influenza vaccination levels in persons older than 65 years rose from

TABLE 9-3. RECOMMENDED GROUPS FOR INACTIVATED INFLUENZA VACCINATION BY THE U.S. ADVISORY COMMITTEE ON IMMUNIZATION PRACTICES, 2005¹⁰⁸

Persons at Increased Risk for Complications

- persons aged ≥65 years
- residents of nursing homes and other chronic-care facilities that house persons of any age who have chronic medical conditions;
- adults and children who have chronic disorders of the pulmonary or cardiovascular systems, including asthma (hypertension is not considered a high-risk condition)
- adults and children who have required regular medical follow-up or hospitalization during the preceding year because of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression caused by medications or by human immunodeficiency virus [HIV])
- Adults and children who have any condition (e.g., cognitive dysfunction, spinal cord injuries, seizure disorders or other neuromuscular disorders) that can compromise respiratory function or the handling of respiratory secretions or that can increase the risk for aspiration
- children and adolescents (aged 6 months–18 years) who are receiving long-term aspirin therapy and, therefore might be at risk for experiencing Reye's syndrome after influenza infection
- women who will be pregnant during the influenza season
- children aged 6–23 months
- persons aged 50–64 years
- persons who can transmit influenza to those at high risk
- employees of assisted living and other residences for persons in groups at high risk
- persons who provide home care to persons in groups at high risk
- household contacts (including children) of persons in groups at high risk health-care workers

33% to 66%.⁸⁷ Results of a national cross-sectional survey showed an average vaccination rate of 70% among respondents aged 65 years and older for the 2002 influenza season.⁸⁸ Vaccination coverage for other groups have been lower. A 1998 study of health-care workers, a group recommended for vaccination by the ACIP, found that only 37% had been vaccinated.⁸⁷ During the 2002–2003 season, approximately 95 million doses of inactivated influenza vaccine were produced in the United States—nearly a two-fold increase from the mid-1990s—but 12 million doses went unused.

Vaccine production and distribution in the United States has been complicated by unexpected delays and shortages of vaccine over the past decade. During the 1990s, two of the four companies that manufactured inactivated influenza vaccine withdrew from the market. In October 2004, one of the two remaining manufacturers of inactivated influenza vaccine announced that it would not distribute vaccine in the United States for the 2004–05 influenza season, leaving the country with approximately one-half of its anticipated supply. The subsequent vaccine shortfall illustrated the need for additional manufacturers and production methods in order to avoid similar problems in the future.

Antiviral Medications Antiviral medications can be used for early treatment and chemoprophylaxis of influenza. Currently four licensed influenza antiviral agents are available in the United States. Amantadine and rimantadine belong to a class of medications called adamantanes and have activity against influenza A viruses only. Zanamivir and oseltamivir are neuraminidase inhibitors that are active against both influenza A and influenza B viruses.

When administered within two days of illness onset, all four antiviral agents can reduce the duration of uncomplicated influenza illness by approximately one day.^{53,66,89–98,99–101} One randomized, double-blind, placebo-controlled trial found that oseltamivir significantly reduced lower respiratory tract complications, particularly bronchitis, by 55% among influenza-infected adults and adolescents (from 10.3% in untreated patients to 4.6% in treated patients).¹⁰²

Antiviral Medications can be used for chemoprophylaxis against influenza, especially in institutional settings. Amantadine and rimantadine can be 70–90% effective in preventing illness from influenza A. Of the two neuraminidase inhibitors, only oseltamivir is approved for prophylaxis. One study of oseltamivir prophylaxis in a nursing home showed a 92% reduction in influenza illness among nursing home residents.¹⁰³

Medication side effects, drug interactions, and antiviral drug resistance affect the choice of antiviral medications. The adamantanes can cause neurological and gastrointestinal side effects when administered to healthy adults at standard dose. Neurological effects are more pronounced with amantadine than rimantadine.¹⁰⁴ Amantadine should be used cautiously or avoided in persons with renal failure or pre-existing neurologic or neuropsychiatric disorders. Among the

neuraminidase inhibitors, zanamivir, which is inhaled orally, may exacerbate respiratory problems in patients with underlying airway disease. Oseltamivir, a tablet administered orally, was associated with nausea and vomiting in clinical trials; the side effects may be reduced if the medication is taken with food.²

Emergence of resistance to adamantanes in outbreak setting can be as high as 30%. In contrast, resistance to neuraminidase inhibitors is lower. In clinical treatment, studies involving oseltamivir, 1.3% of posttreatment isolates from patients more than 13 years old, and 8.6% of isolates from children aged 1–12 were resistant to oseltamivir.²

Avian Influenza

Since 1997, human infections by a number of different avian influenza A viruses have been documented in Europe, North America, and, most extensively, Asia. While wild aquatic birds are thought to be the primary reservoir for influenza A viruses, avian influenza A viruses have also been isolated from horses, pigs, whales, seals, cats, and tigers and pigs.¹⁷

In 1997, an outbreak of highly pathogenic avian influenza A (H5N1) occurred in people and poultry in Hong Kong. Eighteen people were infected, six of whom died. Nearly all of the infected individuals had an identified exposure to live poultry.¹⁰⁵ Further spread of disease probably was curbed by the prompt culling of approximately 1.5 million chickens in Hong Kong.

From December 2003 to March 2005, poultry outbreaks of a highly pathogenic avian influenza A (H5N1) virus were reported in 11 Asian countries, resulting in the death or slaughter of more than 150 million birds and, as of March 2005, 116 laboratory-confirmed cases in humans, 60 of which (52%) were fatal.²⁸ Human-to-human transmission has been documented rarely, but there is concern that the H5N1 virus could adapt to the human host and acquire the ability to conduct sustained transmission in the human population.

The most common risk factor for human infection by highly pathogenic avian influenza A (H5N1) appears to be direct contact with infected birds or possibly surfaces contaminated with their excretions.¹⁷ Consumption of raw poultry products such as duck blood has also been implicated as a possible source of infection.¹⁰⁶ In a cohort of 10 avian influenza A (H5N1) patients in Vietnam in 2004, the average age was 13.7 years. All patients were previously healthy.²² Highly pathogenic avian influenza A (H5N1) infection can begin with typical influenza-like symptoms (i.e., fever, cough, sore throat, and myalgia) and can lead to life-threatening complications and death. An atypical presentation in a four-year-old Vietnamese boy with highly pathogenic avian influenza A (H5N1) has been described. The boy presented with severe diarrhea without respiratory symptoms and developed encephalitis.¹⁰⁷

No studies have been done to evaluate the effectiveness of any of the antiviral medications in treatment and prophylaxis of avian influenza. All H5N1 viruses isolated from patients in Asia in 2004 were resistant to amantadine and rimantadine but sensitive to the neuraminidase inhibitors.^{16,17}

Haemophilus Influenzae Infections

Michelle Chang • Brendan Flannery • Nancy Rosenstein

Haemophilus influenzae was advanced by Pfeiffer in 1892 as the etiologic agent of influenza because of its recovery from the respiratory tracts of persons with that disease. It was later identified as a major bacterial cause of pneumonia and meningitis in children and

immunocompromised or chronically ill adults. The most virulent serotype of this organism—*Haemophilus influenzae* type b (Hib)—was the most common cause of bacterial meningitis and invasive bacterial disease in children in the United States before the introduction of Hib polysaccharide-protein conjugate vaccines. Routine infant immunization against Hib has led to the near elimination of this disease in industrialized countries¹ and developing countries that have introduced the vaccine.² The success of the Hib conjugate vaccines has paved the way for a new generation of vaccines against the other

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

major bacterial diseases of children, *Streptococcus pneumoniae* and *Neisseria meningitidis*. Despite its success, Hib vaccination is not routine for the majority of the world's children, and the disease continues to be a major cause of childhood illness and death.³ The challenge for the future is to expand the global usage of Hib vaccines.

Bacteriology

H. influenzae is a nonmotile, Gram-negative bacterium with varied form, appearing as cocci to small rods in clinical specimens. It can be difficult to stain and may be confused with Gram-positive diplococci in spinal fluid. In vitro culture requires the use of specialized media supplemented with essential growth factors (hemin or "factor X" and nicotinamide adenine dinucleotide or "factor V") and a carbon dioxide rich atmosphere.

H. influenzae are classified into six capsular serotypes (designated a, b, c, d, e, and f) that were first identified by Pittman in 1931. There are also unencapsulated strains that are referred to as "nontypeable." In clinical or reference laboratories, serotyping is performed using a slide agglutination reaction, which takes advantage of the biological property of type-specific antisera to agglutinate organisms of that type. Although used since the 1930s, this technique requires subjective interpretation, and cross-reactivity can result in misclassification.⁴ Verification of serologic classification using a DNA-based method such as the polymerase chain reaction appears to be highly accurate and may be a means to investigate serotyping discrepancies.⁵ Such alternative typing methods are useful for confirmation of type b infections as Hib disease becomes less common.

Antibiotic resistance among *H. influenzae* isolates is widespread and variable depending on geographic region. Strains may acquire resistance to common beta-lactam antibiotics, such as penicillin and ampicillin, via plasmids containing genes for beta lactamase. Approximately 20 years after this mechanism of acquired resistance was first reported in 1974, ampicillin resistance was found in 39% of 1537 *H. influenzae* isolates obtained from 30 U.S. medical centers.⁶ Resistance to chloramphenicol, which was not commonly used to treat meningitis in the United States, was found in less than 1% of these isolates. Data on the prevalence of resistance in different regions of the world are limited. One study in Egypt reported that more than 60% of *H. influenzae* isolates from children with meningitis were resistant to either ampicillin or chloramphenicol.⁷ Antimicrobial resistance is especially relevant in developing countries where ampicillin and chloramphenicol are frequently used for empiric treatment of meningitis.

Clinical Characteristics and Pathophysiology

Meningitis is the most severe, life-threatening illness caused by *H. influenzae*. Prior to routine immunization, Hib was the leading cause of bacterial meningitis among young children in the United States. Peak incidence occurred in infants 6–8 months of age, and case-fatality was less than 5%.⁸ Meningitis is less common in adults than other invasive syndromes, including pneumonia or nonfocal bacteremia, with a higher proportion of cases caused by nontype b strains. In the vaccine era, nontypeable (unencapsulated) strains account for nearly 50% of the remaining cases of *H. influenzae* disease, with pneumonia being the principal presentation.⁹ Epiglottitis, a potentially severe inflammation and edema of the epiglottis and surrounding soft tissue, septic arthritis, and cellulitis due to *H. influenzae* are now uncommonly seen.

H. influenzae colonizes the respiratory tract; organisms enter the bloodstream of susceptible hosts and disseminate throughout the tissues. Bacteria may cross the blood-brain barrier and seed the central nervous system to cause meningitis. Epiglottitis and pneumonia may result from infection of soft tissue by organisms colonizing the respiratory tract. *H. influenzae* evades the host immune system by inhibition of mucosal cilia and proteolytic cleavage of secretory IgA antibody. Capsular polysaccharides play a role in blocking complement-mediated phagocytosis. Immunocompromised hosts, such as asplenic or those infected with human immunodeficiency virus, may be more vulnerable to infection. Chronic smoke exposure or preceding viral infections may increase susceptibility by disrupting respiratory clearance of the organism.¹⁰

In the United States, nontypeable *H. influenzae* and *S. pneumoniae* remain the two most common causes of acute otitis media. The introduction of pneumococcal conjugate vaccine for infants in 2000 has increased the proportion of otitis media reportedly due to nontypeable *H. influenzae*.¹¹ Otitis media is the most common reason for pediatric outpatient visits and is the leading indication for antimicrobial use in the United States, at an estimated cost of \$5.3 billion in 1998.¹²

Clinical characteristics of *H. influenzae* disease have not changed throughout much of the world where vaccination against Hib is not routine. Type b disease still predominates in developing countries—Hib is a major cause of nonepidemic meningitis among children.¹³ Case-fatality rates for Hib meningitis in developing countries (10% or higher) are higher than those in industrialized countries (less than 5%).¹⁴ *H. influenzae* and *S. pneumoniae* are the two most commonly identified bacterial etiologies of pneumonia in many regions of the world. However, the etiology of pneumonia is difficult to establish because only a small proportion is associated with bacteremia. Due to this difficulty, the contribution of *H. influenzae* to the burden of pneumonia is unknown. Culturing *H. influenzae* from the nasopharynxes of patients with pneumonia is of limited value in making a specific diagnosis because the organism may be present without causing disease.¹⁵

Treatment

Initial empiric treatment for the clinical syndromes is based on available antibiotics with broad coverage for the most likely bacterial pathogens. In the United States, for example, practice guidelines for empiric antibiotic treatment of bacterial meningitis are based on age and the specific predisposing condition. The guidelines recommend vancomycin plus a third-generation cephalosporin for most age groups.¹⁶ For severe *H. influenzae* infections, a third-generation cephalosporin, such as ceftriaxone and cefotaxime, is commonly prescribed. In many developing countries, empiric therapy for bacterial meningitis includes ampicillin/penicillin, chloramphenicol, or a combination. A recent meta-analysis of 18 clinical trials conducted over the past 20 years found no significantly increased risk of death, treatment failure, or deafness when a combination of ampicillin-chloramphenicol was used for treatment of bacterial meningitis versus ceftriaxone or cefotaxime. However, 16 of the 18 trials were conducted in the 1980s when antibiotic resistance rates may have been lower than at present.¹⁷ Current studies evaluating the success of different antibiotic regimens, especially in areas with a high burden of disease, are needed.

New treatment guidelines for acute otitis media in the United States reflect efforts to avoid the unnecessary use of antibiotics. Because of high rates of spontaneous resolution of symptoms, deferring antibiotic treatment for select children is an option based on the child's age, diagnostic certainty, severity of illness, and feasibility of medical reevaluation. Antibiotic treatment is recommended for young children with severe symptoms, including intense ear pain and high fever, and for all acute otitis media in children younger than 6 months of age. Other children with otitis media may be followed without antibiotic therapy.¹⁸ The option of observing the course of the infection in select children is an attempt to reduce the overuse of antibiotics, and thereby reduce the development of resistance.

Immunity

In 1933, Fothergill and Wright described an inverse relationship between serum bactericidal activity against Hib and the incidence of *H. influenzae* meningitis, with a nadir in bactericidal activity from age 3 months to 2 years, the age of peak meningitis incidence.¹⁹ This protective immunity is mediated by maternal antibodies or antibodies naturally acquired as a result of nasopharyngeal carriage or infection with the organism. Protection from *H. influenzae* type b disease is associated with antibodies against capsular polysaccharide, polyribosyl-ribitol-phosphate (PRP).²⁰ Pioneers in vaccinology realized that stimulation of anti-PRP antibody in infants could protect against Hib disease.

The first Hib vaccine was made from purified PRP polysaccharide and was variably successful. A large efficacy study in Finland demonstrated protection for children who received vaccine at 18 months or older, but poor immunogenicity in younger children.²¹ The immune

response to polysaccharide vaccine administered in infancy was short lived, with no evidence of long-term immunity.^{1,22} The polysaccharide vaccine was licensed in the United States in 1985 for children 18 months and older, and post-licensure studies showed inconsistent results.²³ The limitations of the polysaccharide vaccine were overcome by a new generation of Hib vaccines. Investigators found that PRP polysaccharide could be coupled with protein antigens that stimulated interaction with T-lymphocytes, so called T-cell-dependent antigens, such as tetanus and diphtheria toxoids.²⁴ The ability of the PRP-protein conjugate to induce T-cell-dependent immunity improved antibody response in infancy and primed the immune system for subsequent doses.

All of the current Hib vaccines contain PRP polysaccharide conjugated to one of a number of protein antigens, including diphtheria and tetanus toxoid derivatives and the major outer membrane protein from *N. meningitidis*. The choice of carrier protein influences the immunogenicity of the PRP polysaccharide, with PRP conjugated to the *N. meningitidis* outer membrane protein stimulating higher levels of antibody after the first dose than other conjugates. Other conjugate vaccines require two or three doses to reach protective levels of antibody. A booster dose may be required after 12 months of age to sustain protective antibody levels throughout childhood. Early vaccination before six weeks of age when maternal antibody is still present may lead to lower antibody titers even following boosting.²²

Hib antigen is increasingly combined with other antigens, such as diphtheria-tetanus-pertussis or hepatitis B, in multivalent vaccines to reduce the number of injections required during a single clinic visit.²³ Combining antigens can affect immune responses, as seen by the reduced antibody response to Hib when combined with acellular pertussis antigen, an effect not observed when combined with whole-cell pertussis.²⁵ Although the clinical significance of these lower antibody levels after vaccination is not definitively known, recent experience in the United Kingdom suggests that in some situations low antibody levels may correspond to lower efficacy.^{26,27}

Transmission

H. influenzae causes disease only in humans, and the human nasopharynx is its only natural reservoir. Unencapsulated organisms predominate in the nasopharynx and can be isolated frequently from children (often from 50% or more of children less than six years old).²⁸ Hib carriage was uncommon even before the introduction of conjugate vaccines, identified in just 3–5% of children younger than five years old.²⁹ Higher prevalence of Hib carriage has been reported from clusters of invasive infections in childcare centers and, in some studies, from populations with high rates of invasive disease.²⁹

Asymptomatic carriers are the major source of transmission, since most patients with Hib disease have not had contact with a person who had invasive disease.²⁹ *H. influenzae* is likely spread via contact with respiratory droplets or secretions. Clusters of invasive

Hib cases may occur in the absence of high prevalence of carriage, even in the vaccine era.³⁰

Occurrence

Industrialized Countries. In the United States, the incidence of invasive Hib disease among children less than five years of age dropped from more than 50 cases per 100,000 children in the pre-vaccine era to less than 1 case per 100,000.³¹ The incidence of type b disease in children younger than five years has fallen below the incidence of nontype b *H. influenzae* (Fig. 9-6). Nontypeable (unencapsulated) strains now account for the majority of invasive *H. influenzae* disease among children in the United States. Dramatic declines in Hib have occurred in other countries since the introduction of conjugate vaccines.¹

In the pre-vaccine era, American Indian, Alaska Native and Australian Aboriginal populations experienced high rates of Hib disease, with the highest occurrence in infants less than one year of age.¹⁴ Rates among American Indian and Alaska Native children have declined substantially but remain higher than in the general U.S. population.^{32,33} Historically higher incidence of Hib disease among African American children compared to Caucasian children in the United States has largely disappeared.³¹ Children with HIV infection, sickle-cell disease or disorders of immunoglobulin synthesis are at increased risk of *H. influenzae* disease. Incidence of *H. influenzae* in adults is low, although adult populations may be susceptible to resurgence of type b disease when there is increased disease transmission in children.²⁶

Resurgence of disease was reported from the United Kingdom and the Netherlands after dramatic declines related to the introduction of conjugate vaccine.^{34,35} In the United Kingdom, the resurgence in cases correlated with low levels of protective antibody in both pediatric and adult populations.^{26,27} Loss of protective immunity was attributed in part to decreased transmission of Hib, resulting in less nasopharyngeal carriage and natural boosting of immunity. Among vaccinated children, low antibody levels in those older than 12 months suggested the need for a booster dose in the second year of life. The resurgence of cases also coincided with the use of a combination Hib vaccine containing acellular pertussis antigen, which was associated with an excess number of vaccine failures among children who had been fully vaccinated.³⁶ In the Netherlands, the resurgence of invasive Hib cases in children was associated with an “accelerated” vaccination schedule at 2, 3, and 4 months, which may have contributed to lower antibody levels in fully vaccinated children and a subsequent rise in Hib cases.³⁵ The experience of these two countries illustrates the potential for Hib disease to reemerge in industrialized countries and highlights the importance of continued surveillance.

Developing Countries. Hib continues to be a major cause of morbidity and mortality among children less than five years of age in developing countries. Estimates suggest that Hib is responsible for more than 300,000 cases of meningitis and an additional 100,000

Figure 9-6. Incidence rate (per 100,000 population) of *Haemophilus influenzae* type b (Hib) and nontype b invasive disease detected through Active Bacterial Core surveillance (ABCs) among children aged less than 5 years—United States, 1990–2000. (Source: Centers for Disease Control and Prevention. Progress toward elimination of *Haemophilus influenzae* type b invasive disease among infants and children—United States, 1998–2000. MMWR 2002;51(11):234–7.)

cases of other invasive syndromes annually.^{13, 14} Ninety-five percent of Hib meningitis cases occur in children less than five years of age, with the highest incidence among children 0–11 months old. Although Hib is often found to be the principal cause of bacterial meningitis in children, the burden of disease is underestimated or unrecognized in many developing countries due to inadequate laboratory capacity to isolate the organism. The absence of country-level data and perceptions of low disease burden have slowed the uptake of Hib vaccines throughout the developing world.

Pneumonia (including bacteremic and nonbacteremic types) may be a more common manifestation of Hib disease than meningitis in developing countries. Pneumonia is one of the leading causes of death among children less than five years old, with the highest burden of disease found in developing countries.³⁷ Studies in Chile and the Gambia showed that as many as 20% of severe, x-ray confirmed cases of pneumonia in children under the age of two years were prevented by Hib conjugate vaccine,^{38,39} and that five times more cases of Hib pneumonia were prevented as cases of Hib meningitis. In contrast, a community-randomized trial in Indonesia found conflicting results, showing no reduction of severe pneumonia in children who received Hib vaccine but uncovering a large burden of meningitis due to Hib.⁴⁰ Evidence of a substantial burden of Hib disease in developing countries would strengthen the case for introduction of conjugate vaccines.

Prevention

Immunization is the most effective means of preventing Hib disease. Hib vaccines were the first protein-polysaccharide conjugate vaccines against bacterial infections, and they have proven extremely safe and efficacious. These conjugate vaccines are immunogenic in early infancy, eliciting protective antibodies in young children at highest risk of invasive disease. Most Hib conjugate vaccines require three doses in the first six months of life to achieve protective levels of antibody. Countries vary in their schedules for administration of Hib vaccine and the inclusion of a booster dose. In the United States, Hib vaccinations are recommended at 2, 4, and 6 months of age, with a booster dose in the second year of life.⁴¹ The vaccine is usually administered at the same time as other vaccines in the routine childhood immunization series, most commonly diphtheria-tetanus-pertussis (DTP) and hepatitis B. For some high-risk populations, specific Hib conjugates may be recommended for different doses of the vaccination schedule. For example, the Hib conjugate vaccine containing the *N. meningitidis* outer membrane protein (PRP-OMP) has been recommended for primary immunization in American Indian and Alaska Native communities that experience high rates of disease in early infancy.⁴² A dose of PRP-OMP conjugate at 2 months may be followed by a different conjugate in order to maximize immune responses for both short-term and long-term immunity.³²

In the United States, undervaccination or failure to vaccinate accounts for a substantial percentage of the remaining invasive Hib disease among children.³¹ Undervaccination also contributes

to continued circulation of Hib, as increased disease transmission has been reported in communities with low vaccination coverage.⁴³

Hib conjugate vaccines elicit “herd immunity” by preventing nasopharyngeal carriage of Hib and decreasing transmission.²⁹ In the United States, Hib conjugate vaccines were first licensed for use in children 18 months of age and older. Before these vaccines were licensed for use in infants, rates in infants had already started to fall due to herd effects achieved by vaccinating older children.⁴⁴ Countries such as the United Kingdom that have conducted national “catch-up” campaigns targeting older children prior to routine infant immunization have observed decreased incidence among unvaccinated groups.²² The magnitude of the herd effects of Hib conjugate vaccine was unexpected when the vaccine was introduced and now provides a model for introduction of newer protein-polysaccharide vaccines.

In the vaccine era in the United States, chemoprophylaxis is recommended to interrupt transmission for close contacts of cases when unimmunized young children are present. Rifampin eliminates carriage of *H. influenzae* and is given to all household or day care contacts to protect any children at increased risk of invasive disease.⁴⁵ These include immunocompromised children (regardless of immunization status), household contacts less than four years of age who are not fully vaccinated, and day care classmates less than two years of age who are not fully vaccinated. If there are no at-risk children present, chemoprophylaxis is not recommended. Clusters of nontype b invasive disease in day care settings have not been reported.

For the majority of the world’s children who do not currently receive Hib vaccine, the future presents both opportunities and challenges. In 2006, the World Health Organization recommended the introduction of Hib vaccine worldwide.³ Hib conjugate vaccine is one of the new-generation vaccines selected for support by the Global Alliance for Vaccines and Immunization, a historic public-private partnership to provide financing for immunizations in the world’s poorest countries including supporting the introduction of Hib in many of these countries.⁴⁶ However, the protein-polysaccharide vaccines are expensive to produce, and the high cost of Hib conjugate vaccines remains a major obstacle. As the price of Hib conjugate vaccines drops, more developing countries may introduce the vaccine for its demonstrated effectiveness against meningitis and other severe Hib disease among young children.

The success of Hib conjugate vaccines has led the way for other protein-polysaccharide vaccines against common bacterial infections, including *Streptococcus pneumoniae* and *Neisseria meningitidis*. The pitfalls encountered in trying to introduce Hib vaccines in developing countries will serve as lessons for the newer vaccines. The hope for the future is that the delay between the introduction of these life-saving vaccines in industrialized countries and their ensuing availability in developing countries can be shortened with coordinated international effort. The Hib conjugate vaccine represents a modern public health triumph, although the goal of eliminating the scourge of Hib disease among all the world’s children may require many years to achieve.

Varicella and Herpes Zoster

Varicella

Public Health Significance

Varicella (chickenpox) and herpes zoster (shingles) are two distinct disease entities caused by the varicella zoster virus (VZV). Varicella

Note: The findings and conclusions in this chapter are those of the author and do not necessarily represent the views of the Centers for Disease Control and Prevention.

is the primary infection caused by VZV, which, like other herpes viruses is capable of maintaining latency in the human body and reactivating to result in the secondary or reactivated form of disease known as herpes zoster or shingles. In temperate climates without a routine vaccination program, varicella is a common, highly communicable, childhood illness characterized by fever and a generalized pruritic vesicular exanthem. In the United States, prior to the availability of a varicella vaccine, this disease affected essentially everyone during their lifetime with more than 95% of adults demonstrating

antibodies to VZV by age 20–29 years.^{1,2} In tropical climates, varicella may be acquired at older ages resulting in more infections and a higher susceptibility in adults. Varicella may result in serious consequences both in healthy persons and those at higher risk for severe disease including newborn infants, immunocompromised persons, pregnant women, and adults.^{3–6} Complications of varicella include sepsis, pneumonia, encephalitis, coagulation defects, shock, and death.^{5–9} In the United States before the vaccine era, annually varicella was responsible for an average of 11,000–13,500 hospitalizations and an average of 100–150 deaths.^{8–12} Substantial burden of school absenteeism, costs of parental leave, and medical costs were associated with childhood varicella with net benefit to cost estimates for a routine childhood vaccination program calculated as \$5.40 and \$66.47.^{13,14}

A live, attenuated, varicella vaccine (VARIVAX) was licensed for use in the United States in 1995. Recommendations for routine use of varicella vaccine among children at 12–18 months of age, older susceptible children, and priority adult groups including health-care workers were established in 1996 and further expanded in 1999.^{15,16} Widespread use of varicella vaccine has resulted in substantial decline in varicella morbidity, mortality, and related health-care expenditures. Based on this progress and changing epidemiology of varicella, further enhancements in the vaccination program have been recommended by the ACIP.¹⁷

Etiology

The varicella zoster virus is a DNA virus of the herpes family. Humans are the only natural host for this highly contagious virus. Although the etiological agent responsible for varicella and zoster was not identified and named until the 1950s, herpes zoster was described in the very early medical literature. Varicella, however, was frequently confused with another “pox” illness, smallpox (variola), until the end of the nineteenth century. In the early 1900s, the association between varicella and zoster was suggested when von Bokay reported on the occurrence of varicella following cases of zoster in two families, and this was confirmed experimentally by demonstrating that inoculation of vesicular fluid from persons with herpes zoster produced varicella in susceptible volunteers in 1925. In 1943, zoster was first suggested to be due to a reactivation of a latent agent that had been originally acquired during varicella. Weller, in 1953, confirmed that varicella and herpes zoster have a common etiology by isolating and propagating the etiological agent from both diseases *in vitro*. He and colleagues then demonstrated that the viruses were morphologically and serologically identical, and the agent was named varicella-zoster virus in 1958.¹⁸

Immune Response

The VZV induces both humoral and cell-mediated immune responses. Cell-mediated immunity (CMI) to VZV is believed to be particularly important in preventing recurrences of varicella after reexposure, in maintaining the latent state of the virus in dorsal root ganglia, and in preventing the occurrence of herpes zoster. Lifelong immunity usually occurs following one attack of varicella. Reexposure to wild-type varicella frequently results in reinfection that boosts immunity without causing clinical illness or detectable viremia. However, rarely, recurrence of chicken pox has been reported in immunocompetent individuals with documented VZV immunity.^{19,20} Although population-based studies suggest that symptomatic second infections of varicella may occur more frequently than anticipated, cases reported in these studies were not laboratory-confirmed.²¹

Laboratory Tests

Laboratory tests are available to (a) confirm diagnosis of varicella, (b) assess immune status, and (c) genotype of varicella zoster virus strains. Diagnosis of varicella is usually made on clinical grounds, based on rash characteristics and on epidemiologic features, such as contact with other varicella cases. However, in severe or vaccinated,

mild cases (i.e., with few lesions, mostly or all maculopapular) laboratory confirmation may be needed. Polymerase chain reaction (PCR) is the preferred test for laboratory confirmation of acute cases. Serologic tests are useful for identifying the immune status of individuals whose history of varicella is negative or uncertain. Viral genotyping is used to distinguish wild-type VZV from the vaccine strain (Oka) and assessing wild-type strains circulating.

PCR. PCR allows rapid amplification of specific sequences of viral DNA. RNA primers that target selected small stretches of viral DNA can be used to replicate small quantities of viral DNA extracted from clinical samples. If a PCR product of the expected size is produced, it is evidence that the virus was present in the sample. Recommended clinical samples for PCR testing are vesicular fluid, scabs, or scrapings from maculopapular lesions. Also, respiratory secretions, cerebrospinal fluid (CSF), autopsy specimens, and buccal smear can be used.

PCR and restriction fragment length polymorphism (RFLP) analysis can be used to differentiate between vaccine and wild-type strains.²² More recently, rapid real-time PCR methods using Light Cycler or TaqMan technology have made it possible to distinguish wild-type strain from vaccine strain in a single tube assay in a few hours.²³ These techniques have been strong tools to identify vaccine-associated adverse events and differentiate vaccine-associated rash from disease that occurs among vaccinated persons (breakthrough disease).

Serology. Serological tests are available to measure IgG and IgM antibodies against VZV. Testing for IgM antibody may not be useful clinically since available methods lack sensitivity and specificity. A capture assay is the preferred method for IgM testing to decrease false positive results that may occur in the presence of high IgG levels.²⁴ Many tests have been used to detect IgG antibody to VZV.²⁵ Rising IgG antibody levels from paired acute and convalescent sera taken 2–3 weeks apart is evidence of acute infection with VZV. Single IgG assays are used to screen or verify an individual's immune status. With automation of testing equipment and high volume testing in the laboratory setting, the enzyme-linked immunosorbent assay (ELISA) test using whole-cell VZV has replaced both latex agglutination (LA) and fluorescent antibody to membrane antigen (FAMA) as the most common serological test available. In unvaccinated persons, the presence of antibody detectable by one of these assays may be considered evidence of past infection with VZV and hence evidence of immunity. Also in unvaccinated persons, history of disease is highly predictive of serological immunity; thus a reliable history of varicella is considered a valid measure of immunity. In adults in the United States, 97–99% of those with a positive history are seropositive. The majority of adults with a negative or uncertain history are also seropositive (71–97%).^{15,26,27} However, a study conducted after 7 or 8 years of varicella vaccine use in the United States indicates that positive predictive value of disease history in children may not be high.²⁷ Therefore, laboratory testing or epidemiological link to typical cases at the time of infection should be sought to assess evidence of immunity.

Levels of antibody following vaccination are usually lower than those following natural varicella infection and may not be detected by commercially available whole-cell ELISA tests. A highly sensitive gpELISA test, using purified viral glycoproteins as antigens, was developed for testing of immunogenicity in vaccine clinical trials but is not commercially available at the present time.²⁸ This test, as well as FAMA, should be considered gold standards for testing immunity in vaccinees.²⁵

Other Virologic Tests. The most commonly available and widely used test is the direct immunofluorescent antibody (DFA) test which is rapid (results are available in several hours), sensitive, and highly specific. The DFA test uses immunofluorescence procedures to label polyclonal or monoclonal antibodies which bind to VZV antigens to allow the rapid identification of VZV proteins in cells from the base

of skin lesions. Direct and indirect immunofluorescence methods may detect VZV infected cells in tissue sections of lung, liver, brain, and other organs in patients with disseminated primary or recurrent VZV infection.

Cultures for VZV, though confirming unequivocally the diagnosis of VZV infection, require a minimum of two days, more frequently *at least* five days, to detect infectious virus in cell culture. Although in clinical cases of varicella, VZV is difficult to isolate from sites other than skin lesions, VZV has been cultured from clinical specimens such as autopsy samples or CSF, and rarely from throat, pharyngeal, and conjunctival specimens.

Clinical Characteristics

Varicella is highly contagious with secondary infection rates in susceptible household contacts ranging from 65% to 100%.^{29–32} Transmission occurs from person-to-person by direct contact from patients with either varicella or zoster lesions or by droplet or aerosol from vesicular fluid of skin lesions or from respiratory secretions. The path of entry of the virus is the upper respiratory tract. The incubation period for varicella ranges from 10 to 21 days, most commonly 14–16 days. This period may be shorter in immunocompromised patients and prolonged (for up to 28 days) in recipients of Varicella-Zoster Immune Globulin (VZIG).^{15,33} A primary viremia occurs 4–6 days after infection which enables the virus to infect and replicate in the liver, spleen, and possibly other lymphatic organs. This is followed by a secondary viremia 10–20 days after infection which results in fever and constitutional symptoms that most commonly occur synonymously with onset of the rash. Systemic symptoms in children are milder than in adults. Fever (~ 38–39°C [100–102° F]) is present during the peak of rash evolution and disappears by the time all the vesicles have either dried or crusted over. Infection usually produces a typical clinical illness; clinically inapparent or asymptomatic primary infection is estimated to occur in no more than 5% of susceptible children.³⁴

The characteristic rash is pruritic; appears in successive crops and quickly (24 hours) evolves from macules to papules to clear, fluid-filled vesicles approximately 2–4 mm in diameter. Early in the illness all stages of the rash can coexist. The vesicles are initially surrounded by an erythematous base, which fades during the process of crusting. Vesicles sequentially become purulent and dry and crust over. The crust, which is not infectious, may remain intact from 1 to 3 weeks. The rash is distributed centrally with more lesions occurring on the face, scalp, and trunk than on the extremities. Lesions are not confined to the skin and can develop on any mucosal surface including inside the mouth and vagina. They can also develop on the cornea³⁵ and tympanic membranes. A person with varicella is contagious from 1 to 2 days before the rash appears until all of the vesicles have crusted, usually 5–6 days after onset of rash. Patients with altered immunity may have a prolonged period of infectivity, because new lesions may develop for an extended period.

Approximately 20% of vaccinated persons may develop varicella if exposed to VZV. Varicella that occurs *more than* 42 days after vaccination is known as “breakthrough” disease. Breakthrough varicella is generally a mild disease with approximately 80% of the cases developing less than 50 lesions.^{36–39} Fever may not develop, and most or all lesions may be of pruritic maculopapular type, rather than vesicular. Therefore, it is easy to miss breakthrough varicella or misclassify it (e.g., insect bites, enteroviral infection).

Complications

Varicella may be followed by complications. The risk of complications is higher among immunocompromised persons, neonates, and adults.^{6,8–11,40} However, severe disease and deaths can occur in previously healthy individuals. Serious complications include secondary bacterial infections, pneumonia, postinfectious encephalitis, cerebellar ataxia, Reye’s syndrome and death.^{6,41–43} Rarer complications include nephritis, arthritis, Guillain-Barré syndrome, stroke, thrombocytopenia, and clinical hepatitis. Though clinical hepatitis occurs rarely, evidence of subclinical hepatitis is frequent.²⁴

Complications from varicella vary by age. In healthy children with varicella, secondary bacterial infections of skin lesions, usually due to *Staphylococcus* or *Streptococcus*, are the most common complications requiring hospitalization.^{10,11,43} Reports of life-threatening or lethal invasive group A beta-hemolytic streptococcus infections include cellulitis, necrotizing fasciitis, septic arthritis, osteomyelitis, septicemia, and toxic shock syndrome. Neurologic complications are the second most common indication for hospitalization for healthy children with varicella. Central nervous system (CNS) complications, meningoencephalitis, and cerebellar ataxia are more frequent in children younger than five years and in adults aged 20 years and older.⁴ Varicella-associated encephalitis is estimated to occur in 1–4 cases per 10000 reported varicella cases.⁴ Cerebellar ataxia is the most common CNS complication occurring in approximately 1 in 4000 cases.⁴⁰ It may persist for longer than encephalitis but usually resolves completely. Reye’s syndrome has become a rare complication following the marked decline in use of salicylates among children with varicella.⁴⁴

A higher rate of complications occurs in adults. Systemic involvement is more prominent, with primary varicella pneumonia the most common, life-threatening complication.⁴³ Estimates of the frequency of pneumonia complicating varicella in healthy adults have varied widely from 0.3% to 50% with wide ranges also in fatality from pneumonia of 9–50%.^{45–48} Hemorrhagic complications occur more commonly in adults than in healthy children and include thrombocytopenia associated with bleeding into skin lesions, petechiae, purpura, hematuria, and gastrointestinal hemorrhage. This may proceed to disseminated intravascular coagulopathy, shock, and death. Some, but not all, studies have suggested that pregnant women have a higher risk of complications than do nonpregnant adults of child-bearing age. However, these data are predominantly from case reports and case series from referral hospitals. In a reported series of 118 cases of varicella in pregnant women in the United States, 24 of them developed pneumonia and 11 died.⁴⁹

Both varicella and herpes zoster are listed as underlying causes of death every year in the United States. Septic and CNS complications, pneumonia, and hemorrhagic conditions are the most common causes of death following varicella disease.^{5,8,9} Overall case-fatality rate is highest among infants, adults, and persons with immunocompromising conditions, and lowest among children 1–9 years of age.⁸ In the United States, during 1970–1994, overall varicella mortality rate was 0.4 deaths per million population. During the same time frame, case-fatality rate ranged between 2–3.6 deaths per 100,000 cases in 5-year periods. By 1999–2001, the average rates of mortality due to varicella among all racial and ethnic groups were below 0.15 deaths per million population. Most varicella deaths occurred among previously healthy individuals; during 1990–1994, 89% and 75% of child and adult deaths, respectively, occurred among individuals without severe underlying conditions while in 1999–2001, 92% of deaths among persons aged less than 20 years were in persons without severe underlying medical conditions.

In immunocompromised patients, all expressions of the infection may be markedly enhanced.^{3,24,33,50} In such patients, atypical severe presentations of varicella may be difficult to distinguish from disseminated herpes zoster. Severe varicella or disseminated zoster and serious complications with multi-organ system involvement have been described in many situations associated with an immunocompromised state including leukemia and other cancers, HIV/AIDS, disorders of the immune system and immunosuppression secondary to use of steroids or cancer chemotherapeutic drugs.^{51,52} Numerous studies suggest that an impaired cellular immune state is the major contributing factor.⁵³

Neonatal Varicella. Prior to the advent of antiviral therapy, as many as 30% of infected infants whose mothers had a varicella rash within five days before delivery died of the disease. The risk of serious illness is highest when maternal onset of varicella is from five days before delivery to two days afterward since the baby acquires VZV via a viremia but does not acquire passive immunity transplacentally.

Disease earlier in pregnancy is associated with the passage of protective maternal antibody to the fetus.⁵⁴

Congenital (Fetal) Varicella Syndrome. Maternal infection within the first 26 weeks of gestation can lead to congenital (fetal) varicella syndrome, a recognized constellation of congenital defects including hypoplasia of an extremity, cicatricial skin scarring, localized muscular atrophy, encephalitis, microcephaly, cortical atrophy, ocular abnormalities, mental retardation, and low birth weight. This syndrome has been estimated to occur in about 0.4% of infections that occur from weeks 0–12 and 2.0% of infections that occur from weeks 13–20; the latest infection reported in pregnancy that resulted in fetal varicella syndrome is 25½ weeks.^{55,56} Other researchers have suggested a wider clinical spectrum of clinical manifestations for this syndrome, including a milder one that may not be easily diagnosed. Gestational varicella is also associated with an increased risk of zoster occurring at an early age especially within the first year of life.⁵⁴

Epidemiology

In temperate climates, in the absence of vaccination, varicella is a disease of childhood with 80–90% cases occurring before 10 years of age.^{1,29,57,58} In the United States, during the 1980s, the highest annual incidence rate was described in 5- to 9-year-old children followed by the 1–4 age group,^{1,5,58} by early adulthood, 95% of the population was immune to varicella.² In the early 1990s, the highest age specific incidence was in pre-school children,^{57,59} a pattern also described in many European countries.^{60,61} During 1988–1994, varicella seroprevalence was 95% and 99% and more among persons 20–29 and more than 30 years of age, respectively. The vaccination program has changed the epidemiology of varicella in the United States. Overall, incidence has declined 80–90%, and the median age of infection has increased; however, declines in incidence have occurred in all age groups. Ten years after the implementation of program, some varicella outbreaks, albeit much smaller in size than in the pre-vaccine era are occurring in elementary and middle schools prompting consideration of a second routine dose of varicella vaccine in childhood.

Varicella has been less commonly a childhood disease in the tropics with more frequent disease occurring among adults. However, susceptibility in adults varies widely in the tropics from more than 50% in St. Lucia, West Indies from a large serosurvey in 1985–1986 to less than 10% in urban Thailand, India, and the Philippines.^{62,63} The reasons for this difference in the age-specific incidence of varicella in tropical compared to temperate climates are unclear but may include differences in population size, population density, crowding, and higher ambient temperatures or humidity resulting in decreased transmission in the tropics.

Routine varicella vaccination program in the United States has resulted in rapid increases in vaccination coverage and dramatic declines in varicella morbidity and mortality. Vaccination coverage among children 19–35 years of age increased from 27% in 1997 to 88% in 2004.⁶⁴ In four states (MI, IL, TX, VW) that have had consistent varicella surveillance over the years, varicella vaccination coverage reached 57–84% in 2001. In these states, the number of cases declined by 67–82% in 2001 compared to the average number of cases reported during 1990–1994.⁶⁵

In three varicella active surveillance sites (Antelope Valley, CA; Travis County, TX; and West Philadelphia, PA), similar reductions in incidence were observed. From 1995 to 2000, reported number of cases and hospitalizations declined by 71% and 84%, respectively.⁵⁸ The highest reduction in incidence was among children 1–4 years of age, the age group that was covered by the vaccination program. However, disease reduction was also observed in other age groups, indicating protection in these age-groups through herd immunity.

At the national level, hospitalizations declined by 75% from an average number of 15073 hospitalizations during 1993–1995 to 3729 in 2001.¹⁰ The number of deaths due to varicella as the underlying cause of death reported to the National Center for Health Statistics declined from 115 in 1996 to 26 in 2001.⁹ The decline was observed in all age groups, except those 50 years of age and older. The highest

declines were among children 1–4 and 5–9 years of age; 89% and 88%, respectively. During 1999–2001, 92% of all deaths occurred among persons with no high-risk conditions.

Although varicella vaccination program resulted in substantial decline in cases and deaths due to varicella, outbreaks continue to be reported among both unvaccinated and vaccinated school children. Of these, outbreaks among highly vaccinated populations are of particular concern. During 2001 and 2004, several outbreaks in schools with 96% and more vaccination coverage were reported.^{66–68} Each outbreak lasted about 2 months with attack rates among vaccinated children ranging from 11% to 17%. Vaccinated cases played a key role in transmitting VZV. Vaccine effectiveness in these outbreaks was in the range of 72–85%, similar to those obtained in the vaccine efficacy trials prior to licensure. Vaccine effectiveness of 80–85% is not sufficient to prevent varicella outbreaks. Therefore, to improve vaccine-induced immunity, a routine second dose vaccination has been recommended.¹⁷

Prevention and Control

Active Immunization. All current varicella¹⁷ vaccine preparations contain the Oka strain of live, attenuated VZV. Three pharmaceutical companies produce varicella vaccine. These vaccines and producers are: Varivax (also available as Varivax Refrigerated and VarivaxII, which do not require freezing) by Merck & Co., Inc.; Varilrix by Glaxo-SmithKline, and Okavax by Biken (distributed by Sanofi Pasteur MSD). Oka/Biken vaccine has been available in Japan and Korea since the 1980s for use in healthy and immunocompromised persons, although it has not been recommended for routine childhood vaccination. In 1995, United States became the first country to implement varicella vaccine into its routine childhood immunization program. As of 2005, Qatar, Uruguay, Germany, Australia, Canada, and some areas of Italy have incorporated varicella vaccination into their routine immunization program. The formulation licensed for use in the United States contains more than 1350 plaque forming units (PFU) ($\sim 1.13 \log_{10}$) of Oka/Merck VZV in each 0.5 mL dose. In 2005, the first combination MMRV vaccine, Proquad (Merck & Co., Inc.) was licensed in the United States. To obtain comparable immunogenicity provided by Varivax, varicella dose has been increased to $3.99 \log_{10}$ PFU in Proquad.

In the United States, varicella vaccine is approved for use in healthy persons aged 12 months and older without evidence of immunity (no history of varicella, no evidence of serological immunity, or never vaccinated). The ACIP and the American Academy of Pediatrics (AAP) recommend that all children be routinely vaccinated at 12–18 months of age, and receive a second dose at 4–6 years of age.^{15,16} There should be at least three months interval between the two doses. Varicella vaccine is administered subcutaneously (0.5 ml dose). Catch-up two-dose vaccination is recommended for persons who are older than six years of age and do not have evidence of immunity. In outbreak settings, a second dose of vaccine is recommended for persons who have received one dose of vaccine to prevent further spread. ACIP recommends assessment of pregnant women for varicella immunity and postpartum vaccination of susceptible women. HIV-infected children with age-specific CD4+T lymphocyte percentages of 15%–24% and adolescents and adults with CD4+T lymphocyte counts >200 cells/ μ L are recommended to receive two doses of varicella vaccine.

Immunogenicity and Persistence of Vaccine-Induced Immunity. Both humoral and cellular immunity are important in the control of primary varicella infection. VZV is a strongly cell-associated virus. The capacity to elicit cell-mediated immunity is an important factor accounting for long-term protection against disease and reactivation of the virus. The vaccine produces both humoral and cell-mediated immune responses detected 6–8 weeks after vaccination. At approximately 4–6 weeks postvaccination, seroconversion (acquisition of any detectable varicella antibodies [>0.3 gpELISA units]) was observed in 97% of 6889 susceptible children 12 months–12 years of age who received one dose of varicella vaccine.¹⁵ Evaluation of data from clinical trials suggests that titers 5 gpELISA and more units at 6 weeks after a single dose of vaccine strongly correlate with

protection against varicella and is a good predictor of vaccine efficacy.^{69,70} Approximately 73–86% of children vaccinated in trials have achieved titers 5 gpELISA units and more after a single dose vaccination.^{71,72} A comparative study of one and two doses administered three months apart to healthy children showed that the proportion of subjects with antibody titers 5 gpELISA units and more in the two dose group was significantly higher six weeks after the second dose (99.6% vs. 85.7%) and remained high at the end of the 9-year follow-up, although the difference between the two regimens did not persist (97% vs. 95%).⁷² Another study revealed that majority (60%) of the children had anamnestic response (≥ 4 -fold increase in antibody titers) when administered a second dose 4–6 years after their first dose.⁷³

In a multicenter clinical trial among 757 adolescents and adults, seroconversion rates four weeks after doses one and two were 72% and 99%, respectively, for those who received vaccine four weeks apart, and 78% and 99%, respectively, for those who received vaccine eight weeks apart.⁷⁴

The humoral immunity has been shown to persist for more than 20 years in Japan and for up to 10 years in the United States in 93–100% of child vaccinees.^{72,75–77} At the end of a 10-year prospective study, 95% and 97% of children who had received one and two doses, respectively, had antibody levels 5 gpELISA and more.⁷² In clinical studies among adolescents and adults who were administered two doses of vaccine 4–8 weeks apart, detectable antibody levels have persisted for at least five years in 97% (Merck and Company, Inc., Varivax package insert).

However, other studies found that 25–31% of adult vaccinees who seroconverted lost detectable antibodies (FAMA) at intervals ranging from 1 to 11 years after vaccination and 9–21% of vaccinees developed breakthrough disease.^{78–82} Cell-mediated immunity persisted in 87–94% vaccinated children and adults for 5–6 years following vaccination.^{75,83,84} In the study of the two doses administered to children 4–6 years apart, results showed that the lymphocyte proliferation response was significantly higher at 6 weeks and 3 months after the second dose than after the same time points following the first dose.⁷³ Data from varicella active surveillance sites in the United States suggested loss of vaccine-induced immunity over time. Multivariate logistic regression analysis adjusting for the year of disease onset (calendar year) and the subject's age at both disease onset and vaccination revealed that the annual rate of breakthrough varicella significantly increased with the time since vaccination, from 1.6 cases per 1000 person-years (95% CI, 1.2 to 2.0) within one year after vaccination to 9.0 per 1000 person-years (95% CI, 6.9 to 11.7) at five years and 58.2 per 1000 person-years (95% CI, 36.0 to 94.0) at nine years.¹⁴⁴ Persistence of immunity in the absence of exposure to the wild virus and natural boosting of immunity should continue to be monitored.

Efficacy, Effectiveness, and Risk Factors for Vaccine Failure. Clinical trials prior to licensure demonstrated vaccine efficacies ranging from 70–100% depending on the age at vaccination, dosage, number of doses given, type of exposure (household or community), length of follow-up, and outcome of disease studied, i.e., level of severity of disease. Since licensure, effectiveness of varicella vaccine under field conditions has been assessed in childcare, school, and household and community settings using a variety of methods. Effectiveness has frequently been estimated against varicella and also against moderate and/or severe varicella. Outbreak investigations have assessed effectiveness against clinically defined varicella. The majority of these investigations have found vaccine effectiveness for prevention of varicella in the range most commonly described in pre-licensure trials (70–90%) with some lower (44%, 56%) and some higher (100%) estimates.^{38,39,66,85–88} A retrospective cohort study in 11 childcare centers found vaccine effectiveness of 83% for prevention of mild/moderate disease.⁸⁹ A study in a pediatric office setting has measured vaccine effectiveness against laboratory confirmed varicella using a case control study design. Vaccine effectiveness was 85% (78–90%) and 87% (81–91%) during the early and later time periods for this study.^{90,91} Finally, in a household secondary attack rate study, considered the most extreme test of vaccine performance due to the intensity of exposure, varicella vaccine was 79% (79–90%) effective in preventing clinically defined varicella in exposed household contacts.³²

Post-licensure studies that have assessed vaccine performance in preventing moderate and severe varicella have consistently demonstrated extremely high effectiveness against these outcome measures. Definitions for disease severity have varied between studies from using a defined scale of illness that includes number of skin lesions, fever, complications, and investigator assessment of illness severity to using the number of skin lesions and reported complications or hospitalizations. Irrespective of definition differences, varicella vaccine has been 90% and more effective in preventing moderate or severe disease with one exception (86%) and 96–100% against severe disease when this was measured separately.^{32,37–39,87,88,90–92}

Breakthrough disease is defined as a case of wild-type varicella infection occurring more than 42 days after vaccination. In clinical trials and post-licensure studies, varicella was substantially less severe among vaccinated persons than among unvaccinated persons. The majority of the vaccinees who develop varicella have less than 50 lesions, shorter duration of illness, and lower incidence of fever. Most illnesses associated with vaccine failure are attenuated and have not increased in severity during the 7–10 years of follow-up study. However, vaccinated cases are infectious. Breakthrough cases who develop lesions similar to unvaccinated cases are as infectious as unvaccinated cases.³² Vaccinated cases with less than 50 lesions are one-third as infectious as unvaccinated cases.

Several studies, including those conducted during outbreak investigations identified various risk factors for vaccine failure. However, to date, no factor has been clearly established as a risk factor for developing breakthrough disease. Out of numerous outbreak investigations, three suggested three- to ninefold increase in breakthrough disease with decreasing age at vaccination (varying between less than 14 to 19 months of age).^{86,87,92} Only in one of these outbreak investigations, age at vaccination was independently assessed by controlling for time since vaccination.⁹² Two studies in outbreaks suggested asthma and eczema as risk factors for vaccine failure.^{37,93} Only one cohort study controlled simultaneously for the effect of multiple risk factors and found that the use of oral steroids within the last three months of varicella, age at vaccination (<15 months) and administration MMR within 28 days of varicella vaccination were risk factors for breakthrough varicella disease.⁹⁴ Another study found that the effectiveness of vaccine in the first year after vaccination was substantially lower (73%) among children vaccinated at age less than 15 months; however, the difference between children vaccinated at age less than 15 months and 15 months and more did not persist in the seven subsequent years.⁹¹ A study following up nearly 7500 children is examining the relation between age at and time since vaccination. Based on data from the U.S. active surveillance sites, varicella incidence increased as time since vaccination prolonged.¹⁴⁴

In the randomized clinical trial of one versus two doses of varicella vaccine administered three months apart, the estimated vaccine efficacy of one versus two doses for a 10-year observation period was 94.4% and 98.3%, respectively ($p < 0.001$).⁷² The two-dose regimen was 100% efficacious against severe varicella.

Safety. The vaccine is well tolerated in healthy individuals. Local pain and/or redness at the injection site, fever, and generalized varicella-like rash may occur. From pre-licensure clinical trials, the reported incidence of rash at the injection site post vaccination was approximately 3–4% among children, adolescents, and adults following the first dose. For generalized rash, these rates are 4% for children and 6% for adolescents and adults, respectively. The median number of lesions was low—two at the injection site and five for generalized rash.¹⁵ The vaccine virus is capable of reactivating to cause herpes zoster.⁹⁵ Incidence of herpes zoster after vaccination of healthy children is estimated as 18 per 100,000 person-years and lower than the zoster rates after natural varicella infection.^{15,96,97} In a health maintenance organization (HMO) setting, HZ rate among vaccinated 0–9-year-old children ranged between 0–0.5 per 1000 person-years during 1998–2002 compared to 0.9–1.5 per 1000 person-years among unvaccinated children during 1996–2002.⁹⁸ Other rarely reported adverse events include pharyngitis, cellulitis, hepatic pathology, pneumonia, erythema multiforme and Stevens-Johnson Syndrome (SJS), arthropathy, thrombocytopenia, anaphylaxis, and aplastic anemia. They all accounted for

reporting rates lower than 1 case per 100,000 doses sold. Neurological adverse events accounted for a reporting rate of 3.8 per 100,000 doses sold and included neuropathy, convulsion, ataxia, encephalopathy, and meningitis.⁹⁹

Post-licensure data suggest that the risk of transmission of varicella vaccine virus from healthy persons is very low; in particular, in the absence of rash in the vaccinee. With over 50 million doses of varicella vaccine distributed in the United States, transmission of vaccine virus from only four immunocompetent persons has been documented by PCR; all five secondary cases were mild.^{95,100,101} In another report, the brother of a child who developed herpes zoster five months following varicella vaccination developed a varicella-like rash from which vaccine virus was isolated, suggesting that the virus was transmitted from zoster.¹⁰²

Contraindications and Precautions. Contraindications and precautions to vaccination include pregnancy (women should avoid pregnancy for one month after receiving a dose of varicella vaccine), allergy to vaccine components (vaccine contains neomycin, but does not contain egg protein or preservatives), recent administration of blood, plasma or immune globulin, altered immunity including malignant conditions, and conditions that require steroid therapy (≥ 2 mg/kg/day or a total of 20 mg/day of prednisone or its equivalent). The vaccine is not recommended for persons with cellular immunodeficiencies, but can be administered to persons with impaired humoral immunity. VARIVAX is contraindicated for HIV-infected children with age-specific CD4+ T-lymphocyte of less than 15%. In the United States and Canada, Merck and Co, Inc, the vaccine manufacturer, in collaboration with CDC, has established the VARIVAX pregnancy register to monitor outcomes of pregnant women who are inadvertently vaccinated 3 months before or at any time during pregnancy Telephone: 800-9-VARIVAX.¹⁰³ No abnormal features have been reported that suggest the occurrence of congenital varicella syndrome or other birth defects related to vaccine exposure during pregnancy.^{104,105} No adverse events associated with the use of salicylates after varicella vaccination have been reported. However, the vaccine manufacturer recommends that vaccine recipients avoid using salicylates for six weeks after receiving varicella virus vaccine because of the association between aspirin use and Reye's syndrome following varicella.

Postexposure Vaccination. One dose varicella vaccine administered within three days of exposure to a person with rash is at least 90% effective in preventing varicella. If administered within five days of exposure vaccine is approximately 70% effective in preventing disease and 100% effective in modifying it.^{106–108} Therefore, vaccination is recommended within 72 hours of exposure; however, vaccination after 72 hours is still recommended given that the vaccine may modify the disease or will provide protection against future exposures for those whose current exposure might not result in efficient transmission.¹⁶

Passive Immunization. Varicella zoster immune globulin (VZIG) is recommended for postexposure prophylaxis in susceptible persons at high risk for developing severe disease who have been exposed to VZV. VZIG has been shown to be effective in reducing the severity of varicella when given up to 96 hours after exposure. It should, however, be given as soon as possible after exposure. The decision to administer VZIG to a person exposed to varicella should be based on whether (a) the person is susceptible, (b) the exposure is likely to result in infection, and (c) the patient is at greater risk for complications than the general population. Identified high-risk groups include newborn infants whose mothers developed varicella around the time of delivery (from 5 days before to 2 days after delivery), immunocompromised persons including those on immunosuppressive medications and steroids, pregnant women without evidence of immunity, hospitalized premature infants of 28 weeks or longer gestation or more than 1000 g whose mother has no history of varicella and/or antibodies to VZV, and premature infants of less than 28 weeks gestation or 1000 g or less regardless of the mother's history of varicella. The recommended dose is one vial (125 U) per 10 kg body weight and up to a maximum of 625 U/person given by intramuscular injection.¹⁵

Isolation Guidelines. Isolation of individuals with varicella until all lesions have crusted is a routine outbreak control measure. Isolation is also recommended for exposed susceptible individuals who may be in contact with persons at high risk of serious complications, e.g., health-care workers and families of immunocompromised persons. Such isolation is required for the duration of the period of communicability, i.e., from the 10th until the 21st day postexposure or until the 28th day if the exposed individual receives VZIG.¹⁰⁹

Treatment

A variety of antiviral drugs are available for treatment of varicella and herpes zoster. Acyclovir is a synthetic nucleoside analog that inhibits replication of human herpes viruses including the varicella zoster virus; it is available in both oral and intravenous forms and is most effective when administered within 24 hours of rash onset.^{15,109} Oral acyclovir is not recommended routinely for the treatment of uncomplicated varicella in healthy children, but is recommended for treatment of primary varicella among certain groups at increased risk of severe disease or its complications. This includes people older than 12 years of age, people with chronic cutaneous or pulmonary disorders, people receiving long-term salicylate therapy, and people receiving short intermittent or aerosolized courses of corticosteroids.¹⁰⁹ Since oral acyclovir is poorly absorbed, IV acyclovir is recommended for the treatment of severe primary varicella and/or serious complications of varicella in healthy or immunocompromised individuals and for recurrent zoster in immunocompromised persons. VZV resistance to acyclovir has not proven to be a problem in immunocompetent hosts. In immunocompromised hosts, acyclovir-resistant VZV infections have been reported and may become an increasing problem with the use of prolonged acyclovir therapy for patients with chronic or recurrent herpes zoster infections. For such patients, the best alternative therapy is foscarnet.^{110,111}

Herpes Zoster

Clinical Characteristics and Complications

Herpes zoster, or shingles, is a localized disease with a painful, vesicular rash that results from reactivation of VZV after latency within sensory ganglia following an earlier attack of varicella.^{33,53,112} It is estimated that the lifetime incidence of zoster is 10–30% in the general population and as high as 50% of persons living up to age 85 years develop HZ.^{113,114} The rash is characterized by a unilateral dermatomal distribution in 1–3 sensory dermatomes. Herpes zoster may present as a disseminated, generalized rash in immunocompromised patients. The VZV may be transmitted from patients with herpes zoster to susceptible individuals resulting in varicella.^{115–117} The latent virus is more likely to become reactivated under certain conditions, most notably advancing age, following varicella acquired in utero or during the first year of life, malignancy and immunosuppression.^{33,53,96,97,112,118–120} Because this reactivation can occur in the presence of circulating antibodies against the VZV, and the majority of predisposing conditions are associated with declining or a relative absence of CMI, it is this decline which is considered to play an important role in reactivation process. Occurrence of complications is associated with increasing age and immunosuppression.^{121–123} Persons more than 65 years of age were estimated to have about eight times higher risk of developing complications compared to those 25 years of age.¹²¹ The most frequent complication in elderly is post-herpetic neuralgia (PHN), a syndrome of pain, allodynia, dyesthesia, and hyperesthesia that persists or develops after the dermatomal rash has healed.¹²⁴ PHN may be prolonged and disabling. Studies suggest that 27–68% of HZ cases more than 60 years of age develop PHN.^{125,126} Other complications include cranial or peripheral nerve palsies, sensory loss, deafness, ocular complications, transverse myelitis, or disseminated infection with pneumonitis, encephalitis, hepatitis, pericarditis or arthritis.^{124,127} In immunocompromised hosts, herpes zoster results in more severe disease which can be disseminated and life-threatening. Individuals who suffer from lymphoproliferative malignancies or require

bone marrow transplantation are at unusually high risk for disseminated herpes zoster with visceral complications, particularly pneumonia.

Epidemiology

In the United States, herpes zoster is a significant cause of morbidity among elderly adults.^{96,98,121,125,126,128–132} Studies in the United Kingdom have described an overall incidence of 3.4 cases per 1000 person-years with incidence of 6.8 per 1000 person-years in persons 60–69 years of age to 11.0 per 1000 person-years for persons 80 years or older.¹¹² It is difficult to make direct comparisons between the rates from different studies, as assessment periods, assessment methods (e.g., prospective population-based studies vs. clinic medical record reviews), case definitions used, and other factors that affect HZ incidence (e.g., age or immunosuppressive conditions) may vary between the populations studied. However, all studies have shown a strong association of HZ with age. Data from the United States conducted in different populations and using different methods and time periods have described annual incidence rates ranging from 1.3 to approximately 4.2 per 1000 person-years.^{96,98,118,131,133} A population-based study in children and adolescents showed that the incidence increased with age from 20 cases per 100,000 person-years in children aged less than five years to 63 per 100,000 person-years in those aged 15–19 years.⁹⁷

Female gender has been associated with increased risk of zoster in several studies.^{131,134–137} Also race has been associated with HZ incidence.^{120,137} In a prospective study, compared to whites African Americans were one third (aOR = 0.37, 95% CI, 0.26–0.53) as likely to have experienced HZ after controlling for age, sex, education, cancer history, cigarette smoking, daily activities, depression, self-rated health, chronic diseases, and hospitalization.¹²⁰

It has been hypothesized that HZ will increase over time as disease incidence and boosting from exposure to VZV will decrease as a result of widespread varicella vaccination.¹³⁸ Some studies suggested that exposure to varicella or children (as a proxy for varicella exposure) were protective against HZ.^{137,139–141} Studies are ongoing in the United States to monitor such an impact of the vaccination program, if it exists. A study in an HMO population in Washington showed no increase in HZ incidence over time compared with pre-vaccine years.⁹⁸ In another, a significant increasing trend was observed during 1997–2002 among HZ in children 10–17 years of age; however, the significant trend disappeared when use of oral steroids was accounted for.¹³¹ Another study, with no baseline data, described a significant increase in HZ between 1999 and 2003.¹³⁰ Preliminary analysis from national data bases indicate that secular trends in HZ rates may have been occurring before the implementation of the varicella vaccination program.¹³³

Active Immunization

A recently completed randomized, double-blind, placebo-controlled trial among approximately 39,000 persons 60 years of age and older indicates that a high-potency Oka varicella zoster virus vaccine (ZOSTAVAX) is effective in preventing HZ and PHN.¹³² Vaccine efficacy was 51% against HZ and 67% against PHN. ZOSTAVAX was

licensed in the United States in 2006. ACIP recommends a single dose of zoster vaccine for persons 60 years of age and older whether or not they reported a prior episode of herpes zoster. (<http://www.cdc.gov/vaccines/recs/provisional/downloads/zoster-11-20-06.pdf>)

Treatment

Acyclovir, famciclovir, and valaciclovir have been approved for treating herpes zoster in immunocompetent persons and are most effective in reducing duration of rash and incidence and duration of post-herpetic neuralgia if given within 48–72 hours of onset of rash.^{24,110,142,143} Severely immunocompromised individuals may require IV acyclovir therapy. Famciclovir and valaciclovir are more bioavailable when administered orally than acyclovir and require less frequent administration.¹¹⁰ Foscarnet and interferon (IFN- α), both antiviral drugs licensed for the treatment of herpes zoster, may be useful for acyclovir resistant strains.

Future Public Health Needs

Ten years of experience with the varicella vaccination program in the United States shows that varicella vaccination program has been tremendously successful in reducing morbidity and mortality in a short period of time. Therefore, wider use of vaccine through its integration into routine childhood vaccination programs in other countries is beneficial. One dose varicella vaccine is approximately 80–85% effective in preventing disease and therefore, although in less numbers, varicella outbreaks continue to be reported in the United States where national vaccination coverage reached 88%. In addition, due to declining exposure to VZV resulting in accumulation of susceptibles (unvaccinated and 15–20% of vaccinated) and may result in future epidemics. Therefore, a second dose of varicella vaccine is recommended. Vaccine-induced immunity can be increased through continued increase in vaccination coverage in all age-groups (in particular in schools) and providing two doses of varicella vaccine to children. Recently licensed combination MMRV vaccine provides an opportunity to administer the second varicella dose, without an additional injection or administration cost.

Surveillance is critical to establish and monitor impact of vaccination programs. However, varicella surveillance in many countries, including the United States is a challenge as the number of varicella cases remains high and varicella in vaccinated persons is mostly a mild disease and difficult to diagnose. In addition to increasing completeness of reporting, surveillance will benefit greatly from reduction in varicella incidence and wide availability of diagnostic tests. Similarly, surveillance of HZ and PHN provides additional challenges to public health community. Countries will have to determine optimal surveillance systems to assess baseline HZ (and perhaps PHN) incidence rates and monitor the impact of HZ and varicella vaccination programs. Countries with varicella vaccination programs in place need to continue to monitor the changing epidemiology of both varicella and herpes zoster. The zoster vaccine will offer the opportunities to decrease the health burden associated with herpes zoster.

Poliomyelitis

Roland W. Sutter • Stephen L. Cochi

Poliomyelitis, or infantile paralysis, is an acute infectious disease characterized by fever, flaccid paralysis, and muscle atrophy as a result of the destruction of motor neurons in the spinal cord and brain

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

stem; three serotypes of poliovirus cause infections that result in severity from inapparent illness to acute flaccid paralysis and death. Paralysis may resolve or lead to permanent disability and deformity. Decades after the acute episode, new paralysis or progressive weakness may appear. This clinical entity is referred to as post-polio syndrome. Poliomyelitis probably has afflicted mankind for thousands of years, however, only in 1789 was the disease first described. Epidemic

poliomyelitis emerged as a public health problem in the United States and Northern Europe in the late nineteenth and early twentieth centuries, with tens of thousands of cases reported annually. Effective vaccines, developed in the 1950s and 1960s, rapidly eliminated poliomyelitis in industrialized countries, but not in the developing world. In 1988, the World Health Assembly resolved to eradicate poliomyelitis globally by the year 2000. Although the target has not been reached, substantial progress has been made, and achievement of eradication remains feasible within the next 2–3 years. (The last wild poliovirus type 2 was detected in 1999.)

Etiology

In 1908, Landsteiner and Popper demonstrated that poliomyelitis was caused by a virus (“filterable agent”). They caused paralytic disease in monkeys by intraperitoneal inoculation of spinal cord materials from a patient with fatal poliomyelitis. In 1931, Burnet and Macnamara established that more than one virus strain can cause poliomyelitis, and that immunity to one strain was not protective against the other strain. A typing effort by the Committee on Typing of the National Infantile Paralysis Society in 1951 determined that there were only three serotypes of polioviruses, designated as poliovirus types 1, 2, and 3.² The closely related but antigenically distinct viruses are part of the *Enterovirus* genus and belong to the family *Picornaviruses*.³ In the early 1940s, it was shown that the infectious agent was present usually in stools of patients with symptomatic disease and their symptom-free contacts. In 1949, Enders, Weller and Robbins successfully propagated poliovirus for the first time in human embryonic non-nervous tissue, and documented virus growth directly in cell cultures (i.e., “cytopathogenic effect”). This method eliminated the need for in-vivo methods (e.g., monkeys) to confirm virus replication.⁴ Together, these breakthroughs were critical to pave the way for efficient virus growth needed for the eventual production of vaccines.

Pathogenesis

After ingestion into the oral cavity, polioviruses replicate initially in the oropharyngeal mucosa (tonsils) and the Peyer’s patches in the ileum after gaining access into cells using the human poliovirus receptor.⁵ Viremia may ensue and central nervous system (CNS) infection may follow; in the latter instance, the virus specifically targets the motor neuron of the spinal cord and occasionally the brain stem. Viral replication in the motor neurons results in cell destruction and flaccid paralysis of the muscles they innervate. Death is usually a result of bulbar involvement with respiratory paralysis.

Infection with polioviruses may result in a spectrum of clinical outcomes. The vast majority of infected persons remain asymptomatic, or experience a mild illness characterized by fever, malaise, headache with nausea, vomiting, constipation, diarrhea, and sore throat. Infections with limited CNS involvement may cause illness with fever and evidence of meningeal irritation—stiff neck and back and elevated protein and leukocyte levels in the spinal fluid—followed by complete recovery. This syndrome is clinically identical to aseptic meningitis caused by other viral agents such as mumps virus, echovirus, and coxsackie viruses. And finally, approximately 1:100–1:1000 infected persons may experience the typical paralytic consequences of poliovirus infection. The differences in attack rates may be due to variations in neurovirulence among the three serotypes, with type 1 being the most neurovirulent virus.

After an interval of 30–40 years, many persons (25–40%) who contracted paralytic poliomyelitis in their childhood may experience muscle pain and exacerbation of existing weakness, or may develop new weakness or paralysis. This disease entity is referred to as post-polio syndrome. To date, this syndrome has only been described in persons infected during the era of wild poliovirus circulation. Factors which enhance the risk of post-polio syndrome include: (a) increasing length of time since acute poliovirus infection, (b) presence of permanent residual impairment after recovery from the acute illness; and (c) female gender. The pathogenesis of post-polio syndrome is

thought to involve late attrition of oversized motor units that developed during the recovery process of paralytic poliomyelitis.¹

Epidemiology

Following development and widespread use of effective poliovirus vaccines, first inactivated poliovirus vaccine (the “Salk vaccine”) and then live attenuated oral poliovirus vaccine (the “Sabin vaccine”), in the United States and other industrialized countries, paralytic poliomyelitis was largely eliminated as a public health concern.⁶ The same success had yet to be achieved in much of the developing world; therefore, in 1988, the World Health Assembly resolved to eradicate poliomyelitis globally by 2000⁷ (see *Global Poliomyelitis Eradication Initiative*). In 1988, an estimated 350,000 cases of poliomyelitis occurred worldwide, and in many countries paralytic disease due to poliomyelitis was the single most important contributor to permanent disability.⁸ The vast majority of the cases emanated from tropical and subtropical regions, where crowding, poor sanitation, and inadequate hygiene facilitate transmission of polioviruses and other enteric pathogens.

Humans (and some nonhuman primates) are the only known reservoir of poliovirus infection and excrete the agent in pharyngeal secretions and feces. The incubation period is most commonly 7–24 days, with a range of 3–36 days. Patients can be infectious before symptoms develop; virus is subsequently excreted in pharyngeal secretions for a few days and in the stool for several weeks. Transmission occurs via the fecal-oral route, particularly in settings where sanitation and personal hygiene are poor, and via the oral-oral route in settings with good hygiene. Boys are at higher risk for paralytic outcomes than girls. In developing countries, poliomyelitis primarily afflicts infants less than two years of age, while in industrialized countries members of groups objecting to vaccination are at highest risk for poliomyelitis.

During the past several years, considerable information has been obtained on the epidemiologic features of poliovirus transmission using molecular techniques.⁹ In contrast to influenza viruses, which tend to spread globally on an annual basis, most polioviruses appear to circulate within relatively limited geographic areas, with occasional instances of spread to adjacent countries and infrequently across continents. The more widespread use of genomic sequencing in recent years has provided an effective tool to monitor the circulation of poliovirus genotypes, to document the spread of poliovirus from endemic areas to non-endemic areas, and to substantiate the gradual elimination of different lineages of poliovirus genotypes in polio-endemic areas. Recombinant mouse cell lines cloned with the human poliovirus receptor gene will facilitate the isolation of poliovirus because these cell lines are relatively resistant to supporting other enterovirus growth. The use of these cell lines and/or application of polymerase chain reaction (PCR) facilitates detection of wild virus in sewage, water, and other environmental samples as an additional means of surveillance at the national, regional, and global levels as global eradication of poliomyelitis approaches.

Prevention and Control

Vaccine Development and Use. After Enders’ successful propagation of poliovirus in human nonembryonic non-nervous tissue culture, Salk used this method to prepare inactivated poliovirus vaccine (IPV), which, after major field trials in 1954, was shown to be highly effective in preventing paralytic disease.¹⁰ Sabin and others soon developed live attenuated strains of the three poliovirus types, which were ultimately incorporated into an orally administered, trivalent polio vaccine (OPV). Because of ease of administration of OPV and improved effectiveness in preventing gut infection with wild polioviruses, Sabin’s vaccine largely supplanted IPV for use in the United States and most of the world beginning in the early 1960s.

The apparent elimination of indigenous spread of wild-poliovirus infections in the United States since 1979 is due to the high coverage with effective poliovirus vaccines. After licensure of IPV in 1955, more than 450 million doses were administered to children and adults during the next five years. During this period, the incidence of

poliomyelitis declined precipitously from 18 cases per 100,000 total population to less than two cases per 100,000. After licensure of OPV in 1961, the incidence of poliomyelitis declined rapidly in the United States and most other industrialized nations, as well as in some developing countries that have achieved high levels of coverage with three or more doses of OPV.¹¹

Immunization, first with IPV, then OPV, eliminated the indigenous wild poliovirus genotypes in the United States in the 1960s. Subsequently, only three outbreaks of poliomyelitis occurred in the 1970s; all of these outbreaks were presumed to be due to imported virus. The only forms of poliomyelitis reported in the United States from 1979–1997 were the 8–10 cases annually of vaccine-associated paralytic poliomyelitis (VAPP).⁶ In addition, during this period on average one poliomyelitis case classified as imported was reported each year. Changes in vaccination policy first decreased, and then eliminated VAPP in the United States after 1999.¹²

Current U.S. Polio Vaccination Policy. Vaccination policies are adjusted periodically to take advantage of new products or scientific findings. From 1955–1961, IPV was the sole vaccine available for polio prevention. Starting in 1961, first monovalent OPVs, and since 1963, trivalent OPV were recommended for routine immunization in the United States. From 1997–1999, a sequential schedule of IPV followed by OPV was used.¹³ Since 2000, polio prevention in the United States relies exclusively on IPV.¹⁴

The recent changes in polio prevention policies were prompted by what in the mid-1990s became an unacceptable risk of VAPP following OPV use, especially since polio had been eliminated in the entire Western Hemisphere by 1991, and the Americas had been certified as free of indigenous wild poliovirus transmission by an international commission in 1994.

A primary series of IPV consists of three doses, administered at 2, 4, and 6–18 months, followed by a booster dose at age 4–6 years just before school entry.¹⁴ One dose of IPV vaccine should be given to previously immunized adults who may be at increased risk of exposure to wild poliovirus (e.g., travelers to polio-endemic areas).

Consequences of OPV Use. While the United States has relied since 2000 on the exclusive use of IPV for polio prevention, more than 160 countries use OPV for routine immunization and campaigns. The use of OPV is associated with VAPP (approximately 250–500 cases each year worldwide), and the emergence of vaccine-derived polioviruses (VDPVs), including circulating vaccine-derived polioviruses (cVDPVs) and immunodeficient vaccine-derived polioviruses (iVDPVs).

cVDPVs have acquired the neurovirulent and transmission characteristics of wild polioviruses, and have caused outbreaks of poliomyelitis in Indonesia (2005), China (2004), Egypt (1988–1993), Hispaniola (2000–2001), Madagascar (2002), and the Philippines (2001).¹⁵ cVDPVs typically have more than 1% sequence diversity from the parental Sabin strains and evidence of recombination with other non-polio enteroviruses. Extensive control efforts relying on massive use of OPV have rapidly controlled these outbreaks.

The World Health Organization (WHO) maintains a registry of cases that have excreted polioviruses for more than 6 months. As of 2006, 33 cases of iVDPVs accumulated over 40 years of observation are included in the registry. All individuals are immunodeficient (with disorders affecting the B-cell system), and live in upper- or middle-income countries. At least one individual in a high-income country has documented evidence of poliovirus excretion for more than 10 years.¹⁶ Analysis of cases from the registry identified two patterns. While most long-term carriers stop virus excretion spontaneously in a 1–3 year period, rarely replication and excretion of virus may continue for a much longer period.

Global Poliomyelitis Eradication Initiative. In 1988, the World Health Assembly adopted the goal of global polio eradication by the year 2000.⁷ The initiative relies on OPV and the following strategies to accomplish the eradication target: (a) achievement and maintenance of high routine vaccination coverage levels among children with at

least three doses of OPV; (b) development of sensitive systems of epidemiologic and laboratory surveillance, including the use of standard case definitions (i.e., acute flaccid paralysis [AFP] surveillance); (c) administration of supplementary doses of OPV to preschool-aged children (generally age <5 years) during National Immunization Days (NIDs) to rapidly interrupt poliovirus transmission; and (d) “mopping-up” vaccination campaigns—localized campaigns targeted at high-risk areas where poliovirus is most likely to persist at low levels.

An extraordinary program of work, and an impressive coalition of partners (including Rotary International), are committed to the eradication of polio. The program of work focuses on surveillance for acute flaccid paralysis (AFP) with stool specimens collected from each case of AFP for virologic investigation in one of the 145 WHO-accredited polio network laboratories, and on support for planning, execution, and evaluation of mass vaccination campaigns. Currently, more than 3000 staff are employed by WHO in the polio-endemic or recently endemic countries.

These efforts have had marked impact on the incidence of reported poliomyelitis cases, which has declined by more than 99% (from an estimated 350,000 cases in 1988 to 784 reported cases in 2003) (Fig. 9-7). During this period, the number of polio-endemic countries decreased from less than 125 to 6. Three WHO regions, comprising 113 member states with more than 3 billion inhabitants, including the Region of the Americas in 1991, the Western Pacific Region in 2000, and the European Region in 2001, are certified as polio-free by international commissions. In addition, at least one poliovirus serotype has already been eradicated; type 2 was last detected in India in 1999.

Although dramatic progress toward a polio-free world has been achieved, by 2003 six countries continued to support the transmission of poliovirus, including Afghanistan, India, and Pakistan in Asia, and Egypt, Niger, and Nigeria in Africa. The polio-endemic countries in Asia represent some of the most densely populated areas in the world. In addition, both in Asia and Africa, high contact rates, tropical climate, and low hygiene and inadequate sanitation, all facilitate poliovirus circulation, and make it particularly challenging to achieve eradication. Furthermore, in 2003, Kano State in northern Nigeria suspended polio vaccination amidst unfounded rumors about vaccine quality and safety. Although the vaccination efforts were resumed in July 2004, in the intervening period a large outbreak in Kano State exported poliovirus into the other parts of Nigeria, and into polio-free countries in West and Central Africa. Thus far, poliovirus was imported in 19 countries in West, Central and the Horn of Africa, as well as the Arabian peninsula (Saudi Arabia, Yemen), and eventually in Indonesia. Control of these imported poliovirus outbreaks has been difficult, requiring several rounds of mass immunization campaigns.

To reach the “finish line” with eradication, since the beginning of 2004, the program has been greatly intensified, focusing on increasing the number of mass campaigns (usually national immunization days [NIDs]) and on enhancing the quality of these campaigns. The key is to reach a very high proportion of the target children aged more than five years. These efforts have met with considerable success, with the incidence of polio reaching its lowest level ever in Asia, and the expansion of the current outbreaks in Africa may have finally been curtailed. In 2005, the intensified efforts will continue, and monovalent OPV, the vaccine that probably eliminated polio in many industrialized countries has been introduced in the most difficult-to-eradicate areas. Monovalent type 1 OPV (mOPV1) is much more immunogenic than trivalent OPV, because of lack of interference with the other Sabin strains, and is expected to provide an additional push to eliminate the final chains of poliovirus transmission, first in Egypt and then in the other polio-endemic countries (Afghanistan, India, Nigeria, and Pakistan).

Although the goal of eradication is an ambitious one, the global poliomyelitis eradication initiative has demonstrated the feasibility of this goal, and it remains for mankind to demonstrate the will and tenacity to see this initiative to a successful conclusion.

*Policy Development for the Post-OPV Era.*¹⁷ A substantial body of research has been compiled since 1988 to assist in long-term strategy

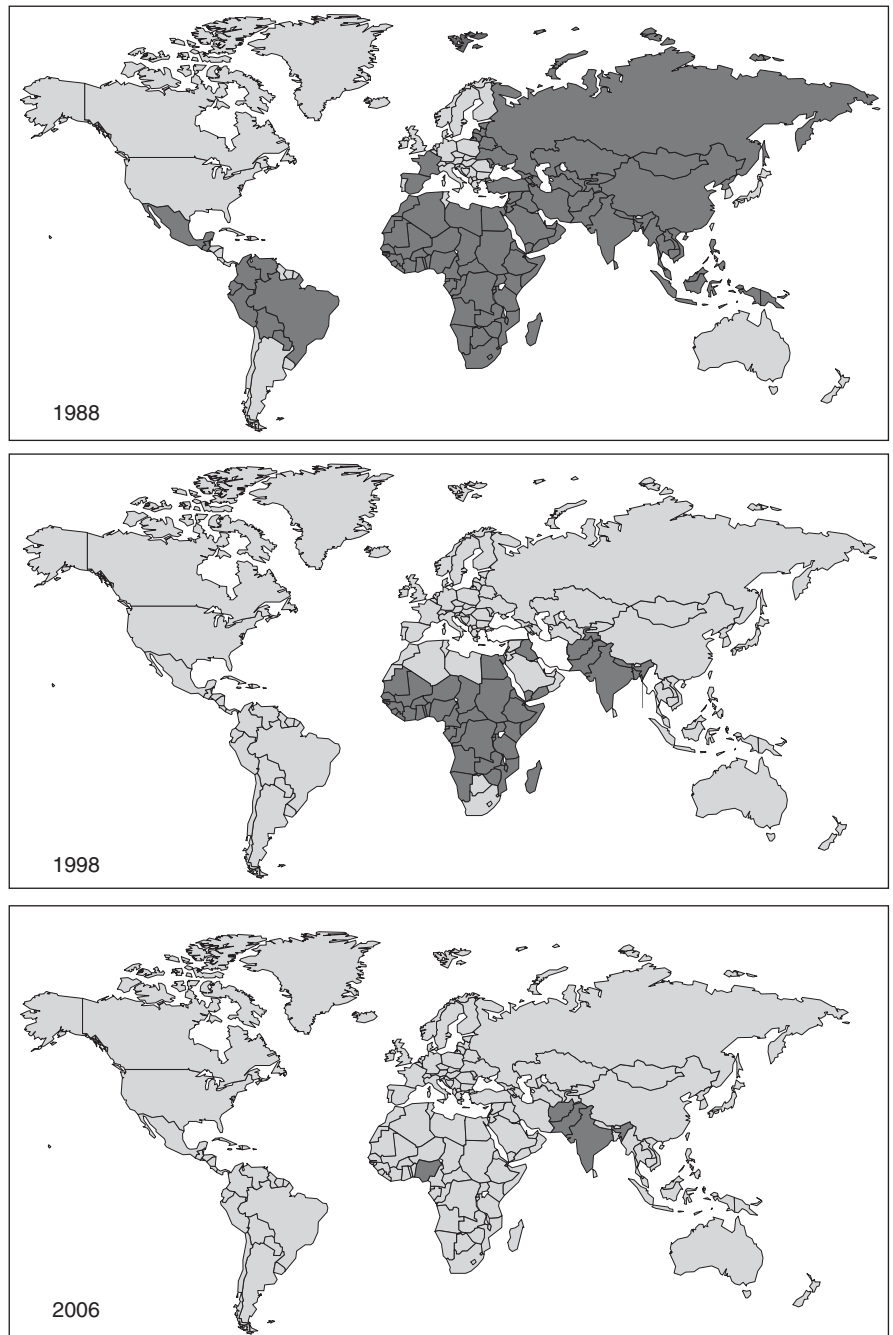

Figure 9-7. Polio-endemic countries, 1988, 1998, and 2006.

development, culminating in 2003, when a WHO consultation on circulating vaccine-derived polioviruses (cVDPVs) concluded that routine use of OPV must be discontinued following polio eradication to ensure eradication of all poliovirus-induced paralytic disease. The consultation recommended that a strategy be developed for coordinated cessation of OPV use as soon as possible after interruption of transmission, when population immunity is expected to be high and before surveillance sensitivity has started to decline.¹⁸ The experts highlighted the need to consider and manage the potential risks associated with stopping OPV.

The priority for OPV cessation planning is to manage the risk of paralytic disease due to any polioviruses among current and future generations of children. After interrupting wild poliovirus circulation globally, the remaining stocks of wild polioviruses and potentially infectious materials will be found only in laboratories and manufacturing sites of IPV. OPV, containing live attenuated strains of all three poliovirus serotypes, will continue to be used in massive quantities (about 2 billion doses per year) for an additional 2–3 years, to verify

eradication and maintain high population immunity levels until OPV use can be discontinued worldwide.

Vaccine-derived polioviruses (VDPVs) can, on rare occasions, establish endemic or epidemic transmission, making continued use of OPV incompatible with polio eradication. Continued use of OPV after interruption of wild poliovirus transmission can cause paralytic disease due to: (a) cases of vaccine-associated paralytic poliomyelitis (VAPP), (b) outbreaks due to circulating vaccine-derived polioviruses (cVDPVs), and (c) long-term excretion of vaccine-derived poliovirus among individuals with primary immunodeficiency disorders (iVDPVs). In addition, there is a risk of paralytic cases due to wild polioviruses from: unintentional release from a contained facility (laboratory or manufacturing site) or intentional release due to an act of bioterrorism or biological warfare. These risk estimates have been quantified, and the evolution of these risks over time estimated (Table 9-4).

While these risks can be quantified assuming current levels of vaccine coverage, the consequences of epidemic virus spread after

TABLE 9-4. RISK ESTIMATES OF PARALYTIC DISEASE DUE TO POLIOVIRUS AFTER POLIO ERADICATION^a

Risks due to	Specific risks	Frequency	Annual burden (paralytic cases)	Expected evolution of risks
Vaccine-derived poliovirus	VAPP ^b	2–4 per million birth cohort	250–500	Stable
	cVDPV ^c	6 episodes during 2000–2005; about 1 episode per year	About 10	Increases (with lower vaccination coverage)
Wild-type poliovirus	iVDPV ^d	33 cases identified since 1961 ^e	<1	Decreases
	Release from IPV ^f manufacturing sites	1 instance, resulting in 1 infection (1990s)	<1	Decreases
	Release from laboratory stocks	2 instances during 2000–2003 (10 paralytic cases)	Unknown	Decreases
	Intentional release	None observed	Unknown	Unknown

^aAssuming continuation of OPV at current levels of use.

^bVAPP = vaccine-associated paralytic poliomyelitis.

^ccVDPV = circulating vaccine-derived poliovirus.

^diVDPV = immunodeficient vaccine-derived poliovirus.

^eBased on WHO unpublished data.

^fIPV = inactivated poliovirus vaccine.

OPV cessation could be substantial. Discontinuation of OPV should eliminate cases of VAPP, substantially decrease and then eliminate the risks of outbreaks due to cVDPVs, and prevent poliovirus exposure among immune-deficient individuals born after OPV cessation.

The rationale for OPV cessation is compelling. A recent WHO advisory committee meeting determined that the following six conditionalities must be met before OPV can be discontinued,¹⁹ including: (a) confirmation of interruption of wild polioviruses; (b) appropriate containment of all polioviruses; (c) global surveillance and notification capacity; (d) mOPV stockpile and response mechanism; (e) coordinated cessation of OPV use; and (f) “post-OPV” immunization policy in place. The timing of OPV cessation is dependent on wild poliovirus

interruption globally. Because of the evolution of the “post-OPV” risks, there may be only a narrow window of opportunity to stop OPV use.

Planning for OPV cessation is focusing on managing the future risks of paralytic disease due to polioviruses. Total elimination of these risks is not feasible. Effective containment should minimize the risks of reintroduction of any poliovirus strains from laboratories or vaccine production sites. Continuing sensitive surveillance should detect the circulation of polioviruses. A coordinated OPV cessation strategy should minimize the risks of emergence of cVDPVs, and the availability of sufficient quantities of stockpile vaccines and the related response capacity should minimize the consequences of poliovirus introduction in a community.

Pneumococcal Infections

Robert B. Wallace

The pneumococcus (*Streptococcus pneumoniae*) is part of the normal bacterial flora of the human nasopharynx and often exists in a commensal relationship with its host. Injury to any region of the respiratory epithelium may disturb this equilibrium, leading to tissue penetration, organism replication, immune system activation, and the development of clinical illness. The pneumococcus was first identified in France and was found in the United States in 1881.^{1,2} Subsequently, data on its recovery from all five continents were reported in 1939, indicating a wide geographic distribution.³ Despite intensive research, widespread antibiotic use, and vaccination, the morbidity and mortality of pneumococcal infections remain significant. *S. pneumoniae* remains the most common cause of bacterial pneumonia^{4,5} and otitis media⁶ worldwide and is a major cause of bacterial meningitis. Before the year 2000, there were approximately 3000 cases of meningitis, 50,000 bacteremias, 500,000 cases of pneumonia, and 7 million cases of otitis media caused by the pneumococcus in the United States.⁷ However, with increased use of pneumococcal vaccine, this may be changing. In the area served by the Acute Bacterial Core Surveillance, the number of invasive pneumococcal infections in 2005 was estimated to be 13.8 per 100,000 and

the death rate 1.5 per 100,000,⁸ about 4425 deaths per year. The public health impact of infections due to this pathogen is only likely to increase with the spread of penicillin-resistant and multidrug-resistant strains.

Pneumococcal Types

Currently 90 different pneumococcal capsular types have been identified.⁹ However, not all isolates can be typed. The composition and quantity of the capsular polysaccharide has an impact on virulence,¹⁰ and as a result, not all serotypes are equally invasive and the majority of infections are due to a relatively small number of serotypes. Approximately one-half of invasive infections are caused by six types, an additional one-fourth by six additional types, and an additional one-eighth by six other types. The distribution of pneumococcal types causing infection has remained fairly stable but does tend to vary somewhat by age, geographic areas, and time.

The distribution of pneumococcal serotypes that cause invasive disease in children is more limited than in adults. As part of ongoing national surveillance, the Centers for Disease Control and Prevention (CDC) recently evaluated 3570 pneumococcal isolates collected between 1978 and 1994 from blood or cerebrospinal fluid (CSF) of children less than six years of age.¹¹ Seven serotypes accounted for 80% of invasive pneumococcal infections. The development of

Note: This chapter was modified from the 14th edition by the editor.

immunologic responsiveness to capsular antigens of many of these types later in life than the immune response to other capsular antigens may explain this distribution. In children older than 2 years of age, the serotypes causing invasive disease are more similar to the strains causing disease in adults.¹² The relatively few serotypes accounting for the majority of invasive infections in young children lead to the licensure in 2000 of a heptavalent conjugate vaccine, which is recommended for all children 2–23 months of age. Although conjugated vaccines may contain antigens for only a limited number of serotypes, unlike the polysaccharide vaccine, they are immunogenic in persons less than two years old.

Compared to infants and young children, a slightly wider range of serotypes account for the majority of invasive pneumococcal infections in the adult population.¹³ In the United States, serotyping of blood and CSF isolates collected between 1978 and 1992 from 2322 unvaccinated persons more than six years of age as part of the CDC's national surveillance program revealed that 65% of invasive infections were caused by 10 different serotypes (listed in descending order: 4, 14, 23F, 9V, 12F, 6B, 3, 8, 1, and 9N).¹⁴ When compared with younger children and with patients from other parts of the world, a slightly different distribution in rank order and capsular types can be appreciated. In North America, infections with type 1 pneumococci occur less frequently than in other parts of the world. Infections with type 2 and 5 pneumococci, which are relatively common in South America, Africa, and Asia, occur only rarely in the United States.¹⁰ Over 30 years ago, organisms of capsular types 1, 3, 4, 7, 8, and 12 caused the majority of invasive diseases. Continued close monitoring of the serotypes responsible for invasive infections in both children and adults will remain important in the formulation and distribution of newer conjugate vaccines.¹¹

Epidemiologic data suggest that genetic constitution may influence susceptibility to infection with certain pneumococcal types.¹² For example, infections with capsular types 45 and 46 have been frequent among black gold miners in South Africa, whereas they have been isolated only rarely from white persons in the same region.

Penicillin resistance was first identified in a type 1 pneumococcus through *in vitro* experiments performed by Eriksen in 1945.¹⁵ In 1967, a penicillin-resistant type 23 pneumococcus was isolated from the sputum of a patient with hypogammaglobulinemia and bronchiectasis who had received multiple prior courses of antibiotics.¹⁶ In 1971, type 4 resistant isolates were recovered from multiple patients in New Guinea who were participating in a trial of prophylactic penicillin use.¹⁷ Substantial surveillance activity has been devoted to documenting the changing rates of pneumococcal antibiotic resistance in the community.^{18,19}

Pneumococcal Colonization

Prior to the advent of conjugated vaccines applied to children, *S. pneumoniae* could be found in the nasopharynx in 5–10% of adults and 20–40% of children without signs or symptoms of clinical disease. Although organisms can be recovered from the nasopharynx of healthy children and adults throughout the year, colonization was apparently seasonal, with an increase in the midwinter period.²⁰ Infants tended to acquire their first pneumococcal type at a mean age of six months, but colonization may begin as early as the day of birth. In this setting, the type acquired is usually the type carried by the mother.^{12,21} The majority of children will have carried at least one type of pneumococcus by the age of two years.¹² In the first years of life, rates of pneumococcal carriage had been high, and children have been found to be colonized sequentially with as many as 12 distinct serotypes.²² Duration of carriage varied somewhat both by serotype and by age. In adults, carriage of a single serotype usually lasted for 1–2 months, but carriage of a single type for longer than three years has been demonstrated.²³ Few data are available concerning the acquisition of new types by adults with the passage of time, but limited findings suggest the number to be one or two per year.²⁴ In the past, rates of pneumococcal carriage tended to decline with age.

Colonization with a given pneumococcal type may be followed by the development of type-specific anticapsular antibody in the

absence of overt signs of clinical illness.²⁵ The presence of circulating anticapsular antibody will not eliminate an established carrier state, but it will reduce the likelihood of being colonized with the same strain by approximately one-half.²⁶ The ability of antimicrobial drugs to eliminate the pneumococcal carrier state in the 1980s seemed limited,²⁷ but there have been few studies in the vaccine era. However, this is consistent with the growing rates of antibiotic resistance among *S. pneumoniae* isolates. In fact, the use of prophylactic antibiotics and frequent antibiotic use has been linked to colonization and infection with penicillin/multidrug-resistant strains. In the past, attempts to eradicate carriage with topical antibiotics, such as mupirocin, have also failed.³⁰

Importantly, the effect of the use of conjugated pneumococcal vaccine in children has led to changes in the carriage rates of *S. pneumoniae* and the serotypes among the isolates found.²⁸ The findings have not always been consistent, but this effect has also been seen on serotype distributions among adults and the elderly.

Organisms spread from person to person in settings that promote close personal contact over prolonged periods. Day care centers have become a well-recognized area of both increased rates of pneumococcal colonization and infection, and the epidemiology of the organism and transmission has been modeled.²⁹ The high carriage rates of pneumococci in children, the selective pressure of antibiotics prescribed for the treatment of otitis media, and crowded conditions make day care centers an optimum environment for the development and spread of penicillin/multidrug-resistant pneumococci.³¹ Increased rates of colonization and infection have also been demonstrated in certain work environments. Outbreaks have been described among adults living in crowded conditions such as military camps, prisons, and homeless shelters.³² Nosocomial outbreaks have been reported as well.^{33,34}

Risk Factors for Invasive Disease

Invasive pneumococcal disease develops when the normal balance between organism colonization and host defense is tipped in favor of disease. Risk factors for invasive pneumococcal disease can be divided into three main categories: (a) factors increasing or altering the normal carrier state, (b) diseases that alter antibody formation or phagocytosis, and (c) multifactorial causes that result in either decreased antibody formation or increased overall susceptibility to infection.

Injury to the epithelial lining of the respiratory tract can disrupt the normal commensal relationship between the organism and the host, causing the development of symptomatic disease. The predisposing injury is usually viral in etiology due to either influenza or another upper respiratory tract pathogen.²⁰ Studies in experimental animals have shown both the normal lung and the normal middle ear to be resistant to pneumococcal infection, but both areas are vulnerable to bacterial multiplication when viral injury has antedated exposure to the bacterium.³⁵ Current and prior tobacco use also increases the risk of invasive pneumococcal disease, presumably from injury to the respiratory lining or impaired mucociliary clearance of organisms.³⁶ Inflammatory conditions of the airways such as asthma and chronic obstructive pulmonary disease (COPD) are also risk factors for pneumococcal disease. As mentioned previously, crowded living conditions can also increase the risk of colonization and thus lead to increased rates of disease when the appropriate conditions or host factors are present.

Diseases such as agammaglobulinemia, IgG subclass deficiency, multiple myeloma, chronic lymphocytic leukemia, lymphoma, and defective complement increase the risk of developing pneumococcal disease, primarily through impaired antibody production. These reduce available opsonizing antibody and diminish the effectiveness of phagocytosis. Neutropenia, either primary or drug-induced, also limits the effectiveness of phagocytosis. A history of splenectomy or autosplenectomy from sickle-cell disease increases the risk of pneumococcal infection through impaired clearance of pneumococcal bacteremia. Other conditions that predispose to pneumococcal disease include hospitalization, malnutrition, cirrhosis, alcoholism, renal

insufficiency, and glucocorticoids. Individuals at extremes of age (infants and elderly) are also at increased risk of pneumococcal infection. Infection with the human immunodeficiency virus (HIV) has become a major risk factor for pneumococcal infection. Pneumococcal pneumonia is 10 times and bacteremia 100 times more frequent in patients with HIV infection than in an age-matched population.³⁷ The frequency of invasive pneumococcal disease did not appear to change much with the introduction of highly active antiretroviral therapy (HAART) therapy.³⁸

Risk factors for colonization and/or infection are similar for penicillin-resistant and multidrug-resistant strains. Risk factors include extremes of age (less than 2 years old or 70 years old and older), previous β -lactam antibiotic treatment, and children and staff in day care centers.³⁹ Other studies have identified as risk factors frequent antibiotic use, use of prophylactic antibiotics for prevention of otitis media, and recent hospitalization in institutions where resistant strains have been introduced.¹⁹

Pneumococcal Resistance to Antimicrobial Drugs

The first drug-resistant pneumococcus recovered from a human was isolated from a patient being treated with Optochin in 1916.⁴⁰ Penicillin resistance was first noted in vitro and in vivo as early as 1943, approximately 15 years after it was first discovered; however, clinical resistance to penicillin was not reported again until 1965.⁴¹ In the late 1960s and early 1970s, an increasing number of resistant strains were identified in New Guinea, Australia, and South Africa. Penicillin interacts with penicillin-binding proteins located in the bacterial cell wall. This interaction impairs the normal synthesis of the cell wall and eventually causes cell death. Resistance to penicillin and cephalosporins develops when genes that encode for penicillin-binding proteins are remodeled with DNA from resistant strains or with DNA from other organisms. This process alters the structure of penicillin-binding proteins, decreasing their affinity for penicillin. Successive mutations are required in the development of penicillin resistance, which may be one reason why, at least initially, penicillin resistance was somewhat slow to develop in the clinical arena.⁴² Since the late 1970s, multiple resistant strains of pneumococci (defined as resistance to at least three antibiotics) have emerged and spread across a wide geographic area.^{43,44} The relation to prescribing of antibiotic use for various purposes in the community has been frequently suggested.⁴⁵

Immunoprophylaxis of Pneumococcal Infections

The high prevalence of pneumococcal infections in all populations, the high mortality unlikely to be further reduced by antimicrobial agents, the high cost of treating pneumococcal infections, and the dissemination of resistant strains provide the basis for immunoprophylactic measures to prevent pneumococcal infections.

The human infant is immunologically immature at birth and demonstrates only a transient IgM response to purified polysaccharide antigens. However, a successful conjugate vaccine for *Haemophilus influenzae* type b has been developed that, when administered to infants, has markedly decreased the incidence of invasive *Haemophilus* infections. Following on that success, in 2000 a conjugated pneumococcal vaccine incorporating capsular types responsible for the majority of invasive disease in children was introduced.⁴⁶ When administered to infants and toddlers, these newer vaccines appear to elicit a good antibody response (IgM and IgG) and show evidence of boosting on repeated vaccination.⁴⁷ Rates of invasive pneumococcal disease have clearly decreased after the vaccine was applied in the community, but surveillance is necessary to assure that outcome persists.^{46,49} Conjugated pneumococcal vaccines also show promise in certain higher-risk populations.⁴⁸

Probably because of exposure and colonization with the more common pneumococcal types during childhood, adults respond to many purified pneumococcal polysaccharide antigens with the formation of IgM and IgG antibodies. Initially a 14-valent pneumococcal vaccine was developed for adults, but this was replaced by a 23-valent vaccine in 1983. The 23-valent vaccine remains in use

today and contains 25 μ g of each of the following capsular types: 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18F, 19F, 19A, 20, 22F, 23F, and 33F. These 23 serotypes cause 88% of invasive pneumococcal infections in both children and adults in the United States. Importantly, 95% of infections due to multi-drug-resistant strains are by serotypes included in the current vaccine. In assessing the efficacy of a vaccine of this complexity, it is important to recognize that the vaccine is designed to prevent 23 immunologically distinct infections, thus its aggregate efficacy can never equal that of a monovalent vaccine.

Several methods had been used to assess the aggregate efficacy of polyvalent pneumococcal polysaccharide vaccines, including randomized, double-blind, controlled trials, quasi-cohort studies, and case-control studies.^{14,50-54} Trials of all three designs found the aggregate efficacy of polyvalent pneumococcal vaccines to be between 60% and 80%, but efficacy is variable, depending on the patient population evaluated. Some authors have questioned whether the vaccine should be strongly encouraged in groups in which efficacy has been less clearly demonstrated. Pneumococcal vaccine is rarely accompanied by untoward reactions, and no permanent injuries or deaths have resulted from its administration. Limited studies in older children and in adults of all ages so far have found no age-related differences in the vaccine's aggregate efficacy. Limited data have also not revealed a decline in protection by the vaccine in the six years following immunization.¹⁴

The vaccine seems to have a protective effect against invasive disease in persons in the general elderly, and likely has some protective effect among high-risk elders as well.⁵⁵ However, the strength of the evidence is modest, depending mostly on observational studies in heterogeneous populations. Clearly, more work is needed to precisely determine the vaccine's effect in the modern era.⁵⁶ Yet, the 23-valent pneumococcal polysaccharide vaccine remains an underutilized preventive health measure, particularly in the prevention of pneumococcal bacteremia.

Epidemiology and Trends in Sexually Transmitted Infections

David Friedel • Suzanne Lavoie

► INTRODUCTION

Three hundred and forty million new cases of curable sexually transmitted infections (STIs) are estimated to occur each year, according to the World Health Organization (WHO).¹ Despite this prevalence, STI infection rates are increasing in most countries, including the United States. In 1997, STIs were labeled a hidden epidemic by the Institute of Medicine (IOM), reflecting that this largely unrecognized U.S. public health threat has a tremendous scope.² Although the IOM report increased awareness of STIs and stimulated progress in prevention and control of STIs, in the United States, STI rates remain the highest in the developed world, even surpassing rates in some developing countries.³

► BURDEN OF DISEASE

In 2004, four of the five most common reportable diseases in the United States were STIs. Approximately 65 million Americans currently live with a chronic viral STI, excluding human immunodeficiency virus (HIV);⁴ and one in two sexually active persons will likely contract an STI by the age of 25.⁵ Yet, because many STIs are asymptomatic and go undiagnosed, current surveillance systems probably underestimate the actual burden of disease. In truth, the prevalence of STIs in the United States is largely unknown; however, STIs are unquestionably a substantial health and economic burden.

Chlamydia, gonorrhea, acquired immunodeficiency syndrome (AIDS), and syphilis ranked first, second, third, and fifth among infectious diseases reportable to the National Notifiable Diseases Surveillance System (NNDSS), with chlamydia and gonorrhea alone accounting for 80% of these cases.⁶ Preliminary data from NNDSS for 2005 indicate similar trends.⁷ For non-reportable diseases such as trichomoniasis and human papillomavirus (HPV), data collection is less complete; however estimates from alternate sources suggest that both occur more frequently than chlamydia.⁸ The estimated incidence of selected STIs in the United States is summarized in Table 10-1.

Estimates of 2004 (by the Centers for Disease Control and Prevention [CDC] and Family Health International) reveal that approximately 18.9 million persons acquire an STI each year.⁸ An estimated 15 million incident cases of STIs occurred in the United States in 1996, a 25% increase from 1988. However, this trend likely reflects expansion of screening programs and increased use of more sensitive diagnostic tests, rather than an actual increase in new infections.^{8,9} Excluding HIV infection, approximately 20 million adverse health events (7515 per 100,000 population) were attributed to sexual behavior in 1998, contributing to 1.5 million disability adjusted life years (DALY).¹⁰

The economic burden of STIs is substantial, with direct medical costs estimated at \$9.3–\$15.5 billion annually (in year 2000 dollars).⁵ And these estimates do not account for indirect costs from productivity losses (lost wages) or intangible costs from pain, suffering, or diminished quality of life. Although adolescents and young adults aged 15–24 years constitute only 25% of the sexually active population, they acquire 9.1 million (48%) of new STIs cases, contributing disproportionately to the total economic burden of STIs. Among 15–24-year olds, the incident cost of the approximately nine million new STIs in 2000 was \$6.6 billion: viral STIs account for 94% (\$6.2 billion), and bacterial STIs for 6% (\$0.4 billion). In this age cohort, HIV and human papillomavirus alone accounted for 90% of the total burden (\$5.9 billion); and genital herpes (\$293 million) and chlamydia (\$248 million) were the third and fourth most costly STIs.¹¹

► STI PROGRAM ORGANIZATION

The public health of the nation is managed by several federal agencies in collaboration with 3186 local health boards, 2864 local health departments (LHDs), 57 state and territorial health departments, 499 tribal health facilities, and approximately 1900 public health laboratories.^{12–16} This governmental network is augmented by numerous national associations, including the National Association of County and City Health Officials (NACCHO), the Association of State and Territorial Health Officials (ASTHO), the Association of Public Health Laboratories (APHL), the Council of State and Territorial Epidemiologists (CSTE), and the National Coalition of Sexually Transmitted Disease (STD) Directors.^{17,18}

Federal Government

The lead federal agency in STI control and prevention is the CDC. The CDC provides leadership through surveillance, epidemiologic research, policy development, technical assistance, funding, and education. The National Institutes of Health (NIH) complements the CDC's mission by providing support for basic science and applied clinical research.

Major CDC-sponsored STI initiatives include the National Plan to Eliminate Syphilis, launched in 1999 and intended to capitalize on the prior decade's declining syphilis rates;¹⁹ the Infertility Prevention Project, designed to control STI-related infertility by providing chlamydia screening and treatment services for sexually active, low-income women attending family planning and public health clinics;²⁰ the Gonococcal Isolate Surveillance Project, established in 1986 to

TABLE 10-1. ESTIMATED INCIDENCE OF SELECTED STIs, UNITED STATES, 1996 AND 2000

STI	1996	2000
Chlamydia	3 million	2.8 million
Gonorrhea	650,000	718,000
Syphilis	70,000	37,000
Herpes	1 million	1.6 million
Human papillomavirus	5.5 million	6.2 million
Hepatitis B	77,000	81,000
Trichomoniasis	5 million	7.4 million
Total	15.3 million	18.9 million

State and Local Government

State and local health departments have statutory responsibility controlling many communicable diseases, including STIs.²³ These departments collaborate with other public agencies, as well as private and nonprofit organizations, to deliver essential services. These partnerships include hospitals, managed care-organizations, community-based organizations, correctional facilities, and academia.²

► **STI PROGRAM INFRASTRUCTURE**

Eight services and functions were identified by the CDC as being essential to STI programming (Table 10-2).²⁴ Delivery of essential services requires a public health infrastructure that enables state and local public health departments to apply the necessary skills, knowledge, and resources. During the past two decades, however, the infrastructure supporting STI programs has been challenged by several emerging trends, including decreased federal funding, state and local fiscal austerity, the emergence of new pathogens and public health threats, and the implementation of managed care.^{18,25} The net effect has been the reduction or elimination of many programs related to STI prevention.

To better understand STI infrastructure needs, in 2001, a needs assessment was conducted among members of the National Coalition of STD Directors (NCSD).²⁵ Forty-seven (72%) of eligible NCSD members participated, representing health department STI programs from 41 states, 5 major cities, and 1 U.S. territory. Approximately 43% of programs in the sample provided integrated STI/HIV services. The remaining 57% offered STI- and HIV-related services in separate programs. A summary of reported infrastructure needs is presented in Table 10-3.

Funding of STI Programs

Funding is critical to maintain and improve STI program infrastructure. The CDC is the nation’s primary distributor of federal funds to state and local health departments for a variety of public health activities. Since the CDC’s inception in 1946, the agency’s annual budget increased from \$9.1 million (adjusted year 2006 dollars) to \$8.4 billion.^{26,27} However, federal funding of the CDC’s National Center for HIV, STD, and Tuberculosis Prevention (NCHSTP) has not proportionately increased. When adjusted for inflation, funding of NCHSTP programs did not increase significantly from

1996–2000;²⁵ and from 2000–2002, the NCHSTP budget increased from \$8.5 billion to a peak of \$11.6 billion.^{28–30} Every subsequent year, NCHSTP funding for STI control and prevention programs has declined.^{31–33} Furthermore, the CDC fiscal year 2006 budget allocated only \$9.5 billion to the NCHSTP,²⁷ with 69% of these funds designated for categorical HIV programs, and only 15% allocated to STI prevention and control.

TABLE 10-3. SELECTED STI PROGRAM INFRASTRUCTURE NEEDS BY PUBLIC HEALTH ACTIVITY

Activity	Program Infrastructure Need
Surveillance	Increased and more flexible spending
	Technical assistance with surveillance program development
	Expanded information systems infrastructure
Intervention services	Enhanced capacity to conduct data analysis
	Increased funding to hire, train, and retain qualified staff
	Rapid access to health education and media materials
	Reduction of state policy barriers regarding staff hiring
Outbreak response	Technical assistance with implementation of behavioral interventions
	Model template for outbreak preparedness
	Capacity to rapidly collect and analyze data
Clinical services	Access to stat laboratory services
	Increased spending for clinical services improvements
	Access to state of the art diagnostic technology
Information Dissemination	Methods to improve efficiency
	Technical assistance with CLIA [†] regulations
	Improved information sharing among STI jurisdictions
	Models of information campaigns
Program Evaluation	Increased funding for sophisticated information dissemination activities
	Technical assistance with program evaluation
	Financial resources for program evaluation
Policy activity	Technical assistance regarding key STI policy initiatives
	Policy skill development

Additional sources of federal funding for STI control and prevention are available. By consolidating several categorical CDC programs, the Omnibus Budget Reconciliation Act of 1981 amended Title XX of the Social Security Act to create Preventive Health and Health Services (PHHS) Block Grants. PHHS block grants provide 50 states, the District of Columbia, 2 Native American Indian tribes, and 8 U.S. Territories with the autonomy to address any of the 265 national health objectives outlined in Healthy People 2010.³⁴ Funding for PHHS block grants decreased from \$145 million in 1996³⁵ to \$119 million in 2005.³⁶ PHHS block grants were eliminated in President Bush's original budget proposal for fiscal year 2006, but Congress restored the program and provided \$100 million in funding.³⁷

Block grant recipients depend heavily on this flexible source of funding to support public health activities unique to their jurisdictions, especially when no other adequate financial resources are available. However, despite recognition of the increasing incidence of STIs, relatively few states dedicate any of the PHHS block grants to STI prevention efforts. During 2005, 13 PHHS grantees allocated a total of \$1.9 million to STI prevention and control,³⁸ with allocations ranging from \$4000 to \$391,419 per funded program.³⁹ Collectively this represented only 1.6% of the total PHHS grant money.³⁵

The precise amount of state- and local-level funding for STI prevention from nonfederal sources is unknown. In 1994, an informal CDC survey estimated the total state and local contributions to STI programming to be approximately \$126 million, representing 58% of combined federal, state, and local funding.² Based on a limited sample of 32 jurisdictions, the National Coalition of STD Directors (NCSDD) estimated that after adjusting for inflation, state contributions to STI programs did not significantly change from 1995–2000.²⁵

In 1994, the public sector spent only \$1 on STI prevention for every \$43 spent on treatment costs, and it invested only \$1 in biomedical and clinical research for every \$94 in disease-related expenditures. Despite these discrepancies, the IOM and CDC stress that STI prevention efforts are cost-effective.^{2,40} For example, every \$1 spent on early detection of chlamydia saves an estimated \$12 in direct and indirect medical costs. Similar studies recently demonstrated the cost-effectiveness of federally funded gonorrhea control programs. From 1971 to 2003, an estimated 32 million new cases of gonorrhea costing \$8.1 billion were averted as a result of \$4.3 billion in federal STI prevention investments.⁴¹

Public Health Workforce

The nation's public health workforce increased steadily from 486,986 full-time employees (FTEs) in 1994 to a peak of 555,584 FTEs in 2003. This trend has since reversed, and the workforce has declined at an average rate of 2828 FTEs per year.⁴² In 2005, the U.S. Census Bureau estimated that 549,928 FTEs were employed in public health, with 23%, 32%, and 45% of these professionals deployed at the federal, state, and local levels, respectively.⁴³

Twenty percent of local health departments (LHDs) employ fewer than 5 FTEs and nearly 60% employ fewer than 25 FTEs. Eighty-one percent of LHD directors do not have a graduate degree in public health. Among the 246,300 salaried public health employees at the local level, approximately 27% are clerical staff, 24% are registered nurses, 6% are managers, 1.2% are physicians, and only 0.8% are epidemiologists.¹³

The recent decreases in the public health workforce have adversely impacted the organizational capacity of state and local health departments. In particular, LHDs serving larger jurisdictions experienced marked reductions in staffing. From 1996–1997 to 2005, the median number of employees decreased by 23% for LHDs serving 500,000–999,999 people and by 15% for LHDs serving one million or more.¹³ These reductions are the result of multiple influences, including decreased federal funding, state and local capitation of FTEs, and the redistribution of financial and human resources to HIV and bioterrorism programs.²⁵

Disease Intervention Services

Disease intervention services (DIS) have been an essential component of the state and local public health effort since 1937, when then Surgeon General Thomas Parran advocated contact tracing to “prevent new chains of (syphilis) infection.”⁴⁴ DIS staff responds to reports of communicable diseases and conducts field investigations of positive STI cases, including client and partner notification.² STI programs expend considerable time and financial resources to provide specialized training to these individuals, as approximately 33% of the average STI program's human resource effort is focused on disease intervention.²⁵

Several STI programs previously relied directly on federal public health advisors (PHAs) provided by the CDC to conduct intervention services. Historically, these federal disease intervention specialists provided significant technical support for many states and served in key STI management positions.^{2,25} In 1993, a federal policy decision reduced PHAs in state STI programs. The mean number of PHAs per jurisdiction providing DIS declined from 6.3 in 1990 to 1.2 in 2000.²⁵ These federal positions have not been replaced by reciprocal federal or state resources, resulting in the inability of some programs to effectively respond to STIs. In the NCSDD needs assessment, one-half of STI program directors indicated that losing PHAs negatively affected local STI prevention efforts.^{2,25}

Information and Data Systems

The foundation of the public health STI surveillance system in the United States is the Nationally Notifiable Diseases Surveillance System (NNDSS), coordinated by the CDC and the Council of State and Territorial Epidemiologists (CSTE). The system relies on passive reporting of cases to local or state health departments by physicians, laboratories, and hospitals.^{2,45,46} NNDSS receives voluntary reports of notifiable diseases from health departments in 50 states, 5 territories, New York City, and the District of Columbia.⁴⁷ Because reporting is mandated by law or regulation only at the state level, the list of diseases that are considered notifiable varies slightly among states.^{45,46} In 2005, all states required reporting of chlamydia, gonorrhea, syphilis, AIDS, and hepatitis B virus (HBV).⁴⁷

Additional monitoring of STI activity can be derived from four ongoing surveys conducted by the National Center for Health Statistics (NCHS):^{2,9} the National Health and Nutrition Examination Survey (NHANES), which collects clinical and laboratory data on a representative sample of Americans;⁴⁸ the National Hospital Discharge Survey, which collects data from approximately 370,000 inpatient records acquired from a national sample of 500 short-stay hospitals;⁴⁹ the National Ambulatory Medical Care Survey, which is a probability survey of 25,000 patient visits to nonfederal, office-based physicians;⁵⁰ and the National Hospital Ambulatory Medical Care Survey, which is a probability sampling of patient visits to emergency departments and outpatient departments of 500 nonfederal, short-stay hospitals.⁵¹ A private survey of 3600 office-based physicians by the National Disease and Therapeutic Index (NDTI) is conducted quarterly and provides additional data on epidemiologic trends and treatment patterns.⁵²

Information about infections that are reportable to state health departments are affected by completeness of diagnosis, screening, and reporting. Because many STIs are asymptomatic, infected individuals may not seek medical attention, and these cases remain unrecognized.^{2,5} As a result, reported disease rates significantly underestimate the true burden of infection. For example, in 2004, the CDC received only 929,462 reports of chlamydia infection, whereas population estimates suggest an actual incidence of 2.8 million cases.^{8,9} Even when symptomatic STI prompts an individual to seek health care, the diagnosis must be correct and then communicated to appropriate public health authorities.^{2,5} Unfortunately, health-care providers may not always report nationally notifiable STIs, such as gonorrhea, chlamydia, and syphilis. For these three bacterial pathogens, completeness of reporting to NNDSS is estimated to range from 42–95%.⁵³

These reporting problems are amplified among diseases such as trichomoniasis, genital herpes, and HPV infection, which are not currently nationally notifiable diseases.

Differential reporting by public and private health-care providers also influences estimates of STI incidence and prevalence. Infections diagnosed in public health facilities are more frequently reported, biasing results to reflect the population who most often use these clinics.⁵⁴ Data from private physicians' offices are often affected by a lack of laboratory validation, relying instead on clinical diagnosis and syndrome management.⁵ Completeness of reporting is influenced by several additional variables, including the diagnostic facilities available; the control and prevention measures in effect; and the interests, resources, and priorities of state and local public health officials. Factors such as changes in case definitions for public health surveillance, introduction of new diagnostic tests, or the discovery of new disease entities can cause changes in disease reporting that are independent of the true incidence of disease.⁴⁶

National surveys are limited by their size and the superficial nature of their analytic variables. Because numbers of STI cases in these samples are relatively small, subpopulation analysis often produces wide confidence intervals of unclear significance.⁵ These surveys are also subject to geographic and population biases. Identifying a history of STI using self-reports also introduces recall and misclassification biases, problems increasingly being addressed by use of biomarkers to measure current or past infections.

Clinical Services

STI clinical services are provided primarily in one of three settings: (a) dedicated public STI clinics operated by local health departments; (b) publicly funded community-based health clinics; and (c) private health-care settings.² The results of population-based surveys suggest that 40–60% of STI care occurs in the private sector.^{55,56} In the National Health and Social Life Survey, 71% of respondents diagnosed with an STI during the previous year received treatment in a private practice, community health center clinic, emergency room, or family planning center.⁵⁶ In contrast, only 5% reported seeking treatment in a dedicated public STI clinic. This latter finding requires cautious interpretation, because 23% of respondents with an STI diagnosis did not specify the care setting. Although dedicated STI clinics appear to serve only a small percentage of patients, research conducted in these public clinics generates most of the science base informing STI policy in the United States.⁵⁷ Because STI clinic patients have unique sociobehavioral characteristics, generalizing this research to other populations is questionable.

Public STI Clinics

Public STI clinics were established in the 1910s, despite opposition by organized medical societies.⁵⁸ These clinics were intended to increase the availability of confidential and anonymous STI services, as well as provide a safety net for medically underserved populations and those with no other access to care. Public STI clinics are located in all 50 states, most metropolitan areas, and a significant number of nonmetropolitan locales. Services are generally provided at no charge to the client, although some clinics require a nominal fee or use an income-based sliding scale. Clinics are most frequently operated by local health departments, often in association with medical school or other academic institutions.²

Approximately 51–65% of STI clinic attendees are younger than 25 years, and the reported proportion of male clients varies from 40–51%. Minorities constitute 45–64% of clients, and, nearly 50% of clinic attendees live below the federally designated poverty level.^{59,60} Fifty-nine percent of attendees are uninsured, 27% have private insurance, and 14% have Medicaid.⁵⁹ A prior history of STI is elicited in as many as 31% of public STI clinic clients.⁵⁶

In 2005, LHDs provided 64% and 61% of STI screening and treatment, respectively. Compared to 1992–1993, this represents a 9% decrease in screening and a 6% decrease in treatment services.

LHDs serving larger jurisdictions are much more likely to provide these services. For example, 89% of LHD serving jurisdictions larger than 100,000 people provided screening services, compared to only 49% of LHDs serving jurisdiction less than 25,000 people. In 6–7% of jurisdictions, screening and treatment services are provided via contract with other organizations. Only 43% of LHDs employed physicians in 2005, a marked decrease from 62% in 1989.¹³ Services are generally available only during weekday business hours. Twenty-three percent of LHDs operate at least one STI service site with hours after 6 pm, and only 5% operate a site with weekend hours.⁶⁰

Community-Based Clinics

A variety of community-based clinics provide ancillary STI-related services, including family planning clinics, prenatal clinics, school-based clinics, homeless programs, and community-based health centers. Although the clients attending community-based and dedicated STI clinics share similar demographic characteristics, there are important differences. Individuals who attend community-based clinics frequently rely on these clinics for regularly scheduled preventive health care, whereas dedicated STI clinics typically provide episodic, acute care. Proportionately more STIs, therefore, are identified through screening activities than by evaluating acutely symptomatic individuals.² In 1999, publicly funded community-based clinics routinely screened 73%, 72%, and 44% of their clients for chlamydia, gonorrhea, and syphilis, respectively. Screening was less common for viral STIs. Forty-eight percent of these clinics routinely screened for HPV, and only 23% screened for genital herpes. Virtually all clinics providing STI testing also provided treatment.⁶¹

Family planning clinics funded by Title X are the best studied of the various community-based clinics. Title X of the Public Health Services Act is a federally administered grant program which funds more than half of the approximately 7000 family planning clinics nationwide. Sixty percent of these sites are operated by state, county, or local health departments.⁶² Program guidelines strongly encourage Title X sites to provide extensive STI services. Approximately 18% of U.S. women who required STI testing and treatment during 1995 relied on Title X-supported clinics to provide these services.⁶² Title X clinics performed nearly 20.8 million STI tests, excluding HIV, between 2002 and 2005, compared to 17.6 million STI tests, between 1995 and 1998.^{62–65} Some evidence suggests that the increasing number of tests being performed represent a true increase in STI caseload, as opposed to a change in screening practices.⁶⁶

Historically, family planning clinics primarily served women. In 1976, only 1% of the 3.4 million clinic attendees were male,⁶⁷ despite approximately 20% of clinics purporting to offer male reproductive health services.⁶⁸ A 1987 pilot study found that most clinics were interested in providing services to men;⁶⁹ by 1995, nearly 40% of family planning clinics were routinely doing so.⁷⁰ Men accounted for 4% of all STI tests performed at family planning clinics in 2001⁷¹ and 6% of all tests in 2005.⁶⁵ Although most family planning clinic attendees are women, a non-negligible number are men (5% in 2005).⁶⁵ The number of men using family planning agencies for STI services has slowly increased,^{72,73} and further increases are anticipated now that the Title X program recently designated men as a priority population.⁷⁴

Several trends have emerged to challenge the ability of Title X sites to provide continued high quality STI care.⁶⁶ Testing and screening costs have markedly increased, reflecting both the increased cost per test and the greater number of tests being performed.^{66,75} The average purchase price for STI tests increased 94% from 1998 to 2001. For chlamydia specifically, the average cost per test increased from \$4.10 in 1998 to \$5.80 in 2001.⁷⁵ Similar to other federally funded programs, financial allocations to Title X programs have decreased. After adjusting for inflation, the program's funding level of \$283 million in 2006 was 59% lower than the 1980 level.⁷⁶

Private Sector Settings

The most recent estimates indicate that 49% of new STI cases are treated by private-practice physicians, and an additional 7% are

treated in emergency departments.⁵⁶ The role of managed care organizations in preventing and treating STIs has received particular attention², and several excellent reviews on this topic have been published recently.^{77–81}

Relatively little data exist on STI practices in the private setting.² A recent national survey of 4226 physicians (87% private practice) representing four primary care disciplines plus emergency medicine revealed that fewer than 20% screened male patients for syphilis, gonorrhea, or chlamydia.⁵⁷ Screening rates of nonpregnant and pregnant women ranged from 20–35% and 30–32%, respectively. When obstetricians were considered separately, STI screening rates for pregnant women increased, although remained 15–22% below the current recommendation for universal screening.⁸² Nearly one-half of physicians surveyed were unfamiliar with disease reporting requirements in their states, and few private physicians engaged in partner notification. Depending on the specific STI, 25–34% of private physicians instructed patients to self-report to the health department, and 80–89% encouraged patients to self-notify their partners.⁵⁷ These findings suggest a potential role for increased public and private sector collaboration in improving the quality of STI care.

► CONSEQUENCES OF STIs

Four key, long-term health consequences make controlling STIs a crucial public health priority: (a) female reproductive morbidity due to pelvic inflammatory disease and its sequelae, (b) STI-related neoplasia, (c) adverse perinatal outcomes, and (d) STI-mediated facilitation of HIV transmission.

Female Reproductive Morbidity

Women are disproportionately affected by the adverse reproductive consequences of STIs. STI-related morbidity in women includes pelvic inflammatory disease, ectopic pregnancy, infertility, and chronic pelvic pain.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an ascending infection of the female reproductive tract that may involve the uterus, fallopian tubes, ovaries, or adjacent pelvic structures. Involvement of these structures results in endometritis, salpingitis, oophoritis, peritonitis, or tubo-ovarian abscess. Most cases are considered to be sequelae of the sexually transmitted pathogens *Neisseria gonorrhoeae* and *Chlamydia trachomatis*.^{83–85} Risk of progression to PID following acute chlamydial or gonococcal cervicitis depends on whether the initial infection is successfully treated. If not diagnosed and treated, an estimated 10–40% of women with cervicitis develop PID.^{86–89} Because approximately 70% of chlamydia infections and 50% of gonococcal infections may be asymptomatic^{9,90}, delays in diagnosis are common, and PID may develop in 3–6% of cases despite adequate antibiotic treatment.^{91–93}

Precise estimates of the incidence of PID in the United States are not clear, as the condition is not reportable. Estimates provided by the CDC, using NCHS and NDTI databases, suggest that 750,000–1 million new cases are diagnosed each year.⁹⁴ Hospitalizations for acute PID declined steadily through the 1980s and early 1990s and have remained relatively constant at approximately 70,000 cases per year since 1995.⁹ Initial visits to physicians' offices for PID have declined by approximately 60% since 1990, and the number of cases of PID diagnosed in emergency departments decreased from 268,018 in 1999 to 168,837 in 2003.^{9,95} The declining incidence in recent years likely reflects improvements in screening and treatment programs nationwide.

PID is associated with significant morbidity, suffering, and cost. The long-term sequelae of PID result primarily from scarring and adhesion formation that accompanies healing of damaged tissue. Among women with a history of PID, tubal scarring causes involuntary

infertility in 20%, ectopic pregnancy in 9%, and chronic pelvic pain in 18%.⁹⁶ Direct medical expenditures for PID, including sequelae, were estimated at \$1.9 billion in 1998: \$1.1 billion for PID, \$360 million for infertility, \$295 million for ectopic pregnancy, and \$166 million for chronic pelvic pain.⁹⁷ More recently, direct expenditures¹¹ and mean productivity losses⁹⁸ per case of acute PID were estimated at \$1334 and \$649, respectively.

Ectopic Pregnancy

The rate of ectopic pregnancies in North America increased dramatically from less than 0.5% of all pregnancies in 1970 to 2% in 1992.^{99–101} Currently in the United States, an estimated 100,000 ectopic pregnancies occur annually.¹⁰² Although fatality rates declined from 35.5 per 10,000 ectopic pregnancies in 1970 to 2.3 per 10,000 in 2003,¹⁰³ ectopic pregnancy remains the leading cause of pregnancy-related maternal death during the first trimester and accounts for 9% of pregnancy-related maternal deaths overall.¹⁰⁴

The rising incidence of ectopic pregnancy is strongly associated with an increased incidence of PID.¹⁰⁵ Chlamydia-associated PID alone has been implicated in nearly one-half of ectopic pregnancies.¹⁰⁶ A prior episode of PID confers a seven- to tenfold increased rate of ectopic pregnancy.¹⁰⁷ Rates also increase with successive episodes of PID, from 6% for one episode to 22% for three or more episodes.¹⁰⁸ Severity of infection also predicts a greater likelihood of ectopic pregnancy.^{96,109,110} Following an episode of laparoscopically mild-to-moderate PID, approximately 10–15% of conceptions will be ectopic. The risk increases to almost 50% following severe PID.¹¹⁰

Infertility

Approximately 12–40% of women with involuntary infertility are infertile as a consequence of PID.^{2,96,107–108,111} Subclinical PID may account for a substantial proportion of these cases. In one study of 112 infertile women, 36 had laproscopic evidence of tubal adhesions or distal occlusion consistent with prior PID but only 11 reported a history of this diagnosis. In addition, one-third of infertile women with no history of PID harbor persistent *Chlamydia trachomatis* in the upper genital tract despite the absence of clinical findings.^{112,113}

Tubal factor infertility after PID is associated with the number and severity of PID episodes.⁹⁶ Risk correlates most closely with the laparoscopic severity of disease. Infertility occurs in 3–10% of patients with mild disease, 13–29% with moderate disease, and 29–50% with severe disease.^{113,114} Risk also increases substantially with recurrent episodes of PID, ranging from 8% following one episode to 40% following three or more episodes.¹¹⁵

Delaying treatment of PID also substantially impairs future fertility. In a case control study of 76 women with infertility or ectopic pregnancy and 367 controls with intrauterine pregnancy, women who delayed seeking medical attention were three times more likely to experience infertility.¹¹⁶ The association was strongest for PID due to chlamydia infection: 17.8% of women who delayed treatment developed impaired fertility, compared to 0% of those who promptly sought care.

Chronic Pelvic Pain

Chronic pelvic pain is the least studied long-term sequelae attributed to PID. The syndrome presumably results from adhesions and fixation of pelvic organs intended to be mobile during physical activity, sexual intercourse, and ovulation. The condition is associated with reduced physical and mental health, social function, and quality of life.^{117,118} The indirect costs of chronic pelvic pain are estimated at \$555 million per year,¹¹⁸ whereas direct medical costs are estimated at \$166 million.¹¹⁹

An estimated 18–56% of women with symptomatic PID subsequently develop chronic pelvic pain.^{110,113,120–122} Similar to ectopic pregnancy and infertility, the probability of developing chronic pelvic pain is proportional to the number and severity of PID episodes.¹²³

Women previously hospitalized for a diagnosis of PID are four to ten times more likely than controls to require future readmission for abdominal or pelvic pain.¹²⁴

STI-Related Neoplasia

Several sexually transmitted pathogens are implicated in cancer pathogenesis. Epstein-Barr virus (EBV) and human herpes virus type 8 (HHV-8) are lymphotropic herpesviruses transmitted via sexual or other intimate contact. HHV-8 is the cause of Kaposi's sarcoma, a disseminated polyclonal tumor in AIDS patients, while EBV is associated primarily with T- and B-cell lymphomas. Human T-cell lymphotropic virus type 1 is associated with adult T-cell leukemia/lymphoma, and Hepatitis B virus (HBV) is a major cause of hepatocellular carcinoma. Lastly, human papillomavirus (HPV) infection is associated with squamous intraepithelial lesions and anogenital malignancies, including cervical, vaginal, vulvar, penile, and anal carcinoma. Liver, cervical, and potentially anal cancers are vaccine-preventable, and these malignancies will be discussed in more detail.

Cervical Cancer

The most important public health consequence of genital HPV infection is cervical cancer. Cervical cancer is the second most common cancer among women worldwide, with an estimated 493,000 new cases and 274,000 deaths in 2002.¹²⁵ Approximately 83% of cases occur in developing countries, where estimated mortality rates are 11.2 deaths per 100,000.¹²⁶ In the United States, an estimated 9700 women developed cervical cancer in 2006; and 3700 women died from the disease.¹²⁷ From 1975–2003, the annual incidence rate for cervical cancer among American women decreased from 14.8 to 7.1 cases per 1,000,000. During the same interval, mortality rates decreased from 5.6 to 2.5 deaths per 100,000 women.¹²⁸ This substantial decline in incidence and mortality in Western countries is the result of well-developed Papanicolaou (Pap) smear screening programs.^{129,130} Cervical cancer typically has a long pre-invasive state, with progression from precancerous lesions to invasive disease requiring an estimated 9–15 years.^{131,132} Therefore, regular Pap screening allows early detection and an opportunity for preventing cervical cancer through management of pre-invasive disease. Approximately 60% of invasive cervical cancers occur in women who have either never been screened or have not been screened in the preceding five years.^{133–136}

Evidence linking HPV to cervical intraepithelial neoplasia^{137,138} and invasive cervical carcinoma is extensive.^{139–142} Polymerase chain reaction (PCR) data pooled from 11 case-control studies showed HPV DNA was present in 90.7% (1739 of 1918) of patients with histologically confirmed cervical cancer, but only in 13.4% (259 of the 1928) of control women.¹³⁹ This study estimated that the pooled odds ratio was 158.2 (95% CI 113.4–220.6) for the association between squamous-cell cervical carcinoma and the presence of HPV DNA. HPV types 16 and 18 account for approximately 50% and 15–20% of cervical cancer cases, respectively.¹⁴³ Both the International Agency for Research on Cancer and the NIH classify these high-risk genital HPV types as human carcinogens.^{142,144}

Persistent HPV infection with high-risk types is the most important risk factor for cervical cancer precursor lesions.^{145–153} Although no consensus definition exists, persistence is most commonly defined as detection of the same high-risk HPV types at two or more visits, 4–6 months apart. Studies demonstrate that, compared to controls, women with persistent high-risk HPV infection increase their risk of having cervical cancer precursors by 10- to 17-fold.^{147,150–151} Fortunately, persistent HPV infection infrequently progresses to cervical intraepithelial neoplasia,^{150–155} with fewer than 5% of those with persistent infection subsequently developing precancerous lesions.^{150,154}

Anal Cancer

In comparison to cervical cancer, anal cancer is uncommon. An estimated 4660 cases occurred in the United States during 2006, comprising

only 0.33% of all new cancer diagnoses.¹²⁷ However, the incidence of anal cancer is increasing,^{128,156–159} especially among men who have sex with men.^{160–163}

Multiple epidemiologic, histopathologic, and molecular associations suggest that anal cancer behaves like cervical cancer in that both share an etiologic link to high-risk types of HPV infection. HPV DNA has been isolated from 46–100% of in situ and invasive anal cancers.^{164–170} As in cervical cancer, HPV 16 is the genotype most frequently isolated in anal cancers, being present either singly or in combination in 73–84%.^{164,165,167,169,171} Similar to cervical intraepithelial neoplasia, a premalignant condition also occurs with anal HPV infections; and both cancers share similar cytologic grading systems for dysplasia.¹⁷⁰ Unlike cervical cancer, the utility of routine screening for anal intraepithelial neoplasia has not yet been rigorously studied.¹⁷² Nonetheless, because cytological screening reduced cervical cancer incidence, some practitioners have adopted anal Pap smear screening as a standard intervention in high-risk populations, including men who have sex with other men (MSM) and HIV-positive individuals.

Liver Cancer

Liver cancer is the sixth most common cancer worldwide¹²⁵ and in the United States, is the eighteenth most common malignancy, with an estimated 18,500 new cases and 16,200 deaths occurring in 2006.¹²⁷ Approximately 83% of all liver cancers are hepatocellular carcinomas (HCC).¹⁷³

Despite an increasing association between liver cancer and hepatitis C virus (HCV) infection in the Western Hemisphere and Japan^{174–176}, chronic hepatitis B virus (HBV) infection remains the most important cause of HCC worldwide.¹⁷⁴ HBV infection causes 35% and 6.2% of HCC in developing countries and North America, respectively.¹⁷⁷ And a meta-analysis of 21 case-control studies of chronic HBV carriers showed that their pooled odds ratio for developing HCC was 22.5 (95% CI 19.5–26.0).¹⁷⁸ An even greater risk was reported in some prospective studies: a class epidemiologic study conducted in Taiwan during the 1970s showed that among HBV chronic carriers, the relative risk of HCC was 233 times that of noncarriers.¹⁷⁹ Screening for HCC does not reduce mortality among chronic HBV carriers, so the National Cancer Institute currently recommends against periodic screening with either serum alpha-fetoprotein or liver ultrasound.¹⁸⁰

Adverse Perinatal Outcomes

Virtually all STIs are associated with potential complications for pregnant women and their infant offspring.² Maternal STIs may be transmitted in utero (congenital infection), during passage through the birth canal (perinatal infection), or after birth during breast feeding (postnatal infection). Identification and early treatment of maternal infection is usually effective in preventing fetal and neonatal infection.

In the developed world, syphilis during pregnancy is rare, with an estimated prevalence of seropositivity between 0.02% and 4.5% in northern Europe and the United States.^{181–185} In contrast, in many developing countries, congenital syphilis remains a major public health challenge. In some regions of Africa, seropositivity is between 3% and 18% among prenatal clinic attendees,^{186–190} and untreated maternal syphilis causes as many as one-half of stillbirths and one-quarter of perinatal deaths.¹⁹¹

In the United States, the congenital syphilis rate peaked at 107.3 cases per 100,000 live births in 1991 and fell 92% by 2004 to 8.8 cases per 100,000 live births.⁹ Transmitting syphilis to the fetus largely depends on the duration of maternal disease: the risk of fetal infection is 60–100% during primary and secondary syphilis, 40% during early latent syphilis, and 8–10% during late latent syphilis.^{192,193} In utero, transmission can occur at any stage of pregnancy, although the highest rate of fetal morbidity and mortality occurs during first-trimester and second-trimester untreated infection.^{194,195} Adequate treatment of the mother usually ensures that the fetus will not be infected. Even with administration of the recommended penicillin regimen, however,

as many as 14% of pregnant women with syphilis will have a fetal demise or deliver a congenitally infected infant.^{196–198}

The prevalence of *Chlamydia trachomatis* in pregnant women varies from 2–15%.^{199–201} Maternal infection is associated with low birth weight, premature rupture of membranes, intra-uterine growth retardation, and preterm delivery in some studies,^{202–208} but not others.^{209–211} Perinatal infection during parturition is a well recognized complication of maternal *C. trachomatis* infection. Acquisition occurs in approximately 50% of infants born vaginally to infected mothers;¹⁹⁹ and several case reports also documented infection in infants born by Cesarean section.^{212–215} Clinical manifestations of neonatal chlamydial infection include inclusion conjunctivitis, pneumonia, and rectovaginal infection.¹⁹⁹

The prevalence of gonorrhea among pregnant women is less than 1% in developed countries and 3–15% in developing countries.²¹⁶ Thirteen percent of women with untreated gonococcal disease experience septic abortion, 29% have premature rupture of the membranes, and 13–67% have premature birth.^{217–223} Gonococcal conjunctivitis (ophthalmia neonatorum) is the most common manifestation of perinatal infection due to *N. gonorrhoeae*.¹⁹⁹ Newborns usually acquire the infection during passage through an infected birth canal, and the risk of transmission is 30–50%.^{217,224}

The prevalence of trichomoniasis in pregnant women is 3–13%.^{225,226} A prospective cohort study involving 13,816 pregnant women in five U.S. cities found that vaginal trichomoniasis was significantly associated with low birth weight (OR 1.3), preterm delivery (OR 1.3), and preterm delivery of a low birth-weight infant (OR 1.4).²²⁵ Another study showed that a premature rupture of membranes occurred at a significantly higher rate in pregnant women with *T. vaginalis* compared to controls ($p < 0.03$)²²⁷ Although the consequences of trichomoniasis during pregnancy are potentially serious, treatment of maternal infection has not been shown to reduce perinatal morbidity^{228–231} and may even increase the risk of preterm delivery (RR 1.8, 95% CI 1.2–2.7).²³²

Several studies demonstrated that human papillomaviruses can be vertically transmitted.^{233–243} Early studies reported vertical transmission rates of 22–73% among newborns delivered by pregnant women with documented genital HPV infection,^{233,235,237,238,239,244,245} but more recent studies suggest that transmission rates are actually much lower (< 4%).^{241,243,246,247} Moreover, the concordance of HPV types between infected mother-infant pairs is only 17–69%,^{240,245,246} suggesting post-natal infection in a number of these cases. Vertical transmission appears to be more efficient in the presence of a high maternal HPV viral load,^{240,244} with vaginal delivery associated with an almost twofold increased risk of transmission compared to Cesarean section.²⁴⁸ C-section is incompletely protective,^{241,243,246,249} however, and transmission rates as high as 27% have been reported post-cesarean section.²⁴⁹ Fewer than 10% of perinatally infected infants demonstrate persistent HPV DNA carriage^{243,247} and sequelae from vertically transmitted HPV are rare.

Genital herpes simplex virus (HSV) infection is common among women of reproductive age, and maternal infection places fetuses and neonates at risk of serious morbidity and mortality. Serologic evidence of prior HSV infection is present in approximately 30% of U.S. women attending prenatal clinics;^{250–252} however, fewer than 10% of all HSV-2 seropositive individuals report a history of genital herpes infection.²⁵³ Among susceptible women, 2% or more experience a first episode of genital herpes during pregnancy, and two-thirds of these women have no symptoms that suggest genital infection.²⁵⁴ This result is consistent with earlier studies demonstrating that 60–80% of women who deliver an HSV-infected infant report no prior history of genital herpes and have no evidence of active HSV lesions at the time of delivery.^{255–257} Acquisition of primary genital herpes during pregnancy has been associated with spontaneous abortion, intrauterine growth restriction, low birth weight, and preterm delivery.^{258–266}

Neonatal herpes infection is the most serious direct consequence of maternal HSV infection. Neonatal herpes clinically presents as localized disease of the skin, eye, or mucous membranes; encephalitis; or

disseminated disease involving multiple organs.²⁶⁷ Untreated neonatal herpes has a significant mortality rate, and one-half or more of survivors suffer from severe neurological impairment.^{257,266} Mortality has been reduced to less than 10% with the advent of effective antiviral therapy,^{268–270} although neurological sequelae remain common.^{257,266,271,272} Transmission at the time of delivery most commonly results from contact with contaminated maternal cervicovaginal secretions. Intrauterine transmission from transplacental or ascending infection can also occur, sometimes through apparently intact fetal membranes.^{250,263} Several factors influence the risk of neonatal transmission. Isolation of HSV at delivery from the mother is a major risk factor for neonatal herpes (OR 346, 95% CI 125–956).²⁵⁰ The frequency of transmission of infection from mother to infant is significantly higher among women who have a primary episode of genital herpes near term than among those who have reactivation of latent infection.^{250,259–261} Zane et al.²⁵⁰ studied a prospective cohort of 40,023 asymptomatic pregnant women and found that 44% of infants delivered to women with primary HSV infection developed neonatal HSV compared with 24% of infants delivered to women with first-episode non-primary infection and 1.3% of women with recurrent HSV disease. The same study also found that maternal HSV serologic status influenced transmission risk. Neonatal HSV infection rates were 54 per 100,000 live births among women who were HSV-seronegative, 26 per 100,000 live births among women who were HSV-1 seropositive only, and 22 per 100,000 live births among all HSV-2 positive women. Other risk factors for neonatal HSV include HSV1 versus HSV2 isolation at the time of labor,²⁵⁰ invasive monitoring,^{250,273–277} and rupture of membranes greater than four hours.²⁵⁹

Preventing neonatal herpes depends on preventing acquisition of genital HSV during late pregnancy. Several strategies are possible, including serologic screening, prophylactic antiviral therapy, and Cesarean section. The use of serologic testing is controversial^{278,279} and there is currently no recommendation for universal screening.^{280,281} The use of acyclovir near term to suppress genital HSV recurrences has become increasingly common. Several small studies suggest that suppressive acyclovir or valacyclovir can diminish the frequency of Cesarean section among pregnant women who have recurrent genital herpes by decreasing the number of recurrences at term.^{282–286} Viral shedding does not appear to be fully suppressed in all patients, suggesting that neonatal transmission may still be possible despite maternal antiviral suppression.²⁸⁷ Cesarean section is effective in the prevention of HSV transmission.^{250,259} In the study by Zane et al.,²⁵⁰ neonatal herpes occurred in 1.2% of Cesarean deliveries and 7.7% of vaginal deliveries (OR 0.14, 95% CI 0.02–1.08). However, as noted in this and other studies,^{250,256,259,288} Cesarean section does not prevent all neonatal herpes. Decision analyses estimate that 1580 excess Cesarean deliveries are performed for every poor neonatal outcome prevented, and an estimated \$2.5 million is spent for every neonatal case averted by this approach.²⁸⁹

HIV-STI Synergy

Strong evidence indicates that both ulcerative and non-ulcerative STIs promote HIV transmission, and this epidemiologic synergy has been the subject of numerous reviews.^{290–298} Prospective studies conducted on four continents provide risk estimates ranging from 2.0–23.5 for the facilitative effect of STIs on HIV transmission.²⁹⁰ The most recent meta-analysis reported combined risk estimates of 2.7 (95% CI 2.2–3.3) and 1.7 (95% CI 1.5–2.1) for ulcerative and non-ulcerative STIs, respectively.²⁹⁶ Mathematical models have estimated the contribution of STIs to the HIV epidemic.^{299–302} In 1996, an estimated 5052 new cases of HIV in the United States were directly attributable to four curable STIs:²⁹⁹ Chlamydia and syphilis accounted for 3249 (64%) and 1002 (20%), respectively, of these new HIV cases with the remaining 16% due to gonorrhea and genital herpes. Collectively, these 5052 potentially preventable HIV cases cost \$985 million in direct treatment costs. In 2004, an estimated 746 U.S. women were infected by HIV because trichomoniasis facilitates HIV transmission.³⁰¹

► STI TRANSMISSION DYNAMICS

Studies of STI epidemics led to the development of a model program to study the spread of STIs. The Ro model³⁰³ includes three major components that determine the spread (Ro) of STIs in populations. These three components are infectivity (β), rate of exposure between infected and susceptible individuals (C), and duration of infection (D). Each of these factors has implications for public health interventions.

Infectivity

Infectivity is affected by a number of variables. There is variation in infectivity from organism to organism. As such, it may be difficult to show that a common intervention (i.e. condom use) significantly affects the transmission of certain illnesses, particularly if those infections are less efficiently transmitted or less prevalent in the community. Other factors, independent of the organism, which could affect infectivity include condom use, circumcision status, role of other STIs as cofactors, and the effect of suppressive treatments (in the case of HIV).^{303,304}

Rate of Exposure

Most studies of STI transmission use the number of sex partners and the rate of sex partner acquisition as a measure of the exposure rate between infected and susceptible individuals (C).^{305,306} In addition to these two major factors, timing of sex partnerships and the frequency of concurrent partnerships or short gaps between sex partners (in serial monogamous relationships) also have been found to be associated with transmission of STIs.³⁰⁵ The role of core groups in maintaining STIs in populations may also affect this variable.

Duration of Infectiousness

The duration of infectiousness varies depending on the organism. Bacterial STIs are best approached by timely diagnosis (either through screening or symptom directed testing) and treatment with appropriate antibiotics. The duration of infectiousness for the viral STIs may be affected by appropriate antiviral treatments even if these treatments do not result in cure of the infection.^{304,305}

Given both the overt and subtle interactions between these variables, effective management of STIs within communities requires attention to many different issues. In fact, they are so interrelated that an effective strategy for control of one variable may or may not have an effect on the overall prevalence of any specific STI.

► FUNDAMENTAL CONCEPTS IN STI PREVENTION AND CONTROL

Abstinence

Abstinence from sexual intercourse is an important behavioral strategy for STI risk reduction, especially among adolescents. Sexual debut during adolescence is associated with increased risk of STI, and the age-specific rates of many STI are highest among adolescents.^{9,307,308} Abstinence appears to be most effective when promoted within the context of a comprehensive sexuality education program that also provides information about condoms and other means of STI prevention. Controversy arises, however, when abstinence is promoted as the sole option for sexual health for young people.

The term abstinence is poorly defined, inconsistently applied, and user-dependent.^{309,310} In behavioral terms, there is general acceptance that abstinence refers to the postponement of penile-vaginal intercourse. However, this definition may or may not include other sexual behaviors. For example, self-identified virgins engage in a variety of noncoital activities, including mutual masturbation, oral

sex, and anal sex.³¹¹ Among adolescents who adopt virginity pledges, 13% of pledgers versus 2% of nonpledgers report oral but no vaginal sex ($p \leq 0.000$). Similarly, 1.2% of virginity pledgers report anal sex but no vaginal sex, compared with only 0.7% of nonpledgers.³¹²

The federal government began supporting abstinence education programs in 1981 via the Adolescent Family Life Act. Subsequently, federal support was significantly expanded under Section 510(b) of the Social Security Act (1996) and under Community-Based Abstinence Education projects (2000), funded through the Special Projects of Regional and National Significance (SPRANS) program. Both programs specifically prohibit federally funded abstinence-only education (AOE) programs from providing information on contraception and STI prevention.³¹³

Funding for AOE programs has increased from \$60 million in 1998 to \$168 million in 2005.³⁰⁹ Concurrently, there has been significant erosion in comprehensive sexuality education. In 1999, 23% of sexuality education teachers promoted abstinence as the only method for STI prevention, compared with 2% in 1988.³¹⁴ Data from the School Health Policies and Programs Study in 2000 revealed that only 21% of junior high and 55% of high schools provided instruction in the correct use of condoms.³¹⁵

Supporting abstinence as a behavioral goal is not the same as AOE. The goal of AOE programs is abstinence until marriage, and supporters of AOE promote this strategy as the sole option for preventing STI. Advocates of AOE insist that abstinence is the only safe and 100% effective method for avoiding the potentially adverse consequences of sexual activity.^{316,317} To describe abstinence as fully protective against STIs, however, is misleading and potentially harmful. Many STIs can be spread via sexual activities other than penile-vaginal intercourse. Moreover, as an applied public health intervention at the population level, abstinence will have a failure rate.³¹⁸ Two systematic reviews found no evidence that AOE programs delay sexual debut and concluded that comprehensive reproductive health programs are efficacious in promoting abstinence and other protective behaviors.^{319,320} No clinical trials have been conducted to document the efficacy of abstinence in preventing STIs. The most useful data in understanding the efficacy of abstinence derives from examination of the virginity pledge movement in the National Longitudinal Survey of Youth (Add Health).³¹²

Adolescents who adopted virginity pledges consistently had less exposure to conventional STI risk factors. Pledgers had delayed sexual debut, fewer sexual partners, less cumulative sexual exposure, and lower levels of nonmonogamous partners. Rates of chlamydia, gonorrhea, trichomonas, and HPV infection, however, were not significantly different between pledgers and nonpledgers. Despite having comparable STI rates, virginity pledgers appear to be much less aware of their STI status. In the Add Health analysis, female virginity pledgers were less likely than nonpledgers to be tested for an STI (18.5% vs. 30.3%, $p \leq 0.000$). Furthermore, pledgers were less likely to report seeing a doctor because they were concerned about an STI (10.9% vs. 22.9%, $p \leq 0.000$).³¹² Studies also indicate that pledgers are significantly less likely than nonpledgers to use a condom at first intercourse.³²¹ Based on the available evidence, the Society of Adolescent Medicine recently published a position statement on AOE policies and programs.³²² The statement endorses abstinence within the context of health education programs that provide complete and accurate information about sexual health, including personal responsibility, risks of STIs, and contraceptive methods.

In contrast to AOE, there is broad public and professional support for comprehensive sexuality education. A recent nationwide poll revealed that 90% of middle school and high school patients support sexuality education in schools, and only 15% wanted an abstinence-only form of education.³²³ Comprehensive sexuality education is also supported by the American College Health Association,³²² the American Academy of Pediatrics,^{324,325} the American Medical Association³²⁶, and the Institute of Medicine.³²⁷ The recently published Society of Adolescent Medicine position statement additionally asserts that federal abstinence-only funding laws are ethically flawed and should be repealed.³²²

Behavioral Interventions

Behaviors such as number of sex partners, types of sex practiced, condom use, and partner selection influence a person's vulnerability to STIs. Consequently, clinicians and public health officials have endeavored to create interventions to alter these high-risk behaviors. During the past decade, studies focused primarily on behavioral interventions for HIV prevention. However, HIV and STIs are interdependent, and similar behaviors place people at risk for both infections. For this reason, HIV behavioral studies have direct implications for the prevention and control of other viral and bacterial STIs.

Components of behavioral interventions include the underlying behavioral theory, context (level of intervention, e.g. individual, group, and community), target population (e.g. STI clinic attendees, MSM, and adolescents), duration (e.g. single brief interaction vs. multiple sessions), content (risk perception, barriers to safer sex, triggers of unsafe sex, etc.), modality (e.g. observational learning and role play), and quality of delivery.³²⁸

Risk reduction counseling has been the most frequently employed strategy for behavior change and primary prevention of STIs. Historically, risk reduction counseling focused on providing general information about HIV/STI in didactic fashion. Since 1993, the CDC has recommended client-centered counseling for HIV/STI prevention.³²⁹ In this model, counseling is an interactive process with risk reduction messages tailored to the patient's individual situation. Early studies supported direct, personalized counseling for initiating changes in high-risk sexual behaviors.^{330–333} The effectiveness of this approach, as compared to didactic messages, was convincingly demonstrated in Project RESPECT,³³⁴ a multicenter randomized controlled trial of 5758 heterosexual STI clinic attendees. Brief, individualized counseling was shown to significantly increase the frequency of self-reported condom use through 6 months and reduced the rate of STI acquisition by 30% through 6 months and 20% through 12 months ($p = 0.008$).

In addition to a client-centered approach, the CDC recommends that counseling includes education regarding specific actions to reduce sexual risk (e.g., abstinence, condom use, and limiting the number of sex partners).³⁰⁷ Counseling is most likely to be effective if provided in a nonjudgmental manner appropriate to the patient's culture, language, gender, sexual orientation, and age.

Heterosexual Adults

Relatively few individual-level interventions have addressed STI acquisition among heterosexual adults. Project RESPECT³³⁴ demonstrated substantial reductions in the rates of gonorrhea, chlamydia, and syphilis among study participants who were counseled in individualized risk reduction. The Voluntary HIV-1 Counseling and Testing Efficacy Study³³⁵ reported a significant decrease in unprotected sex, but a nonsignificant decrease in gonorrheal, chlamydial, and trichomonal infections. Cohen et al.³³⁶ reported a 50% reduction in STI rates among males following a single session emphasizing condom skills. Conversely, an individual counseling intervention based on the AIDS Risk Reduction Model failed to show a reduction in STI acquisition rates, but only 38% of potentially eligible subjects participated.³³⁷ Trials examining the impact of group-level interventions on STI acquisition among heterosexual men and women yielded conflicting results with statistically significant reductions in incident STIs observed in some studies^{338–344} but not others.^{345–350}

High-risk sexual behaviors are often used in these studies as surrogate markers for STI acquisition. Most studies found that the frequency of unprotected vaginal intercourse decreases in the post-intervention period^{334,335,337,338,340,341,346,348,349,351–362} although some trials reported no difference in pre- versus post-intervention condom use.^{345,363–365} The trial by Kelly et al.³⁵⁸ provides some of the strongest evidence for the success of such behavioral interventions. In this study, condom use increased from 26% to 56% following a cognitive behavioral intervention aimed at high-risk, heterosexual women. Among trials that examined the impact of behavioral interventions

on number of sex partners, five studies reported decreases relative to controls,^{337,339–341,360} two reported increases,^{345,363} and two reported no difference.^{343,364} Neumann et al.³⁶⁶ conducted a meta-analysis of 14 behavioral and social interventions for HIV prevention among U.S. heterosexual adults (mean age 26 years old) and demonstrated a small but statistically significant reduction in sexual risk behavior across 10 studies (OR 0.81, 95% CI 0.69–0.95). In addition, a reduction in bacterial STI incidence (OR 0.74, 95% CI 0.62–89) was observed across the six studies considering this outcome.

In a separate meta-analysis, Ward et al.³⁶⁷ reviewed randomized controlled trials (RCTs) of behavioral interventions to reduce STIs risk in clinic attendees. Only 3 of the 14 trials identified in this systematic review were included in the analysis by Neumann et al. The target population in all of these trials except one (representing 2.6% of total subjects in the meta-analysis) was heterosexual. Pooled results across nine studies demonstrated no significant effect (RR 1.00, 95% CI 0.81–1.23) on the incidence of laboratory confirmed STIs relative to controls. Unexpectedly, pooled data across four studies that measured clinically diagnosed STIs revealed higher rates in the intervention groups (RR 1.23, 95% CI 1.01–1.50). A significant increase in consistent condom use was observed across seven trials (RR 1.17, 95% CI 1.10–1.25).

Adolescents

Compared to adults, sexually active adolescents are at higher risk of acquiring STIs due to a combination of developmental, behavioral, and biological reasons. Therefore, numerous studies and programs focused on adolescent HIV/STI prevention and control.^{368–388} Detailed reviews of these adolescent risk-reduction programs were recently published.^{389–393} In general, trials were conducted in schools, adolescent health clinics, community agencies, and juvenile detention centers. Most study populations have consisted of ethnic minorities with varied ages (range 9–19-year old) and degrees of baseline sexual experience (range 8–100%). Almost all interventions included interpersonal skill training.

Five randomized controlled trials examined the impact of behavioral interventions on adolescent STI acquisition.^{368–371,394} A subgroup analysis of Project RESPECT data demonstrated that counseling sessions were more effective than didactic, educational messages in reducing STI incidence among adolescents.³⁹⁴ Results of the other four studies, however, were more disappointing. An individual-level intervention based on the Health Belief Model reported a nonsignificant reduction in STIs despite positive associations with condom use,³⁶⁸ and one group-level intervention demonstrated a significant reduction in incident cases of chlamydia but not gonorrhea or trichomonas.³⁷⁰ The remaining two trials showed no difference in STI rates between the intervention and control groups.^{369,371}

Trials examining the effect of behavioral interventions on adolescent condom use provided conflicting results. A meta-analysis of 13 U.S. studies concluded that behavioral interventions resulted in significantly less sex without condoms (OR 0.66, 95% CI 0.55–0.79) among adolescents.³⁹¹ Conversely, the same analysis concluded that such interventions have no significant impact on number of sex partners.

Men Who Have Sex With Men

The introduction of highly active antiretroviral therapy (HAART) in 1996 may have resulted in unintended effects on sexual behavior among MSM. Some HIV-positive persons receiving HAART, especially those with undetectable HIV RNA levels, may feel protected from transmitting HIV. Perhaps as a consequence of this lessened concern, some evidence suggests an increase in unsafe sex practices^{395–403} and an increase in bacterial STIs among MSM.^{395–397,404–406} Despite these trends, there have been relatively few rigorously conducted trials addressing behavioral prevention strategies in this population.

Studies of behavioral interventions among MSM focused primarily on HIV prevention, though relatively few reported directly on HIV seroconversion or STI acquisition. Rather, most defined behavioral

outcomes in terms of unprotected sex, condom use, and the number of sex partners. A systematic review of 54 interventions designed to reduce HIV/STI transmission in MSM was recently published.⁴⁰⁷ This review, along with an earlier meta-analysis of nine randomized controlled trials, found that behavioral interventions reduced the likelihood of unprotected anal intercourse among MSM by 17–27%, depending on the control group.^{407,408} Since unprotected anal intercourse is a causal link in the acquisition and transmission of HIV and other STIs, a risk reduction of this magnitude could have substantial public health implications. Meta-analysis also identified favorable effects for increasing condom use (OR 0.61, 95% CI 0.47–0.79) and for reducing the number of sexual partners (OR 0.74, 95% CI 0.52–1.06) post-intervention.⁴⁰⁸

Antimicrobial Prophylaxis

Relatively few trials examined the role of pre- or postexposure antibiotic prophylaxis in STI risk reduction. Kaul et al.⁴⁰⁹ randomized female sex workers in Kenya to receive monthly chemoprophylaxis with azithromycin versus placebo and found a significant reduction in acquisition of gonococcal, chlamydial, and trichomonal infection. Similarly, prophylactic minocycline administered to U.S. sailors returning from shore leave in the Philippines resulted in a statistically significant reduction in incident rates of gonorrhea compared to placebo.⁴¹⁰ The potential public health benefits of this intervention, however, were limited because of the concomitant selection for drug resistant *Neisseria gonorrhoea* isolates among those who acquired infection despite prophylaxis. Concerns that chemoprophylaxis creates a false sense of security regarding STI vulnerability also limit this approach.^{411,412} A more recent study, however, challenged this contention: in a cohort of Louisiana STI clinic attendees, syphilis prophylaxis with either intramuscular benzathine penicillin or oral azithromycin was widely accepted and not associated with increased high-risk sexual behaviors.⁴¹³ Antibiotic prophylaxis for victims of sexual assault is a widely accepted practice that is recommended by expert opinion³⁰⁷ but is unlikely to be studied rigorously due to the inherent ethical issues.

Topical Microbicides

Female controlled STI prevention strategies have focused primarily on the development of safe and effective topical microbicides. Microbicides are intravaginal compounds, variously formulated as gels, foams, films, suppositories, and creams, which are intended to prevent male to female transmission of STIs. To date, studies of microbicides have focused exclusively on the use of nonoxynol-9 (N-9).

Observational studies and early randomized trials indicated that N-9 provides substantial protection against both gonococcal and chlamydial infection.^{414–422} Subsequent trials, however, produced conflicting results and even suggested an increased risk of genital ulcer disease and vulvitis with N-9.^{423,424} Attempts to limit these risks by decreasing the concentration of N-9 resulted in loss of the microbicide's protective effect. Two studies of reduced N-9 concentrations demonstrated increased acquisition rates of gonorrhea,^{425,426} and a triple-blind, placebo-controlled trial among female sex workers in four countries demonstrated no effect on either gonococcal or chlamydial infection.⁴²⁷ A recent systematic review of these and other studies concluded that N-9 cannot be recommended as a safe or effective intervention for STI prevention.⁴²⁸

Condoms

The surgeon general and the Centers for Disease Control and Prevention (CDC) advocate the use of male latex condoms for reducing the risk of STI transmission.^{429,430} Latex condoms provide a mechanical barrier to contact with pre-ejaculate emissions and semen; penile lesions; and oral, cervicovaginal, and anal discharges. Latex condoms have proven efficacy for STI prevention in laboratory studies. In

vitro, physiologic simulations demonstrated that intact latex condoms are impermeable to particles comparable in size or smaller than STI pathogens.^{431–441} Polyurethane condoms provide an equivalent degree of protection and can be substituted for persons with latex allergy.^{307,442–443} Conversely, natural membrane condoms, derived from lamb cecum, can have pores as large as 1500 nm in diameter. Although these pores do not allow the passage of sperm, they are ineffective barriers to some viral pathogens, including HIV and HBV.^{307,441,444} Using natural membrane condoms for protection against STIs is not recommended.³⁰⁷

Condom Use Trends

Condom use has generally increased among Americans during the past 15–20 years. The National Survey of Family Growth (NSFG) reported that condom use among American women 15–44 years of age increased from 14.6% in 1988 to 20.2% in 1995, but then decreased slightly to 18% in 2002.^{445,446} The largest increases in condom use have been among adolescents and young adults, the age groups most at risk for STI. From 1988 to 2002, condom use at last intercourse increased from 31.3% to 54.3% among adolescent females and 53.3% to 70.7% among adolescent males.⁴⁴⁷ This trend is corroborated by data from the Youth Risk Behavior Survey, an anonymous school-based questionnaire. From 1991 to 2005, condom use during last coitus significantly increased from 38% to 55.9% for females and from 54.5% to 70% for males.^{448,449}

Condom Use Determinants

Determinants of condom use are multifactorial and influenced by complex psychosocial variables. Groups more likely to use condoms include adolescents and young adults, never-married and non-cohabitating men and women, people with higher educational levels and socioeconomic status, and those with higher numbers of sexual partners.^{446,450–453} Perceptions of societal norms, peer group acceptance, and partners' attitudes are strongly associated with condom use.⁴⁵³ The association between condom use and alcohol consumption is less defined. A recent meta-analysis concluded that alcohol use at first sexual intercourse is associated with decreased condom use, but the relationship between alcohol and unprotected sex subsequently depends on context and the sexual experience of the partners.⁴⁵⁴ Reasons commonly cited for failure to use a condom include reduced spontaneity, reduced sexual sensation, lack of condom availability, and low perceived risk of STIs.^{455–460}

Condom Effectiveness

Although latex condoms have proven efficacy under laboratory conditions, establishing their effectiveness in epidemiologic studies has been more difficult. In contrast to HIV, studies of condom use to reduce the risk of other STIs have provided inconsistent results, an observation highlighted in a 2001 report by the National Institute of Health (NIH).⁴⁶¹ Some of this inconsistency can be explained by methodological limitations in study design. In a recent systematic review, all 45 studies identified had one or more of the following limitations: inability to distinguish consistent use from inconsistent use; failure to report correct versus incorrect use; lack of differentiation of incident from prevalent infection; and failure to include a population with documented exposure to infection.⁴⁶² Additionally, because objective measurement of condom use is not possible, all studies must rely on self-reported use, which may be inaccurate due to recall and social desirability biases.^{462–467} In general, these inadequacies cause condom effectiveness to be underestimated.^{462,468}

Other factors that influence estimates of condom effectiveness include method failure and user failure. Method failure typically refers to condom breakage and slippage. Because all condoms are regulated as medical devices by the Food and Drug Administration (FDA),⁴⁶¹ strict quality control measures ensure that manufacturing defects are uncommon and physical integrity is sound.⁴⁶⁹ Breakage rates for male latex condoms range from 0.1% to 7.3%, and slippage rates range from 0.1% to 6.6%.^{461,470} Method failure is associated with

an increased risk of STI transmission.^{471–473} Risk factors for condom failure include young age, low education level or socioeconomic status, and high-risk behaviors.^{470,474} Conversely, there is an inverse relationship between experience with condom use and failure rates.^{474–478} A French national survey by Messiah et al.⁴⁷⁸ compared method failure rates between couples with more than 5 years of condom experience and couples with less than 5 years of experience. The more highly experienced cohort reported a 0.8% breakage rate and a 0.7% slippage rate, for a combined total method failure of 1.5%. Those with less than 5 years of condom experience reported 6.2% breakage and 1.8% slippage, for a combined failure rate of 8.0%.

User failure results from incorrect or inconsistent condom use. Any protective benefit afforded by condom use is substantially diminished or lost when condoms are not used with each and every act of intercourse. Despite encouraging trends in overall condom use, studies continue to demonstrate high rates of inconsistent use.^{446,447,450,479–483} Other studies have documented high frequencies of incorrect condom application,^{484–486} late application (after initial penetration), and early removal.^{455,487–491} Studies have also found that people use condoms more often with new and casual partners than with regular partners,^{492–494} presumably reflecting differences in perceived STI risk. This practice creates a false sense of security,⁴⁹⁵ provides no protection from HIV or STI transmission,^{489,495–497} and may even increase the risk of gonorrhea and chlamydial infection.⁴⁹⁵

Based on the available epidemiology literature, the previously mentioned NIH report concluded that the use of male latex condoms reduced the risk of gonorrhea among men and the risk of HIV among men and women.⁴⁶¹ Insufficient evidence prevented the panel from forming conclusion about all other STIs. Since 2000, several new studies prospectively addressed the effectiveness of condoms in STI risk reduction,^{495,498–508} and excellent reviews of this subject have been published.^{462, 463,509,510} In contrast to the NIH findings, the cumulative evidence now suggests that consistent and correct use of male latex condoms reduces the risk of gonorrhea, chlamydia, and syphilis among men and women.^{462,463,506} In early retrospective and cross-sectional studies, the risk reduction associated with condom use was highly variable, ranging from 13–100% for chlamydia and from 10–100% for gonorrhea.⁴⁶² Recent trials have refined these estimates and suggest an actual risk reduction of 50–90% for chlamydia and gonorrhea infection.^{495,501,506–508} Two well-designed, prospective clinical trials recently provided convincing evidence that consistent condom use reduces the risk of HSV-2 infection.^{499,500} Condoms may also reduce the risk of trichomoniasis and PID in women, although data for these effects are more limited.^{501,511}

Data on the effectiveness of condoms in reducing male-to-female HPV transmission remain inconclusive. Several studies have found that condom use by men does not prevent HPV infection in women, as measured by cervical HPV DNA.⁵⁰⁹ However, most of these studies had methodological limitations that prevent accurate interpretation of results. A limited number of studies provide evidence of a protective effect; one recent prospective clinical trial demonstrated that consistent condom use was associated with a 70% reduction in risk for HPV transmission among newly sexually active college women.⁵⁰³ Condoms may facilitate HPV clearance among women whose partners consistently use condoms.⁵⁰⁴ Additionally, condoms may mitigate the adverse sequelae of HPV infection; their use has been associated with accelerated regression of cervical and penile HPV-associated lesions.^{504,505} Evidence also suggests that condoms are effective in reducing the risk of HPV-associated diseases, such as genital warts, cervical intraepithelial neoplasia, and invasive cervical cancer.⁵⁰⁹

Vaccination

The high prevalence of asymptomatic STIs and the persistent nature of many viral STIs underscore the importance of primary prevention. Vaccination is an ideal prevention strategy, given the potential advantages of durable protection and the indirect protection afforded to unimmunized individual through herd immunity. Unfortunately,

relatively few vaccines are available for STI prevention, and successful vaccine development for many classic STI pathogens remains elusive despite decades of research.

Investigational Vaccines

Chlamydia vaccine development began in the 1950s with the primary objective being the control of ocular trachoma. Because early studies with inactivated whole cell preparations were unsuccessful, the focus of research shifted to producing subunit vaccines that contain individual protective antigens. The development of a mouse model of vaginal chlamydial infection and the complete sequencing of the *C. trachomatis* genome greatly facilitated identification of potential subunit vaccine candidates, such as major outer membrane protein (MOMP) and polymorphic outer membrane protein (POMP). TRAC-VAX, a POMP-based recombinant vaccine from Emergent BioSolutions (Rockville, MD), demonstrated immunogenicity in animal studies, and phase-I clinical trials are pending.^{512,513}

Development of a *Neisseria gonorrhoea* vaccine has been hindered by several obstacles, including a limited understanding of the immune response to infection and the biology of reinfection. Additionally, there is no valid experimental animal model in which to study the in vivo growth of the organism and the host response to infection. Using a human model of urethral infection, vaccines based on pilin and porin proteins have been studied in humans with disappointing results. More recently, vaccine development has focused on transferrin-binding protein. Studies in the human model demonstrated that gonococci that cannot use iron via the transferrin receptor are incapable of producing urethritis. Although these research developments are encouraging, an effective gonococcal vaccine likely will not be available for several years.⁵¹⁴

The increasing prevalence of genital herpes despite effective antiviral therapy poses a significant worldwide public health problem and emphasizes the urgent need for an effective HSV vaccine.⁵¹⁵ Current research efforts are focused on developing vaccines to treat chronically infected patients (therapeutic vaccines) and vaccines to prevent acquisition of infection (prophylactic vaccines).

Therapeutic HSV vaccines are intended for patients with established latent infection. These vaccines will not eliminate latent infection but should ideally reduce symptomatic recurrences and unrecognized (asymptomatic) viral shedding.^{514,516} A well-controlled human trial demonstrated that a therapeutic HSV subunit vaccine was modestly effective in controlling recurrences among patients with four or more baseline episodes of genital herpes per year.⁵¹⁷ Subsequent trials of HSV vaccine candidates produced conflicting results. Vaccines developed by Chiron Corporation (Emeryville, CA)⁵¹⁸ and Cantab Pharmaceuticals (Cambridge, UK)⁵¹⁹ were ineffective in phase-2 clinical trials, whereas a genetically attenuated vaccine developed by AuRx Inc. (Elkridge, MD) reportedly reduced the number of recurrences among vaccinees by twofold.⁵²⁰ A plasmid-based vaccine by Powdermed Ltd. (Oxford, UK) and a heat shock protein-based vaccine by Antigenics (New York, NY) entered phase-I clinical trials in October 2004 and March 2006, respectively.^{521,522} Despite these promising advances, an effective therapeutic vaccine for genital herpes will probably not be available for several years.

The goals of a prophylactic HSV vaccine are to prevent primary infection by either HSV-1 or HSV-2; prevent the acute clinical disease caused by initial infection; and prevent the establishment of latent infection, the source of virus responsible for recurrent infection.^{514,516} Unfortunately, phase-III clinical trials of a prophylactic subunit vaccine failed to prevent HSV-2 infection despite high levels of circulating antibodies, suggesting that induction of a broad and durable sterilizing immunity is probably not possible.⁵²³ Although primary HSV infection may not be preventable, animal studies do suggest that prophylactic vaccines can prevent disease and human studies are encouraging.⁵¹⁶ In advanced clinical trials, a prophylactic vaccine developed by GlaxoSmithKline (Research Triangle Park, NC) and termed HerpeVac demonstrated an efficacy of 73–74% against acquisition of genital HSV-2 disease in women who were seronegative for both HSV-1 and HSV-2 at baseline.⁵²⁴ For unclear

reasons, the vaccine did not prevent disease among men or HSV-1 seropositive women. A recent study confirmed the safety and immunogenicity of HerpeVac in a large, multicenter randomized controlled trial.⁵²⁵

Preventing disease without preventing HSV infection is potentially problematic. An important but unresolved issue is the impact of such a vaccine on vertical transmission and neonatal disease. Additionally, the absence of symptoms during primary or recurrent infection in vaccinated individuals may result in episodes of asymptomatic viral shedding and transmission to susceptible partners. From a public health perspective, a prophylactic vaccine that does not prevent primary HSV infection should reduce the burden of latent infection, the frequency of recurrences, and the frequency and magnitude of viral shedding. Animal studies are encouraging and suggest that these goals are achievable, although additional research is needed. Ultimately, if prophylactic vaccines prevent HSV disease but have no impact on the epidemic spread of infection, then an alternative public health strategy might be mass immunization. This approach would protect against the morbidity and sequelae of disease and thus minimize the importance of viral transmission.^{514–516}

FDA Approved Vaccines

Hepatitis A virus (HAV) is predominantly transmitted from person-to-person via the fecal-oral route. Sexual activity involving oro-anal contact is considered the major mode of transmission among MSM and bisexual men.^{526–530} Currently, five HAV vaccines are available, although only two are licensed for use in the United States.⁵³¹ Havrix (GlaxoSmithKline) and Vaqta (Merck & Company) were approved for use in preventing HAV infection by the FDA in 1995 and 1996, respectively.⁵³² Following a single intramuscular dose, HAV neutralizing antibodies are present in 32–73% of persons within 2 weeks, in 91–100% of persons within 4 weeks, and in 100% of persons at 24 weeks.^{533–539} Administering a second dose (6–18 months after the first) confers durable immunity.^{540,541} Since 1995, the Advisory Committee on Immunization Practices (ACIP) has recommended HAV vaccination for selected high-risk populations, including MSM.⁵⁴² The recommendation for targeted vaccination was reiterated in the 1999 and 2006, along with plans to incrementally implement a universal childhood HAV vaccination program.^{543,544}

Hepatitis B virus (HBV) infection became the first vaccine-preventable STI in the late 1970s, following the successful development of a vaccine produced from purified human hepatitis B antigen. In a placebo-controlled, double-blind, randomized trial involving 1083 MSM, the efficacy of this vaccine was 92% through 18 months of follow-up.⁵⁴⁵ Subgroup analysis later revealed a vaccine efficacy of 100% among persons who had received the complete vaccination series.⁵⁴⁶ Although plasma-derived vaccines constitute 80% of all HBV vaccines produced worldwide, these first-generation vaccines have largely been abandoned in developed countries due to the potential transmission of blood-borne infections.⁵⁴⁷ Yeast-derived recombinant vaccines are now favored, and two products are available in the United States; Recombivax HB (Merck & Company) and Engerix-B (GlaxoSmithKline) were approved by the FDA in 1986 and 1989, respectively.⁵⁴⁸ Vaccine efficacy in preventing HBV infection is typically 95%, with a reported range of 80–100% among adults who complete the primary vaccination series.⁵⁴⁹ Although antibody titers decrease with time, the duration of protection is prolonged and appears to extend beyond 12–18 years;^{550–553} and booster doses of vaccine are not recommended for otherwise healthy adults.⁵⁴⁹ From 1982 to 1990, the ACIP recommendations for HBV vaccination were risk-based and included MSM, sexual contacts of HBV carriers, and heterosexual adults with more than six partners or a history of another STI.^{554–557} This strategy was changed to an age-based immunization program with the 1995 recommendation for immunization of adolescents and the 1999 recommendation for all persons less than 19 years of age.^{558,559} In 2006, the ACIP further expanded HBV vaccination recommendations to now include universal immunization of adults in settings which have a high proportion of at-risk adults

(e.g., STI treatment facilities, health-care settings targeting services to MSM, and correctional facilities).⁵⁶⁰

In May 2001, the Food and Drug Administration licensed a combination hepatitis A-hepatitis B vaccine (Twinrix, GlaxoSmithKline) for use in persons older than 17 years of age.^{561,562} Twinrix is equivalent to the pediatric dose of Havrix plus the adult dose of Engerix-B. Clinical trials indicate that the safety, efficacy, and immunogenicity of Twinrix are equivalent to the individual component vaccines.⁵⁶³ The vaccine's primary advantage is convenience and potentially improved compliance for those who require protection against both HAV and HBV.

Human papillomavirus (HPV) vaccine development has focused on the HPV major capsid protein L1, which self-assembles into non-infectious virus-like particles (VLP).⁵⁶⁴ Preclinical research demonstrated that L1 is highly immunogenic, and a proof-of-concept vaccine trial with HPV 16 VLP revealed that HPV infection could be prevented.⁵⁶⁵ Subsequently, a quadrivalent HPV 6/11/16/18 L1 VLP vaccine (Gardasil, Merck & Company) was approved by the FDA in June 2006. In a randomized, double-blind, placebo-controlled trial involving 552 women, the incidence of persistent infection associated with HPV 6, 11, 16, or 18 decreased by 89% in women allocated active vaccine compared to placebo.⁵⁶⁶ Vaccine efficacy with regard to clinical disease caused by HPV 6, 11, 16, or 18 was 100%. Seropositivity rates at 36 months for HPV types 6, 11, 16, and 18 were 94%, 96%, 100%, and 76%, respectively. Preliminary results from a large, ongoing multinational trial involving more than 12,000 women aged 16–26 years support the findings of the original efficacy trial. In June 2006, the ACIP made provisional recommendations for use of the quadrivalent HPV vaccine. These recommendations included routine vaccination of females 11–12 years of age and catch-up vaccination of females aged 13–26 years who have not received or completed the primary vaccine series.⁵⁶⁷

A bivalent HPV 16/18 L1 VLP vaccine (Cervarix) is actively being developed by GlaxoSmithKline. Vaccine efficacy was demonstrated in a randomized, double-blinded, placebo-controlled trial involving 1113 women aged 15–25 years.⁵⁶⁸ In extended follow-up (mean 47.7 months), intention to treat analyses revealed an 89% efficacy against incident HPV 16/18 infection and 94% efficacy against persistent (>12 months) infection.⁵⁶⁹ More than 98% of vaccine recipients remained seropositive for HPV 16 and 18 during extended phase follow-up. No cases of carcinoma in situ caused by HPV 16/18 were reported in the vaccine group, compared to eight cases in the placebo group.

Partner Notification/ Contact Tracing

Partner notification, the process where sexual partners of people diagnosed with STIs are identified, informed of their exposure, and tested or treated for illness has been used as a method of STI control for many years. The goals of partner notification include limiting the spread of STIs within a population by treating patients who are asymptomatic, preventing reinfection of the index case, and preventing illness in contacts. These goals are limited by the efficacy of partner notification as well as the ease or completeness of partners presenting for diagnosis and care. Partner notification as an effective STI control measure has been only studied in a limited format.

In order to be successful, partner notification must first identify details of sexual contacts from whom the index case might have acquired the illness, as well as any partners who might have been exposed to the index case during the latent period. The latent period is variable but, in general, is 1–3 months prior to the onset of symptoms and includes all contacts until the time of diagnosis. Several approaches to partner notification have been used: provider referral, where the provider, usually the health department, notifies the identified contacts of their exposure; patient referral, where the health department personnel encourage the patient to contact referrals with or without materials/reminders/brochures; and contract referral where the patient is given a period of time to make a referral after which the health department will do it. In a review of 11 randomized

controlled trials, Matthews et al.⁵⁷⁰ found that provider referral or the choice between provider referral and patient referral increased the rate of partners presenting for medical evaluation. One trial for HIV infected patients found that offering patients the choice between provider and patient referral compared to patient referral alone resulted in more partners being notified (2 per index patient vs. 0.29 per index patient). A study in Zambia, where any STI was identified in the index, found that offering male index cases a choice between provider and patient referral resulted in more partners notified (1.8 vs. 1.3).

In the Matthews et al. review,⁵⁷⁰ only two studies investigated potential harms resulting from partner notification, whether it is patient or provider referred. In one of the studies, 27% of men given a choice between patient and provider referrals reported domestic quarrels versus 11% of men receiving patient referral only. The fear (whether justified or not) of retaliatory violence is the largest drawback to all strategies.

Despite modest enhancements in delivering care to partners by provider referral, this method is costly and time consuming. Expedited partner therapy (EPT), the practice of treating sex partners without an intervening medical examination is a newer model of care that has promise as a partner notification option. The CDC recently reviewed the available literature on EPT and funded four randomized clinical trials designed to compare EPT to traditional partner management protocols. These RCTs assessed EPT in men and women with gonorrhea, chlamydia, and trichomoniasis. In these four studies, EPT was at least as effective as partner referral for chlamydia and gonorrhea but no difference was seen in the trial of trichomoniasis. Behavioral outcomes of these studies showed that EPT was associated with at least equivalent confidence that partners had received treatment, and two trials that addressed gonorrhea and chlamydia found EPT to be associated with reduced rates of sex with untreated partners by the index case. EPT should be studied more as an alternative to traditional partner notification.

► EPIDEMIOLOGY AND TRENDS OF INDIVIDUAL DISEASES

Bacterial STIs

Chlamydia

The epidemiology of genital infections due to *C. trachomatis* serovars B and D–K (e.g., urethritis and cervicitis) are reviewed in this section. Infections caused by lymphogranuloma venereum serovars (L1, L2, L3) are discussed separately.

Chlamydia is the most commonly reported bacterial STI in the United States. In 2004, a total of 929,462 genital chlamydia infections were reported to the CDC, an increase of approximately 33% since 2000.⁹ Because 75–85% of infections in women and 50–90% of infections in men are asymptomatic,^{571–574} most cases of chlamydia remain undiagnosed, and assessing the true burden of disease is difficult. Estimates suggest that the actual incidence of chlamydia in the United States is approximately 2.8 million cases per year.⁸

From 1987 to 2004, the reported rates of chlamydia infection increased from 50.8 to 319.6 cases per 100,000 population.⁹ This increase likely reflects the expansion of chlamydia screening activities among females, the use of more sensitive diagnostic tests (i.e., nucleic acid amplification tests), and improved case reporting by physicians and laboratories. Chlamydia reporting and screening will likely expand further in response to the recently implemented Health Plan Employer Data and Information Set (HEDIS) measure for chlamydia screening of sexually active women 15–25 years of age who receive care through managed care organizations.⁵⁷⁵

In most studies, chlamydia infection is more common among females than males, although this discrepancy may simply be the result of more complete surveillance of females. In 2004, the chlamydia case rate for females was 485.0 per 100,000 women, compared to 147.1 cases per 100,000 men. Among women, the highest age-specific

rates of reported chlamydia were among adolescents aged 15–19 years and young adults aged 20–24 years (2761.5 and 2630.7 cases per 100,000 females, respectively). Collectively, these two groups accounted for nearly 60% of all reported chlamydia cases in 2004. Case finding among males has improved in recent years, largely due to the availability of highly sensitive urinary nucleic acid amplification tests. From 2000–2004, the chlamydia rate in men increased by nearly 50% from 99.6 to 147.1 cases per 100,000 population, compared with only a 22.4% increase in women during the same period.

Racial and ethnic minorities are disproportionately affected by chlamydia, possibly reflecting a lack of access to screening and treatment programs. In 2004, the incidence of chlamydia per 100,000 population was 1209.4 among African Americans, 705.8 among American Indians/Alaska Natives, 436.1 among Hispanics, and 143.6 among non-Hispanic whites. The rate among African American females was 7.5 times higher than the rate among white females (1722.3 and 226.2 cases per 100,000 respectively), and the rate among African American males was 11 times higher than that among white males (645.2 and 57.3 cases per 100,000 population, respectively).⁹

Because of the potential for reporting bias associated with case-based surveillance, the true burden of chlamydia infection is best determined from population-based prevalence studies. The National Longitudinal Study of Adolescent Health (Add Health), a nationally representative sample of more than 12,000 persons aged 18–26 years, provides one of the most comprehensive estimates of chlamydia prevalence.⁵⁷³ In this study, the prevalence of chlamydia infection in the United States was estimated to be 4.2%. Results of the Add Health analysis are generally consistent with incidence data derived from national surveillance. Women were more likely to be infected than men (4.7% vs. 3.7%), and the prevalence of infection varied significantly by race/ethnicity. The prevalence rate among African American young adults (12.5%) was six times higher than that of white young adults (1.9%). The highest prevalence rates were noted among African American women (14%) and African American men (11.1%). In comparison, the lowest prevalence groups were Asian American men (1.1%), white men (1.4%), and white women (2.5%). The National Survey of Adolescent Males (NSAM), a survey of 500 men conducted in 1995, provided estimates similar to those of Add Health.⁵⁷⁴ In NSAM, the prevalence of *C. trachomatis* infection was 3.1% among 18–19-year olds and 4.5% among 22–26-year olds. Other population-based studies provided more geographically restricted estimates of chlamydia prevalence. The Baltimore STD and Behavior Survey conducted during 1997–1998 included 728 adults aged 18–35 years; the reported chlamydia prevalence rates among men and women in this study were 2.2% and 4.3%, respectively.⁵⁷⁶ Estimates of chlamydia (and gonorrhea) prevalence have been obtained in a variety of settings and special populations (Table 10-4).^{577–607} Although these estimates are usually not representative of the general population, this information is essential to the development of targeted public health interventions for high-risk groups.

Gonorrhea

In 2004, a total of 330,132 cases of gonorrhea were reported to the CDC from 50 states and the District of Columbia. This case count corresponds to an incidence rate of 113.5 cases per 100,000 population, a 1.5% decrease compared with the rate 115.2 in 2003. Following the implementation of a national gonorrhea control program in the mid-1970s, the rate of reported gonorrhea infection declined 76% from a high of 467.7 cases per 100,000 population in 1975 to the current record low. Gonorrhea continues to affect racial/ethnic minorities disproportionately. In 2004, the gonorrhea rate among African Americans (629.6 cases per 100,000 population) was 19 times greater than whites (33.3 cases per 100,000 population) and 9 times greater than Hispanics (71.3 cases per 100,000 population).

Historically, reported rate of gonorrhea has been higher in men than women, primarily due to the higher incidence of asymptomatic disease among women and the occurrence of infection among MSM.

TABLE 10-4. CHLAMYDIA AND GONORRHEA PREVALENCE IN SPECIAL POPULATIONS

Population	CT-M	CT-F	GC-M	GC-F	References
Adolescents in school-based settings/clinics	2.3–11.4%	7.9–20.6%	1.0–2.3%	1.6–14.7%	577–583
STI clinic attendees	6.7–21%	5.7–20%	8.0–31%	1.3–14%	584–587
Military recruits	4.7–5.3%	9.5%	0.4–0.6%	—	588–591
Family planning clinic attendees	—	0.1–16.3%	—	0.1–4.2%	9592–595

Abbreviations: CT: Chlamydia; GC: Gonorrhea; M: Male; F: Female; MSM: Men who have sex with men; WSW: Women who have sex with women.

In 2002, however, the rate of gonorrhea among women exceeded the rate among men for the first time and has remained slightly higher since that time. In 2004, the overall gonorrhea rate among women was 116.5 and the rate among men was 110.0 cases per 100,000 population. Rates were 20–97% higher among women than men for all racial/ethnic groups, except African Americans. In this latter group, the male gonorrhea rate (670.3 cases per 100,000) was 13% higher than the female rate (592.5 cases per 100,000). Improved screening and the use of more sensitive diagnostic tests may partially explain the observed rate increases among women. Gonorrhea most dramatically affects adolescents and young adults. In 2004, the overall gonorrhea rates were highest among 15–19-year olds (427.1 cases per 100,000 population) and 20–24-year olds (497.8 cases per 100,000 population). Relative to 2000, these rates represent a decrease of approximately 15%. In 2004, the reported gonorrhea rates among females aged 15–19 and 20–24 years were 610.9 and 569.1 cases per 100,000 population, respectively. Among men, 20–24-year olds had the highest rate (430.6 cases per 100,000 population).⁹ Patients with gonorrhea are frequently coinfecting with *C. trachomatis* (and vice versa). Dual infection rates are estimated to range from 19–54%, depending on the population studied.^{572,580,585,592,599}

Population-based estimates of gonorrhea prevalence were recently published. In Add Health, the summary estimate of gonorrhea prevalence was 0.4% (4 cases per 1000 population).⁵⁷³ The prevalence rates among African American men and women were 2.4% and 1.9%, respectively. In comparison, the rates among white men and women were substantially lower (0.1% each). In the Baltimore STD and Behavior Survey, the estimated population prevalence of gonorrhea was 5.3% among adults aged 15–35 years.⁵⁷⁴ The gender-specific rates were 3.8% and 6.7% for men and women, respectively. Gonorrhea prevalence rates were substantially higher among African American men (5.3%) and women (9.3%), as compared with whites (1.3% in men and women). Prevalence rates of gonorrhea among special populations are in Table 10-4.

An emerging consideration in the prevention and control of gonorrhea is the development of antimicrobial resistance. The Gonococcal Isolate Surveillance Project (GISP) was established in 1986 to monitor trends in antibiotic susceptibilities of *N. gonorrhoeae* and provide a rationale basis for gonorrhea treatment recommendations.^{9,608} In 2004, 15.9% of GISP isolates were resistant to penicillin, tetracycline, or both. Resistance to the fluoroquinolone ciprofloxacin, one of the preferred therapies for gonorrhea, was first identified in 1991; ciprofloxacin resistance has since progressively increased from 0.1% of isolates in 1998 to 6.8% of isolates in 2004. Rates of fluoroquinolone resistant *N. gonorrhoeae* (QRNG) are highest in Hawaii and California, where as many as 29% of isolates are resistant. Significant increases in QRNG have also been noted in MSM nationwide. Based on GISP surveillance data, the CDC

no longer recommends ciprofloxacin as a first-line therapy for patients in Hawaii and California or for MSM; third generation cephalosporins are now the preferred agents in these populations.³⁰⁷

Syphilis

The rate of primary and secondary (P & S) syphilis declined 89.6% from 20.2 cases per 100,000 population in 1990 to a record low of 2.1 cases per 100,000 population in 2001. During the past four years, however, this trend has reversed, and the overall reported rate of P & S syphilis in the United States has been increasing. Between 2003 and 2004 alone, the rate increased by 8%, from 2.5 cases to 2.7 cases per 100,000 population. The corresponding case count increased from 7177 cases in 2003 to 7980 cases in 2004. The recently observed rise in syphilis rates is almost exclusively the result of increased rates among men: between 2000 and 2004, the P & S syphilis rate among men increased 81%, from 2.6 to 4.7 cases per 100,000 population. During this same time period, the P & S rate in females decreased by 53% and has remained stable at 0.8 cases per 100,000 between 2003 and 2004.⁹

More specifically, the rise in P & S syphilis is being driven by an increase in diagnosis among men who have sex with other men (MSM). Although the CDC has not traditionally collected data on P & S syphilis by risk group, the overall male to female ratio has increased from 1.5 in 2000 to in 2004. Cases among MSM comprised an estimated 64% of all P & S cases in 2004 (up from 5% in 1999), and cases are seen among all racial and ethnic groups.

Syphilis continues to be a major public health problem in metropolitan areas, particularly those with large populations of MSM. The MSM prevalence monitoring project has reported increases in syphilis serologic reactivity across virtually all cities where surveillance is being performed. Rates of seropositivity among MSM presenting to STI clinics range from 5.7% in Denver to 14% in Houston.

Rates of P & S syphilis increased for blacks for the first time in over a decade in 2004. This increased rate was driven primarily by increases in black men. The rate among black men increased from a rate of 7.7 per 100,000 in 2003 to a rate of 9.0 per 100,000 (a 16.9% increase) whereas the rate among black women increased only 2.4% (from 4.2 to 4.3 per 100,000). Overall, the rates of P & S syphilis reported in 2004 were highest among black men (14.1 per 100,000) and Hispanic men (5.5 per 100,000). For women, the highest rates were found among black women (4.3 per 100,000) and American Indian women (2.8). Rates for white men and women were 3.0 and 0.3 per 100,000, respectively.

Chancroid

Chancroid is a major cause of genital ulcer disease in sub-Saharan Africa and in many parts of Southeast Asia and Latin America. In comparison, the disease is relatively uncommon in the United States and western Europe.⁶⁰⁹ The number of cases reported to the CDC

steadily declined from 1987 until 2001, when 38 cases were reported. There were only 30 cases reported in 2004. These cases were identified in 16 states and one U.S. territory; the greatest number of cases in any one state was four, reported from both New York and South Carolina.⁹

National surveillance data should be cautiously interpreted, however, as chancroid is probably substantially underdiagnosed and underreported.^{610–615} Prior to 1990, reporting was complicated by the absence of standardized surveillance definitions for clinically compatible cases.⁶¹⁶ Even with these definitions for guidance, the clinical diagnosis of chancroid is often inaccurate. For example, a CDC study using multiplex PCR implicated *H. ducreyi* in 20% of genital ulcer cases in Memphis, TN; among the ten cases identified, the clinical diagnosis was suspected in none.⁶¹⁵

Patients in whom chancroid is clinically suspected often do not receive confirmatory laboratory testing, thereby contributing to the problem of underdiagnosis. A survey of 405 STI treatment facilities found that only 8% tested patients for chancroid.⁶¹⁰ The lack of regular confirmatory testing may be due to the unavailability of adequate laboratory services. A survey of 115 STI clinics in 32 states, the District of Columbia, and Puerto revealed that only 14% had culture media available for *H. ducreyi*, and only 8% had adequate laboratory facilities to differentiate among chancroid, syphilis, and genital herpes.⁶¹¹ The potential importance of lack of testing was demonstrated in studies from Brooklyn⁶¹² and New Orleans,⁶¹⁷ which identified *H. ducreyi* as the cause of genital ulcer disease in 42% and 39% of cases, respectively.

Several epidemiological features of *H. ducreyi* infection are apparent. Transmission is primary heterosexual, and minority populations are disproportionately affected.^{609,614,618–621} Cases are more common among men than women, probably because chancroid is more easily diagnosed in males.^{9,619} Infected males frequently report a history of sexual contact with commercial sex workers.^{617,620–624} Additionally, chancroid is highly associated with illicit drug use, especially crack cocaine.^{614,617,619,625} Coinfection with syphilis occurs in 5–17% of patients.^{612–614,620}

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is common in tropical and subtropical regions of the world, including East and West Africa, India, the Caribbean, Central America, and Southeast Asia.⁶²⁶ In contrast, the infection is relatively uncommon in the United States and Europe, and sporadic cases in the developed world are generally considered to be imported from endemic areas.⁶²⁷ From 1980–2003, only two clusters of LGV were described in the developed world (by Scieux et al.⁶²⁸ in Paris and Bauwens et al.⁶²⁹ in Seattle). Since 2003, however, a slowly evolving epidemic of LGV anorectal infection has emerged in western Europe.

Initial cases of this epidemic were diagnosed among MSM in Rotterdam, the Netherlands between April and November 2003.^{630–632} Additional cases were subsequently reported in Antwerp,⁶³³ Paris,^{634,635} Stockholm,^{636,637} Hamburg,^{638,639} Barcelona,⁶⁴⁰ London,^{641,642} Edinburgh,⁶⁴³ and Geneva.⁶⁴⁴ European surveillance systems since identified hundreds of cases among MSM: 61 cases in Germany by November 2005,⁶⁴⁵ 244 rectal cases in France by December 2005,⁶³⁴ 179 cases in the Netherlands by December 2005,⁶⁴⁶ and 344 cases in the United Kingdom by March 2006.⁶⁴² The true incidence of the disease is difficult to determine due to variable reporting practices among European countries and the lack of a standardized diagnostic test or surveillance definition.

More recently, small numbers of cases of LGV proctitis were identified in the United States.⁶⁴⁷ Although LGV was removed from the list of nationally notifiable diseases in 1995, reporting is mandated by 24 states, and some of these states continue to report cases to the CDC. In 2004, the CDC received 27 reports of laboratory confirmed LGV infection.⁹ Twenty-two cases of LGV were identified in Canada between January 2004 and May 2005, and all genotyped strains were similar to the strain initially isolated in the Netherlands.⁶⁴⁸ At least two cases were also diagnosed in Australia.^{649,650}

A case-control study was conducted in the Netherlands to identify risk factors for LGV infection during the current epidemic.⁶⁵¹ HIV seropositivity was the strongest independent risk factor for anorectal LGV infection among MSM (OR 5.7, 95% CI 2.6–12.8). Other risk factors identified in this study included concurrent ulcerative disease, previously diagnosed STI, and unprotected receptive anal intercourse with a casual partner. In addition, other studies also reported a high proportion of HIV-Hepatitis C virus coinfection among LGV-infected patients.^{642,652}

Trichomonas

Vaginal infections due to *Trichomonas vaginalis* are among the most common STIs. The true incidence and prevalence of trichomoniasis in the United States are unknown, as the infection is not reportable. Estimates suggest that 7.4 million new cases occur each year, accounting for 4–35% of all episodes of symptomatic vaginitis diagnosed in the primary care-setting.⁶⁵³ Studies of *T. vaginalis* prevalence among women have largely been limited to clinical settings and special populations (Table 10-5).^{654–676} In studies presenting data on race/ethnicity, the prevalence of *T. vaginalis* has been highest among African American women (23–51%), with a 1.6- to 4.4-fold increased risk compared to other racial/ethnic groups.^{669,672,677–679} Reinfection is common, especially in adolescent females.^{673,680–682} In one study of high-risk 13–17-year olds, greater than 31% of participants experienced multiple episodes of trichomoniasis during the 27-month follow-up period.⁶⁷³

Prevalence data for men are even more limited, reflecting the large proportion of asymptomatic cases and the poor sensitivity of culture to detect the organism in the male genital tract.⁶⁸³ Studies using culture reported prevalence rates among men ranging from 2.8–12%.^{684–688} Such rates are much lower than those among women attending STI clinics. Using more recently available PCR assays, however, *T. vaginalis* has been found in 13–17% of men attending STI clinics.^{689–691}

Relatively few studies attempted to define the prevalence of *T. vaginalis* in the general population. The Add Health data provided the first population-based estimate of the current prevalence of trichomoniasis in young adults, as identified by urine PCR was 2.3%. The prevalence in women was higher than in men (2.8% vs. 1.7%), and African American women had a higher prevalence than white women (10.5% vs. 1.1%).⁶⁹²

The age distribution of *T. vaginalis* infections differ markedly from other common, curable STIs such as chlamydia and gonorrhea. For the latter two, prevalence rates decline steadily with increasing age; in contrast, the point-prevalence of *T. vaginalis* is higher during middle aged than during adolescence.^{674,687,692,693} The pathogen is recovered from 22–80% of the male sexual partners of infected women and from 60–100% of the female partners of infected men.⁶⁸⁴

Viral STIs

Herpes Simplex Infection (Genital Herpes)

Genital Herpes is one of the most common STIs in the United States with estimates of disease prevalence as high as 45 million or 1 in 5 adults. True prevalence of genital herpes is difficult to assess because the disease is asymptomatic in a large percentage of those infected and because it is not a reportable illness in all states.

Two national U.S. studies gathered data on the seroepidemiology of HSV infection. The National Health and Nutrition Examination Survey (NHANES) study—NHANES III,²⁵³ conducted between 1988 and 1994—found the overall prevalence of HSV-2 antibody was 21.9% for people 12 years and older. The seroprevalence was higher in women than in men and higher among blacks than whites. Seroprevalence rose rapidly in the young and adolescent ages and then remained stable in those over 30 years of age. In a smaller study of 500 randomly selected patients attending a family medicine clinic, there was a prevalence of 23% of HSV-2 antibodies detected.⁶⁹⁴ Despite this, only a minority of those infected had a clinical history

TABLE 10-5. TRICHOMONIASIS PREVALENCE RATES AMONG US WOMEN

	Van Der Pol et al. ⁶⁷³	2005	6	PCR

of genital herpes (27%). This suggests that there is a large reservoir of patients unaware of their infection.

Two studies of U.S. adolescents showed an overall seroprevalence of 12% among teens and young adults at high risk for STI.^{695,696} Both studies showed that seroprevalence was higher in girls and that girls tended to become infected at a younger age than boys. The difference may be related to partner selection as adolescent girls are more likely to have older partners who are at higher risk of STIs. In these studies, the relationship between sexual history variables and likelihood of HSV-2 infection varied. In the first study, HSV-2 seropositivity was associated with the number of STI episodes in boys and the number of lifetime sexual partners in girls. In the second study, only female gender and African American ethnic origin remained predictors of HSV-2 infection.

Project RESPECT⁶⁹⁷ found a seroprevalence of 40.8% among 4128 patients from five STI clinics. HSV-2 was higher in women than in men (52% vs. 32.4%) and higher in blacks than in whites, Hispanics and other ethnic groups (48.1% vs. 29.6%). For both sexes, past sexual history, particularly the number of lifetime sexual partners or prior history of gonorrhea or syphilis, were predictors of HSV-2 seropositivity. Approximately 85% of patients with HSV-2 seropositivity had never been diagnosed with genital herpes.

Although the two NHANES surveys documented an increase in HSV-2 seropositivity, the true incidence of disease in the U.S. is unknown. CDC data of first-time diagnosis for genital herpes show a continuing rise from 179,000 in 2000 to 266,000 in 2005.⁹ While these cases may represent first episode genital herpes, they may still underrepresent the true incidence of new infections because they may reflect more severe cases or visits from those with greater awareness and concern about herpes.

Human Papillomavirus

The estimated prevalence of anogenital HPV infections in the United States is 20 million, with an annual incidence of 6.2 million.^{5,8,9} Evidence suggests that 80% of sexually active adults will acquire a genital tract HPV infection by 50 years of age.^{145,698} HPV infection is especially common among female adolescents and young adults. In studies using convenience samples of women attending managed care, STI, or university clinics, the prevalence of genital HPV infection among 15–24-year-old women

ranges from 17–72%,^{9,699–715} with most estimates clustering near 30%.⁷⁰⁹ Prevalence subsequently decreases with advancing age. Interim results from a CDC-sponsored sentinel surveillance project being conducted in six states revealed a HPV prevalence of 35% among 14–19-year olds, 29% among 20–29-year olds, 14% among 30–39-year olds, 12% among 40–49-year olds, and 6% among 50–65-year olds.⁹

Prospective studies among HPV-negative college women documented incidence rates of 32% at 24 months,⁵⁰² and 43% at 36 months.¹⁵³ Rates of new HPV acquisition among women using routine gynecological or family planning services range 11–41% at 12 months and 44–55% at 36 months.^{154,704,706,716,717}

Incidence and prevalence studies consistently demonstrate that most cervical HPV infections in women are due to high risk (oncogenic) types, especially HPV type 16.^{137,143,146,154,502,704,706,710,711,717,718} Infection with multiple HPV types is common, occurring in 4–45% of HPV-positive women.^{131,143,702,706,719} Although rates of HPV infection among women are high, most infections are asymptomatic and transient. As many as 70% of new HPV infections spontaneously clear within 12 months and 91% clear within 24 months of acquisition.^{148,150,153,502,704,706,710,720,721} The median duration of infection ranges 4.3–13.5 months, with infection due to oncogenic strains persisting longer than non-oncogenic types.^{153,502,704}

Genital HPV infection is rare in virgins (< 2%),^{502,722–724} suggesting that risk factors for HPV acquisition are primarily related to sexual behavior. Risk factors among women include lifetime number of sexual partners,^{700–703,705,709,711–713,715,725} introduction of new partners,^{154,502,702,704,725} and partner's sexual history.^{153,502} In addition, most studies demonstrate that young age (usually defined as less than 25 years) is a risk factor.^{9,131,153,700–702,711} Genital contact in the absence of penetrative intercourse (e.g., oro-genital, digital-genital) can lead to HPV infection, although these routes of transmission are significantly less common.^{502,726,727,728}

Data on the prevalence of genital HPV infection in men is more limited. Penile HPV DNA has been detected in 15–45% of heterosexual, male STI clinic attendees, depending on the anatomic site tested (e.g., urethra, glans, coronal and sulcus).^{729–733} A recent study documented a higher prevalence of infection in uncircumcised men than in circumcised men (19.6% vs. 5.5%).⁷³³ In addition, HPV DNA has been detected in the anal canal of 33–61% of HIV-negative MSM^{731,734} and in 65–93% of HIV-positive MSM.^{731,735}

TABLE 10-6. SELECTED HEALTHY PEOPLE, 2010—OBJECTIVES

	Objective	Baseline Year	Baseline	2000	2002	2004	Target 2010
7-02	Increase the proportion of STI education among junior and high school students	1994	65%	62%	—	—	90%
9-09	Increase the proportion of adolescents who have never had sexual intercourse						
	Females	1995	62%	—	70%	—	75%
	Males	1995	57%	—	68%	—	75%
13-06	Increase the proportion of sexually active persons (18–44 years old) who use condoms						
	Females	1995	23%	—	31%	—	50%
	Males	2002	42%	—	42%	—	54%
14-03	Reduce hepatitis B (# of cases)						
	Heterosexually active adults	1997	15,021	8421	7868	—	1223
	MSM	1997	5209	6220	4555	—	1302
14-28	Increase hepatitis B vaccination among MSM	1994–1999	9%	13%	—	—	60%
25-1	Reduce chlamydia infections among 15–24-year old STI clinic attendees						
	Male	1997	12.2%	13.5%	13.5%	15.3%	3.0%
	Female	1997	15.7%	16.4%	17.5%	19.2%	3.0%
25-2	Reduce gonorrhea (new cases per 100,000 population)						
	Female	1997	119	126	123	117	19
	Male	1997	125	131	121	110	19
25-03	Eliminate sustained domestic transmission of P&S syphilis (new cases per 100,000 population)	1997	3.2	2.1	2.4	2.7	0.2
25-04	Reduce the proportion of 20–29 year olds with genital HSV infection	1988–1994	17%	—	11%	—	14%
25-06	Reduce the proportion of females (15–44 years old) treated for PID	1995	8%	—	5%	—	5%
25-09	Reduce congenital syphilis (new cases per 100,000 live births)	1997	28	14	11	9	1

Viral Hepatitis

A complete discussion of viral hepatitis can be found in another chapter of this text. In brief, the overall incidence of hepatitis A virus (HAV) infection has decreased from 12 cases per 100,000 population in 1995 (pre-vaccine licensure) to 3.1 cases per 100,000 population in 2002. Similarly, the cumulative effect of hepatitis B virus (HBV) vaccination has been a reduction in the incidence of acute HBV infections from 9.2 cases per 100,000 population in 1981 to 2.8 cases per 100,000 in 2002.⁷³⁶ Although the overall incidence of HAV and HBV infections has decreased, certain populations still experience high levels of infection. For example, the incidence of HBV continues to increase in MSM and in heterosexual men and women with multiple sexual partners,⁷³⁷ and HAV outbreaks among MSM in urban areas are reported frequently.⁵⁴⁴ Studies also suggest that hepatitis C virus (HCV) is sexually transmitted.^{738–742} The risk of infection via this route appears to be low; one study reported an annual risk of intercourse transmittance of less than 0.23% per year.⁷³⁸

► CONCLUSIONS AND SUMMARY

Healthy People 2010⁷⁴³ is a comprehensive set of national health goals and objectives for the United States to achieve during the first decade of the new century. Table 10-6 outlines selective objectives for reducing STIs and STI complications, as well as addressing sexual risk behaviors. There continues to be a high burden of disease from STIs in the United States, and it is unlikely that we will achieve many of the goals in the next 5–6 years without further advances and funding of STI prevention and control efforts.

The Epidemiology and Prevention of Human Immunodeficiency Virus (HIV) Infection and Acquired Immunodeficiency Syndrome (AIDS)

Alan E. Greenberg • D. Peter Drotman • James W. Curran • Robert S. Janssen

► INTRODUCTION

AIDS emerged as one of the most important public health issues of the late twentieth and early twenty-first centuries and is now one of the leading causes of global morbidity and mortality. The AIDS epidemic has prompted wide-reaching changes in public health, clinical practice, and scientific research, and has had a great impact upon societies throughout the world.

History and Origin

AIDS was an unrecognized medical syndrome before the 1980s.^{1,2} In the United States, investigations into the increase of opportunistic diseases occurring in previously healthy young adult males resulted in the first reports of AIDS among homosexual men in 1981.^{3,4} In Africa, AIDS was initially described in both men and women in 1984,^{5,6} with the earliest known HIV-1 seropositive specimen identified through retrospective studies from Central Africa in 1959.⁷ HIV-2, a related retrovirus that is less transmissible and pathogenic but that can still cause AIDS, was first isolated in West Africans in the mid-1980s, with the earliest known recorded HIV-2 infection probably having occurred in Guinea Bissau in the 1960s.⁸ Based on molecular analyses comparing human and simian (monkey) retroviruses, it is believed that the HIV-1 virus that became epidemic was first transmitted to humans from chimpanzees in Central Africa in the 1930s, and that the HIV-2 virus was first transmitted to human from sooty mangabeys in West Africa.⁹⁻¹²

Both social and biologic factors explain why AIDS initially became epidemic in the industrialized world after HIV was introduced in the population. Among these were changes in sexual behaviors, particularly increases in the numbers of sexual partners and sexually

transmitted diseases among substantial numbers of men who have sex with men, high rates of injection drug use (both opiates and cocaine), and sharing of contaminated needles and syringes, and the development of technology to use large plasma pools with thousands of donors for manufacture of clotting factor concentrates. These factors represented amplification systems that, in combination with the long incubation period for AIDS, allowed extensive transmission of HIV to occur even before the first clinical cases were discovered. In Africa, a number of factors are hypothesized to have contributed to the rapid early spread of HIV in the 1980s, including rural-to-urban migration patterns, the establishment of HIV infection in female sex workers with spread to their male clients, and subsequent extensive sexual networking with both regular and casual partners.^{13,14} A number of important biologic risk factors for HIV transmission in Africa were identified, including high HIV viral load, young age at first sexual intercourse among women, age differential between spouses, herpes simplex type 2 infection, trichomoniasis, and lack of male circumcision.^{15,16} Spread between geographically distant regions was attributed to highly mobile populations such as truck drivers, seasonal workers, and migrant populations.^{17,18} The epidemic then spread globally to North America and the Caribbean, Europe, Australia, Asia, and South America.

Etiologic Agent and Natural History

In 1983 and 1984, researchers at the Institut Pasteur (Paris) and the National Cancer Institute isolated a retrovirus, subsequently named HIV, and demonstrated it to be the cause of AIDS.¹⁹⁻²³ In 1985, a genetic variant of the AIDS virus was isolated and named HIV-2.^{8,24} HIV-1 has developed great genetic diversity, with 13 distinct circulating genetic subtypes and 11 additional recombinant forms identified globally.²⁵⁻²⁸ By 2005, these were classified as group M (main), O (outlier), and N (non-M, non-O) HIV-1 viruses, with almost all of the globally transmitted strains being from group M. Group M is composed of nine distinct subtypes, with predominantly subtype B in North America and Western Europe; subtypes B and F in South

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

America; subtype C in Southern Africa; subtypes A and D in East Africa; recombinant subtype A/G in West Africa; subtype B and recombinant subtype A/E in Asia; and a great diversity of subtypes found in Central Africa, where HIV-1 is believed to have first been introduced in humans. Differences in the clinical manifestations and the transmissibility of these various subtypes have been hypothesized but not proven. The genetic diversity of HIV is important in the development of diagnostic tests and perhaps for HIV vaccine candidates, as well as in the tracking of the global spread of HIV.

HIV can enter the body parenterally, through the gastrointestinal tract, or through the genitourinary tract. HIV infects local cells such as dendritic cells and replicates locally for a few days before it becomes a systemic infection. Within about 10 days after infection, HIV nucleic acids are detectable in blood, and antibodies to HIV are detectable generally within 1–2 months following infection. HIV preferentially infects T-helper lymphocytes (often termed CD4 cells because of the so-named receptor molecule on their surface that identifies them), white blood cells that are critical to human immune function, through a complex mechanism whereby a glycoprotein (gp 120) of the HIV viral envelope binds strongly to the surface of the CD4 lymphocytes and a few other cell types.²⁹ HIV is an RNA virus, which replicates by a process known as reverse transcription. HIV RNA is initially transcribed into DNA of the host cell which is then transcribed into RNA, which in turn is then copied multiple times, turning the cell into a virtual “factory” for producing multiple HIV viral particles. These particles are then released from the CD4 lymphocyte into the bloodstream, destroying the host cell in the process. When these particles invade many new CD4 cells, the life cycle of HIV is complete. This cellular destruction results in the characteristic decrease in CD4 cell and total lymphocyte counts causing a progressive immunodeficiency; when the immune compromise is severe enough (defined as a CD4 count of less than 200 cells/uL), an HIV-infected person becomes susceptible to potentially life-threatening “opportunistic” infections and diseases. Although the immune system is extraordinarily resilient and regenerative, HIV reproduces at a rate of 10 billion new virions per day.³⁰ Infection with HIV, as with all human and animal retroviruses, is presumed to be lifelong.

Modes of Transmission and Distribution of Infection

HIV has been recovered from peripheral blood, semen, vaginal secretions, breast milk, other body fluids, and numerous anatomical sites.^{31,32} There are three main modes of transmission: sexual transmission through rectal, vaginal, and more rarely oral contact; parenteral transmission through injection, transfusion, or accidental exposure to infected blood or its components; and perinatal transmission from infected mothers to their infants either before, during, or after childbirth. Epidemiologic observations and controlled studies have confirmed these routes of transmission in homosexual and bisexual men,³³ heterosexual men and women,³⁴ injecting drug users³⁵ and infants.³⁶ Previously documented risks to persons with hemophilia^{37–39} and transfusion recipients⁴⁰ have been remarkably well controlled by educating donors, testing all donations of blood and plasma for HIV-1 and HIV-2 antibody, HIV-1 antigen, HIV RNA, and by developing safe clotting factor concentrates.^{41,42} Compared to the low risk of HIV infection through receptive oral intercourse which is estimated at 1 per 10,000 exposures, the risk of HIV infection has been estimated to be 9000 per 10,000 exposures for blood transfusion, 67 per 10,000 exposures for needle-sharing injection drug use, 50 per 10,000 exposures for receptive anal intercourse, 30 per 10,000 exposures for percutaneous needle stick, 10 per 10,000 exposures for receptive penile-vaginal intercourse, 6.5 per 10,000 exposures for insertive anal intercourse, and 5 per 10,000 exposures for insertive penile vaginal intercourse.⁴³

Health-care and laboratory workers have been infected through occupational exposure to blood or specimens from HIV-infected patients. Risk of infection following parenteral exposures was about 0.3% in several long-term prospective studies.^{44,45} Reports of seroconversion and HIV infection following skin or mucous membrane exposure to HIV-infected blood indicate that these can occur, but the risk is much lower than following parenteral exposures. Because of

this risk and the uncertainty of trying to identify every infected patient, health-care workers should always follow standard precautions with all patients to minimize exposures to HIV, hepatitis B and C viruses, and other blood-borne pathogens. These precautions include the use of appropriate barrier protection (such as gloves, masks, gowns, and goggles) whenever contact with blood or nonintact tissue seems likely.⁴⁶ Postexposure prophylaxis with a course of antiretroviral agents is recommended for workers who sustain percutaneous or mucous membrane exposure to HIV-infected materials.⁴⁷ Similarly, the U.S. Public Health Service recommends the use of 28 days of highly active antiretroviral therapy (HAART) for use as postexposure prophylaxis for persons with significant and recent (<72 hours) sexual or parenteral exposures to persons known to be HIV-infected.⁴³

There is no evidence that HIV is spread by air, water, food, casual contact, or insect vectors. If such modes of transmission did exist, the epidemiology of HIV and AIDS would be much different, with clusters occurring in schools, nursing homes, and households. Only a small fraction of the reported cases do not fall readily into a characteristic patient group. Extensive follow-up of household contacts of both adults and children with AIDS has failed to demonstrate evidence of HIV transmission via shared living space, kitchens, or bathrooms or through casual contact.⁴⁸ However, very rare instances of HIV transmissions in households where direct care of AIDS patients was the risk factor indicates that the standard precautions originally developed for use in hospitals should apply to home health care as well.⁴⁹

Surveillance of HIV and AIDS

Before the cause was known, AIDS was initially defined as the occurrence of a severe opportunistic illness in a person without a previously known cause of immunodeficiency; the most frequently reported illnesses in the United States were *Pneumocystis carinii* pneumonia and Kaposi’s sarcoma.^{50,51} Identification of HIV as the cause of AIDS and growing knowledge of the disease’s epidemiology and clinical presentations led to the expansion of the U.S. surveillance case definition in 1987 to include such conditions as HIV encephalopathy and wasting syndrome, and in 1993 to include tuberculosis, recurrent bacterial pneumonia, invasive cervical cancer, and severe immunodeficiency as measured by a CD4 cell count less than 200 cells/uL.^{52,53} Currently, the most frequently reported AIDS condition is a CD4 count less than 200 cells/uL, responsible for the majority of newly reported AIDS diagnoses in the United States. Because the distribution of time from infection to development of opportunistic infections was known through cohort studies, AIDS incidence was initially used to estimate historical HIV incidence when antiretroviral therapy was of limited value. However, the addition of CD4 count criteria to the AIDS case definition and the efficacy of highly active antiretroviral therapy eliminated the ability to estimate HIV incidence through the reporting of AIDS cases. Subsequently, the HIV incidence in the United States was estimated using a number of imprecise methods to be about 40,000 cases per year between 1992 and 2000.⁵⁴

In 1996, when the use of highly active antiretroviral therapy became widespread in the United States, the interval between HIV infection and the development of severe HIV-related disease was greatly increased and trends in AIDS cases became much less useful in modeling trends in HIV transmission. This made it critical to monitor the number of persons reported with HIV as well as with AIDS.⁵⁵ National surveillance systems for HIV/AIDS were consequently expanded to include monitoring of new HIV diagnoses, HIV incidence, behaviors that put people at high risk for HIV, and HIV related morbidity and mortality. In the United States, a National Behavioral Surveillance System was established to monitor behaviors that place individuals at high risk for HIV infection;⁵⁶ this surveillance system uses serial cross-sectional surveys in high-risk populations including men who have sex with men, injection drug users, and heterosexuals at high risk for HIV infection throughout the United States.

Trends can now be observed in reported HIV cases for 33 states and territories that have reported HIV infections to CDC since 1999.⁵⁷

Figure 11-1. Annual numbers of AIDS cases, deaths of persons with AIDS, and persons living with AIDS, United States, 1985–2005.

However, these areas represent only approximately 43% of the U.S. epidemic.⁵⁸ Moreover, HIV case reporting may not be representative of recent trends in new HIV infections since persons are often infected for many but an unknown number of years before they are diagnosed with HIV. Accordingly, CDC has established HIV incidence surveillance in the United States. As of 2006, this system was established in 34 areas, and is based on the serologic testing algorithm for recent HIV seroconversion (STAHRS) that uses a novel HIV antibody assay to estimate the proportion of HIV infections that have occurred within the past 6 months.⁵⁹ Monitoring of HIV incidence is critical to assessing in real time whether HIV prevention programs are having an impact in stemming the epidemic.

In Figure 11-1, trends in AIDS cases, AIDS deaths, and persons living with AIDS in the United States are shown by year from 1985 to 2005. There was a steady increase in the numbers of AIDS cases and deaths from 1985 through 1993; followed by a sharp decline from 1993 through 1997. The sharp rise and decline around 1993 are a result of having added immunologic criteria to the AIDS case definition. Numerous people with HIV with CD4 counts below 200 cells/ul were not diagnosed with AIDS until 1993. This reporting artifact was seen in AIDS cases but not deaths and provided a key lesson for public health officials who oversee case definitions for reportable conditions. The decline in deaths and incident AIDS cases from 1995 through 1997 has largely been attributed to the widespread availability and use of combination antiretroviral therapy, and may also be due to the declining HIV incidence that occurred in the mid- to late-1980s. This was followed by a plateau in AIDS cases and deaths from 1997 through 2004, with an increase in reported AIDS cases observed in 2005. The concurrent reduction in AIDS-related mortality to fewer than 20,000 per year and the continued incidence of approximately 40,000 new persons being diagnosed with HIV each year has led to a continued increase in the numbers of persons living with HIV/AIDS. This has implications for ensuring the availability of treatment and care for these persons, as well as for the increasing number of persons who need interventions to prevent further transmission.

As shown in Table 11-1, a cumulative total of 956,666 AIDS cases were reported in the United States through 2005, predominantly in whites (40%), blacks (42%), and Hispanics (16%); and in men who have sex with men (47%), injection drug users (25%), and persons who acquired the infection through heterosexual contact (17%). The epidemiology of HIV in the United States is continuing to evolve,

however; of the estimated 38,096 HIV/AIDS cases reported in 2005 from 33 areas with confidential name-based HIV reporting, an increasing proportion occurred in blacks (49%) and persons who acquired the infection through heterosexual contact (32%), with a decreasing proportion in injection drugs users (14%). A cumulative total of 530,756 AIDS deaths were reported in the United States since the beginning of the epidemic through 2005.

For cases of AIDS among children, there was a prolonged period of increase from 1981 through 1993, when the discovery that the antiretroviral drug zidovudine, when administered during pregnancy and labor to HIV-infected mothers and postpartum to their exposed infants, could decrease the risk of mother-to-child HIV transmission,⁶⁰ and Public Health Service guidelines were issued to support its use.^{61,62} Currently, the use of combination antiretroviral therapy, obstetrical interventions such as cesarean sections,⁶³ the avoidance of breast feeding, and recommendations for routine HIV screening during pregnancy and during labor for delivering women with unknown HIV status⁶⁴ further reduced mother-child HIV transmission, and the implementation of these practices⁶⁵ led to a dramatic reduction of more than 90% in perinatally acquired AIDS cases in the United States between 1993 and 2005. Similar reductions in perinatal HIV transmission and pediatric AIDS have been observed in nations where such interventions have been implemented, but many nations in the developing world have lacked the resources to duplicate this accomplishment.

Globally, the United Nations Joint Programme on AIDS (UNAIDS) and the World Health Organization issue annual updated HIV/AIDS surveillance estimates. In the developing world, AIDS and HIV case surveillance systems tend to be less complete, and HIV trends are generally monitored through repeated cross-sectional HIV seroprevalence surveys among women attending antenatal clinics as proxies for the population of sexually active adults of child-bearing age.⁶⁶ According to UNAIDS/WHO, and as shown in Table 11-2, by the end of 2006, 39.5 million persons were living with HIV, the majority of whom (63%) were living in sub-Saharan Africa.^{67–69} In 2006, an estimated 4.3 million persons were newly infected with HIV, and an estimated 2.9 million persons died from AIDS. Important differences mark the global transmission patterns of HIV.^{67–69} In sub-Saharan Africa, where an estimated 24.7 million persons are living with HIV, heterosexual transmission is predominant, with the highest HIV prevalence rates in the

^aIncludes persons diagnosed in 33 states and territories with confidential name-based reporting, and those diagnosed with either HIV infection and/or AIDS.

^bIncludes persons diagnosed with AIDS from the beginning of the epidemic through 2005.

^{6-8,19}Numbers represent point estimates which result from numbers of reported cases adjusted for reporting delays and for redistribution of cases in persons initially reported without an identified risk factor. Because column totals were calculated independently of the values for the subpopulations, and because only the major subpopulations are included, the values in each column may not sum to the column total.

TABLE 11-2. ESTIMATED NUMBER OF ADULTS AND CHILDREN NEWLY INFECTED WITH HIV IN 2006, LIVING WITH HIV AS OF END 2006, AND DYING FROM AIDS IN 2006, BY REGION¹²¹

	Estimated number of adults and children		
	<i>Newly HIV infected in 2006</i>	<i>Living with HIV as of end 2006</i>	<i>Dying from AIDS in 2006</i>
Total	4,300,000	39,500,000	2,900,000
Sub-Saharan Africa	2,800,000	24,700,000	2,100,000
South and Southeast Asia	860,000	7,800,000	590,000
Latin America	140,000	1,700,000	65,000
Eastern Europe and Central Asia	270,000	1,700,000	84,000
North America	43,000	1,400,000	18,000
East Asia	100,000	750,000	43,000
Western Europe	22,000	740,000	12,000
North Africa and Middle East	68,000	460,000	36,000
Caribbean	27,000	250,000	19,000
Oceania	7100	81,000	4000

general adult population of 17–39% found in southern Africa. The highest HIV seroprevalence rates among pregnant women in the world (20–50%) have been found in southern Africa; rates of 5–20% have been demonstrated in East, West, and Central Africa as well. HIV rates in Africa were noted generally to have stabilized by 2006, although increased rates were noted in some Southern African countries such as Mozambique, South Africa and Swaziland, and stabilized or decreased rates were noted in East African countries such as Kenya and Tanzania. In Asia, with 7.8 million (19.7%) HIV-infected persons, the epidemic has continued to expand, initially in injection drug users, sex workers and their clients, and currently among men who have sex with men as well. In China, the epidemic is gradually spreading from high-risk populations to the general population, and India is experiencing a diverse epidemic with increased rates in some parts of the country and decreased or stabilized rates in others. The HIV epidemic also expanded in Eastern Europe, Central Asia, and Russia, where about 1.7 million persons were living with HIV by 2006. Injection drug use was largely responsible for HIV transmission in this region, predictably followed by increasing heterosexual transmission. Latin America accounted for about 1.7 million HIV-infected persons, and injecting drug use and male-to-male transmission predominated in this region. In the industrialized nations of Western Europe and Australia, epidemiologic patterns are similar to those seen in the United States though HIV prevalence is generally lower.

Treatment of HIV infection in the era of Highly Active Antiretroviral Therapy (HAART)

Before the era of combination antiretroviral therapy, approximately 50–70% of HIV-infected adults developed AIDS within 10 years of HIV infection. The introduction of zidovudine (ZDV or AZT) in the United States in 1987 ushered in the era of antiretroviral therapy. As additional anti-HIV drugs were introduced, HIV-infected patients were treated with monotherapy through about 1993 and subsequently the concurrent use of two antiretrovirals (“dual therapy”) became common from 1993 to 1996. However, due in part to its rapid replication rate, HIV exhibits a remarkable rate of mutation and became largely resistant to both mono- and dual therapy. However, when the use of three concurrent agents (“triple therapy,” or HAART) began in 1996, highly successful therapy for HIV became commonplace in industrialized nations.⁷⁰ Although no patient could be said to have been “cured” of HIV infection, replication of the virus could be held in check and immune function could effectively be preserved.

Clinical decisions regarding when to initiate HAART in HIV-infected persons are based on laboratory measurements of the patient’s immune status (CD4 lymphocyte count) and on the concentration of HIV in the patient’s blood (“HIV viral load”). Department of Health and Human Services (DHHS) guidelines issued in 2006⁷¹ recommended that HAART be initiated for HIV-infected persons with a history of an AIDS-defining illness or with a CD4 count less than 200 cells/uL. HAART can also be considered for patients with a CD4 count between 201–350 cells/uL, and some clinicians opt to consider treatment for patients with a CD4 count of >350 cells/uL and an HIV viral load of >100,000 copies/mL. The more than 20 licensed antiretroviral medications in the United States as of 2006 fell into four categories—nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and entry inhibitors (EIs). HAART is generally defined as the use of two NRTIs with either a single NNRTI, one or two PIs, or a third NRTI. In addition, the use of prophylactic oral antibiotics such as trimethoprim-sulfamethoxazole to prevent opportunistic infections such as pneumocystis pneumonia are recommended for patients whose CD4 lymphocyte counts are less than 200 cells/uL.⁷² The impact of HAART in countries where it has been widely available has been almost as dramatic as was the dawn of the antibiotic era following World War II, with steep declines in the incidence of AIDS and deaths among HIV-infected persons.⁷³ The regular monitoring of clinical status, CD4 counts, and HIV viral load in HIV-infected persons is critical so that decisions can be made about

the appropriate time to begin HAART as well as when to change to alternative HAART regimens due to antiretroviral resistance or side effects.

Despite the successes of HAART, important challenges remain.⁷⁴ First, since infection with HIV is lifelong, patients beginning on HAART need to take these pills on a daily basis indefinitely because therapy suppresses viral replication, but does not eradicate HIV from the host. Second, they must adhere very closely to the prescribed regimens, because missing doses can allow the virus to mutate and become resistant to antiretroviral drugs, which will then necessitate changing to potentially more complex, toxic, and expensive regimens.⁷⁵ Third, there are many side effects associated with antiretroviral regimens, which can vary among drug and classes of drugs, but can include liver toxicity, hyperglycemia, fat maldistribution, hyperlipidemia, insulin resistance, cardiovascular disease, osteoporosis, and rash.⁷⁶ Last, but most important from the public health perspective, has been the stark inequities in access to antiretroviral drugs between HIV-infected persons in developing countries, who represent the vast majority of HIV-infected persons globally, and their counterparts in nations with adequate health-care systems. The differences have largely been due both to the high cost of these medicines and lack of clinical and laboratory infrastructure to support effective patient management.⁷⁷

Several important global initiatives began to address these disparities in the early 2000s. The World Health Organization launched the “3 by 5” initiative with the goal of treating 3 million persons with HAART by 2005. WHO promulgated the first guidelines for scaling up antiretroviral therapy in resource-limited settings in 2003.⁷⁸ A “Global Fund” was established to finance international efforts to address AIDS, tuberculosis, and malaria in the developing world.⁷⁹ The United States government committed significant resources to expanding antiretroviral therapy in the developing world through the President’s Emergency Plan for AIDS Relief that established as five-year goals to provide treatment to two million persons and to prevent seven million HIV infections in 15 designated countries.⁸⁰ As of the end of 2006, UNAIDS and WHO reported that more than 2 million persons with advanced HIV infection were receiving antiretroviral therapy in low- and middle-income countries.⁸¹

Prevention and Control

More than one and a half million people have become infected with HIV in the United States. New infections peaked in 1985 at 150,000 and over the past decade HIV incidence has been estimated at 40,000 cases per year. The rapid decline in HIV incidence may have been related to the early successes of HIV prevention programs, but more recently continued progress in prevention has been challenging.

There have been important successes in controlling the HIV epidemic in the United States and other industrialized countries. Serologic tests to screen donated blood and to aid in the diagnosis of patients were licensed for use in the United States in March 1985. Screening donated blood for HIV antigens and nucleic acid, begun and widely implemented in the late 1990s and early 2000s, has reduced the risk of HIV transmission to less than one per million transfusions. In Africa, transmission of HIV through transfused blood was commonplace in areas of high HIV prevalence⁸² but programs creating centralized blood banking systems and systematic HIV screening have begun to reduce that risk.

Antiretroviral therapy administered to mothers and infants has effectively reduced perinatal transmission in the United States and in other industrialized countries. HIV can be transmitted to infants from infected mothers during pregnancy, at labor, or postpartum through breast-feeding.⁸³ Without interventions, the rate of mother-to-child HIV transmission is about 25% in non-breast-feeding populations, and about 35–40% in breast-feeding populations. With appropriate interventions such as antiretroviral therapy, obstetrical interventions such as avoidance of prolonged rupture of membranes and cesarean section when indicated, and avoidance of breast-feeding, perinatal transmission rates can be reduced to less than 2%.^{84–86} In 1995, the US Public Health Service recommended that pregnant women be offered

HIV counseling and testing, and in 2006 updated these recommendations to further emphasize HIV testing as a routine part of prenatal care and rapid HIV testing during labor for mothers of unknown HIV status.⁸⁷ The implementation of routine testing and use of antiretroviral drugs resulted in a dramatic decline in HIV transmission to newborns in the United States. For developing countries, WHO has issued guidelines for preventing perinatal HIV transmission,⁸⁸ and numerous international organizations have begun working to implement them. These efforts face a number of important challenges including the development of improved prenatal care programs and addressing the postpartum transmission of HIV through breast-feeding.

Reducing HIV transmission through injecting drug use and sexual intercourse has been a great challenge to public health agencies everywhere. In the United States, HIV transmission through injection drug use has been addressed through referral to drug treatment programs and methadone maintenance programs to diminish drug use itself,⁸⁹ and for those who continue to inject, through programs that encourage and facilitate the consistent use of sterile injection equipment.⁹⁰ Innovative approaches to injection drug users have shown some effectiveness. These include use of nontraditional outreach workers (such as former drug users, including some living with HIV), reducing or eliminating charges for services, repeated counseling and follow-up contacts,⁹¹ and needle and syringe exchange programs. In the United States, HIV prevention programs and drug treatment programs reduced the proportion of AIDS cases among injecting drug users from 40% in the 1980s to 20% in 2002.⁵⁸ Trends in HIV cases among injecting drug users in the United States declined in the early twenty-first century, but this trend was not observed in Eastern Europe, Central Asia, Vietnam, and China, where injecting drug use fueled growing HIV epidemics.

In the United States, about 80% of AIDS cases occur among people infected through sexual contact; most sexually acquired HIV infections have occurred among men who have sex with men (MSM). Many MSM changed their sexual practices by increasing condom use and greatly reducing their number of sexual partners in the 1980s to avoid infection with HIV, as indicated by a dramatic decline in the incidence of sexually transmitted diseases (STDs) with short incubation periods, such as syphilis and rectal gonorrhea.⁹² However outbreaks

of syphilis, as well as increasing trends in reported HIV cases in men who have sex with men, have indicated that prevention efforts may not be working optimally in this population.⁹³ This may be attributable to multiple factors including decreased attention to HIV prevention in the media and by the general public, as well as to complacency by young MSM due to the availability of antiretroviral therapy and the observed decrease in HIV-related morbidity and mortality. This highlights the importance of addressing HIV prevention for each new generation as it matures, and not relying on past messages and prevention successes.

Historically, the focus of U.S. prevention efforts has been on counseling and testing and health promotion awareness and education aimed at both the general population and targeted to high-risk populations.⁹⁴ Sensitive and specific antibody tests on both serum and oral fluid specimens were incorporated into clinical prevention-oriented practices and public health services throughout the United States soon after they became available in the late 1980s. Rapid HIV testing kits were licensed in the United States in 2003 and have added to the HIV prevention armamentarium by facilitating the provision of same-day testing results, targeted HIV counseling, and increased access to HIV testing in nonmedical settings. In most settings, persons receive information regarding HIV transmission and prevention and the meaning of HIV test results prior to HIV testing, and individuals are tested after giving informed consent. In persons with a recent (less than 3 months) high-risk exposure, repeat testing is warranted to rule out an initial “false-negative” result from low antibody titers.⁸⁷ Counseling and testing have helped persons with HIV get the medical and preventive services they need; importantly, people who learn that they are infected with HIV reduce their risk behavior by nearly 70%.⁹⁵ With the emphasis on HIV testing, approximately 75% of those infected in the United States know their serostatus.⁹⁶

Another important approach to reducing sexual HIV transmission is through health education and the dissemination of information about behavioral skills that can reduce HIV risk. Every clinician has a role to play in this effort. Specific evidence-based recommendations have been promulgated by the U.S. Preventive Services Task Force (Table 11-3). The reduction of sexual transmission of

TABLE 11-3. CLINICAL PREVENTIVE SERVICES¹²²

The ACPM and the U.S. Preventive Services Task Force (USPSTF), based at the Agency for Healthcare Research and Quality, have each developed evidence-based recommendations regarding the delivery of clinical preventive services.

U.S. PREVENTIVE SERVICES TASK FORCE RECOMMENDATIONS

Clinicians should assess risk factors for human immunodeficiency virus (HIV) infection by obtaining a careful sexual history and inquiring about injection drug use in all patients. Periodic screening for infection with HIV is recommended for all persons at increased risk of infection (see *Clinical Intervention*). Screening is recommended for all pregnant women at risk for HIV infection, including all women who live in states, counties, or cities with an increased prevalence of HIV infection.

HIV INFECTION AND OTHER SEXUALLY TRANSMITTED DISEASES

U.S. PREVENTIVE SERVICES TASK FORCE RECOMMENDATIONS

All adolescent and adult patients should be advised about risk factors for human immunodeficiency virus (HIV) infection and other sexually transmitted diseases (STDs), and counseled appropriately about effective measures to reduce the risk of infection (see *Clinical Intervention*). Counseling should be tailored to the individual risk factors, needs, and abilities of each patient. This recommendation is based on the proven efficacy of risk reduction, although the effectiveness of clinician counseling in the primary care setting is uncertain. Individuals at risk for specific STDs should be offered testing in accordance with recommendations on screening for syphilis, gonorrhea, hepatitis B virus infection, HIV infection, and chlamydial infection (see *Screening for Hepatitis B Virus Infection*, *Screening for Syphilis*, *Screening for Gonorrhea*, *Screening for HIV Infection*, and *Screening for Chlamydial Infection*). Injection drug users should be advised about measures to reduce their risk and referred to appropriate treatment facilities (see *Screening for Drug Abuse*).

HIV and other sexually transmitted diseases can be achieved through avoiding or postponing the initiation of sexual activity, and for sexually active individuals, through mutual monogamy and the correct and consistent use of condoms. These behaviors can be increased through risk reduction counseling and through building condom and sex negotiation skills with individuals and in small groups, or through interventions aimed at communities. Such interventions are becoming the core of HIV prevention programs in the United States.^{97,98}

In the United States, HIV prevention programs have focused on people at risk for HIV, as well as on those who are already infected. Given that additional HIV prevention efforts in the United States are needed to reduce the incidence of new HIV infections, the CDC launched a new strategy for HIV prevention in 2001 called the Serostatus Approach to Fighting the Epidemic (SAFE),⁹⁹ a program designed to increase (a) the number of persons who know their serostatus, (b) the use of health care and prevention services, (c) high-quality care and treatment services, (d) adherence to therapy by individuals with HIV, and (e) the number of individuals with HIV who adopt and sustain HIV and STD risk reduction behavior. This strategy was intended to enhance existing HIV counseling and testing programs and to complement health education and risk reduction programs aimed at those who were not infected or did not know their HIV status. SAFE led to the launch of a new initiative in 2003 by CDC and the U.S. Department of Health and Human Services called "Advancing HIV Prevention: New Strategies for a Changing Epidemic" that formalized such interventions.¹⁰⁰ In 2006, CDC issued guidelines recommending routine HIV screening for patients in health-care settings unless the patient declines ("opt-out" testing), and recommending that persons at high risk for HIV infection be screened at least annually.⁸⁷

Internationally, preventing HIV and AIDS in developing countries is an enormous challenge that has been notable for some national successes. In Thailand, a concerted national HIV prevention program that included a "100% condom campaign" resulted in dramatic reductions in HIV incidence through sexual contact.^{101,102} In Uganda, the government took bold action against HIV by making HIV counseling and testing widely available and promoting risk reduction messages emphasizing abstinence, monogamy, and the correct and consistent use of condoms for sexually active persons. HIV prevention strategies utilized in developing countries include HIV awareness campaigns; voluntary counseling and testing; HIV risk reduction messages; promotion of condoms for sexually active individuals; establishment of a safe blood supply through HIV testing of donated blood; promotion of safe injection practices in health-care settings; mother-child prevention programs to identify HIV-infected pregnant women and provide antiretrovirals for prevention and care to both mothers and infants; provision of care and treatment to HIV-infected persons; the development of sustainable infrastructure for HIV prevention and care; involvement of local communities and national leaders in HIV prevention; the reduction of stigma associated with HIV infection; and support for the orphans of HIV-infected families.⁸⁰ As in the United States, it is important in the developing world to integrate HIV prevention and HIV treatment efforts to optimize their success^{80a}; and in areas of the world such as Africa where tuberculosis is a leading cause of morbidity and mortality among HIV-infected persons, emphasis has been placed on the integration of national HIV/AIDS and tuberculosis control programs^{80b}.

HIV Prevention Research Issues

Researchers are trying to improve our understanding of risk factors for HIV infection among understudied U.S. populations, as well as developing new behavioral interventions for HIV-infected and uninfected persons. Numerous innovative interventions are being developed and tested including intensive one-on-one counseling; groups skills-building interventions; interventions to promote the delay of sexual debut and the correct and consistent use of condoms in those who are sexually active; and structural interventions

such as providing housing to homeless persons living with HIV. A number of biomedical interventions are also being studied as potential HIV prevention research tools that would be used in addition to behavioral interventions. First, a global effort is under way to identify a safe and effective vaccine that could prevent HIV infection. A variety of products are being developed to stimulate neutralizing antibody responses, cell-mediated immunity, or both. The various HIV vaccine strategies under development included live vector viruses, naked DNA, HIV peptides, live bacterial vectors, and pseudovirions.^{103–105} Two phase III HIV vaccine efficacy trials of a gp120 vaccine sponsored by the company VaxGen were completed in 2003 in men who have sex with men and high-risk heterosexual women in North America,¹⁰⁶ and in injection drug users in Thailand.¹⁰⁷ Although both of these trials failed to demonstrate efficacy, they did prove that HIV vaccine efficacy trials could be completed in high-risk populations using high scientific and ethical standards. A third efficacy trial is being conducted of an HIV vaccine designed to stimulate both the humoral and cellular arms of the immune system in a community-based population in Thailand.¹⁰⁸ Trials of another vaccine designed to stimulate primarily the cellular arm of the immune system are ongoing in 2007 in the Americas, Australia, and South Africa.^{109,110} Numerous other new vaccine candidates are currently being tested in safety and early immunogenicity trials.

HIV microbicides are creams or gels that could be used vaginally or rectally to prevent HIV transmission. There has been great interest in the development of microbicides to enhance women's control of HIV prevention when condom use is not feasible. Multiple approaches to microbicide product development are being developed including disrupting the HIV membrane, blocking HIV infectivity, inhibiting intracellular HIV replication, and altering the vaginal environment (e.g. acidity).^{111,112} To date, efficacy trials have been conducted in female sex workers of nonoxynol-9 which failed to demonstrate efficacy and in some cases increased HIV transmission. A third failed efficacy trial of a cellulose sulfate microbicide was also reported in 2006.¹¹³ Several additional trials of new products are currently being conducted and multiple other new agents are now being assessed in safety trials.

A relatively new area of research is the use of antiretroviral pre-exposure prophylaxis ("PREP") to prevent HIV infection.¹¹⁴ Antiretrovirals such as tenofovir and emtricitabine have been used extensively for HIV treatment, are relatively safe and well tolerated, have long half-lives, and have been shown in monkey models to prevent infection following retroviral exposure. Accordingly in 2004 and 2005, PREP studies with tenofovir alone or in combination with emtricitabine were begun or planned in high-risk women and men in Africa, high-risk men in the Americas, and injection drug users in Thailand; and an extended safety study was begun in homosexual men in the United States. Results from an initial study of daily tenofovir used as PREP in women in West Africa supported the safety of this approach,¹¹⁵ and results from larger efficacy trials will be available in the years ahead.

Three randomized clinical trials were completed in 2005–2006 in South Africa, Kenya, and Uganda demonstrating that male circumcision reduces HIV transmission in men.^{116–118} In 2007, based on the results of these trials, WHO/UNAIDS recommended that male circumcision be recognized as an effective intervention for HIV prevention;¹¹⁹ important issues about the population-based safety, efficacy, and acceptability of this HIV prevention approach will be assessed in the years ahead. A fourth study is ongoing in Uganda to assess whether male circumcision can reduce HIV transmission in the female sexual partners of men who have been circumcised.¹²⁰

Lastly, there are a number of important unresolved issues in the prevention of mother-to-child HIV transmission that are now being addressed. For example, although antiretrovirals have proved successful in preventing prepartum and intrapartum transmission of HIV, postpartum HIV transmission through breast-feeding remains a significant problem in areas of the developing world where formula

feeding is not recommended due to the importance of breast-feeding for the nutritional and immunologic health of infants, and concerns about the safety of the water supply. Accordingly, scientists are now conducting studies in Africa to determine whether more prolonged courses of antiretrovirals administered to mothers and/or their infants can further reduce mother-child HIV transmission. These data should be available in several years and will provide critical information to help inform improved HIV prevention programs in the future.

Summary

We are living in an extremely challenging period in the history of the HIV/AIDS pandemic. On one hand, the current magnitude of the epidemic is staggering, with an estimated 40 million persons living with AIDS, mostly in sub-Saharan Africa. On the other hand, it is a time of unprecedented opportunity in the global struggle against HIV/AIDS, both because of the availability of new and powerful tools such as antiretroviral medications for treatment as well as prevention of mother-child and perhaps other modes of transmission, and because of the recent focus of international donors who are contributing billions of dollars annually to promote HIV treatment and prevention in the developing world. There is an important legacy of successful prevention interventions that have been developed to date, including HIV serologic counseling and testing; use of rapid tests; screening of the blood supply; behavioral prevention programs for men who have sex with men, injection drug users, and heterosexuals; and prevention of mother-child transmission. However, there is a concurrent legacy of failures and omissions as well, such as the delay in mobilization of global resources to fight the HIV epidemic in developing countries, continued stigma against persons infected with HIV and groups at high risk of infection, and the delay in expanding antiretroviral therapy to the developing world. The years ahead will demonstrate whether the public health and political leaders of tomorrow will rise to this challenge, implementing proven HIV prevention strategies, ensuring that underserved populations have access to antiretroviral therapy, and having the vision to support the discovery and dissemination of new behavioral and biomedical HIV prevention interventions.

Infections Spread by Close Personal Contact

Acute Respiratory Infections

Javier Ena

Upper respiratory tract infections, mainly common cold and acute pharyngitis, accounted for 10.8% (27.5 million) of all visits to physicians in the United States in 1991.¹ In 1–4-year-old children, otitis media is one of the most common reasons for visits to physicians, and accounted for an additional 2.7 million office visits.¹ To diagnose and treat upper respiratory tract infections and otitis media costs billions of dollars. Furthermore, the diagnostic criteria for upper respiratory tract infections are often subjective and based on symptoms alone; because of this, treatment varies significantly from physician to physician.²

Pneumonia is a severe and common upper respiratory tract infection that remains a substantial cause of morbidity and mortality in adults and children. In Europe and North America, the annual incidence of pneumonia in children younger than five years is 34–40 cases per 1000; and in the developing world the incidence is several-fold higher.³ Worldwide more than two million children die of pneumonia annually.⁴

In children under five years of age, respiratory syncytial virus (RSV) has been described as the single most important cause of acute respiratory tract infections; and repeated RSV infections are common in all age groups.⁴ In elderly patients, RSV infection causes 10% of hospital admissions, 10% of which have fatal outcomes.⁵ (These values are similar for influenza.) Vaccines for RSV, although immunogenic, do not protect from subsequent infections. Monthly administration of RSV immune globulin is effective but cumbersome. Currently there are humanized monoclonal antibodies available to prevent infections caused by RSV.⁶

Streptococcus pneumoniae and *Haemophilus influenzae* are significant respiratory bacterial pathogens that are amenable to prevention and treatment, but the emergence of resistant strains have induced changes in the empirical treatment.⁷ The development of conjugated vaccines for *S. pneumoniae* and *H. influenzae* have increased the immunogenicity compared with previous polysaccharide vaccines.⁸ However, the vaccination coverage against these two pathogens is far from optimal, especially in adults.

Pertussis remains endemic in the United States despite routine childhood vaccinations for more than half a century, and high coverage levels in children for more than a decade. A primary reason for the continued circulation of *Bordetella pertussis* is that immunity to pertussis wanes approximately 5–10 years after childhood pertussis vaccination is completed; this leaves adolescents and adults susceptible.⁹ Before 11–12-year olds were routinely vaccinated against diphtheria and tetanus, a number of developed countries suffered a reemergence of pertussis cases and outbreaks.

Diphtheria is currently considered a rare infectious disease but remains a matter of concern both for travelers to countries where this infection is still active or from cases imported from endemic regions.¹⁰ Giving vaccination boosters containing diphtheria toxoid to adolescents and adults remains an important measure to prevent sporadic cases of respiratory diphtheria.

Finally, governments and hospitals must be prepared to fight outbreaks of new viral infections. The severe acute respiratory syndrome (SARS) coronavirus and avian influenza A H5N1 are the latest in a series of continually emerging pathogens related to globalization and to the proximity of dense populations of people to wild and domestic animals. SARS caused a significant morbidity and mortality during the 2003 outbreak in Hong Kong.¹¹ A global outbreak was likely avoided both through early recognition and prompt quarantine of suspected cases. SARS led to more than 700 deaths worldwide and the lessons learned have hopefully prepared health-care systems for a possible avian influenza pandemic. However, the SARS coronavirus is not contagious before the onset of symptoms, while in contrast avian influenza virus can be transmitted before symptoms appear and is highly contagious during the first few days of illness, facilitating the emergence of secondary cases. Thus at the dawn of the 21st century, the main strategies for preventing epidemics are still to prevent exposure to individuals at risk and vaccinate susceptible populations. In addition, improving animal and human surveillance, and continuing international research are essential to reduce the global impact of future epidemics.

► CLASSIFICATION

Acute respiratory tract infections are classified depending on whether they affect the upper or lower respiratory tract. The upper respiratory tract consists of the airways from the nostrils, to the vocal cords in the larynx, including the paranasal sinuses and the middle ear. The lower respiratory tract covers the continuation of the airways from the trachea and bronchi to the bronchioli and alveoli. Upper respiratory tract infections are the most common infectious diseases. They include rhinitis (common cold), sinusitis, ear infections, acute pharyngitis or tonsillopharyngitis, epiglottitis, and laryngitis. Ear infections and pharyngitis cause the more severe complications (deafness and acute rheumatic fever, respectively). The most common lower respiratory tract infections are pneumonia, bronchitis, and bronchiolitis.

► PATHOGENESIS OF ACUTE RESPIRATORY TRACT INFECTIONS

Upper Respiratory Tract Infections

The human respiratory tract is exposed to many pathogens via the smoke and dust that is inhaled in the air. It has been calculated that the average individual ingests about eight microorganisms per minute or 10,000 per day. To avoid infections, the upper respiratory tract possesses major defense mechanisms: the anatomy of the respiratory tract, normal microorganisms of the upper respiratory tract, and the immune response.

The Anatomy of the Respiratory Tract

The anatomy of the respiratory tract includes many features that help to clear the system of particles and potential pathogens. The nasal cavity has a mucociliary lining similar to that of the lower respiratory tract. The inside of the nose is lined with hair that prevent large particles from being inhaled. The turbinate bones are covered with mucus that collects particles not filtered by nasal hairs. Usually particles 5–10 μm in diameter are either trapped by nasal hairs or the nasal mucosal surfaces. The change in direction of the airway from the sinuses to the pharynx causes a large number of larger particles to adhere to the back of the throat. The adenoid and tonsils are lymphoid organs in the upper respiratory tract that are quite important for developing immune responses to pathogens. A layer of mucus and ciliated cells covers the lower portion of the lower respiratory tract. Mucus is secreted by both single and subepithelial mucus-secreting cells; and particles or respiratory pathogens that reach the lower respiratory tract are first trapped in the mucus layer and are then driven up to the back of the throat by ciliary action.

Thus to initiate a respiratory tract infection, a bacteria or virus must overcome several obstacles. The microorganism must avoid being trapped in the mucus layers of the upper respiratory tract, being transported to the back of the throat by the mucociliary elevator, and eventually being swallowed. If the microorganism has avoided these physical defense mechanisms of the upper respiratory tract and is deposited in the lower respiratory tract or lung, it must either avoid phagocytosis, or be able to survive and multiply in the phagocytic cell.

Normal Flora of Organisms of the Nose, Nasopharynx, and Oropharynx

Most surfaces of the upper respiratory tract (including nasal and oral passages, nasopharynx, oropharynx, and trachea) are colonized by normal flora. These microorganisms are regular inhabitants that rarely cause disease; in fact, they compete with pathogenic bacteria for potential attachment sites.¹² In addition, these microorganisms produce bactericidal substances (toxins).

Different regions of the respiratory tract harbor particular species of normal, and often symbiotic, bacteria. In the nose, the regular inhabitants include aerobic corynebacteria (“diphtheroids”) and Staphylococci, including *Staphylococcus aureus* and *S. epidermidis*. In the nasopharynx, there are small numbers of *Streptococcus pneumoniae*, *Neisseria meningitidis* and *Haemophilus influenzae*. Although most of these strains are not encapsulated or virulent, it should be noted that unencapsulated nontypeable *H. influenzae* can play significant roles in causing otitis media. In the oropharynx, the most prevalent bacteria are alpha haemolytic streptococci or viridans streptococci such as *S. mitis*, *S. mutans*, *S. milleri*, and *S. salivarius*. It is believed that these bacteria act as antagonists against invasion by pathogenic streptococci. Additionally, cultures from oropharynx usually show large concentrations of diphtheroids, *Moraxella* (formerly Branhamella) *catarrhalis*, and small gram-negative cocci related to *Neisseria* species.

Lower Respiratory Tract Infections

The lower respiratory tract is formed by the respiratory airways (trachea, bronchi, and bronchioles) and the lungs, that include the respiratory bronchioles, alveolar ducts, alveolar sacs, and the alveoli.

The alveoli are lined with two types of cells: Type 1 and Type 2 pneumocyte. Type 1 pneumocyte is a very large thin cell, stretched over a very large area; this cell cannot replicate and is susceptible to a large number of toxic insults. Type 1 pneumocytes are responsible for the gas exchanges in the alveoli. Type 2 granular pneumocyte is a smaller, roughly cuboidal cell that is usually found at the alveolar septal junctions. This cell produces and secretes surfactant. Type 2 pneumocytes replicate in the alveoli to replace damaged Type 1 pneumocytes.

Mechanisms of Defense

Particles from 2 μm to 0.2 μm can travel from the upper respiratory tract down to the alveoli, thereby avoiding the defense mechanisms of the upper respiratory tract and the mucociliary elevator (most bacteria and all viruses are 2 μm and smaller). In the alveoli, several defense mechanisms protect the parenchymal cells from invasion by microorganisms. These are:

- Alveolar macrophages
- Complement components
- Alveolar lining fluid containing surfactant, phospholipids, neutral lipids, IgG, IgE, IgA, secretory IgA, certain complement components, factor B, and other unidentified agents that may be important in activating alveolar macrophages
- B cells, T cells, and null cells that can elicit a localized immune response to infection
- Lymphoid tissue associated with the lungs

Once in the lung, a microorganism can be opsonized by IgG in the fluid lining the alveoli and then be ingested by a macrophage. Even if no specific antibody is present to facilitate phagocytosis, the macrophage may still engulf the invader, albeit at a slower rate. Once the microorganism is phagocytized, the macrophage will destroy the microorganism, cleave its proteins by proteolysis, and present microbial antigens in the form of peptides to the surface of the circulating B and T cells. If activated through this antigen presentation, the B and T cells can produce more antibody and/or activate additional macrophages. Meanwhile, the macrophage will also release factors that help bring in polymorphonuclear (PMN) from the blood stream to initiate an inflammatory response. Along with the PMNs come more antibodies and complement components, useful in destroying the invader. At this time, the invaders can also leave the lung and enter the general circulation. In pneumonia, this causes the systemic signs of infection (fever, malaise, myalgia, etc.).

Mechanisms Used by Respiratory Tract Pathogens to Initiate Disease

Before a respiratory disease can be established at least four conditions need to be met:

1. There must be a sufficient “dose” of infectious agent inhaled.
2. The infectious particles must be airborne.
3. The infectious microorganisms must remain alive and viable while in the air.
4. The microorganisms must be deposited on susceptible tissues in the host.

Once the pathogen is in the respiratory tract, it is essential that it colonizes these surfaces before it can cause obvious disease. Most microorganisms cause disease by only a few pathogenic mechanisms:

1. Bacterial adherence factors—these include proteins F and M of *Streptococcus pyogenes* and the hemagglutinins of *Bordetella pertussis*.
2. Extracellular toxins—such as diphtheria and pertussis toxins, the leukocidins and cytotoxins produced by *S. aureus*, or the exotoxin produced by *P. aeruginosa* which destroys cells like the diphtheria toxin.

TABLE 12-1. TRANSMISSION OF RESPIRATORY PATHOGENS AND HICPAC SYSTEM FOR ISOLATION PRECAUTIONS

Type of Precaution	Target Patients	Measures
Standard	All patients	Handwashing before and after every patient contact Gloves, gowns, eye protection as required Safe disposal or cleaning of instruments and linen
Airborne	Known or suspected: tuberculosis, varicella, measles	In addition to standard precautions, private room with negative air pressure and door closed, hospital personnel entering the room wearing a mask
Droplet	Known or suspected: <i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> type b, <i>Bordetella pertussis</i> , diphtheria, pneumonic plague, influenza, rubella, mumps, adenovirus, parvovirus B19	In addition to standard precautions, private room but door may remain open, hospital personnel wear a mask within 1 m of patient
Contact	Colonization with multidrug resistant bacteria, enteric infections, scabies, impetigo, noncontained abscesses or decubitus ulcers	In addition to standard precautions, private room or cohorting, nonsterile gloves for all patient contact, gowns for direct substantial patient contact

- Growth in host tissue—like viruses and *Chlamydia spp.*
- Evasion of host defense mechanisms—such as the inhibition of phagocytosis displayed by the encapsulated microorganisms *N. meningitidis*, *S. pneumoniae*, and *H. influenzae*.

Transmission of Respiratory Pathogens

Most respiratory pathogens are transmitted by a combination of direct contact (touch), short range (large droplet, within 1 m), and long range (droplet nuclei, beyond 1 m and further). There are several infectious diseases agents that are known to spread by all three routes with equal importance, for example, tuberculosis, measles, and chicken pox; but most are transmitted by direct contact or short-range routes, and occasionally long-range transmission is the only explanation, for example, influenza (Table 12-1). The source of transmission is normally the infected upper respiratory tract of the patients. According to the type of transmission, the Hospital Infection Control Practices Advisory Committee (HICPAC) has developed a series of guidelines for isolation precautions¹³ (Table 12-1). The basic R_0 (reproductive number) of an infectious disease agent represents the number of secondary cases occurring after each index case. Generally the R_0 gives an indication of the transmissibility of the agent and can also estimate the vaccine coverage required in an otherwise susceptible population to prevent person-to-person spread of the agents. Among the pathogens with higher transmissibility rate are measles, pertussis, mumps, and influenza. On the other hand, SARS coronavirus has relatively low case reproduction number¹⁴ (Table 12-2).

► MAJOR SYNDROMES

Common Cold

The common cold is a heterogeneous group of diseases caused by different types of viruses belonging to different families. The common cold is usually a self-limited upper respiratory tract infection characterized by nasal stuffiness and discharge, sneezing, sore

TABLE 12-2. TRANSMISSIBILITY INDEXES (R_0) FOR VARIOUS RESPIRATORY PATHOGENS

Infectious Disease	Basic R_0
Measles	15–17
Pertussis	15–17
Mumps	10–12
Rubella	7–8
Diphtheria	5–6
Influenza	1.68–20
SARS	2–3

throat, and cough. Yearly, common cold accounts for 25 million visits to family doctors in the United States and results in about 20 million lost workdays and 22 million days of absence from school.¹⁵

The relative proportions of viruses that cause common cold vary depending on several factors like age, season, and methods of viral sampling and detection. Rhinoviruses cause 30–50% of all respiratory illnesses, more than 100 different types having been identified. Coronaviruses are found in 7–18% of adults with upper respiratory tract infections.¹⁶ Parainfluenza viruses, RSV, adenoviruses, enteroviruses, and the recently discovered metapneumovirus all account for minor proportions.¹⁷

Risk factors for acquiring common cold are age (up to two years old), psychological stress, heavy physical training, and genetic factors. The transmission of viruses can occur by any of the three mechanisms already described. In the case of rhinoviruses, hand contact followed by self-inoculation with the virus onto the nose or eye is the most efficient mode of transmission.

Studies confirm that the common cold's effects are not limited to the nasal cavity, but that paranasal sinuses are also frequently affected because blowing the nose causes high intranasal pressure that can propel liquid from the nasal cavity to the maxillary sinuses.¹⁸ In addition, viral infections of the upper respiratory tract often cause dysfunction in the Eustachian tube, likely the most important factor in developing acute otitis media.¹⁹ Several respiratory viruses, for example, influenza viruses, respiratory syncytial viruses, and parainfluenza viruses, can also replicate in the lower respiratory tract and cause infections there.²⁰

Although the common cold is a self-limited infection, it is occasionally accompanied by a bacterial complication. In children, the most common complication is acute otitis media, which occur in 20% of children with upper respiratory tract infections; other common bacterial complications include sinusitis and pneumonia. And there is a clear association between viral respiratory infections and acute exacerbations of asthma.

The clinical diagnosis of common cold is often simple: symptoms are nasal discharge and sore throat. (In infants and young children however, the diagnosis is problematic because they are incapable of expressing their symptoms.) The sore throat caused by streptococcal pharyngitis often resembles the initial symptoms of the common cold; however, nasal discharge is atypical in streptococcal infections. In the typical presentation of each virus however, there is a wide range of clinical variations making it impossible to ascertain the specific etiology. Even for influenza, the positive predictive value of clinical signs and symptoms is estimated to range widely, between 27% and 79%.

Relieving cold symptoms usually amounts to using oral or intranasal decongestants to ameliorate nasal stuffiness and mucous discharge. Nonsteroidal anti-inflammatory drugs can also reduce fever and sore throat. Although commonly used, data on the efficacy of zinc, extracts of Echinacea, or vitamin C are still inconclusive. Due to the major role of rhinoviruses in causing the common cold, there has been an extensive investigation into finding effective anti-rhinovirus drugs. Plecoranil, a viral capsid binder, is

Figure 12-1. Syndromes and most common causative pathogens of acute respiratory infections.

administered orally and is active against a wide range of rhinoviruses and enteroviruses.²¹ Rupintrivir, a human rhinovirus 3C protease inhibitor, has also been tested.²² Early clinical trials showed that these two drugs shortened the duration of the illness by 1–1.5 days. Optimum use of the forthcoming antiviral agents is likely to lead to the development of a simple, rapid, and inexpensive test to identify the specific virus causing the infection.

Sore Throat (Pharyngitis and Tonsillitis)

Although sore throat is a self-limiting disease, it causes unacceptable morbidity, school absenteeism, and a high number of general-practice office visits. Most cases of sore throat have a viral etiology, particularly in children under three years old. Nevertheless, one type of sore throat, caused by group A streptococcus, causes significant morbidity and requires timely treatment. Documents are available that give guidelines for the appropriate diagnosis and antibiotic treatment of group A streptococcus.²³

Regarding the diagnosis of sore throat, a number of scoring systems have been developed, which combine clinical and epidemiological findings to differentiate between a bacterial and viral etiology; however the results are conflicting and none accurately identify those patients who require antibiotic treatment.²⁴ Rapid tests for detecting group A streptococcus, the causative agent of rheumatic fever, are commonly used in the clinical management of sore throat. While some studies have reported a sensitivity of antigen-detection tests of 90%,²⁵ in clinical practice such tests have proved to be less sensitive, although specificity may be as high as 88–100%. A recent study aimed at reducing the unnecessary use of antibiotics²¹ suggested a strategy that tested throat cultures of either all adults or a selected population, according to a prediction rule.

The majority of children with acute sore throat will only require symptomatic treatment with analgesia; however, penicillin was shown to provide a symptomatic improvement in children with severe symptoms. In recurrent sore throat associated with group A streptococcus, there

is evidence that a 10-day antibiotic course may reduce the number and frequency of episodes. Although oral penicillin V (given four times daily) is the standard treatment, several studies demonstrated that group A streptococcus is more effectively eradicated by cephalosporins, macrolides, or clindamycin.²⁶

Otitis Media

Otitis media has a considerable impact on child health. In the United Kingdom, it is estimated that out of every 1000 children under five years old, 31 with otitis media will visit primary care doctors. Peak incidence occurs in children under two years of age, typically those between six months and 18 months old.²⁷ Major risk factors for otitis media are attending child day care and being around other young children, presumably because these conditions increase exposure to upper respiratory tract infections.²⁸ Exposure to tobacco smoke also significantly increases the incidence of childhood otitis media.²⁹ Breast-feeding appears to inhibit development of otitis media, likely because it reduces infant nasopharyngeal colonization by *S. pneumoniae* and *H. influenzae*.

S. pneumoniae, *H. influenzae* and *Moraxella catarrhalis* are the main bacterial pathogens causing acute otitis media; however, there is also evidence that respiratory viruses also play a significant role. Several studies documented the presence of viruses in middle ear of children with acute otitis media, including RSV (the principal agent), influenza, parainfluenza, and rhinoviruses, and less commonly adenoviruses.³⁰

The proper diagnosis of acute otitis media requires establishing both a history of acute onset, and that middle ear effusion and inflammation are present. If the patient has pain, the physician should recommend analgesics to reduce it; acceptable analgesics include acetaminophen or ibuprofen. The current guidelines suggest withholding antibiotics for an initial observation period, during which 81% of cases should resolve spontaneously.³¹ If there is no improvement after 48–72 hours, or if the infection gets worse,

antibiotics should be prescribed, with amoxicillin the preferred agent. A recently published systematic review showed limited benefit of antibiotics for acute otitis media: after two days, only one out of sevenenteen children benefited.³²

It has been suggested that children under two years old who are at particular risk of poor outcome from otitis media may benefit most from antibiotic treatment. However, in cases of recurrent otitis media, prophylactic antibiotics likely cause resistant strains to emerge. In those high-risk patients, it has been suggested that tympanostomy with a ventilation tube reduces the frequency of episodes, providing a valid alternative to prophylactic antibiotic therapy.³³ Nevertheless, surgical intervention for otitis media has generated a strong debate and there is no consensus on the indications for tympanostomy. To reduce the incidence of acute otitis media, conjugated pneumococcal and influenza vaccination have been advocated. In a recent study, the overall efficacy of influenza vaccine in patients with recurrent acute otitis media was 43.7%.³⁴ However, the effects of pneumococcal vaccine on reducing episodes of acute otitis media have been conflicting, ranging from no effect³⁵ to a modest effect (less than 10%).³⁶

Pneumonia

Pneumonia is a lower respiratory tract infection that is potentially life threatening, especially in older adults and those with comorbid conditions. The predominant causative agent is *Streptococcus pneumoniae*, which accounts for about two-thirds of all cases of bacteremic pneumonia. In immunocompetent nonelderly adults, cigarette smoking is the strongest independent risk factor for invasive pneumococcal disease. Other causative agents include *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae* (Chlamydia pneumoniae), *Chlamydophila psittaci* (Chlamydia psittaci), *Coxiella burnetii*, *Legionella pneumophila*, enteric gram-negative bacteria (enterobacteriaceae), *Pseudomonas aeruginosa*, *Staphylococcus aureus*, anaerobes (aspiration pneumonia), and respiratory viruses (influenza virus, adenovirus, respiratory syncytial virus, parainfluenza virus, and coronavirus).³⁷ Although when addressing the etiology of pneumonia, studies defined a cause in 52–83%, in clinical practice an etiological diagnosis is achieved in only 6% of outpatients and 25% of inpatients.

Diagnostic evaluation of patients with symptoms suggestive of pneumonia is important for an accurate diagnosis, assessment of severity, and appropriate use of microbiological analysis. A chest radiograph is required to complete the diagnosis in patients with non-specific respiratory symptoms, including cough, sputum production, difficulty in breathing, and fever. The presence of lung infiltrates confirms the diagnosis of pneumonia and differentiates it from other lower respiratory tract infections such as bronchitis, or noninfectious diseases, for example, asthma, congestive heart failure, pulmonary embolism, and malignant disease.³⁸ Spiral CT scans are much more sensitive in detecting pulmonary infiltrates, but the clinical significance of this finding is unclear.³⁹

In children, the clinical symptoms of community-acquired pneumoniae are more subtle. Children are often brought to medical attention because they have fever and difficulty breathing, with or without a cough. Tachypnea is the main indicator for the clinical diagnosis of lower respiratory tract infections (respiratory rate >50 breaths/min in infants and > 40 breaths/min in children one year or older).⁴⁰ For children in developing countries, the WHO proposed tachypnea warrants treating the young patient with antibiotics or admitting them to the hospital. In developed countries where laboratory and radiological tests are more available, the workup for diagnosis usually includes a chest radiograph and blood cultures.

After the diagnosis of pneumonia is established, the patient should be stratified into one of five risk categories developed by the pneumonia Patient Outcome Research Team (PORT).⁴¹ The prediction rule identifies patients at risk of death using a point system based on several variables and four factors: age, presence of comorbid conditions, vital signs, and mental status. Another severity index, developed by the British Thoracic Society, was based on the presence of

adverse prognosis features, such as age more than 50 years, coexisting disease, and four additional features: mental confusion, elevated urea, respiratory rate greater than 30 breaths/min, and low blood pressure.⁴² These stratification systems are used to determine the location of care (home, hospital intensive care unit) for patients with community-acquired pneumonia.

Routine identification of the causative agent is recommended for patients who require hospital admission, and include blood cultures, sputum gram stain and culture, and thoracentesis if pleural fluid is present. Other tests, that might be useful in patients admitted to hospital, include the urinary antigen assays for *Legionella spp* and *S. pneumoniae*.^{43,44} Invasive methods, such as percutaneous transthoracic needle aspiration and bronchoscopy to obtain a representative sample from the lower respiratory tract, are not routinely recommended.

Most patients receive empiric treatment based on the likelihood that one of the key pathogens is responsible for the disease. It is necessary to take into account that the prevalence of drug resistant *S. pneumoniae* is increasing worldwide.⁴⁵ In one U.S. study, the dominant factor in the emergence of drug resistant *S. pneumoniae* was the human-to-human spread of clonal groups that carry resistance genes to multiple classes of antibiotics (including cephalosporins, macrolides, doxycycline, and trimethoprim-sulfamethoxazole)⁴⁶. There has been increased prevalence of pneumococcal resistance to newer fluoroquinolones; although the rates are still low in most countries— in Hong Kong in 2000, the level rose to 13.3% because of the dissemination of a fluoroquinolone resistant clone.⁴⁷ For empirical treatment of adult community-acquired pneumonia, clinical guidelines vary depending on the country. However, in absence of risk factors for drug resistant *S. pneumoniae*, most guidelines recommend using an antipneumococcal fluoroquinolone or a beta-lactam (amoxicillin/clavulanate, or a second, or third generation cephalosporin), plus a macrolide.^{40,48} To prevent community-acquired pneumonia, guidelines recommend using the polysaccharide pneumococcal and influenza vaccines.⁴⁹

Bronchiolitis

Bronchiolitis is an acute respiratory illness that affects infants and young children. Their symptoms initially are coryza and low-grade fever; but over a few days, this progresses to cough, tachypnea, hyperinflation, chest retraction, and widespread crackles, wheezes, or both. In infants and young children, bronchiolitis-associated deaths are currently very rare in developed countries: in the late 1990s, rates in the U.S. were reported to be 2.0 per 100,000 livebirths.⁵⁰ Risk factors for death are low birthweight, higher birth-order, low Apgar score at 5 min, birth to a young or unmarried woman, and tobacco exposure during gestation. RSV is the most common pathogen, although more than one pathogen is sometimes detected, mostly RSV plus either rhinovirus or adenovirus.⁵¹ Other viruses commonly implicated in bronchiolitis are human metapneumovirus, influenza, parainfluenza, adenovirus, and rhinovirus. Human metapneumovirus infection was discovered in 2001 and has a pattern similar to RSV.⁵²

Bronchiolitis is often associated with acute respiratory tract inflammation, also possibly affecting the Eustachian tubes and middle ear. Other complications include apnea, encephalopathy, and electrolyte disturbances, particularly hyponatremia. In children with severe pulmonary dysplasia who require oxygen, giving intravenous RSV immunoglobulin has been the standard of treatment and prophylaxis for relapses. The introduction of giving palivizumab (15 mg/kg) intramuscularly to prevent RSV bronchiolitis is considered a major advance for controlling the disease. Palivizumab is a humanized monoclonal antibody that costs U.S. \$5000–\$6000 per patient per season. Palivizumab is most cost-effective for an infant whose gestational age at birth was equal to or less than 32 weeks and who is discharged from the hospital between September and November. The number of infants that need to be treated to avoid one hospital admission is estimated at eight.⁵³ In systematic reviews of standard therapy, using bronchodilators, nebulized epinephrine, and inhaled corticosteroids did not provide significant differences in

outcomes when compared to supportive therapy that included giving fluid and oxygen replacement.⁵⁴ Similarly, Ribavirin did not show conclusive evidence of benefit. Live attenuated vaccines were tested, but occasionally reverted to pathogenicity to cause disease in young infants.⁵⁵

► SIGNIFICANT PATHOGENS

Streptococcus pneumoniae

S. pneumoniae is the leading cause of community-acquired pneumonia and bacterial meningitis. The annual incidence of pneumococcal bacteremia is 23 cases per 100,000 persons. Pneumococcus also accounts for 30–40% of cases of otitis media (approximately 7 million cases per year in the United States). Pneumococcal infections are transmitted from person to person by direct contact with respiratory secretions. *S. pneumoniae* infection begins with colonization of mucosal epithelium of the nasopharynx followed by translocation either to the middle ear, the paranasal sinuses, the alveoli of the lungs, or the bloodstream.⁵⁶ Cigarette smoking and passive exposure increase the risk of invasive infections in nonelderly adults. Children with underlying diseases or attending day care centers are at increased risk for invasive pneumococcal disease.

More than 80 capsular types of *S. pneumoniae* have been identified, but most infections are caused by a few serotypes. Pneumococcal otitis media and sinusitis presents with findings typical of infection at the sites and cannot be distinguished clinically from other etiologies of infection. Pneumococcal pneumonia often presents with an abrupt onset of fever, chills, and cough with purulent sputum.

The emergence of antimicrobial resistant strains has a major impact on therapy.⁵⁷ Resistance to penicillin and other beta-lactam antibiotics occurs through decreased affinity for penicillin-binding proteins. *S. pneumoniae* contains six penicillin-binding proteins; and all six can occur as low affinity variants. Resistant *S. pneumoniae* contain mosaic genes, encoding penicillin-binding proteins, that were transferred from related species.⁵⁸ There is a continuum of resistance that depends on the number of changes in the penicillin-binding proteins. Resistance is unrelated beta-lactamase expression, so inhibitors of beta-lactamase are ineffective in treating penicillin-resistant pneumococci. Penicillin-resistant strains are often somewhat resistant to cephalosporins, including third-generation cephalosporins, because they also require penicillin-binding proteins for their activity. Currently most resistance is clustered within several serotypes, including 6A and B, 9V, 14, 19A, and 23F; immunity to many of them are provided by the heptavalent (4, 6B, 9V, 14, 18C, 19F, and 23F) conjugated vaccine. Introduction of this vaccine in the USA caused at least a three-fold increase in the incidence of non-vaccine serotype invasive disease; but so far, in absolute terms this represents only a fraction of the disease that was prevented by vaccination.^{59,60}

Haemophilus influenzae

H. influenzae infections are usually caused by extension from the nasopharynx to contiguous, normally sterile foci, such as the sinuses, middle ears, and lower respiratory tract. In both children and adults, nontypeable *H. influenzae* strains cause approximately 25% of all otitis media, and a similar proportion of acute sinusitis. *H. influenzae* infections of lower respiratory tract can exacerbate chronic bronchitis and pneumonia with secondary bacteremia. Virtually all patients with chronic bronchitis are colonized by nontypeable *H. influenzae* that show individual strain variations over time. *H. influenzae* is thought to be the second or third most common cause of community-acquired pneumonia in adults, and may be associated with severe disease and a high rate of mortality.

The protein-polysaccharide conjugate vaccine for *H. influenzae* type B was introduced into many industrialized countries over the past 15 years and resulted in the virtual elimination of invasive disease. Because of this widespread vaccination of children, meningitis due to

H. influenzae type B infection usually only occurs in unvaccinated adolescents and adults. When infection does occur, *H. influenzae* can invade the epiglottis producing a characteristic syndrome that affects children aged 4–5 years. Similarly in children, severe *H. influenzae* type B pneumonia may be associated with local complications such as empyema and secondary bacteremia. In children under two years of age, *H. influenzae* type B infections reflect bloodstream invasion from a primary nasopharyngeal site.

Bordetella pertussis

Pertussis (whooping cough) is caused by the bacterium *Bordetella pertussis*, an exclusively human pathogen found worldwide. The differential diagnosis includes a wide range of respiratory pathogens such as *Bordetella parapertussis* and RSV. For several decades we have had an effective vaccine; yet, worldwide pertussis remains one of the top 10 causes of childhood deaths, mainly in unvaccinated children.⁶¹ Pertussis is very infectious with high secondary attack rates in households. Incubation periods range from 5 days to 21 days, with 7 days being most common. Symptoms start with a nonspecific coryzal illness. The infectious period usually lasts for three weeks from the onset of this catarrhal period. The cough that follows the prodrome is characteristic and is most typically paroxysmal, followed by a whoop or vomiting, or both. In childhood, complications usually include pneumonia, failure to thrive, seizures, encephalopathy, brain hypoxia (leading to brain damage), secondary bacterial infection, pulmonary hypertension, conjunctival hemorrhage, and rectal prolapse. Nearly all deaths take place in the first six months of life. In recent times, asymptomatic infection without carriage has been recognized. Infants might not develop paroxysms or a whoop and present only with hypopnea or sudden death.⁶²

The challenge for all countries is to provide basic laboratory diagnostic service. Traditionally diagnostic methods have evolved from culture and serology, to antigen detection and PCR.⁶³ The Centers for Diseases Control and Prevention recommends that all patients with presumed pertussis have samples taken and cultured to identify the etiologic agents during the infectious period.⁶⁴

Supportive treatment is most important for infants. A seven-day treatment with erythromycin has been recommended; but newer macrolides azithromycin and clarithromycin have similar efficacy and fewer side effects.⁶⁵ Trimethoprim-sulfamethoxazole can be used as an alternative antibiotic to macrolides. If antibiotic therapy is started more than one week after the onset of the illness however, there is no probable effect on outcome.

Pertussis has not been eliminated from any country despite decades of high vaccination coverage. In adolescents and pre-vaccination infants, there is a resurgence of the disease in some high-coverage countries, including the Netherlands, Belgium, Spain, Germany, France, Australia, Canada, and the U.S.⁶⁶ Studies of adolescent and adults have reported rising rates that have reached incidences of 300 cases per 100,000 person-years to more than 500 cases per 100,000 person-years. The control of pertussis requires an increase in the immunity of all age groups. A suitable formulation of acellular pertussis can be used to vaccinate all adolescents to reduce both the risk of disease later in life, as well as the transmission to infants. In Canada and Germany, there is an adolescent diphtheria and pertussis booster using a reduced dose.⁷

Corynebacterium diphtheriae

Diphtheria is an acute disease usually localized in the upper respiratory tract. It produces ulceration of the mucosa and induces the formation of an inflammatory membrane. The causative agents are *Corynebacterium diphtheriae* and *Corynebacterium ulcerans* which produce an exceedingly potent exotoxin that can damage myocardium and peripheral nerves. *C. diphtheriae* is usually transmitted by direct contact, or by sneezing or coughing. No age group is completely immune, but nonimmune children are commonly affected before age five.

Reports of respiratory diphtheria are rare in the United States in all age groups. During 1998–2004, seven cases of respiratory diphtheria were reported to the CDC, one of which was imported. The last culture-confirmed case of respiratory diphtheria in a U.S. adolescent was reported in 1996.⁶⁷ A widespread epidemic of diphtheria was documented in Russia in 1990. This epidemic was notable for the high incidence of infection in adults and the extent of the disease.

In children, the upper respiratory tract mucosa is the most common site of infection. Anterior nasal infection presents with serous or seropurulent nasal discharge, associated with whitish patches on the mucosa of the septum. *C. diphtheriae* multiplies on the surface of the mucous membrane, resulting in the formation of pseudomembrane. A membrane typically develops on one or two tonsils, with extension to the tonsillar pillars, uvula, soft palate, oropharynx, and nasopharynx. Initially the pseudomembrane is white, but late in the course of infection becomes grey and can have patches of green or black necrosis. Satellite infections can occur in the oesophagus, stomach, and lower respiratory tract. Chest radiographs may reveal bronchopneumonia.

The growth of the organism is localized, but exotoxin is absorbed into the blood and evokes severe systemic pathology. Weeks after the initial illness, human diphtheria infection can cause myocarditis and acute cardiac failure during convalescence. Myocarditis progression undergoes two stages: early exudative (at about day three of the disease) and late productive (beginning nine days into disease). The end result for patients is myocardiosclerosis. About 75% of patients with severe disease develop neuropathy. The first indication of neuropathy is paralysis of the soft palate and posterior pharyngeal wall, resulting in regurgitation of swallowed liquids. Thereafter cranial neuropathies are common. Peripheral neuritis develops later, from 10 days to 3 months after the onset of pharyngeal disease. There is also diphtheria of the skin in the context of wound diphtheria, umbilical diphtheria, or impetiginous diphtheria. It begins with a vesicle or pustule filled with straw-colored fluid, which breaks down quickly. The lesion progresses to a single or multiple ulcers. The lesions are painful and may be covered with an adhering scar.

Information about the clinical management of diphtheria, use of diphtheria antitoxin, immunization, and the public health response is available at <http://www.cdc.gov/nip/vaccine/dat/default.htm> and are summarized here briefly. The mainstay of therapy is equine diphtheria antitoxin. Because only unbound toxin can be neutralized, treatment should commence as soon as the diagnosis is suspected, and each day of delay increases the likelihood of a fatal outcome. A single dose is given ranging from 20,000 units for localized tonsillar diphtheria to up to 100,000 units for extensive disease. Antibiotic therapy eliminates the organism, halts toxin production, and prevents transmission. Parenterally administered penicillin is the drug of choice. The patients should be in a strict isolation unit until follow-up cultures are negative. Convalescing patients should receive diphtheria toxoid. People with close contact should be cultured and given prophylactic antibiotics. All contacts without a full primary immunization and a booster within the preceding five years should receive tetanus-diphtheria toxoid. When a diphtheria case is identified, the local health department should be notified immediately.

Exposure to diphtheria remains possible during travel to countries where diphtheria is endemic or from imported cases. There are documented cases of *C. ulcerans* being acquired after contact with animals or consumption of unpasteurized dairy products. Boosters of tetanus and diphtheria toxoid vaccines have been recommended among adolescents and adults to prevent sporadic cases of diphtheria.

► EMERGENT RESPIRATORY PATHOGENS

SARS Coronavirus

Severe acute respiratory syndrome (SARS) was the first global epidemic in the 21st century; it affected over 8500 people in approximately 30 countries, with a crude mortality of 9%. Its cause was

quickly identified as a novel coronavirus that had jumped species from animals to man.⁶⁸ An almost identical virus, although with 29 extra nucleotides, was isolated from the palm civet cats bought in the city of Shenzhen. The SARS coronavirus epidemic, which began in the fall of 2002, was related to the exotic food industry in southern China, and initially involved disproportionate numbers of animal handlers, chefs, and caterers. Subsequently, person-to-person transmission spawned the outbreak. The transmission is a combination of direct contact (touch), short range (large droplet, within 1 m), and long range (droplet nuclei, beyond 1 m and further).⁶⁹ What clinically distinguished this illness was that approximately half of the victims were health-care workers, infected while caring for patients with recognized or unrecognized SARS.⁷⁰

Coronavirus produces an acute viral infection in humans with an incubation period ranging from 2 days to 10 days. The presenting features are high fever, chills, rigor, malaise, myalgia, headache, and dry cough; most patients also have some degree of dyspnea at presentation. Diarrhea is observed in 20% of patients, mainly watery without blood or mucous. Reactive hepatitis is a common complication; and 69% of patients have raised alanine aminotransferase (ALT) levels. Lymphopenia, low-grade disseminated intravascular coagulation, elevated L-lactate dehydrogenase (LDH) and creatine kinase (CK) are common laboratory abnormalities. Chest radiographs show predominant involvement of lung periphery; in 20% of patients the infection leads to acute respiratory distress syndrome.⁷¹

The clinical course of SARS is divided into two phases: Phase I refers to active viral replication where patients experience systemic symptoms that generally improve after a few days. Phase II refers to a stage of tissue damage, where patients experience a recurrence of fever, increasing hypoxemia, and radiological progression of pneumonia, all while the viral load drops. With respect to these two phases, the timing of treatment needs to be considered when evaluating its efficacy.

During the 2002 epidemic, patients required supportive treatment and specific treatment. Approximately 20% of patients required mechanical ventilation due to respiratory failure. Noninvasive positive pressure ventilation was safe when applied in a ward environment with adequate air exchange. (During this treatment, health-care workers needed full personal protective equipment and observed strict contact and droplet precautions.⁷²) For specific treatment HIV protease inhibitors such as lopinavir-ritonavir combinations (400 mg of lopinavir/100 mg of ritonavir) led to a significant reduction in overall death rate (2.3% compared with 11%).⁷³ Nelfinavir, another HIV protease inhibitor, inhibited viral replication of SARS in Vero cell cultures. Oseltamivir and high-dose ribavirin did not show significant activity against SARS in vitro. The use of pulsed-methylprednisolone during the clinical progression was associated with clinical improvement. However, a retrospective study showed that the use of pulsed methylprednisolone was associated with an increased risk of 30-day mortality (adjusted odds ratio 26.0; 95% confidence interval, 4.4–154.8).⁷⁴

Coronaviruses are large, lipid-enveloped, single-stranded RNA viruses. The SARS coronavirus encodes several proteins: these include an RNA-dependent RNA polymerase; a surface glycoprotein (S protein), which attaches the virus to a host cell and is the target for neutralizing antibodies; an envelope protein (E); a membrane protein (M); and a nucleocapsid protein (N). Currently different SARS vaccines are being tested in animals such as an adenovirus vector vaccine and a recombinant S protein vaccine.^{75,76} An adenoviral-based vaccine induced strong SARS-specific immune responses in rhesus macaques. And in experiments in mice, a DNA vaccine containing the S gene induced the production of specific, efficient IgG antibodies recognizing the SARS S-protein.

Since there is currently no proven effective treatment for this highly contagious disease, early recognition, isolation, and stringent measures to control infection are crucial. Patients with SARS must be housed in isolation facilities. Health-care workers managing SARS patients must maintain strict droplet and contact precautions (hand hygiene, gown, gloves, N95 masks, and eye protection) and avoid using nebulizers on general wards. Tracing and quarantining close contacts is also important for controlling the spread of the infection.

The SARS coronavirus has renewed the role of infection control at different societal levels including governments, hospitals, infection control practitioners, and health-care workers. SARS coronavirus outbreak has also renewed the importance of quarantine, used in the medieval times to stop plague epidemics. There are algorithms for managing unprotected health-care workers exposed to SARS,⁷⁷ however, at least one out of five quarantined people showed symptoms of post-traumatic stress disorder and depression.⁷⁸ Therefore, such action must be reserved for serious epidemics, explained clearly by experts to the population involved. Furthermore, local authorities must be supportive and provide quarantined people with all of their needs (food, water, heat, lodging, etc) without prejudice.

Influenza

About 20% of children and 5% of adults worldwide develop symptomatic influenza A or B every year. It causes a broad range of illness, from asymptomatic infection to syndromes affecting lung, heart, liver, kidneys, and muscles, to fulminant pneumonia. Severity depends on patient’s age and underlying comorbidities.⁷⁹ Most influenza infections are spread by droplets several microns in diameter that are expelled (1 m and further) during coughing and sneezing.

Influenza viruses are classified as types A, B, and C, according to their genomes’ diversity. Influenza A viruses are classified into subgroups based on antigenic differences in the two surface glycoproteins: hemagglutinin (15 subtypes, H1–H15) and neuraminidase (9 subtypes, N1–N9). Virus from all hemagglutinin and neuraminidase subtypes have been recovered from aquatic birds; but since 1918, only three hemagglutinin subtypes (H1, H2, and H3) and two neuraminidase subtypes (N1 and N2) have established stable lineages in the human population. Only one subtype of hemagglutinin and one subtype of neuraminidase are recognized in influenza B virus. Hemagglutinin attaches to sialic acid receptors to facilitate the entry of the virus in host cells. Neuraminidase assists in the release of progeny virions. Neuraminidase has been an important target in the development of antiviral drugs.

During the 20th century, there were four to five influenza pandemics. The H1N1 pandemic of 1918–1919 caused 40–50 million deaths. There is evidence that three subsequent pandemics originated in China; these were the H2N2 pandemics in 1957, H3N2 influenza in 1968, and the reemergence of H1N1 influenza pandemic in 1977. (In southern China, influenza circulates throughout the year.) It is likely that the H3N2 subtype of influenza A virus caused more severe illness than H1N1 of influenza B.⁸⁰

In people, the epidemiological behavior of influenza is related to two types of antigenic variation of the envelope glycoproteins: antigenic drift and antigenic shift. During antigenic drift, new strains of virus evolve by accumulating point mutations in the surface glycoprotein genes. The new strains are antigenic variants but are related to those that circulated during the preceding epidemics. This feature allows the virus to evade the immune system, leading to repeated outbreaks during the interpandemic years. In contrast, antigenic shift occurs when the influenza A virus acquires a novel hemagglutinin or a novel neuraminidase creating a new virus that is antigenically distinct from earlier human viruses. It is believed that genes encoding the hemagglutinin surface glycoprotein may either be introduced in people, by direct transmission of an avian virus from birds (as occurred with H5N1 virus) or after genetic reassortment in pigs, animals that support the growth of human and avian influenza viruses (Fig. 12-2).

In May and November–December 1997, 18 human cases of influenza A H5N1 infection were identified in Hong Kong. There were also cases of avian influenza A H9N2 in people in southern China. The human influenza isolates were drift variants of avian origin and were not derived from reassortment.⁸¹ Six out of 18 patients died from acute respiratory distress syndrome or multiple organ failure. The fact that most patients were previously healthy adults and their deterioration was rapid suggested an unusually virulent strain.⁸¹ Striking features were the early onset of lymphopenia and high concentration of serum transaminases. The outbreak ceased when all chickens in Hong Kong (about 1.5 million) were slaughtered. It is thought that southern China provides an appropriate ecological niche with potential to initiate a pandemic due to the proximity of dense

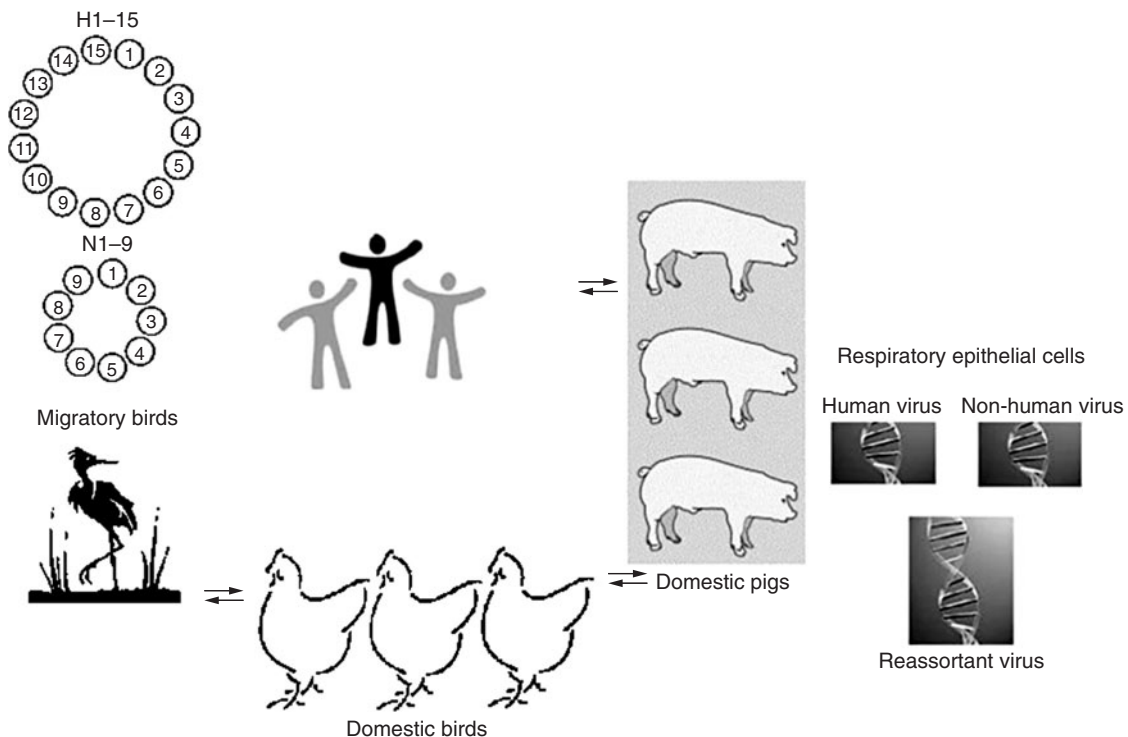

Figure 12-2. Antigenic shift hypotheses as model for causing pandemic influenza.

populations of people, pigs, and wild and domestic birds. In the Netherlands in 2003, a total of 83 cases of H7N7 avian influenza were confirmed in poultry workers and their families. These patients suffered an influenza-like illness and conjunctivitis.⁸²

Although influenza has no pathognomonic features, it is correctly diagnosed in about two-thirds of adults based on the presence of cough and a temperature equal or greater than 37.8°C.⁸³ Rapid tests for influenza can aid in clinical management; but because the tests are complex or have low sensitivities their usefulness is limited for guiding decisions on whether to start antiviral drug treatment. However, rapid influenza tests can show whether virus is circulating in specific areas and can be a useful adjunct to surveillance programmes. Currently two drug classes are available to treat influenza: the inhibitors of M2, amantadine and rimantadine, and the neuraminidase inhibitors, zanamivir and oseltamivir. Amantadine is active on influenza A but not on influenza B. Amantadine inhibits the M2 ion channel protein that regulates the internal pH of the virus. Estimates of amantadine's therapeutic effectiveness are uncertain due to low trial qualities. In those 12 years or older, Zanamivir is licensed for the treatment of influenza A and B.⁸⁴ The main concern is that inhaled zanamivir may cause bronchospasm; in addition, difficulty in utilizing the inhaler may limit its use.

Oseltamivir is an orally taken active pro-drug of oseltamivir carboxylate^{85,86} that is licensed for treatment of influenza A and B, in people aged one year or older and for prophylaxis in people aged 13 years or older. Clinical data show that with oseltamivir symptoms were alleviated 0.8 days sooner than with placebo. Treatment with oseltamivir reduces the frequency of otitis media, antibiotic use, pneumonia, and hospital admissions. The frequency of nausea and vomiting, however, is 2–7% higher than placebo. In non-vaccinated healthy adults, 75 mg of oseltamivir given once daily gave an estimate of 74% of protection as a seasonal prophylaxis. In households, post-exposure prophylaxis showed an efficacy of 89%.

The UK National Institute for Clinical Excellence (NICE) has published guidance on the use of influenza antivirals.⁸⁷ Amantadine is not recommended. During the influenza season, Zanamivir and oseltamivir are recommended for treatment of children at risk, who present with influenza symptoms and can start therapy within 48 h. Oseltamivir is recommended for adults older than 13 years of age if they live in a residential care institution and can begin prophylaxis within 48 h, whether or not they have been vaccinated. Oseltamivir is not recommended for postexposure prophylaxis in healthy people up to the age of 65 years of age.

Annual immunization against influenza A and B is the most effective method of preventing infection. Two types of influenza vaccines are available in the U.S. inactivated intramuscular vaccine and a live-attenuated intranasal vaccine.⁸⁸ A recent vaccine included the influenza A H3N2 strains of the current year, and the influenza A (H1N1) and influenza B strains of the last season. The inactivated vaccine is targeted to people at risk of developing complications from influenza. The live-attenuated vaccine can be offered at any time to eligible healthy nonpregnant individuals, but should not be used in immunosuppressed patients and is not recommended in patients with chronic cardiovascular, pulmonary, renal, or metabolic disease.

► PREVENTION AND CONTROL OF RESPIRATORY TRACT INFECTIONS

Prevention of acute respiratory tract infections requires three steps: minimizing exposure, protecting susceptible populations, and identifying and treating infected patients early.

Minimizing Exposure

Transmission-based precautions are for airborne, droplet, or contact routes (see Table 12-1).

Airborne Precautions

Airborne precautions should be used when caring for patients with suspected or confirmed tuberculosis, measles, varicella, or disseminated varicella zoster virus infection. Patients admitted to a hospital should be placed in a private room with negative air pressure, with a minimum of 6–12 air changes per hour. The door to all isolation rooms must remain closed. Personnel entering the room must wear a mask with a filtering capacity of 95%. Although all persons caring for patients with tuberculosis should use airborne precautions, persons immune to measles or varicella need not wear respiratory protection. Patients being transported from the room for diagnostic or therapeutic procedures should wear a mask covering the mouth and nose.

Droplet Precautions

Droplet precautions are required to prevent infection by pathogens such as *Neisseria meningitidis*, *Haemophilus influenzae*, and *Bordetella pertussis*. Patients should be placed in private rooms, and hospital personnel should wear a face mask when within 3 feet (1 meter) of the patient.

Contact Precautions

Occasionally respiratory pathogens can be transmitted by contact (hands to body surfaces, or from a contaminated object to hands). The following precautions are recommended to prevent transmitting multidrug-resistant bacteria (like methicillin-resistant *S. aureus*, vancomycin-resistant enterococci, multiresistant *Pseudomonas* or *Acinetobacter*) and various viral pathogens (RSV, influenza, parainfluenza, or coronavirus). Health-care workers are required to use non-sterile gloves for all patient contact, and gowns are required if there is likely to be substantial direct contact with the patient or any infective material. Gowns and/or gloves should be removed prior to exiting isolation rooms, and hands must then be washed immediately after patient contact. Ideally, patients who require contact isolation should either be in a private room, or cohorted with patients who have the same active infection or are colonized with the same pathogen. The Severe Acute Respiratory Syndrome (SARS) epidemic, and the potential spread to humans of the H5N1 avian influenza epidemic have changed the way hospitals approach isolation precautions because of the unprecedented degree of nosocomial spread. Although these viruses are transmitted predominantly by droplet spread and direct contact, facilities tend to recommend stringent droplet, contact, and airborne precautions to prevent nosocomial transmission.

Protection of Susceptible Populations

Pneumococcal Vaccine

The pneumococcal vaccine was the first vaccine obtained from a capsular polysaccharide. Capsular polysaccharides are antigens that induce the production of type-specific antibodies that enhance opsonization, phagocytosis, and killing of pneumococci by phagocytic cells. In 1983, this vaccine was manufactured as a 23 antigen-valent formulation of pneumococcal vaccine (PPV23). The currently available pneumococcal polysaccharide vaccine includes purified capsular polysaccharide antigens (serotypes 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F). Twenty-five micrograms of each capsular polysaccharide antigen is dissolved in an isotonic saline solution, using phenol (0.25%) or thimerosal (0.01%) added as preservative; there is no adjuvant. These serotypes represent 85–90% of the serotypes that cause invasive disease in the United States. Pneumococcal vaccination protects against invasive disease including bacteremia and meningitis. Randomized trials showed that the vaccine does not protect against non-bacteremic pneumonia or death in adults and does not reduce nasopharyngeal carriage of *S. pneumoniae* among children.^{89,90,91} These observations do not support the use of pneumococcal vaccination beyond high-risk groups (Table 12-3).⁹²

Since polysaccharides are not immunogenic in children under the age of two years, in year 2000 a protein conjugate heptavalent vaccine (PCV7) was licensed to prevent invasive pneumococcal infection.

TABLE 12-3. AVAILABLE VACCINES FOR PREVENTING ACUTE RESPIRATORY INFECTIONS

Microorganism	Vaccine Type	Target Population
<i>Streptococcus pneumoniae</i>	Polysaccharide (0.5 mL dose i.m.): PNEUMOVAX-23, PNU-IMUNE-23 Conjugated (0.5 mL dose i.m.): PREVNAR	Adults > 65 years of age; adults 19–64 years of age with alcoholism, cardiovascular diseases, chronic pulmonary diseases, chronic liver diseases, diabetes, CSF leaks as underlying conditions Immunocompromised persons Children
<i>Haemophilus influenzae</i>	TriHibT (<i>Haemophilus influenzae</i> b Conjugate Vaccine and Diphtheria, Tetanus Toxoids, and Acellular Pertussis Vaccine). ActHib (ActHIB: <i>Haemophilus</i> b capsular polysaccharide 10 mcg and tetanus toxoid 24 mcg per dose); HibTITER (<i>Haemophilus</i> b saccharide 10 mcg and diphtheria CRM 197 protein 25 mcg per 0.5 mL [0.5 mL]); PedvaxHIB (PedvaxHIB: <i>Haemophilus</i> b capsular polysaccharide 7.5 mcg and <i>Neisseria meningitidis</i> OMPC 125 mcg per 0.5 mL [0.5 mL])	The combination can be used for the DTaP dose given at 15–18 months when a primary series of Hib vaccine has been given Age at first dose: 2–6 months
Diphtheria, tetanus, pertussis	Diphtheria, tetanus, and whole pertussis vaccine (DTP); in 1997, the Advisory Committee on Immunization Practices (ACIP) recommended that pediatric DTaP (a less reactogenic vaccine) be used routinely instead of pediatric DTP Pediatric DTaP vaccines (0.5 ml) (INFANRIX and DAPTACEL) Adolescent-adult vaccines (0.5 mL) (with reduced quantities of antigens) BOOSTRIX and ADACEL, with lower rates of adverse reactions Vaccines with reduced quantities of antigens showed no inferior immune responses to pediatric vaccines	Not routinely recommended since 1997 Scheduled at ages 2, 4, 6, and 18 months and 4–6 years; use pediatric vaccines BOOSTRIX (persons aged 10–18 years) and ADACEL (persons aged 11–64 years) in children aged ≥ 7 years (preference for age 11–12 years), in pre-vaccinated children with DTP (5-year interval minimum between the last pediatric DTaP and the adolescent TD dose) Thereafter, adult boosters every 10 years through life
Influenza	Inactivated vaccine (split virus) • FLUVARIX (0.5 mL syringe) • FLUVIRIN (5 mL multidose, 0.5 mL syringe) • FLUZONE (5 mL multidose, 0.25 mL syringe, 0.5 mL syringe) • Live (attenuated virus) • FLUMIST (sprayer)	High-risk population: pregnant women, persons aged 65 years or older, children 6–23 months of age, and patients 2–64 years with chronic medical conditions Healthy individuals

PCV7 contains 2 µg each of seven capsular polysaccharides—4, 9V, 14, 19F, 23F, oligosaccharide of 18C, and 4 µg of 6B—each conjugated to inactivated diphtheria toxin (20 µg).⁹³ In population-based data from the CDC, the rate of invasive disease in 2001 compared to 1998–1999 (prior to the introduction of the conjugate vaccine) fell significantly by 32% in adults between the ages of 20 and 39, and by 8–18% in older adults.⁹⁴ There was a 35% reduction in invasive disease caused by penicillin-resistant pneumococci, a finding also noted in adults after introduction of the conjugate vaccine in another report.⁹⁵

Haemophilus Influenzae Vaccine

In developed countries, the introduction of *H. influenzae* type b (Hib) vaccines into routine immunization schedules has been followed by a rapid decline in disease occurrence, but vaccine cost is a significant barrier to use in developing countries. By 2002, only 84 of the 193 WHO member nations had introduced Hib vaccine.

H. influenzae type b has a polyribosylribitol phosphate (PRP—the capsular polysaccharide) that determines its virulence. Antibodies against PRP directly confer protection against Hib disease. In 1970s, the vaccines made from PRP capsular polysaccharide showed low immunogenicity in children under two years old. Therefore, new *H. influenzae* type vaccines were produced by combining PRP capsular antigen with a protein. The types of proteins tested have been

diphtheria toxoid, tetanus toxoid, acellular pertussis antigens, and *Neisseria meningitidis* outer membrane protein.⁹⁶

Regulatory approval of diphtheria and tetanus toxoids and acellular pertussis (DTaP)-based combination vaccines containing *Haemophilus influenzae* type b (Hib) has been delayed in the United States because of difficulty in assessing the effect of lower Hib immunogenicity on vaccine efficacy compared with the immunogenicity of the specific Hib component administered separately⁹⁷ (Table 12-3). Hib conjugate vaccines confer protection by eliciting serum anticapsular antibody and priming for immunologic memory. The concern of lower efficacy is for children in the first year of life. There is general agreement that in infants primed with the combination vaccine, a booster injection given in the second year achieves antibody concentrations that are greatly in excess of those required for protection. The size of the effect could possibly allow between a 46% and 93% reduction in Hib invasive disease before the effect of herd immunity is taken into account.

Tetanus, Diphtheria, Pertussis Vaccine

In the 1940s, whole-cell vaccines against pertussis were available, and have been part of the WHO Expanded Program of Immunization since its launch in 1974. Reports of anaphylaxis reactions, febrile seizures, and prolonged or inconsolable crying led to the development

of acellular vaccines containing up to five specific *B. pertussis* antigens. Although most nations use whole-cell vaccines because they are cheap, effective, and easy to produce, most developed countries have switched to acellular vaccines. There are multiple formulations of this vaccine (DTaP: diphtheria, tetanus toxoids, and acellular pertussis vaccine), with each formulation containing 1–4 antigens, and being produced by multiple manufacturers (Table 12-3).⁹⁸

Influenza Vaccine

Current influenza vaccines are produced from virus grown in fertile hen's eggs and inactivated by either formaldehyde or β -propiolactone. They consist of whole virus, detergent-treated split product, or purified hemagglutinin and neuraminidase surface antigen formulations of the three virus strains recommended by the WHO (Table 12-3). Vaccine recommendations include elderly people and those with chronic medical disorders.⁹⁹

Whole-virus vaccines are not recommended because they cause adverse reactions in children, whereas those containing a purified surface antigen are extremely safe. In adults of working age, controlled trials estimated at 80% the efficacy of inactivated influenza vaccines in preventing symptomatic laboratory-confirmed influenza. In nursing home residents, there was a 60% reduction in laboratory-confirmed influenza illnesses among vaccinated people. Vaccinations in elderly reduce hospital admission for pneumonia and influenza by 52%, all cause mortality by 70% and complications (death, exacerbations of lung disease, and myocardial infarction) by 50%.¹⁰⁰

Vaccination of health-care workers who work with elderly people in institutions, showed that the influenza vaccine significantly reduced deaths from pneumonia as well as all causes of mortality.¹⁰¹ At present there are no licensed vaccines against avian influenza, although it is an area of active study.¹⁰² One major problem with the development of an effective vaccine against avian influenza has been poor immunogenicity. In a multicenter, randomized, double-blind, placebo-controlled trial, the safety and efficacy of a subunit influenza H5N1 vaccine prepared from an attenuated Vietnam 2005 strain was evaluated in 451 healthy adults.⁶¹ Participants received two doses of vaccine without adjuvant, each of which contained 90, 45, 15, or 7.5 μ g of hemagglutinin antigen, or placebo. Although the vaccine was safe, immunogenicity was only modest.¹⁰³ The only group where more than 50% of subjects reached the predefined threshold for immunogenicity occurred with administration of 90 μ g, a total dose nearly 12 times that of seasonal influenza vaccines.

More encouraging findings were demonstrated in a German study of alum-adjuvant whole-virus A/Hong Kong/1073/99 (H9N2) vaccine given to adults.¹⁰⁴ Monovalent alum-adjuvanted vaccine containing either 7.5, 3.8, or 1.9 micrograms of H9 hemagglutinin was compared with a 15 microgram vaccine containing plain whole virus. The use of alum in the vaccine preparation allowed H9 content to be reduced to 1.9 microgram per dose, while maintaining immunogenicity. If these findings are duplicated in larger studies, the addition of alum may enable the antigen content needed for vaccine to be reduced, resulting in a significant increase in vaccine supplies.

Viral Hepatitis

Joanna Buffington • Eric Mast

► INTRODUCTION

Certain forms of jaundice or hepatitis have been recognized as infectious entities for many centuries; however, the diversity of viruses causing hepatitis has only recently been recognized. Five hepatitis viruses have been characterized, each belonging to a different taxonomic family, whose common characteristic is replication in the liver. Hepatitis viruses transmitted by the fecal-oral route (hepatitis A virus [HAV], hepatitis E virus [HEV]) produce acute, self-limited infections, while hepatitis viruses transmitted by parenteral exposures to blood and body fluids (hepatitis B virus [HBV], hepatitis C virus [HCV], hepatitis D virus [HDV]) have the ability to produce a persistent infection and chronic liver disease. There remain additional cases of hepatitis not caused by these five viruses, whose epidemiologic characteristics suggest an infectious etiology as well.

Historically, two major forms of hepatitis were described based on their means of transmission. Infectious hepatitis produced large epidemics in various settings and was transmitted by the fecal-oral route through food, water, and person-to-person contact. It appears that this disease entity was primarily caused by HAV infection, but may have also included epidemics caused by HEV. The injection of medicinal products produced from human lymph or serum resulted in outbreaks of serum hepatitis that were primarily due to HBV infection but probably also included HCV infection.

Human volunteer studies conducted in the mid-1940s and early 1950s firmly established the viral etiology, clinical features, and routes of transmission of the two major types of hepatitis, and determined the

mutually exclusive specificity of immunity produced by each type of infection. Studies conducted by Krugman and colleagues¹ showed that hepatitis with a short incubation period (31–38 days) could be transmitted either orally or parenterally using a serum pool (MS-1) collected from a patient prior to the onset of illness. A second serum pool (MS-2) obtained from the same patient following a second episode of hepatitis was shown to only transmit disease when inoculated parenterally, and this disease had a longer incubation period (41–83 days). Subsequently, MS-1 hepatitis was shown to be caused by HAV and MS-2 hepatitis by HBV.

In 1965, Blumberg, studying the production of isoantibodies in Australian aborigines, identified an antigen which was subsequently found to be the hepatitis B surface antigen (HBsAg).^{2,3} Characterization of the antigens and antibodies produced during HBV infection led to the development of diagnostic tests, the routine screening of blood for HBsAg to prevent HBV-related posttransfusion hepatitis, and the development and licensure of hepatitis B vaccines.

In 1973, HAV was identified in the stools of persons involved in a foodborne outbreak of hepatitis and in the stools of the volunteers inoculated with MS-1.^{4,5} These findings led to the development of diagnostic tests that could differentiate acute from past HAV infection, the propagation of HAV in cell culture, and the development and licensure of hepatitis A vaccines.

In 1977, Rizzetto and colleagues described second episodes of hepatitis in patients chronically infected with HBV and characterized a new antigen in the liver of these patients.⁶ Subsequent studies showed this form of hepatitis was only transmitted in the presence of

TABLE 12-4. DISEASE BURDEN FROM VIRAL HEPATITIS A, B, AND C IN THE UNITED STATES, 2005

	Hepatitis A	Hepatitis B	Hepatitis C
Number of acute clinical cases reported	4488	5494	No data
Estimated number of acute clinical cases	19,000	15,000	3200
Estimated number of new infections	42,000	51,000	20,000
Number of persons with chronic infection	No chronic infection	1.25 million	3.2 million
Estimated annual number of chronic liver disease deaths	No chronic infection	3000–5000	
Percent ever infected	31.3%	4.9%	1.6%

acute or chronic HBV infection and that HDV was a defective virus that required HBsAg to produce infection.⁷

By the early 1970s, another type of bloodborne hepatitis was characterized because of the availability of serologic tests to identify HAV and HBV infection, and the occurrence of posttransfusion hepatitis in spite of donor testing for HBsAg.⁸ Population-based surveillance studies showed that most parenterally transmitted non-A, non-B (PT-NANB) hepatitis occurred outside of the transfusion setting, and in 1988, HCV was characterized by molecular cloning and found to be the primary cause of PT-NANB hepatitis.^{9,10} These findings led to the development of diagnostic tests and the routine screening of blood for antibody to HCV (anti-HCV) and HCV RNA to prevent HCV-related posttransfusion hepatitis.

The ability to make the serologic diagnosis of acute HAV infection led to the identification of enterically transmitted NANB (ET-NANB) hepatitis, a disease that produced large epidemics and was transmitted by the fecal-oral route.¹¹ Although the virus associated with ET-NANB hepatitis was identified in 1983, HEV was not characterized until 1989, with the subsequent development of diagnostic tests and prototype vaccines.¹²

With the increasing use of safe and effective vaccines to prevent HAV and HBV infection, incidence of these infections in the United States has been steadily decreasing. However, there continues to be considerable morbidity and mortality attributable to the acute and chronic sequelae of viral hepatitis in the United States and worldwide. In the United States alone, in 2005, an estimated 11,000 to 15,000 persons died of viral hepatitis-related acute or chronic liver disease (Table 12-4). We have adequate knowledge to prevent or control most types of viral hepatitis. The challenge is to turn this knowledge into effective prevention programs.

Hepatitis A

Etiologic Agent

HAV is a 27–28 nm, spherical, nonenveloped virus with an icosahedral capsid configuration. The HAV genome is composed of a single-stranded, positive sense RNA molecule whose organization and replication scheme are similar to polio virus and other members of the family Picornaviridae. However, when compared to other picornaviruses, HAV is more resistant to inactivation by heating to pH less than three, to drying at ambient temperature, and to low concentrations of free chlorine or hypochlorite.^{13,14} HAV remains infectious in feces or on environmental surfaces for several weeks, but can be inactivated by many common disinfecting chemicals, including hypochlorite (bleach) and quaternary ammonium formulations containing 23% HCl, found in many toilet bowl cleaners.^{15,16} HAV is only partially inactivated by pasteurization (60°C for one hour), but is completely inactivated in food by heating at higher than 85°C for at least one minute.¹⁵ HAV grows poorly in cell culture, where it requires a very long adaptation period (up to one month), rarely produces a cytopathic effect, and rapidly becomes attenuated.^{13,14} Although previously classified in the genus *Enterovirus*, HAV has been placed in its own genus, *Hepatovirus*, because of several unique features that distinguish it from other enteroviruses.¹³

Although man appears to be the only natural host of HAV, a number of non-human primates (chimpanzees, tamarins, macaques) are susceptible to experimental infection.¹⁷ Antibody binding studies

indicate there is only a single HAV serotype. HAV isolates from diverse geographic areas are recognized by polyclonal antibody generated against capsid proteins (anti-HAV), and by neutralizing monoclonal antibodies to human HAV. Although HAV has little phenotypic diversity, enough genetic diversity exists in the capsid region to define four genotypes and allow for studies of molecular relatedness.¹⁸

Clinical Illness, Pathogenesis and Immune Response

HAV infection can cause both acute disease and asymptomatic infection, but does not cause chronic infection.¹⁹ Manifestations of HAV infection include fecal shedding of virus, viremia, age-dependent expression of clinical illness (e.g., jaundice), and the occasional occurrence of fulminant liver failure. Children under six years of age are usually (70%) asymptomatic. If symptomatic, they generally have mild, nonspecific symptoms that include malaise, nausea, vomiting, diarrhea, fever, and dark urine. Jaundice is uncommon in children; less than 5% of children aged less than three years and about 10% of children aged 4–6 years are icteric.²⁰ Among adolescents and adults infected with HAV, the majority have classical signs or symptoms, including jaundice, fever, malaise, nausea, vomiting, loss of appetite, and dark urine.²¹

Fulminant hepatitis A is rare. Before hepatitis A vaccine is licensed, an estimated 100 persons died as a result of acute liver failure due to hepatitis A each year in the United States.²² The case-fatality rate for fulminant hepatitis A is approximately 0.3–0.5%, based on all reported cases of hepatitis A in the United States summarized since 1983.^{16,23–25} Host factors reported to be associated with an increased risk of fulminant hepatitis include older age and underlying chronic liver disease.^{23,26} The proportion of reported cases hospitalized in 2005 with hepatitis A increased with age from 20% among children less than five years of age to 47% among persons 60 years of age or older.²⁵

Although HAV infection or hepatitis A does not cause chronic liver disease or persistent infection, up to 10% of symptomatic persons may have prolonged or relapsing disease lasting up to six months.²⁷ In addition, a cholestatic form of hepatitis A has been reported in which patients experience persistent jaundice, usually accompanied by itching.¹⁶ Other atypical clinical manifestations are rare, and may include immunologic, neurologic, hematologic, and renal extrahepatitis manifestations.

The pathogenic events that occur during the course of infection have been determined from experimental infections in chimpanzees and naturally acquired infections in humans (Fig. 12-3). The incubation period ranges from 15 days to 50 days after exposure, with a median of 28 days.^{13,14} Virus is found in hepatocytes throughout the course of infection, is excreted in bile, and found in highest concentrations in feces during the 2-week period prior to onset of clinical illness. Viral shedding declines rapidly after jaundice appears in adults, although shedding may be prolonged in infected infants and children.^{28–31} Using polymerase chain reaction (PCR) techniques, HAV RNA has been detected in stools of infected newborns for up to six months after infection, and from one month to three months after clinical illness in older children and adults.^{16,30} Chronic HAV shedding does not occur, but virus has been detected in feces during relapsing illness. Although infectivity of stools has been demonstrated in experimental studies 14–21 days before to eight days after

Figure 12-3. Events during hepatitis A virus infection. HAV, hepatitis A virus; ALT, alanine aminotransferase; IgM, antibody of the immunoglobulin M subclass to HAV; IgG, antibody of the immunoglobulin G subclass to HAV. (Source: CDC Website, [www.cdc.gov/ncidod/diseases/hepatitis/slideset_online_hepatitis_A_slide_set, slide number 6.](http://www.cdc.gov/ncidod/diseases/hepatitis/slideset_online_hepatitis_A_slide_set_slide_number_6.))

onset of jaundice, data from epidemiologic studies suggest that peak infectivity occurs during the two weeks before onset of symptoms.³² For practical purposes, children and adults with hepatitis A can be assumed to be noninfectious 1 week after jaundice appears.

Available data suggest the pathogenesis of liver injury is immune mediated rather than due to direct cytotoxicity, and probably involves cell-mediated immune responses.³³ Although liver damage occurs at the same time that circulating antibodies become detectable, studies have failed to show that the pathologic process is antibody-dependent. A specific IgM antibody response to HAV capsid proteins (IgM anti-HAV) develops prior to the onset of clinical illness, which is accompanied by a nonspecific rise in the concentration of serum IgM.^{13,14} Neutralizing IgG antibodies are usually detectable at or before the onset of clinical illness, and persist to provide lifelong immunity.

Diagnosis

Because hepatitis A is clinically indistinguishable from other forms of acute viral hepatitis, diagnosis requires serologic detection of IgM anti-HAV in a single acute-phase serum sample using commercially available immunoassays. IgM anti-HAV is usually detectable from 5 days to 10 days prior to the onset of symptoms and declines to undetectable levels within six months after infection (Fig. 12-3).^{23,34} Previous HAV infection is diagnosed by the detection of IgG anti-HAV, which persists for life. Some commercially available immunoassays only detect total anti-HAV (IgG and IgM). These tests are not helpful for diagnosis of acute illness because patients with distant past exposure maintain IgG anti-HAV for life. The total antibody assays are used most often in epidemiologic investigations or in determining susceptibility to HAV infection.

IgG anti-HAV is produced following an acute infection and following immunization with hepatitis A vaccine. Serologic testing following hepatitis A vaccination is not recommended and commercially available tests do not all have the sensitivity to detect low concentrations of anti-HAV achieved after vaccination.²³ However, anyone found to be anti-HAV positive with commercially available tests should be considered to have protective levels of antibody.

Methods to detect HAV are generally limited to research laboratories. HAV antigen can be detected in feces, cell culture, and some environmental specimens by enzyme immunoassay.¹³ Growth in cell culture requires a long period of adaptation, and changes the genetic makeup of the virus. Amplification of HAV RNA by PCR is the most sensitive means to detect HAV in feces, blood, cell culture, or environmental samples. However, detection of HAV RNA by PCR

does not necessarily correlate with infectivity, and the difficulty and experience of performing these tests preclude use outside of research settings.

Biochemical evidence of hepatitis includes elevated levels of serum bilirubin and serum hepatic enzymes, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, and gamma-glutamyltranspeptidase. Elevations in AST and ALT may occur a week or more prior to symptom onset. Serum bilirubin and ALT levels usually return to normal by 2–3 months after illness onset.

Epidemiology

Routes of Transmission. Person-to-person transmission by the fecal-oral route is the predominant mode of HAV transmission, both in the United States and throughout the world. In addition, because HAV can remain infectious in the environment, common-source outbreaks and sporadic cases can occur from exposure to fecal-contaminated food or water.

Hepatitis A represents a rare cause of blood-borne transmission, which can result from transfusion of blood or blood derivatives from a donor during the viremic phase of their infection. The largest outbreaks of posttransfusion hepatitis A have occurred in neonatal intensive care units with silent transmission to hospital staff and parents from infants infected by whole-blood or packed-cell transfusions.³⁰ Clotting factor concentrates (Factor VIII, Factor IX) prepared from plasma have also been implicated in the transmission of hepatitis A, and one study indicated that persons routinely receiving clotting factors prepared from plasma might be at increased risk of HAV infection.^{35,36} Vertical intrauterine transmission from an infected mother is also a rare mode of transmission of HAV infection.

Worldwide Patterns of Disease. Hepatitis A is an important cause of illness throughout the world and there are several patterns of endemicity of infection (Fig. 12-4). Endemicity of HAV infection is closely related to sanitary and living conditions and other indicators of the level of development. In areas of high endemicity, represented by the least developed countries (e.g., parts of Africa, Asia, and Central and South America), poor socioeconomic conditions result in easy spread of HAV, which is transmitted person-to-person through the fecal-oral route. In these areas, almost all adults have been infected, usually as children before 10 years of age.³⁷ In countries that have had significant changes in socioeconomic levels over the past several decades (e.g., Greece, Taiwan, Italy, parts of China), improved sanitation and living standards have significantly reduced the endemic rate of HAV infection. In such areas, a significant decrease in the prevalence of HAV infection has occurred among young children. However, HAV infection continues to occur among older children and young adults, and a paradoxical increase in the incidence of hepatitis may occur because of the greater likelihood of symptomatic infection in older age groups. In addition, as long as HAV is present in the population or the environment, including food sources, the potential remains for epidemics to occur. Shifts in infection patterns were observed in 1988 in Shanghai, China, when over 300,000 young adults became ill when shellfish contaminated with HAV were sold in the marketplace and subsequently prepared in a traditional manner at temperatures that did not kill the virus.³⁸

Low endemic rates of HAV infection are found in the United States, Canada, western Europe, Australia, and other developed countries. There is an increased risk of hepatitis A among persons from these countries traveling or working in countries with a high or intermediate endemicity of infection, and risk of infection increases with the duration of time in the country.³⁹

Epidemiology in the United States. In the United States, historically, hepatitis A rates have differed by race, with the highest rates among American Indians/Alaskan Natives, and the lowest rates among Asians; and by ethnicity, with higher rates among Hispanics

Figure 12-4. Geographic distribution of hepatitis A virus infection. (Source: CDC Website, www.cdc.gov/ncidod/diseases/hepatitis/slideset online hepatitis A slide set, slide number 9.)

than non-Hispanics.^{23,25} Higher rates of infection in these racial/ethnic groups most likely reflected differences in the risk for infection related to socioeconomic levels and resulting living conditions (e.g., crowding) and more frequent contact with persons from countries where hepatitis A is endemic (e.g., Mexico, Central America). Rates among American Indians, which were greater than 60 per 100,000 prior to 1995, however, have decreased dramatically following widespread vaccination in this group, and by 2002, were approximately the same as in other races.^{24,40}

In both low and high endemic populations, HAV infection behaves like most other acute infectious diseases, producing periodic epidemics as the pool of susceptible individuals increases. In the United States, cyclic increases in the incidence of hepatitis A have occurred approximately every decade, with the last nationwide increase in 1995.²⁴

Since 1995, rates have declined among all age groups in the United States. Although the decline in rates has been greatest in children aged 5–14 years, the lowest rates since 2000 have occurred among children less than five years of age. However, asymptomatic infection is common among very young children, and reported cases in children less than five years old represent only a small proportion of infections in this age group.

Historically, most U.S. cases of hepatitis A resulted from person-to-person transmission during community-wide outbreaks in areas with high and intermediate rates of hepatitis A.^{23,41} Surveillance data demonstrated that communities with high and intermediate rates were concentrated in states with consistently elevated disease rates.²⁴ High rates of disease generally occurred in small communities on Indian reservations, in Alaskan Native villages, the United States-Mexican border, or in religious communities.^{41–44} With a high prevalence of infection present throughout the community, most infections occurred among children less than 10 years of age, and epidemics occurred with regular periodicity. Intermediate rates of disease generally occurred in larger cities and the pattern of infection has been more variable (i.e., children, adolescents, and young adults) throughout the community. Highest rates of infection in these areas had often been found among children identified by race/ethnicity or socioeconomic level living in certain neighborhoods or census tracts.

Hepatitis A outbreaks among children attending day care centers and persons employed at these centers have been recognized since the 1970s.^{23,45} In these reported outbreaks, transmission often occurred to adult contacts, who would comprise 70–80% of the recognized cases.⁴⁶ Transmission among children who wore diapers and the handling and changing of diapers by staff contributed to the spread of HAV infection; outbreaks rarely occurred in day care centers in which care was provided only to children who were toilet trained. In

general, however, day care providers have not been at increased risk of infection.⁴⁷

During community-wide epidemics of hepatitis A in the United States, contact with children less than six years of age has appeared to be a risk factor for infection. During such community-wide outbreaks, serologic studies of members of households with an adult case without an identified source of infection have found that 25–40% of contacts less than six years of age living in the household had serologic evidence of recent HAV infection.^{16,48}

Cyclic outbreaks of hepatitis A have occurred among men who have sex with men (MSM) and among users of both injection and non-injection illicit drugs.^{16,49–52} The fecal-oral route is most likely responsible for transmission of infection among MSM, but both percutaneous and fecal-oral routes may contribute to transmission among drug users.

Common source outbreaks due to contaminated food or water continue to occur, but appear to account for a small proportion (<4%) of cases in the United States.²⁵ Implicated foods are generally eaten raw and have been contaminated during growing, harvest, final processing, or preparation.^{13,53} Foods contaminated during preparation have included salads, sandwiches, and glazed or iced pastries. Shellfish-associated outbreaks have been due to eating raw or partially cooked oysters, clams, or mussels harvested from contaminated waters.^{13,54} Fruits or vegetables contaminated during harvest or packing and eaten raw (e.g., lettuce, green onions, strawberries, raspberries) have accounted for a number of hepatitis A outbreaks, including a large outbreak (>700 persons infected) at a single restaurant, associated with imported green onions.^{13,55–58} Contaminated water rarely accounts for infection in the United States. Water treatment processes and dilution within municipal water systems appear to be sufficient to render HAV noninfectious.⁵³ Hepatitis A has been reported among persons using small private or community wells or swimming pools, and contamination by adjacent septic systems has been implicated as the source.^{13,53}

With the availability of hepatitis A vaccine for use in individuals at least two years of age beginning in 1995, subsequent recommendations for its use in individuals at increased risk of hepatitis A (1996), for routine vaccination for children living in states with the highest rates of hepatitis A in 1999, and the drop in age for use of this vaccine to 12 months in 2005 followed by recommendation for universal vaccination of children age 12 months and older in 2006, there has been a major reduction in transmission of HAV in the United States.^{22,25,49} In 2005, the overall hepatitis A rate was the lowest yet recorded (1.5 per 100,000). Associated with the decline in incidence, there have been substantial shifts in the epidemiologic profile of this disease in the United States, with an increasing proportion of cases occurring among adults.²⁵

Among cases where information about exposures during the incubation period was determined, the most common risk factors for hepatitis A reported in 2005 were international travel (15%), primarily to countries endemic for hepatitis A, sexual or household contact with a person known to have hepatitis A (12%), or association with a suspected food or waterborne outbreak (11%); 59.7% had no specific risk factor identified.²⁵ The proportion of cases attributed to male homosexual activity increased steadily from 1.5% in 1992 to 8.4% in 2002, then decreased to 3% in 2005. The proportion of cases attributed to illegal drug use declined steadily from almost 10% of cases in 1996 to 5.9% in 2002, and 5% of cases in 2005.

Prevention and Control

Active immunization is the primary means for preventing HAV infection. Currently licensed inactivated hepatitis A vaccines are highly immunogenic and produce long-term immunity that makes the elimination of HAV transmission an achievable goal if high vaccine coverage is achieved in appropriate target populations. The hepatitis A vaccines licensed in the United States are produced from cell culture adapted virus that is formalin inactivated and adsorbed on an alum adjuvant.⁵⁹ These vaccines have been shown to be highly immunogenic in children, adolescents, and adults using a two-dose vaccination schedule.²³ In controlled clinical trials, preexposure vaccination with inactivated hepatitis A vaccine has been shown to be more than 95% effective in preventing hepatitis A and HAV infection.^{60,61} Although the duration of immunity provided by hepatitis A immunization has not been measured directly, models of antibody decline indicate that protective levels of anti-HAV could be present for at least 20 years.²³

Vaccine immunogenicity is diminished when passively acquired anti-HAV is present, such as in persons given immune globulin (IG) and vaccine concurrently or infants born to anti-HAV positive mothers.²² In adults receiving both IG and vaccine, the final rate of seroconversion is not decreased, but final serum concentrations of anti-HAV are lower when compared to persons receiving vaccine alone. However, for infants born to anti-HAV positive mothers and vaccinated at 2, 4, and 6 months of age, both the final antibody concentration and the seroconversion rate appear to be decreased. Currently available vaccines are licensed for use in children 12 months of age and older.⁴⁹

In the United States, recommendations for the use of hepatitis A vaccine are directed at the prevention and control of community-wide outbreaks of disease, the protection of individuals in groups at high risk of HAV infection, and the protection of persons who experience significantly increased mortality or morbidity from HAV infection.^{16,49} Beginning in 2006, children aged 12 months and up are recommended to be routinely vaccinated. Various vaccination strategies can be used, including vaccinating one or more single-age cohorts of children or adolescents, vaccination of children in selected settings (e.g., day care), or vaccination of children and adolescents in health-care settings. Maintenance of active disease surveillance and analysis of surveillance data with respect to demographic characteristics and risk factors for infection is essential to tailor hepatitis A vaccination programs and evaluate their effectiveness. Implementation of routine vaccination of children should prevent outbreaks of community-wide hepatitis A in the future.

Persons traveling or working in countries with a high or intermediate endemicity of HAV infection (Fig. 12-4) should be vaccinated prior to departure.⁴⁹ Although immunogenicity studies show a high rate of seroconversion two weeks following receipt of the first vaccine dose, available data suggest that 40–45% of vaccinated persons might lack neutralizing antibody at this time. Travelers who receive the first dose at least four weeks prior to travel can be assumed to be protected. Vaccination of persons in other groups at high risk of infection include drug users (injection and non-injection), MSM, persons who work with HAV-infected primates or with HAV in a research laboratory setting, and persons who have clotting-factor disorders.⁴⁹ In addition, vaccination is recommended for persons with chronic liver disease, because of their increased risk of mortality and morbidity from hepatitis A. Studies conducted among U.S. workers

exposed to raw sewage do not indicate a significantly increased risk for HAV infection, and therefore are not recommended for vaccination on the basis of increased occupational risk.^{49,62} Routine vaccination of food handlers is not recommended, because their profession does not put them at higher risk for infection.⁵³ However, persons who work as food handlers can contract hepatitis A and potentially transmit HAV to others. To decrease the frequency of evaluations of food handlers with hepatitis A and the need for postexposure prophylaxis of patrons, consideration may be given to vaccination of employees who work in areas where state and local health authorities or private employers determine that such vaccination is cost-effective.^{16,49}

When vaccinating adults or persons in groups at high risk of HAV infection, some will already have been infected with HAV. Vaccinating a person who is immune because of prior infection is not harmful. However, because of the relatively high cost of vaccine, pre-vaccination testing might be considered if the cost of the vaccine is greater than the cost of testing and the follow-up visits.⁴⁹ Based on age-specific patterns of HAV infection in the United States, pre-vaccination testing could be considered in persons more than 40 years of age, persons who were born in or lived for extensive periods in geographic areas that have a high endemicity of HAV infection, and adults in other groups that have a high prevalence of infection (e.g., injection drug users). Postvaccination testing is not warranted.

Passive immunization with IG is also available as a preventive measure and provides short-term protection from HAV infection. Numerous studies have confirmed that preparations of human immunoglobulin that contain anti-HAV are more than 85% effective in preventing symptomatic HAV infection if given before, or within two weeks of exposure.^{49,63} When given following exposure, passive-active immunization often occurs from an infection that produces little or no symptoms and limited virus shedding. With the availability of hepatitis A vaccines, IG is primarily recommended for postexposure prophylaxis for unvaccinated persons who are exposed to HAV. It may also be used for preexposure prophylaxis, particularly for children less than 12 months of age traveling to countries with a high or intermediate endemicity of HAV infection, because hepatitis A vaccine is not licensed for this age group.

A single IM dose of IG (0.02 mL/kg) should be administered as soon as possible, but no more than two weeks after the last exposure, to unvaccinated household and sexual contacts of persons with hepatitis A, to persons who have shared illegal drugs with a person with hepatitis A, and to children and staff exposed in day care or certain other institutional settings.⁴⁹ If a food handler is diagnosed with hepatitis A, IG should be administered to other unvaccinated food handlers at the same establishment. Because common-source transmission to patrons is unlikely, IG administration to patrons is usually not recommended but can be considered if (a) during the time when the food handler was likely to be infectious, the food handler both directly handled uncooked foods or foods after cooking and had diarrhea or poor hygienic practices; and (b) patrons can be identified and treated within two weeks after the exposure. If hepatitis A vaccine is recommended for a person being given IG, it can be administered simultaneously with IG at a separate anatomic injection site. The use of hepatitis A vaccine alone is not recommended for postexposure prophylaxis of previously unvaccinated persons.

Other prevention and control measures include attention to good personal hygiene and environmental sanitation, which were considered the primary means to control and prevent hepatitis A before hepatitis A vaccines became available. Complete inactivation of HAV in food requires heating to 85°C (>185°F) for at least one minute, or disinfection with a 1:100 dilution of household bleach in water or cleaning solutions containing quaternary ammonium and/or HCl.^{15,16} Although improved sanitation and socioeconomic conditions in developed countries are presumed to have resulted in the decline in disease incidence observed from the mid-1960s to the mid-to late 1990s, these improvements have not resulted in elimination of HAV transmission and would not be expected to further decrease incidence.

Hepatitis B

Etiologic Agent

Hepatitis B virus (HBV) is a member of the family Hepadnaviridae, whose members replicate in the liver and cause hepatic dysfunction. The only natural host for HBV appears to be humans, but the Hepadnaviridae family includes viruses that infect woodchucks, ducks, ground squirrels, and herons.

HBV has a small (3.2 kilobase) genome with a circular DNA that is partially double stranded and a retroviral replication strategy with an RNA intermediate. The genome codes for a surface glycoprotein, nucleocapsid protein, DNA polymerase, and the X protein, a small transcriptional transactivator that influences the transcription of HBV genes.^{64,65}

The complete HBV virion (Dane particle) is 42 nm in diameter and is composed of an outer lipoprotein coat containing the hepatitis B surface antigen (HBsAg) and a 27-nm nucleocapsid core, the hepatitis B core antigen (HBcAg). In addition to being a component of lipoprotein coat of the virus, HBsAg circulates independently in the blood as 22-nm spheres and tubules. HBsAg is antigenically heterogeneous, with a common antigen, *a*, and two pairs of mutually exclusive antigens, *d* and *y*, and *w* and *r*, resulting in four possible subtypes: adw, adr, ayw, and ayr.^{66,67} Antibodies to the *a* antigen confer immunity to all the subtypes. Although no clinical differences have been identified between subtypes, there are distinct geographic distributions which have been useful in epidemiologic studies.⁶⁸ A third hepatitis B antigen, the *e* antigen (HBeAg) is a soluble protein that is not part of the virus particle, but can be detected in the serum of patients with acute HBV infection, and in patients with chronic HBV infection who have high virus titers.

HBV has a higher frequency of mutations than other DNA viruses due to its replication via an RNA intermediate, using a reverse transcriptase that seems to lack a proofreading function.⁶⁷ The clinical significance of these mutations is not well established, but may include increased virulence, decreased host response to therapy, and viral replication in the presence of protective levels of antibody to HBsAg after vaccination or hepatitis B immune globulin administration.^{69,70}

HBV has been shown to retain infectivity in serum for at least one month when stored at either room temperature or frozen. HBV is also stable on environmental surfaces for seven days or longer; thus, indirect inoculation of HBV can occur through inanimate objects.^{15,71} Infectivity is destroyed at 90°C after one hour.⁷²

Clinical Illness, Pathogenesis and Immune Response

HBV infection can be asymptomatic, cause acute self-limited hepatitis, or result in fulminant hepatitis and death. Persons infected with HBV also may develop chronic infection, which can lead to chronic liver disease and death from cirrhosis or hepatocellular carcinoma (HCC).

The incubation period for acute infection is usually 3–4 months, with a range of six weeks to six months. The age that HBV infection is acquired is the main factor determining clinical expression of disease. Fewer than 10% of children under 5 years of age who become infected have initial clinical signs or symptoms of disease (i.e., acute hepatitis B) compared with 30% to 50% of older children and adults.⁷³ In persons who develop symptomatic infection, the clinical onset of hepatitis B is usually insidious, with malaise, weakness, and anorexia being the most common findings. In 5–10% of patients, a serum sickness-like syndrome may develop during the prodromal phase that is characterized by arthralgias or arthritis, rash, and angioedema.⁶⁷ In 10–30% of patients with acute hepatitis B, myalgias and arthralgias have been described without jaundice or other clinical signs of hepatitis; in one third of these patients, a maculopapular rash appears with joint symptoms.^{67,74} In patients with icteric hepatitis (30% or more of infected adults), jaundice usually develops within 1–2 weeks after onset of illness; dark urine and clay-colored stools may appear 1–5 days before onset of clinical jaundice.^{67,75} Liver enzyme elevations usually occur prior to the onset of jaundice. HBV infection is also associated with extrahepatic disease such as vasculitis and mem-

branoproliferative glomerulonephritis.⁷³ Clinical signs and symptoms of acute hepatitis B usually resolve within 1–3 months.

Among reported hepatitis B cases in the United States in 2005, the proportion of cases hospitalized was 40%, increasing from 20% among children less than 15 years of age to 47% among persons 60 years of age or older.²⁵ Fulminant liver failure occurs in approximately 0.5–1% of infected adults, but rarely in infected infants or children.

The risk of developing chronic HBV infection (persistence of HBsAg for longer than six months) varies inversely with age: approximately 80–90% of infants infected during the first year of life, 30–60% of children infected between 1 year and 4 years of age, and 2–6% of adults develop chronic infection.^{65,76} Among individuals in whom HBV infection persists, both HBsAg and anti-HBc remain detectable, usually indefinitely (Fig. 12-5). During the early stage of chronic HBV infection, HBeAg is present and indicates a high level of viral replication and infectivity. Each year approximately 10% of persons with chronic HBV infection will lose HBeAg and up to 0.5–2% per year may naturally lose HBsAg.⁷⁷ Persons with chronic HBV infection are at risk of chronic liver disease (i.e., chronic active hepatitis, cirrhosis) and HCC. Prospective studies have shown that 25% of persons who acquired chronic HBV infection as infants or young children will die as adults (average age 45 years) from HBV-related cirrhosis or hepatocellular carcinoma (HCC).^{78,79} Among persons who acquire chronic HBV infection as adults, it is estimated that 15% will die from HBV-related chronic liver disease at an average age of 55 years.

HBV must gain access to the circulation and arrive in the liver for primary replication in hepatocytes. Access occurs through direct percutaneous inoculation, breaks in the skin that allow inapparent inoculation, or passage through mucous membranes. Although HBsAg has been detected in tissues other than the liver, there is little evidence to suggest sustained replication at these sites. The number of hepatocytes affected during the acute phase of replication is variable and can reach almost 100%. During persistent infection, approximately 10% of hepatocytes remain infected.

There is strong evidence that the hepatocellular injury that occurs during HBV infection is immune mediated, rather than due to a direct cytopathic effect of HBV.^{67,80} Cell-mediated injury is targeted at hepatocytes through a combination of human leukocyte antigen (HLA) molecules and HBV antigens.⁸¹ The precise mechanism(s)

that lead to viral persistence are unknown, but may include the induction of immune tolerance by HBeAg. Integration of HBV DNA does occur during chronic infection, which may be important for the development of HCC.

During acute infection, HBsAg may become detectable 1–2 months prior to the onset of clinical symptoms and is soon followed by the appearance of IgM anti-HBc (Fig. 12-6). In late convalescence, there is a transition period (window phase) when the concentration of HBsAg declines and the concentration of antibody to HBsAg

(anti-HBs) increases. As these markers reach equivalency, neither may be detectable because they form immune complexes; however, both IgG anti-HBc and IgM anti-HBc remain detectable. For infections that resolve, HBsAg disappears from circulation and the virus-neutralizing anti-HBs becomes detectable, along with anti-HBc. Although HBV-specific humoral and cellular immunity is maintained for life, this immunity is not sterilizing. Trace amounts of HBV DNA persist and remain intermittently detectable in blood and liver using sensitive diagnostic techniques.⁸⁰ These trace amounts of HBV appear to continuously activate and maintain HBV-specific immune responses, which control and limit HBV replication.

Diagnosis

Serologic tests are available commercially for a number of antigens and antibodies associated with HBV infection, including HBsAg, anti-HBs, total (immunoglobulin [Ig] G and IgM) antibody to HBcAg (anti-HBc), IgM anti-HBc, HBeAg, and anti-HBe (Table 12-5). In addition, there are hybridization assays and gene amplification techniques (e.g., polymerase chain reaction, [PCR]) to detect HBV DNA). Although HBsAg, IgM anti-HBc, total anti-HBc, and HBeAg can all be detected in serum as early as 1–2 months after exposure to HBV, IgM anti-HBc is the only reliable marker of acute infection, as the other three can also be detected in persons with chronic HBV infection. IgM anti-HBc usually becomes undetectable within 6–9 months after acute infection, and HBsAg and HBeAg are usually cleared within six months following illness onset in those who recover from the acute infection. Anti-HBs and anti-HBe develop during the convalescent phase, with anti-HBs being a protective antibody that neutralizes the virus. Presence of anti-HBs following acute infection indicates recovery and immunity from reinfection. Anti-HBs can also be detected in persons who have received hepatitis B vaccine, and transiently in persons who have received hepatitis B immune globulin (HBIG). Detection of anti-HBs is not routinely performed during diagnostic testing of persons with clinical illness but may be used in certain instances to determine a person’s immune status following vaccination.

In persons who develop chronic HBV infection, HBsAg and total anti-HBc remain detectable, generally for life (Fig. 12-5). Although all persons with detectable HBsAg should be considered infectious, the presence of HBeAg and HBV DNA, which are variably present

TABLE 12-5. INTERPRETATION OF SEROLOGIC TEST RESULTS FOR HEPATITIS B VIRUS INFECTION

Serologic Markers				
HBsAg ^a	Total Anti-HBc ^b	IgM ^c Anti-HBc	Anti-HBs ^d	Interpretation
—	—	—	—	Susceptible; never infected
+	—	—	—	Early acute infection; transient (21 days) after vaccination
+	+	+	—	Acute infection
—	+	+	—	Acute resolving infection
—	+	—	+	Past infection; recovered and immune
+	+	—	—	Chronic infection
—	+	—	—	False positive (i.e., susceptible); past infection; or “low-level” chronic infection ^e
—	—	—	+	Immune if titer is ≥ 10 mIU/mL ^f when tested 1–2 months following the full vaccination series ^g

^aHepatitis B surface antigen; repeat reactive should be confirmed with a licensed neutralizing confirmatory test; all HBsAg-positive persons are potentially infectious.
^bAntibody to hepatitis B core antigen
^cImmunoglobulin M
^dAntibody to hepatitis B surface antigen
^ePersons positive for anti-HBc alone are unlikely to be infectious except under unusual circumstances involving direct percutaneous exposure to large quantities of blood (e.g., blood transfusion).
^fMilli-international units per milliliter.
^gA titer of 10 mIU/mL or higher obtained 1–2 months after the completion of the vaccine series is considered protective; without repeated exposure to HBV, titres will naturally decline over time, but immunity is likely maintained despite a decline below this level.

in chronically infected persons, correlates with higher titers of HBV and greater infectivity.

Epidemiology

Routes of Transmission. Hepatitis B virus is transmitted by either percutaneous or mucosal exposure to infected blood or blood-derived body fluids. The virus is found in highest concentrations in blood and serous exudates (as high as 10^{8-9} virions/mL); 1–2 log lower concentrations are found in various body secretions, including saliva, semen, and vaginal fluid.⁷⁵ The most probable mechanisms of person-to-person transmission involve inapparent percutaneous or permucosal contact with infectious body fluids such as exudates from dermatologic lesions, breaks in the skin, or mucous membranes with blood or serous secretions. HBV may also spread because of contact with saliva through bites or other breaks in the skin, as a consequence of the pre-mastication of food, and through contact with virus from inanimate objects such as shared towels or toothbrushes or reuse of needles.^{82–85} HBV remains infectious for at least seven days outside the body and can be found in titers of 10^{2-3} virions/mL on objects, even in the absence of visible blood.^{86,87} The primary routes of transmission are perinatal, non-sexual person-to-person exposures, sexual contact, and percutaneous exposure to blood (e.g., injection drug use, unsafe injections in medical settings). HBV is not transmitted by air, food, or water.

Perinatal Transmission. Perinatal HBV transmission is one of the most efficient modes of infection. Most perinatal HBV infections occur among infants of pregnant women with chronic HBV infection. Pregnant women with acute hepatitis B in the first and second trimester rarely transmit HBV to the fetus or neonate.^{88,89} However, the risk of transmission from pregnant women who acquire infection during the third trimester is approximately 60%. Perinatal transmission occurs most often at the time of birth, with in utero transmission rarely accounting for infections transmitted from mother to infant. Although HBV can be detected in breast milk, there is no evidence that HBV is transmitted by breast-feeding.⁹⁰ The primary determinant of infection is a high concentration of maternal HBV DNA, as indicated by the presence of HBeAg.⁹¹ Without postexposure immunization, 70–90% of infants born to HBeAg-positive mothers will become infected by 6 months of age; about 90% of these children will remain chronically infected.^{92,93} In addition, up to 20% of HBeAg negative mothers have moderately high levels of HBV DNA and may infect their newborns during the perinatal period.⁹³

Non-Sexual Person-to-Person Transmission. Non-sexual person-to-person HBV transmission during early childhood accounts for a high proportion of HBV infections worldwide.⁶⁷ Most early childhood transmission occurs in households of persons with chronic infection, and widespread HBsAg contamination of surfaces has been demonstrated in homes of persons with chronic infection.⁸⁶ Approximately 30% of children living in a household with an HBsAg-positive person become infected, and infants born to HBsAg-positive mothers and not infected at birth remain at high risk of infection during the first five years of life.⁹⁴ Transmission has rarely occurred in child day care centers, but has not been identified between children in school settings.⁸⁵

Before integration of hepatitis B vaccine into the infant immunization schedule in the United States, an estimated 16,000 children less than 10 years of age were infected annually with HBV beyond the postnatal period.⁹⁵ Although these infections represented only 5–10% of all HBV infections in the United States, it is estimated that 18% of persons with chronic HBV infection acquired their infection postnatally during early childhood, before implementation of perinatal hepatitis B immunization programs and routine infant hepatitis B immunization.⁹⁶ In some populations, childhood transmission was more important than perinatal transmission as a cause of chronic HBV infection before hepatitis B immunization was widely implemented. For example, in studies conducted among U.S.-born children

of Southeast Asian refugees during the 1980s, approximately 60% of chronic infections in young children were among those born to HBsAg-negative mothers.^{97–99}

Sexual Transmission. HBV in semen and vaginal secretions provides the means for efficient transmission by sexual contact, which is one of the most frequent routes of transmission among adults.^{71,100} The most common sexual risk factors for acute infection among heterosexual adults include having more than one sex partner in the 6-week to 6-month period prior to infection or having sex with a known infected person during this time period.^{67,100} Among prevalent cases of HBV infection (presence of any HBV marker), the most common risk factors among heterosexuals include increased number of sex partners, history of sexually transmitted disease, and a history of sex with an infected partner.⁷¹ Men who have sex with men (MSM) are one of the groups at highest risk for sexual transmission of HBV, with infection associated with receptive anal intercourse, increased numbers of sex partners, and numbers of years of sexual activity.⁷¹

Percutaneous Transmission. HBV is efficiently transmitted by percutaneous exposures, which predominantly occur in health-care settings or among injection drug users. The risk of HBV infection is approximately 30–60% from needlestick exposures to HBsAg-positive, HBeAg-positive blood, and approximately 10–30% from needlestick exposures to HBsAg-positive, and HBeAg-negative blood.^{101,102} By comparison, the risks of hepatitis C virus and human immunodeficiency virus transmission from percutaneous exposures are approximately 2% and 0.2%, respectively.^{103,104}

Patient-to-patient transmission of HBV from percutaneous exposures has been identified in a variety of health-care settings, including chronic hemodialysis centers, inpatient services, outpatient clinics, and long-term care facilities.^{71,105} In most cases, transmission resulted from noncompliance with aseptic techniques for administering injections and recommended infection control practices designed to prevent cross-contamination of medical equipment and devices.

Although HBV infection was recognized as a frequent occupational hazard among persons who worked in laboratories or were exposed to blood while caring for patients, hepatitis B vaccination of health-care workers and implementation of standard precautions has made HBV infection a rare event in these populations in countries where prevention measures have been implemented.^{106,107} Chronically infected health-care workers performing invasive procedures may, on rare occasions, transmit infection. Risk factors associated with these infections have been high levels of HBV DNA in the health-care worker and the blind palpation of suture needles.¹⁰⁸ While an increased frequency of exposure to blood or body fluids occurs in a number of other occupations (e.g., policemen, firefighters, correctional officers), increased rates of HBV have not been identified that are attributable to occupational exposures.¹⁰⁹

The primary nonmedical source of percutaneous HBV exposures is through injection of illicit drugs, which is a common mode of HBV transmission in many countries. In the United States, the prevalence of any marker of hepatitis B infection among injection drug users ranges from 30–90%, and the risk of infection in unvaccinated drug users increases with number of years of drug use. It has been estimated that greater than 80% of injection drug users are infected after 5 years of using.^{110,111}

Worldwide Patterns of Transmission. The endemicity of HBV infection varies greatly throughout the world (Fig. 12-7).^{67,112} Endemicity is considered high in those areas where the prevalence of chronic infection is 8% or more and where 60–90% of the populations have serologic evidence of previous infection. In these areas, infection during the perinatal period and early childhood accounts for high rates of chronic infection and its sequelae. In most developed countries, the prevalence of HBV infection is low, with rates of HBsAg positivity being less than 1%, and the overall infection rate 5–7%.¹¹² For example, the prevalence of chronic HBV infection in the United States is approximately 0.38%, and approximately 5% of the

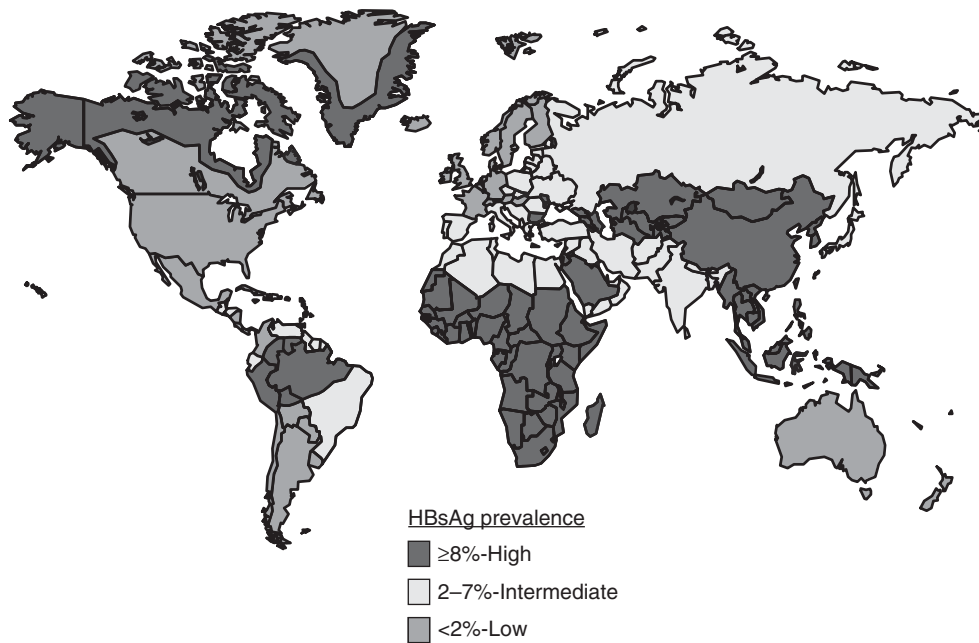

Figure 12-7. Geographic distribution of chronic hepatitis B virus infection. (Source: CDC Website, [www.cdc.gov/ncidod/diseases/hepatitis/slideset_online_hepatitis_B_slide_set, slide number 9.](http://www.cdc.gov/ncidod/diseases/hepatitis/slideset_online_hepatitis_B_slide_set_slide_number_9))

general population has serologic evidence of HBV infection.¹¹³ In these low-endemic areas, most infections occur among young adults, and high-risk sexual activity and injecting drug use account for most cases of newly acquired hepatitis B.¹⁰⁰ Historically, within some areas of low endemicity, the prevalence of infection has varied widely. For example, within North America, Eskimo populations have had a high endemicity of HBV infection, and first generation immigrant populations from high endemic areas (e.g., Asia, Africa, Middle East, former Soviet Union) have continued to have high rates of HBV transmission.^{97-99,114} In those parts of the world with an intermediate endemicity of HBV infection, transmission in all age groups maintains the level of chronic infection.

Worldwide, nosocomial transmission of HBV from inadequate sterilization of medical and dental instruments and unsafe injection practices continues to be a significant problem in developing countries and may cause as many as 8–16 million HBV infections each year.¹¹⁵⁻¹¹⁹ In most developed countries, nosocomial transmission of HBV from inadequately sterilized medical instruments or reuse of injection equipment has not been a significant problem. However, occasional outbreaks continue to occur from the contamination of multiple dose vials, the reuse of disposable needles and syringes, and inadequately sterilized medical devices.¹²⁰⁻¹²² These outbreaks usually represent lapses in infection control practices.

Direct transmission via blood or blood products has been eliminated in those countries that routinely screen donors for HBsAg and require viral inactivation of clotting factor concentrates.⁷¹ However, blood transfusion is a major source of HBV transmission in countries where the blood supply is not screened for HBsAg.

Epidemiology in the United States. With the implementation of a comprehensive immunization strategy to eliminate HBV in the United States since 1991, the incidence of hepatitis B has declined dramatically, particularly among younger age groups covered by the recommendation for routine childhood immunization.^{25,123} During 1990–2005, the incidence of acute hepatitis B declined 79%, from 8.5 to 1.8 per 100,000 population, with the largest decline (97%) among persons aged 0–19 years (from 3.0 to less than 0.1 per 100,000). Although the incidence of acute hepatitis B declined 76% among adults aged 20 years and older from 1990 to 2005 (from 10 to

2.3/100,000). The incidence of acute hepatitis B among men has been consistently higher than that among women with this ratio increased from 1.5 in 1990 to 1.6 (2.3 per 100,000 among males versus 1.4 per 100,000 among females) in 2005. This difference in hepatitis B rates by sex is highest among adults over 35 years of age.

In addition to declines by age, racial disparities in hepatitis B incidence have narrowed. The reduction of the disparity between Asian/Pacific Islanders and other children is consistent with recent observations noting a decline in seroprevalence of HBV infection and successful implementation of routine hepatitis B vaccination among Asians who have recently immigrated to the United States. Rates of hepatitis B have been declining among all racial and ethnic groups, though rates remain highest among non-Hispanic blacks (2.9 per 100,000) in 2005.

The proportion of reported acute hepatitis B cases among MSM has increased from 4% of reported cases in 1990 to 15% of reported cases in 2005.^{123,25} Although the proportion of MSM reporting multiple sex partners has remained constant (about 50%) over this period, the proportion of heterosexuals reporting multiple sex partners has increased from 14% to 31%. The proportion of persons reporting injection drug use (IDU) as a risk factor for acute hepatitis B remained stable over this time period, accounting for approximately 15–18% of reported cases.^{25,100,123} Outbreaks among injection drug users continue to be reported.¹²⁴

Among other U.S. reported cases of acute hepatitis B in 200 for which information on exposures during the incubation period was determined, receiving hemodialysis or a blood transfusion, both of which were previously major sources of infection, accounted for less than 0.5% of cases each.²⁵ This is likely a result of the vaccination of dialysis patients, improvements in infection control, and the required screening of donated blood for markers of HBV infection. Similarly, the percentage of cases attributable to occupational exposure to blood is approximately 1%, following widespread hepatitis B vaccination of health-care workers.

Prevention and Control

The primary goal of hepatitis B prevention programs is reduction of chronic HBV infection and HBV-related chronic liver disease. A secondary goal is the prevention of acute hepatitis B. Hepatitis B

immunization is the most effective prevention measure. In addition, HBV infection can be prevented by screening blood, plasma, organ, tissue, and semen donors; virus inactivation of plasma-derived products; risk-reduction counseling and service; and implementation and maintenance of infection control practices.⁷¹

Two products are available to prevent HBV infection, hepatitis B vaccine and hepatitis B immune globulin (HBIG). Hepatitis B vaccines are composed of HBsAg adsorbed to an aluminum hydroxide or aluminum phosphate adjuvant. Both plasma-derived and recombinant vaccines are available worldwide, although only recombinant vaccines are now used in the United States. HBIG is prepared from plasma containing high concentrations of anti-HBs. It provides short-term (i.e., 3–6 months) protection and is recommended in certain postexposure settings.¹²⁵

Hepatitis B vaccines are highly immunogenic, with seroconversion rates of at least 95% in healthy infants, children, adolescents, and adults.¹²⁵ Seroprotection to HBV infection is defined as an anti-HBs response of 10 milli-International Units per milliliter (mIU/mL) or more 1–2 months after the vaccination series. There is long-term protection against hepatitis B after vaccination despite the loss of detectable levels of anti-HBs over time; booster doses are not recommended for persons with normal immune status.^{125–127} Due to the high immunogenicity of hepatitis B vaccines, postvaccination testing to detect anti-HBs is not indicated after routine vaccination, except for the following groups: (a) health-care workers at continued risk of needlestick or other percutaneous exposures, (b) immunocompromised persons at continued risk of HBV exposure (e.g., patients on long-term dialysis), (c) the sexual partner of a chronically infected person, and (d) infants who have received postexposure prophylaxis because they were born to an HBsAg-positive mother (both anti-HBs and HBsAg should be measured).

More than three decades of experience have shown that hepatitis B vaccination is a safe and cost-effective means to prevent HBV infection and its acute and chronic consequences.^{128–130} The effectiveness of routine infant hepatitis B immunization in significantly reducing or eliminating the prevalence of chronic HBV infection has been demonstrated in many countries. In general, studies conducted in high HBV-endemic areas have demonstrated declines in the prevalence of chronic HBV among children to less than 2% after introduction of the vaccine.^{131–136} The greatest impact has been achieved in countries that have achieved high vaccine coverage among infants, and where a birth dose of vaccine was administered. In Alaska, where high vaccine coverage among infants has been achieved, and all infants receive a birth dose of vaccine, HBV transmission among children has been eliminated.¹³¹

Since 1992, the World Health Organization has called for all countries to add hepatitis B vaccine into their national childhood immunization services, and substantial progress has been made in implementing this recommendation.^{137,138} By early 2003, more than 150 countries worldwide had introduced the vaccine.¹³⁹ In addition to routine infant vaccination, WHO recommends considering administration of a dose at birth to prevent perinatal HBV transmission, particularly in countries where a high proportion of chronic HBV infections is acquired perinatally (e.g., East and Southeast Asia, Pacific Islands).

In the United States, a comprehensive immunization strategy has been recommended to prevent HBV-related chronic liver disease in all age groups, and to ultimately eliminate HBV transmission. Components of this strategy are: (a) prevention of perinatal HBV infection through routine screening of all pregnant women for HBsAg and appropriate immunoprophylaxis of infants born to HBsAg-positive women, (b) routine vaccination of infants, (c) routine vaccination of all adolescents who have not previously been vaccinated, and (d) vaccination of adults at high risk of infection, who have not been previously vaccinated.^{71,125,140}

To date, most of these components have been widely implemented. Hepatitis B vaccine has been successfully integrated into the childhood vaccine schedule, and infant vaccine coverage levels are now equivalent to those of other vaccines in the childhood schedule.

As of 2003, more than 92% of 19- to 35-month-old children had been fully immunized with three doses of hepatitis B vaccine, and a survey of states found that more than 95% of children enrolled in kindergarten during the 2003–2004 school year were up-to-date with recommended hepatitis B vaccine.^{141,142} Part of this success can be attributed to the established infrastructure for vaccine delivery to children, which ensures high coverage levels. Because hepatitis B vaccine provides long-term protection against chronic HBV infection, these children will be protected as they move through adolescence and adulthood.

Vaccine coverage among adolescents has increased substantially. In response to the 1996 recommendation for routine hepatitis B immunization of adolescents, a growing number of states are requiring vaccination for middle-school entry, and a number of programs provide hepatitis B vaccine to high-risk youth.^{140,143} Vaccine coverage data from 2002 indicate that more than 60% of 13- to 15-year olds have been vaccinated against hepatitis B (CDC, unpublished data).

High HBsAg screening rates have also been achieved among pregnant women. Currently, every state and large metropolitan area receives federal funding to support perinatal hepatitis B prevention programs, and more than 95% of pregnant women are tested for HBsAg (CDC, unpublished data). However, only about 50% of expected births to HBsAg-positive women are identified for case management, which has been effective in ensuring high levels of initiation and completion of postexposure immunoprophylaxis (CDC, unpublished data). For women without prenatal care, the need for proper management, including HBsAg testing of the mother at the time of admission for delivery and administration of the first dose of hepatitis B vaccine to the infant within 12 hours of birth is underscored by the higher prevalence of HBsAg seropositivity in this group compared to women who are screened prenatally.¹⁴⁴ However, studies have found that infants born to mothers with unknown HBsAg status at the time of delivery often do not receive a birth dose.^{145,146} In addition, errors in maternal HBsAg testing and omissions in test reporting have resulted in failure to administer postexposure immunoprophylaxis to infants born to HBsAg-positive mothers.¹⁴⁷

The greatest remaining challenge for hepatitis B prevention in the United States is vaccination of high-risk adults. Despite longstanding recommendations for vaccination of persons who report a history of multiple sex partners, STD treatment, or male sexual activity with another male, vaccine is rarely offered in settings that provide health care to adults, including settings that provide services targeted specifically to high-risk adults (e.g., STD treatment clinics, HIV counseling and testing programs, drug treatment centers). As a result, many opportunities to vaccinate high-risk adults are missed. For example, approximately 60% of adults with acute hepatitis B report previously receiving care in a setting where vaccination is recommended, such as an STD clinic, drug treatment center, or correctional facility.^{100,CDC unpublished data} Thus, efforts to vaccinate adults at increased risk for HBV infection need to be greatly expanded to accelerate elimination of HBV transmission.

Although hepatitis B vaccination programs have been highly successful, there remain a large number of persons with chronic HBV infection, most of whom were born either outside the United States, or before U.S. vaccination programs were implemented. These persons should be provided counseling about how to protect their liver from further harm and how to reduce the risk of transmission to others. In addition, persons with chronic HBV infection should be evaluated for chronic liver disease and possible treatment.

Five therapeutic agents have been approved by the Food and Drug Administration (FDA) for treatment of chronic hepatitis B: alpha-interferon, pegylated interferon, lamivudine, entecavir, and adefovir.^{149–151} The aims of treatment are to achieve sustained suppression of HBV replication and remission of liver diseases. In general, less than half of patients treated achieve seroconversion from HBeAg-positive to HBeAg-negative. The most important predictor of response is high pretreatment ALT levels.

Hepatitis C

Etiologic Agent

Hepatitis C virus (HCV), an enveloped RNA virus, has been shown to be the primary etiologic agent of parenterally transmitted non-A, non-B (PT-NANB) hepatitis worldwide.¹⁰ HCV has a single-stranded, positive-sense RNA genome with an organization and replication strategy similar to that found in the family *Flaviviridae*, which includes yellow fever virus, St. Louis encephalitis virus, and West Nile virus. However, HCV has been classified in its own genus, *Hepacavirus*, because of similarities to both flavivirus and pestivirus genomic organization. The single-translated polyprotein contains structural proteins, including the core and two envelope proteins, and nonstructural proteins, including a virus-specific protease, helicase, and polymerase.^{152–154} Replication occurs through an RNA-dependent RNA polymerase that lacks a “proofreading” function, resulting in the rapid evolution of a population of viruses (quasispecies) within an infected individual that are heterogeneous but closely related. Two regions of one of the envelope proteins, called hypervariable regions, have an extremely high rate of mutation. It is postulated that the rapid evolution of genetic variation within an individual represents an immune escape mechanism that facilitates viral persistence in most infected persons.^{152,154,155} There are six distinct HCV genotypes and more than 50 subgroups.

HCV has not been propagated in cell culture except for what appear to be abortive replication cycles, and it has not been ascribed a physical structure because it has not been visualized by electron microscopy. Native proteins have not been purified from any sources. However, infectious clones of HCV have been identified and are being used to further characterize the virus.¹⁵⁶

Clinical Illness, Pathogenesis, and Immune Response

The spectrum of illness ranges from an asymptomatic infection to acute fulminant hepatitis (very rare). The incubation period for acute, symptomatic HCV infection (hepatitis C) following a known exposure (e.g., transfusion, needlestick) averages 6–7 weeks, with a range of 2–26 weeks.^{157,158} Most persons (60–80%) with newly acquired HCV infection are asymptomatic and only 15–30% become jaundiced.¹⁵⁹ The clinical illness in persons with acute hepatitis C is similar to that observed in hepatitis of other viral etiologies, and the diagnosis of hepatitis C can only be made with appropriate serologic testing.

In the experimentally infected chimpanzee, HCV is detectable in liver and serum within 72 hours of inoculation, and in human recipients of infectious blood transfusions, HCV RNA is detectable 1–2 weeks after exposure.^{160,161} Anti-HCV is detectable in approximately 40% of infected persons 10 weeks after exposure, in 80% at 15 weeks, and in virtually all infected persons by 6 months following exposure.¹⁶²

A striking feature of HCV infection is that a persistent infection develops in up to 85% of newly infected adults and children, and may occur with or without evidence of chronic hepatitis.^{163,164} While the majority of newly infected persons are asymptomatic, one small study has indicated that persons with symptomatic acute illness may be more likely to clear HCV infection spontaneously than persons with asymptomatic illness.¹⁶⁵ Of persons with chronic HCV infection, an average of 67% (range 58–81%) develop chronic hepatitis with elevated liver enzymes (alanine aminotransferase [ALT]) within six months after the onset of their acute infection, and no epidemiologic features of patients appear to be predictive of the progression to chronic infection or hepatitis.^{162,166,167} Among patients with biopsy proven HCV-related chronic hepatitis, there is a wide spectrum of ALT patterns, ranging from persistent elevations to prolonged periods (12 months) of normal activity. This variable pattern of disease activity requires that patients with new HCV infection receive long-term follow-up to ascertain the extent of their disease.

The progression or course of chronic liver disease associated with chronic HCV infection is not completely known, having been inferred from a limited number of prospective studies of patients beginning

with their acute infection, and retrospective cross-sectional studies of persons with chronic HCV infection. In addition, studies that only examine disease outcome may underestimate the severity or progression of HCV infection, since persons with biopsy proven liver disease that is relatively severe (i.e., cirrhosis, chronic active hepatitis) may be asymptomatic for many years. Long-term studies (16–23 years) of cohorts of patients with transfusion acquired HCV infection have shown 3–5% died of HCV-related chronic liver disease, and up to 33% had evidence of cirrhosis.^{166,168,169} Among patients followed prospectively from the onset of acute hepatitis C acquired from a variety of sources, 26–68% had chronic active hepatitis and 3–26% had cirrhosis on liver biopsy within five years of the acute infection.^{162,164,170} However, among a cohort of women who became chronically infected from HCV-contaminated Rh₀ immune globulin, approximately 55% had elevated alanine aminotransferase (ALT) levels (biochemical evidence of chronic hepatitis), 93% had minimal or chronic mild inflammation on biopsy, and only 2% had histologic evidence of cirrhosis after 17 years of follow-up; none had died.¹⁷¹ Thus, it is clear that most chronic HCV infections will lead to hepatitis and to some degree of fibrosis (scarring), which may be accompanied by relatively nonspecific symptoms such as fatigue. Severe complications and death usually occur only in persons who have developed cirrhosis.

Factors that have been associated with more rapid progression of HCV-related chronic liver disease include alcohol use, older age at infection, male gender, and immunodeficiency. Although persistently elevated ALT levels indicate ongoing liver damage, significant hepatic damage has also been documented in some asymptomatic chronically-infected persons with persistently normal ALT levels.¹⁷²

Case-control studies have shown a 5–50-fold increased risk of HHC among anti-HCV positive persons, compared to anti-HCV negative persons.¹⁷³ When cirrhosis is established (usually over 20–30 years with chronic disease), the rate of development of HCC may be 1–4% per year.^{111,154,174}

HCV infection is also associated with extrahepatic diseases, including essential mixed (type II) cryoglobulinemia, membranoproliferative glomerulonephritis, and sporadic porphyria cutanea tarda.^{175–177} A number of other non-hepatic diseases have been attributed to HCV infection (e.g., autoimmune thyroiditis, lichen planus, idiopathic pulmonary fibrosis), but definitive associations have not been established.

The immunologic factors associated with the pathogenesis of persistent HCV infection and HCV-related chronic liver disease are not well known because of the lack of experimental systems such as cell culture, small animal models, or well-characterized transgenic mouse models of infection. What is known comes from the chimpanzee model of infection and studies in humans. The high rate of persistent infection in the face of antibodies produced to various viral epitopes suggests these are not neutralizing antibodies. Experiments in chimpanzees have shown that rechallenge with the same or different strains of HCV resulted in the reappearance of viremia, and early postexposure administration of HCV immune globulin did not prevent infection.^{178–180} In the chimpanzee model, high titer antibodies to recombinant capsid proteins (E2) appear to provide short-term protection against chronic infection with the homologous virus, but do not appear to provide long-term protection upon rechallenge.¹⁸¹ Although the presence of lymphocytes within the hepatic parenchyma may be evidence of immune-mediated damage, the role of cell-mediated immunity in virus clearance and liver injury has not been defined.¹⁵⁴

Diagnosis

During the course of active HCV infection, antibodies are produced to most viral proteins. However, antibody to no single antigen is associated with resolution of HCV infection. Antibodies to nonstructural and core proteins are used for diagnostic immunoassays and cannot differentiate an active from a resolved infection. HCV antigen has been detected in the liver of infected persons; and while circulating virus-associated antigens have been detected during the course of

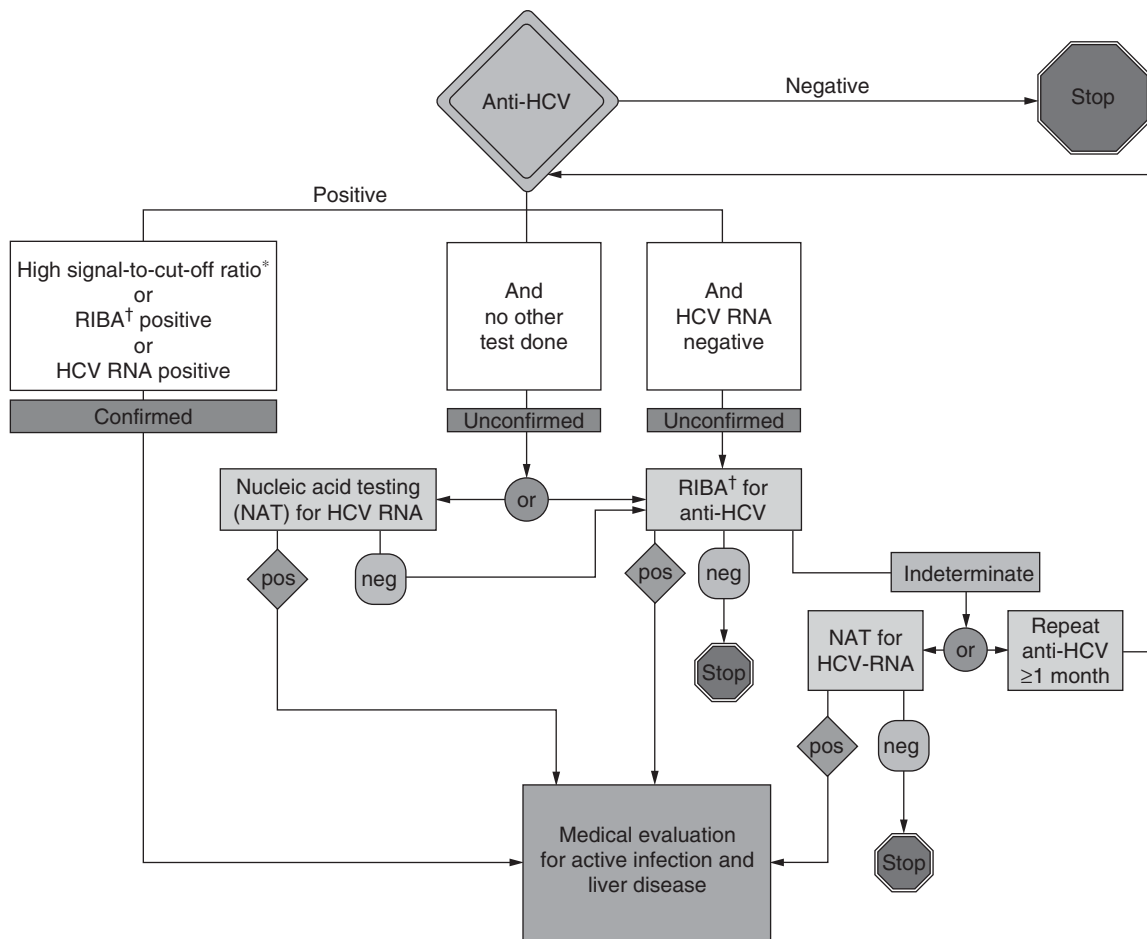

infection, the immuno-assay used for detection has not yet been licensed.¹⁶⁰ This has limited the detection of active HCV infection to the identification of HCV RNA by nucleic acid amplification methods such as the polymerase chain reaction (PCR).

Diagnostic tests for HCV infection include serologic assays for antibody to HCV and nucleic acid tests to detect HCV RNA.⁴ Currently licensed anti-HCV screening tests for use in the United States include two enzyme immunoassays (EIA, Abbott HCV EIA 2.0, ORTHO HCV Version 3.0 ELISA) and an enhanced chemiluminescence immunoassay (CIA, VITROS Anti-HCV assay). Both types of immunoassays use HCV-encoded recombinant antigens from the core and nonstructural regions, and are highly sensitive, identifying more than 95% of HCV infected persons.¹⁸²⁻¹⁸⁴ However, as with all immunoassays used for diagnostic or screening purposes, the predictive value of a positive test depends on the prevalence of the condition in the population being tested.

Although a true confirmatory test is not available for the immunoassays, since native HCV proteins have not been identified, a supplemental serologic assay (Recombinant Immunoblot Assay, RIBA, Ortho Diagnostic Systems) has been produced from synthetic HCV proteins. In addition, supplemental molecular nucleic acid tests (NATs) are approved for diagnostic qualitative detection of HCV RNA using reverse transcriptase PCR (RT-PCR) amplification or transcription-mediated amplification (TMA).^{153,185} These tests have a

lower limit of detection of approximately 50 IU/mL (PCR) and from 5–10 IU/mL (TMA), and require that the serum or plasma be collected and handled in a special way. Other NATs for both qualitative and quantitative testing are available on a research-use basis.¹⁸⁴

In certain clinical settings, false-positive anti-HCV results are rare because the majority of persons being tested have evidence of liver disease, and the sensitivity and specificity of the screening assays are high. However, among immunocompetent populations with anti-HCV prevalences less than 10% (e.g., volunteer blood donors, active duty and retired military personnel, persons in the general population, health-care workers, clients attending sexually transmitted disease clinics), the proportion of false-positive anti-HCV results averages 35% (range: 15–60%).¹⁸⁴ Because anti-HCV screening tests are performed in a variety of settings (e.g., hospitals, physician offices, health department clinics, HIV counseling sites), and clinical information is often missing, interpretation of anti-HCV screening-test-positive results can be problematic. To facilitate and improve the practice of reflex supplemental testing, which many laboratories were not providing, the recommended anti-HCV testing algorithm was expanded to include an option for more specific testing based on the signal to cutoff ratio of screening-test positive results that could be easily implemented (Fig. 12-8).¹⁸⁴ Simultaneously, recommendations for the reporting of results of anti-HCV testing by type of reflex supplemental testing performed were made to assist in the interpretation of test results (Table 12-6).

*Samples with high s/co ratios usually (>95%) confirm positive, but supplemental serologic testing was not performed. Less than 5 of every 100 might represent false-positives; more specific testing should be requested, if indicated.

†Recombinant immunoblot assay

Figure 12-8. Hepatitis C virus (HCV) infection: testing for diagnosis. (Source: Centers for Disease Control and Prevention. Guidelines for laboratory testing and result reporting of antibody to hepatitis C virus. MMWR. 2003;52(No.RR-3):9.)

TABLE 12-6. RECOMMENDATIONS FOR REPORTING RESULTS OF TESTING FOR ANTIBODY TO HEPATITIS C VIRUS (ANTI-HCV) BY TYPE OF REFLEX SUPPLEMENTAL TESTING PERFORMED

<i>Anti-HCV Screening Test Results</i>	<i>Supplemental Test Results</i>	<i>Interpretation</i>	<i>Comments</i>
Screening-test-negative*	Not applicable	Anti-HCV-negative	Not infected with HCV unless recent infection is suspected or other evidence exists to indicate HCV infection.
Screening-test-positive* with high signal-to-cutoff (s/co) ratio	Not done	Anti-HCV-positive	Probable past or present HCV infection; supplemental testing not performed. Samples with high s/co ratios usually ($\geq 95\%$) confirm positive, but < 5 of every 100 might represent false-positives; more specific testing can be requested, if indicated.
Screening-test-positive	Recombinant immunoblot Assay (RIBA)-positive	Anti-HCV-positive	Past or present HCV infection.
Screening-test-positive	RIBA-negative	Anti-HCV-negative	Not infected with HCV, unless recent infection suspected or other evidence for HCV infection.
Screening-test-positive	RIBA-indeterminate	Anti-HCV indeterminate	HCV antibody and infection status cannot be determined; another sample should be collected for repeat anti-HCV testing (> 1 month) or for HCV RNA testing.
Screening-test-positive	Nucleic acid test (NAT)-positive	Anti-HCV-positive HCV RNA-positive	Active HCV infection.
Screening-test-positive	NAT-negative RIBA-positive	Anti-HCV-positive HCV RNA-negative	Past or present HCV infection; single negative HCV RNA result does not rule out active infection.
Screening-test-positive	NAT-negative RIBA-negative	Anti-HCV-negative HCV RNA-negative	Not infected with HCV.
Screening-test-positive	NAT-negative RIBA-indeterminate	Anti-HCV-indeterminate HCV RNA-negative	Screening test anti-HCV result probably false-positive, which indicates no HCV infection.

*Screening immunoassay test results interpreted as negative or positive on the basis of criteria provided by the manufacturer.

The diagnosis of recent HCV infection is limited by the lack of a sensitive and specific immunoassay, such as IgM anti-HCV. The diagnosis of recent infection can be made in rare instances where the patient has a documented anti-HCV seroconversion, with or without signs or symptoms of disease. Among patients with signs or symptoms of acute viral hepatitis, serologic tests must be obtained to rule out acute HAV (IgM anti-HAV) and acute HBV (IgM anti-HBc and HBsAg) infection, along with a test for anti-HCV. In addition, if the initial anti-HCV result is negative it should be repeated, since upwards of 20% of persons with acute hepatitis C are anti-HCV negative at the time of initial presentation.^{162,182} The course of acute hepatitis C is variable, although fluctuating elevations in serum ALT levels is a characteristic feature. After acute infection, 15–25% of persons appear to resolve their infection without sequelae, as defined by sustained absence of HCV RNA in serum and normalization of ALT levels (Fig. 12-9).¹¹¹

Chronic HCV infection develops in most persons (75–85%), with persistent or fluctuating ALT elevations indicating active liver disease developing in 60–70% (Fig. 12-10). ALT can be normal in 30–40% of chronically infected persons; and even in those with ALT elevations, the pattern can be variable, with periods of normal ALT levels. Although detection of HCV RNA more than 6 months following initial infection is an indication of chronic infection, there can be periods where HCV RNA is undetectable in the blood, therefore a single HCV RNA negative test more than 6 months after infection is not sufficient to rule out chronic HCV infection.

Nucleic acid testing for HCV RNA is most useful to confirm the presence of viremia, and to assess treatment response.¹⁵⁴ A qualitative NAT should also be used in patients with negative results on

enzyme immunoassay in whom recent infection is suspected, in patients who have hepatitis with no other identifiable cause, and in persons with known reasons for false negative results on antibody-testing (e.g., immunosuppression).^{154,186} In addition, NAT of blood

(Source: CDC Website, [www.cdc.gov/ncidod/diseases/hepatitis/slideset online hepatitis C slide set, slide number 5.](http://www.cdc.gov/ncidod/diseases/hepatitis/slideset%20online%20hepatitis%20C%20slide%20set,%20slide%20number%205))

donations was implemented in 1999 to detect “window-period” infections, and other infections not determined by donor history questions.¹⁸⁷

Viral genotyping can help to predict the outcome of therapy and help determine the choice of therapeutic regimen, as genotypes other than 1 are more responsive to therapy.¹⁵⁴ Liver biopsy, though not necessary for diagnosis, is helpful for grading the severity of disease and staging the degree of fibrosis and permanent architectural damage.

Epidemiology

Routes of Transmission. HCV is transmitted by percutaneous or mucosal exposure to infectious blood or blood-derived body fluids. The primary route of transmission is percutaneous exposure to blood. Other less efficient routes of transmission include perinatal exposures and sexual contact. Transmission among family contacts is uncommon, but could occur from direct or inapparent percutaneous or mucosal exposure to blood.

Percutaneous transmission. Injection drug use is a major source of HCV transmission in developed countries. Injection drug users (IDUs) acquire HCV infection by sharing contaminated needles and equipment, sometimes among groups of persons.^{122,188} Even persons who injected just once or twice in the past should be considered at high risk of infection, since HCV infection is acquired more rapidly among IDUs than either HBV or HIV infection.^{111,122}

Transfusion of blood or plasma-derived products and transplantation of solid organs from HCV-infection donors are highly effective routes for transmitting HCV infection. However, in most developed countries, screening of blood and organ donations has eliminated most transfusion and transplant-related HCV transmission.¹⁸⁹

Prior to 1987, when heat inactivated clotting factor concentrates were widely introduced, most persons with hemophilia became infected with HCV and most older patients suffered from chronic liver disease. However, since the introduction of viral inactivation methods, the incidence of HCV infection has dropped dramatically in persons who require clotting factor infusions, and anti-HCV screening of donors has diminished the risk of infection among persons who receive multiple blood transfusions. Immune globulin preparations, either for intramuscular injection or intravenous infusion, had not

been associated with infection until an outbreak of HCV infection among recipients of intravenous immune globulin in the mid-1990s.¹⁹⁰ This outbreak emphasized the need for viral inactivation of these products as well.

Nosocomial transmission of HCV infection due to poor infection control practices and aseptic techniques (including unsafe injections) is a common means of transmission in developing countries. Although rare in developed countries such as the United States, outbreaks of infections spread from patient-to-patient are being increasingly recognized.¹²¹ Occupational exposure to HCV-infected blood is also a risk factor for infection. Persons with direct percutaneous (e.g., needlestick) exposures from HCV infected persons are at increased risk of infection, with an average seroconversion of 1.8% (range 0–7%).^{182,189,191}

Sexual transmission. Sexual transmission of HCV infection appears to be inefficient, occurring at a frequency lower than that observed for HBV and HIV infection.^{162,182} In studies done in North America and western Europe, the average anti-HCV positivity rate among spouses of persons with HCV infection who report no other risk factor for infection is 1.3%.¹⁸⁹ While transmission appears to be low (<3%) in most studies of monogamous heterosexual partners and among non-drug using men who have sex with men, persons with multiple sexual partners and persons seen in STD clinics continue to have a somewhat increased risk of infection.^{111,192–194} Additionally, several studies have shown increased prevalence of HCV infection among persons reporting sex with an IDU or prior infection with another STD.^{195–198}

Perinatal transmission. Perinatal exposures account for a small proportion of HCV infections. Average risk for transmission from an HCV-infected mother to child is 6%, and transmission of infection appears to occur exclusively from mothers who are HCV RNA positive at the time of delivery.¹⁹⁹ Maternal coinfection with HCV and HIV has been found to be consistently associated with an increased risk of HCV transmission to the fetus.

Worldwide Patterns of Transmission. HCV infection appears to be endemic in most parts of the world, with an estimated overall prevalence of 2.2%, or 130 million persons infected.²⁰⁰ However, there is considerable geographic and temporal variation in the incidence and prevalence of HCV infection, with three distinct transmission patterns identified based on age-specific seroprevalence data.¹⁸⁹ In countries where infections are found to be concentrated among persons 40–59 years old, risk appears to have been greatest in the past 20–40 years and primarily affected young adults. The United States and Australia fit this pattern, with injection drug use the predominant risk factor for HCV infection. In countries with infections concentrated in older adults (e.g., Japan, Italy), risk was in the more distant past. In countries with infections observed in all age groups (e.g., Egypt), it appears that there is an ongoing high risk for acquiring HCV infections. In countries with the second and third patterns, unsafe injections and contaminated equipment used in health-care-related procedures appear to have played, or be playing a major role in transmission.

In the United States and other developed countries, nosocomial transmission of infection appears to be infrequent, except in the hemodialysis setting where there continues to be a low rate of infection, along with occasional outbreaks.²⁰¹ However, there have been several outbreaks of HCV infection in both inpatient and outpatient settings in recent years, and transmission has typically been associated with unsafe injection practices, or other breaks in infection control practices.^{202–204} In contrast, in countries without routine blood donor screening, or with poor infection control or injection practices, there appears to be a high rate of nosocomial HCV transmission that accounts for high rates of infection in the general population. In 2000, it has been estimated that contaminated injections caused two million HCV infections, accounting for 40% of new infections.²⁰⁵

Epidemiology in the United States. The prevalence of HCV infection as measured by anti-HCV positivity in the general U.S. civilian population is 1.6%, or an estimated 4.1 million persons, with 3.2 million estimated to have chronic infection.²⁰⁶ Genotype 1 (a and b) accounts for an estimated 70–75% of all HCV infections (15% genotype 2, 7% genotype 3, 1% genotype 4, and 3% genotype 6).²⁰⁷ The highest prevalence of HCV infection is in persons born from 1945 to 1965, who acquired infection during a period of high incidence of HCV infection from 1970 to 1990.²⁰⁶ Prevalence is higher in non-Hispanic blacks (3.0%) compared with non-Hispanic whites (1.5%), and higher among males (2.1%) than females (1.1%).

Several population-based studies have shown that 40–60% of persons with symptomatic chronic liver disease are infected with HCV, and HCV infection is the single most common reason for liver transplantations in the United States.¹⁰⁴ HCV-related chronic liver disease is responsible for an estimated 8000–10,000 deaths each year.^{104,208}

Most HCV infections in the United States can be accounted for by risk factors identified by cohort studies and by case-control studies of acute disease. During 1995–2000, 68% of newly acquired infections were associated with IDU, 18% with high-risk sexual exposures (HCV-positive partner, multiple partners), 4% with occupational exposures, and 1% with nosocomial and perinatal exposures.²⁰⁹

Before 1990, transfusion accounted for an estimated 10% of infections. The risk of transfusion associated HCV infection in the United States has declined from an estimated 5% per transfused unit prior to 1970 to 1 in two million units by 2000.²¹⁰ This change has occurred in a stepwise fashion beginning with the elimination of paid blood donors in the early 1970s, donor screening for human immunodeficiency virus (HIV) infection beginning in 1985, anti-HCV testing of donors beginning in 1990, and minipool nucleic acid testing beginning in 1999.¹⁸²

In the United States, persons with occupational exposure to blood have not been found to have an increased prevalence of HCV infection, compared to the general population.¹⁰⁴

The number of cases of acute hepatitis C has declined dramatically in the United States since 1989, largely due to a decrease in cases reported among IDUs; however, both incidence and prevalence of HCV infection remain high in this group. The prevalence of infection among IDUs is 30%–90%, depending on age and years of injecting, and IDU history accounts for 60% of all prevalent infections.^{104,110,211} The reason for the recent decline in disease incidence is not known, but may represent saturation of the susceptible population with HCV infection and/or a decrease in new IDU.

Prevention and Control

Currently, there is little evidence that a vaccine to prevent acute or chronic HCV infection will be available in the foreseeable future. A high degree of genetic diversity, a high mutation rate, and little evidence for the existence of a durable neutralizing antibody suggest that the development of effective pre- or postexposure prophylaxis may require innovative approaches. While high titer antibodies to recombinant envelope proteins have been shown to afford short-term protection to a homologous virus challenge in the chimpanzee model, there does not appear to be long-term protection.¹⁸¹ In addition, postexposure prophylaxis with specially prepared hepatitis C immune globulin has not been shown to protect against infection in the chimpanzee model of infection.¹⁸⁰ Until an effective immunoprophylactic measure becomes available, prevention of HCV infection must rely on: (a) reduction of risk behaviors that facilitate transmission; (b) screening of blood, solid organ, and tissue donors; (c) the use of standard and universal precautions to prevent occupational and nosocomial transmission; and (d) identification of infected persons for counseling and possible treatment.¹⁰⁴

A major primary prevention challenge is to prevent transmission among IDUs. Until recently, the presumption was that efforts directed at the prevention of injection drug use to prevent HIV infection would also prevent HCV infection. In particular, studies have demonstrated

that programs that provide access to clean syringes can prevent HIV transmission among IDUs without increasing the use of illegal drugs.²¹² However, programs that provide clean syringes to IDUs have not been consistently demonstrated to prevent acquisition of HCV infection, either because of syringe sharing or indirect sharing of drug paraphernalia (e.g., cottons, cookers, water).^{213,214} These programs have been shown, however, to facilitate entry into drug treatment which may prevent transmission in persons who stop or reduce drug injection, and they can be used to provide hepatitis C prevention education and counseling.²¹⁵

Practices that exclude blood, plasma, organ, tissue, or semen donors determined to be at increased risk for HCV infection by history or who are anti-HCV or HCV RNA positive, as well as testing of donated blood and organs must be maintained to prevent HCV transmission from transfusions and transplants. Viral inactivation of clotting factor concentrates and other products derived from human plasma also must be continued, and all plasma-derived products that do not undergo viral inactivation should be HCV RNA negative by RT-PCR before release.

In all types of health-care settings, infection control practices need to be reviewed and improved to prevent nosocomial and iatrogenic transmission of HCV and other bloodborne pathogens. Injection practices should be reviewed to ensure that disposable injection equipment is not reused, and that reusable injection equipment is appropriately sterilized. Infection control practices in chronic hemodialysis centers should be updated according to current recommendations.²¹⁶ In addition, to prevent contamination of multidose medication vials, they should be limited to a single patient, or restricted to a clean centralized preparation area.

Identification of HCV-infected persons is important so that they can receive counseling about how to protect their liver from further harm and how to reduce the risk of transmission to others. In addition, HCV-infected persons should be evaluated for chronic liver disease and possible treatment. Because most infected persons are asymptomatic, serologic testing of persons most likely to be infected with HCV is recommended. In the United States, routine testing is recommended for the following persons: (a) anyone who ever injected illegal drugs, (b) persons who received plasma-derived products known to transmit HCV infection that were not treated to inactivate viruses, (c) persons who have received blood products that might have been contaminated with HCV, including products prepared from blood that was either donated before the widespread use of second-generation EIA testing or came from a donor who later tested positive for HCV infection, (d) persons who have been on long-term hemodialysis, (e) health-care workers after needlesticks, sharps, or mucosal exposures to HCV-positive blood, (f) children born to HCV-positive women, and (g) persons with HIV infection.^{104,217} All persons with HCV infection should be considered infectious and should be counseled concerning available measures to prevent transmission of HCV infection to others. They should not donate blood, semen, body organs, or other tissues; cover cuts or skin lesions, and not share personal articles such as toothbrushes, razors, or other items that could be contaminated with blood. Although there are no recommendations for changes in sexual practices for persons with a steady sex partner, infected persons should be informed of the potential risk of sexual transmission so they can decide if they should take precautions. Persons with multiple sex partners should be advised to follow safer sex practices and use barriers to prevent contact with body fluids. Infected persons should also be provided information about ways to prevent further harm to their liver, including avoidance of alcohol, getting hepatitis A vaccination, and hepatitis B vaccination when appropriate. Infected individuals should also receive appropriate medical evaluation for chronic liver disease and possible antiviral treatment.

Treatment of hepatitis C has evolved rapidly since the discovery of HCV. Combination therapy with pegylated interferon and ribavirin is the treatment of choice for chronic hepatitis C.^{218,219} Over 50% of patients receiving combination therapy have a sustained virologic response (SVR), defined as normalization of liver enzymes, and a loss of HCV RNA 6 months or more after therapy.²²⁰ There are multiple

potentially serious side effects to treatment with both interferon and ribavirin, and careful pretreatment assessment and monitoring throughout therapy is essential. For HCV-infected patients for whom liver histology is available, treatment is generally recommended for those with significant fibrosis.²¹⁷ Treatment decisions should be individualized based on the severity of liver disease, the potential of serious side effects, the likelihood of treatment response, and the presence of comorbid conditions. Genotype 1, present in most infected persons in the United States, is more resistant to therapy, with lower rates of SVR (around 50% with 48 weeks of treatment) than genotypes 2 or 3 (over 70% with 24 weeks of treatment)²²⁰. In addition, pretreatment viral load can help determine response to treatment. Recent studies indicate that treatment early in the course of established chronic infection may be more likely to result in SVR.^{165,221}

Delta Hepatitis

Etiologic Agent

The hepatitis delta virus (HDV) is a 1.7kb RNA virus particle containing a circular, single-stranded RNA genome. HDV encodes a single protein, the delta antigen, which is encapsulated with HBsAg, encoded by the hepatitis B virus (HBV).^{222,223} HDV is classified as a satellite virus or subviral agent because it requires HBsAg as a surface protein to replicate.^{223,224}

Clinical Illness, Pathogenesis, and Immune Response

Because HBV must be present for transmission of HDV, HDV infection comes in two forms, an acute coinfection that occurs with HBV, and superinfection of a person with chronic HBV infection.^{7,223} Coinfection in a person susceptible to HBV infection follows exposure to an inoculum containing both HBV and HDV. The incubation is period similar to HBV infection (6 weeks to 6 months), and infection produces a biphasic illness in 15–20% of cases—something not observed in most other forms of viral hepatitis. The first peak of liver enzymes is related to appearance of HBV antigens in the liver, while the second is related to appearance of HDV antigens.²²⁵ HDV replication is limited by the resolution of HBV infection, with chronic HDV infection occurring only when the patient acquires a chronic HBV infection. Following acute HBV-HDV coinfection, approximately 2% of individuals will become chronically infected, compared with 2–6% of adults after infection with HBV alone.

HDV superinfection may appear within 2–8 weeks after exposure of a person with chronic HBV infection to an HDV inoculum.^{7,223} Acute HDV infection may partially suppress HBV replication and occasionally allows a patient to eliminate a chronic HBV infection. However, the majority (up to 90%) of persons with chronic HBV followed by HDV superinfection have chronic hepatitis and persistent infection with both viruses. Chronic HDV infection can be asymptomatic, manifest as chronic active hepatitis, or progress rapidly to cirrhosis and death due to liver failure.²²⁶

The spectrum of clinical disease in acute HDV coinfection or superinfection, as with other viral hepatitis infections, varies from no illness to fulminant hepatitis. In general, HDV infection augments the severity of both acute and chronic HBV infection, with 50–70% of acute infections (coinfection or superinfection) resulting in an episode of clinical hepatitis with jaundice, compared to 30% of HBV infections. The risk of fulminant hepatitis is higher than with HBV infection alone, and may reach 10% for clinically apparent HBV-HDV coinfections and 30% in HDV superinfections.^{223,226} HDV infection has been found in 30–50% of HBsAg-positive fulminant hepatitis cases.²²⁷

The rate at which cirrhosis develops once chronic HDV infection is established appears to be greater than with HBV infection alone. However, persons with cirrhosis may remain clinically stable for several years. Although there is a well-documented association between chronic HBV infection and development of HCC, none has been documented with chronic HDV infection.

During coinfection, serologic markers of acute HBV infection are accompanied by detectable hepatitis D antigen (HD-Ag) and antibodies to HDV (IgG or IgM anti-HDV). HD-Ag is usually present during the

early part of the acute illness, while IgM anti-HDV appears within days to weeks after onset of symptoms.²²³ The antibody response to HDV is not strong and accurate diagnosis is best accomplished during the acute illness or early convalescence. In acute superinfection, serologic markers of chronic HBV infection are present, HD-Ag may be present early in the illness, and IgG and IgM anti-HDV appear rapidly. In fulminant hepatitis, serum markers of HDV infection may be negative in spite of detectable HD-Ag in the liver. In chronic HDV hepatitis, HBsAg is present along with IgM anti-HDV and HD-Ag in the liver.

Diagnosis

Both IgM and IgG antibodies develop during the course of HDV infection. However, the only serologic tests commercially available in the United States detect total antibody (IgG and IgM) to HDV and may result in under-diagnosis of HDV infection. Tests for HD-Ag in serum are generally available only in research laboratories, and can detect HD-Ag during the acute phase of the illness. However, tests for HD-Ag have modest sensitivity because they require the detergent treatment of the specimen to disrupt the HBsAg coat of the virus particle. Immunoperoxidase and immunofluorescence assays for HD-Ag in liver are more sensitive and can be used to verify infection in liver biopsies from cases of chronic hepatitis. Assays to detect HDV-RNA are also generally available in research laboratories; hybridization assays for HDV-RNA in serum have proven more sensitive than assays for HD-Ag and appear useful in determining the potential infectivity of persons with chronic HDV infection.²²³ HDV RNA detection by PCR has been shown to be positive in 93% of patients with HBV-HDV coinfection, and in 100% of patients with HDV superinfection.

The diagnosis of acute HBV-HDV coinfection is made by the presence of serologic markers of acute HBV infection (IgM anti-HBc and HBsAg) and either serum HD-Ag or anti-HDV (total and/or IgM), although the anti-HDV response is often weak and may be delayed by several months. Therefore, testing of acute and convalescent sera may be required to diagnose acute HDV infection. Acute HDV superinfection is diagnosed by the presence of either HD-Ag or anti-HDV (total and/or IgM) in a patient with acute hepatitis and serologic evidence of chronic HBV infection (HBsAg positive and IgM anti-HBc negative). However, in cases of fulminant HDV hepatitis, serologic markers of HDV infection may be negative, but HD-Ag should be present in liver tissue.

Patients with chronic HDV infection have serologic evidence of chronic HBV infection (HBsAg positive and IgM anti-HBc negative) and HDV infection (total anti-HDV positive or HDV RNA positive).

Epidemiology

Routes of Transmission. The epidemiology of HDV infection parallels that of HBV infection. The highest concentrations of HDV are found in the blood of persons with acute or chronic infection, and HDV is presumed to be present in serum-derived body fluids such as wound exudates. However, its presence in other body fluids has not been confirmed. Transmission of HDV, like HBV, occurs by percutaneous or mucous membrane exposure to blood or body fluids either directly, indirectly, or by sexual contact. Perinatal transmission from mother to infant can occur, but is of minimal public health importance. Like HBV, casual contact does not result in virus transmission, but HBsAg-positive non-sexual household contacts of persons with chronic HDV infection are at significant risk of superinfection over long periods of time.

Among persons with chronic HBV infection in certain risk groups, (e.g., injection drug users, hemophiliacs) there is a high prevalence (30–50%) of HDV infection. However, the prevalence of HDV infection is much lower among persons with chronic HBV infection in other risk groups such as homosexual men (5%), persons with multiple heterosexual partners, and household contacts of persons with chronic HBV infection.²²³ These data suggest that HDV is transmitted less efficiently by sexual contact than by blood exposure.

Outbreaks of HDV infection have been recognized among IDUs and in certain populations with a high endemicity of HBV infection.

Outbreaks among IDUs usually involve coinfection with HBV and HDV, may cause high mortality due to fulminant hepatitis, and result in secondary transmission to sexual contacts.^{228,229}

Worldwide Patterns of Transmission. The highest prevalences of HDV infection are found in the Amazon basin, parts of Africa, and Romania, where 20% of persons with chronic HBV infection and up to 90% of patients with HBV-related chronic liver disease have HDV infection. In other areas of intermediate and high HBV endemicity (e.g., southern Italy, parts of Eastern Europe, the Middle East, Africa, some Pacific Island group, the Central Asian Republics of the former Soviet Union), HDV prevalence tends to be high infecting 15% of persons with chronic HBV infection and 30–50% of patients with HBV-related chronic liver disease. HDV has been identified as the cause of an endemic form of fulminant hepatitis in northern Columbia that has been recognized since the 1930s and is the cause of Labrea hepatitis which is endemic in the Amazon basin.²³⁰ Curiously, the prevalence of HDV infection is low in eastern and southeastern Asia despite the high endemicity of chronic HBV infection in this region.²³¹

The age-specific risk of HDV infection closely parallels that of HBV infection with several notable exceptions. In areas with a low endemicity of HBV infection such as the United States or western Europe, the prevalence of HDV infection among persons with chronic HBV infection is low (0–5%), but reaches 10–25% among persons with HBV-related chronic liver disease. Outbreaks of HDV superinfection in populations with a high endemicity of chronic HBV infection have been recognized in Brazil, Venezuela, Columbia, and the Central African Republic.^{231,232} These epidemics characteristically affect children and young adults, cause high mortality among persons with acute disease, and produce high rates of chronic liver disease. Transmission occurs primarily via open skin wounds and sores and through sexual contact. Risk is highest for those persons with chronic HBV infection who live with an index case and accounts for familial clustering of cases of fulminant hepatitis observed in these regions.

Epidemiology in the United States. In the United States, HDV infection is found in about 5% of acute hepatitis B cases and in up to 25% of cases of fulminant hepatitis B.²²³

Prevention and Control

Prevention of HDV infection is dependent on the prevention of HBV infection. Vaccination to prevent acute and chronic HBV infection is the best protective measure against HDV coinfection. Routine vaccination of infants and catch-up vaccination of older children in areas with previous outbreaks of delta hepatitis have eliminated the transmission of both HBV and HDV infection. However, persons with chronic HBV infection continue to remain at risk of HDV superinfection. General measures which include attention to sterilization and safe injection practices to prevent nosocomial transmission and screening of blood and blood products for HBsAg are effective in preventing both HBV and HDV infection. Otherwise no specific prevention measures can be offered for persons at risk of superinfection other than counseling to avoid contaminated needles and occupational or sexual exposure to HBV-HDV infected persons.

The medical treatment of chronic HBV-HDV infected persons with chronic liver disease is currently limited to monotherapy with interferon. Treatment with high doses of alpha interferon for at least 12 months has been shown to significantly reduce disease severity in most patients.^{225,233–235} Sustained biochemical and virologic responses to therapy were usually accompanied by the clearance of serum HBsAg and seroconversion to anti-HBs, with decrease in hepatic injury and HD-Ag staining.

HEPATITIS E

Etiologic Agent

The development of specific serologic tests for acute HAV infection resulted in the retrospective determination that large outbreaks of hepatitis in developing countries with a fecal-oral mode of transmission were

not hepatitis A.²³⁶ Laboratory investigations identified this new virus, hepatitis E virus (HEV) in the feces of experimentally infected cynomolgus macaques.²³⁶ HEV is a 32–34 nm icosahedral, nonenveloped single-stranded RNA virus that has been cloned and fully sequenced.^{12,237,238} The genome has approximately 7.2 kilobases with three open reading frames. Although there is a modest degree of genetic variability between isolates from various geographic regions, there appears to be serologic cross-reactivity among isolates. Although the physical structure of HEV resembles that of caliciviruses, the genomic organization is substantially different from other caliciviruses, and HEV has been reclassified to an unassigned genus of “hepatitis-E-like viruses.”²³⁹

Clinical Illness, Pathogenesis, and Immune Response

The incubation period of hepatitis E is longer than that of hepatitis A, ranging from 15 days to 60 days, with an average of 40 days. A prodromal phase lasting 1–10 days has been described followed by nausea (40–85%), dark urine (92–100%), abdominal pain (41–87%), vomiting (50%), pruritus (13–55%), joint pain (28–81%), rash (3%), and diarrhea (3%). Fever and hepatomegaly have been present in over 50% of patients.²³⁷

Clinical signs and symptoms or liver function tests cannot differentiate hepatitis E from other types of hepatitis. A human volunteer study showed that transmission of HEV could occur via the enteral route in a person immune to HAV infection.²⁴⁰ In the human volunteer study and the nonhuman primate model of infection, the relationship of virus excretion in feces to liver enzyme elevations was similar to that observed in hepatitis A; the peak of shedding occurred prior to the onset of illness.^{240,241} Histopathologic examination of liver biopsies from non-fulminant cases of hepatitis E have shown a cholestatic form of hepatitis with gland-like transformation and a preserved lobular structure. Liver cell necrosis has varied from single cell degeneration to bridging necrosis.²⁴²

The ratio of clinical to subclinical infection has not been determined, but it appears that children may have a lower rate of symptomatic infection.²³⁷ A high case-fatality rate among pregnant women, especially those in the second or third trimester, has been a consistent feature of hepatitis E and has ranged from 5–25%.^{14,237} A high perinatal death rate among infants of mothers with fulminant hepatitis has also been observed. Most persons with hepatitis E have a self-limited disease and follow-up studies of persons with hepatitis E indicate that chronic liver disease is not an outcome.

Diagnosis

Immunoassays to detect antibody to HEV (anti-HEV) are available worldwide, but no serologic tests are licensed in the United States, although enzyme immunoassays are available on a research basis in some commercial laboratories.^{14,239} All assays are constructed from synthetic HEV antigens derived from ORF 2 epitopes, and some include ORF 3 epitopes. In the United States, the very low rate of HEV infection does not warrant HEV serologic testing of every person with acute hepatitis. However, those patients remaining after exclusion of acute hepatitis A, hepatitis B, and hepatitis C should be tested for hepatitis E.

Immunoassays to detect HEV in stool specimens are not available. However, HEV RNA can be detected in feces or serum after nucleic acid amplification by PCR, and HEV antigen can be visualized in liver biopsies.²⁴³

Epidemiology

Routes of Transmission. HEV is primarily transmitted by the fecal-oral route. In endemic areas, the primary source of infection is fecally contaminated drinking water, although foodborne transmission has been suggested but not proven.^{237,244,245} Person-to-person transmission is rare and secondary attack rates in households are low, ranging from 0.7% to 2.2%, which is in contrast to the approximately 30% household secondary attack rate observed for hepatitis A. Person-to-person

nosocomial transmission has been reported in endemic areas, but bloodborne transmission from the viremic stage of infection has not been documented. In the United States and other non-endemic areas where outbreaks of disease due to HEV have not been documented, travel to endemic areas is the primary source of acute cases of hepatitis E.²⁴⁶

The reservoir for HEV is unknown. While fecally contaminated water is the source of most infections, the source of the HEV contamination is not known. The stability of HEV is not known, but it is unlikely that persistence in the environment is the major reservoir of infection, especially since epidemics occur following intervals of little or no disease activity. While serial transmission among susceptible individuals could sustain HEV in a population and result in periodic outbreaks, the low rate of infection among children tends not to support this model for persistence. Another possibility is that HEV infection is primarily zoonotic with humans being an end or inadvertent target. Experimental infection has been reported in pigs and sheep and a high prevalence of anti-HEV has been detected among domestic animals (i.e., pigs, cattle, sheep) from endemic areas.^{246–248} Recently, HEV was isolated from domestic pigs, as well as rats in the United States.^{249,250}

Worldwide Patterns of Transmission. Epidemics of hepatitis E have been reported worldwide and hepatitis E is endemic in many parts of the world, almost always where HAV infection is also highly endemic. Disease identification requires a high index of suspicion, but several epidemiologic features distinguish hepatitis E from hepatitis A, and include a high attack rate among adults and an unusually high case-fatality rate among pregnant women.^{14,237} Although asymptomatic infections occur among children, seroprevalence studies in high endemic areas have not identified high rates of infection in this age group, which is in contrast to HAV infection where approximately 90% of children less than 15 years of age have been infected.

Epidemiology in the United States. Cases of hepatitis E are rarely reported in the United States, and most reported cases have occurred among travelers to endemic regions. However, several cases of hepatitis E among U.S. residents who did not travel to endemic areas have been reported; the HEV strains isolated from these patients were genetically similar to the strain isolated from domestic swine.^{239,CDC unpublished data}

Prevention and Control

The most important means to prevent hepatitis E is protection of water systems from contamination with fecal material. Epidemiologic

evidence indicates that boiling water will interrupt HEV transmission. Data concerning the inactivation of HEV by chlorination of water are not available. Travelers to areas endemic for HEV infection should be advised to avoid potentially contaminated water or food. They also should be advised to avoid drinking beverages (with or without ice) of unknown purity, eating uncooked shellfish, and eating uncooked fruits or vegetables that are not peeled or prepared by the traveler personally.

Although no products are currently available to prevent infection with HEV, prevention of hepatitis E by immunization may be possible. Studies of postexposure immunization using immune globulin prepared from plasma collected in endemic areas has generally not had a protective effect.^{251,252} However, cynomolgus macaques given preexposure immunization with immune globulin prepared from previously infected animals were protected from symptomatic infection.^{253–255} Prototype hepatitis E vaccines have been developed that have been shown to be highly immunogenic and to protect nonhuman primates from hepatitis E caused by heterologous and homologous viral challenge. In preliminary studies, a hepatitis E vaccine candidate was found to be safe and immunogenic in humans, and efficacy studies using this vaccine are being conducted.²⁴⁹

Non-A to E Hepatitis

Patients with acute viral hepatitis in whom recognized viral and non-viral causes have been excluded are considered to have non-A–E hepatitis. Recently, several new viruses were isolated during an attempt to find the etiology of non-A–E hepatitis. These have been shown to be new flaviviruses that have been termed GB viruses (GBV) A, B, and C.^{256,257} A virus essentially identical to GBV-C, the only one of the GB viruses associated with human infection, was isolated from patients with non-A–E hepatitis and has been called hepatitis G virus (HGV). GVB-C/HGV has been shown to produce a persistent infection in a high proportion of persons with or without acute hepatitis or hepatitis-related chronic liver disease.^{228,259} Thus, it does not appear that GBV-C/HGV is a hepatotropic virus associated with liver disease.

More recently, a heterogeneous family of bloodborne DNA viruses designated transfusion-transmitted viruses (TTV) have been identified. Viruses in this family, including the group of SEN viruses (SENV), appear to be prevalent among blood donors as well as groups at increased risk of infection with bloodborne pathogens, such as injection drug users. Their role, if any, as hepatitis agents is unclear.^{239,260}

Aseptic Meningitis

Jeffery L. Meier

► ASEPTIC MENINGITIS

Aseptic meningitis is a syndrome characterized by acute onset of meningeal symptoms, fever, and cerebrospinal fluid (CSF) pleocytosis, with absence of bacteria and fungi on standard microbiologic stains and cultures.^{1,2} It is caused by an inflammation of the meningeal tissues covering the brain and spinal cord that results from multiple etiologies (infectious and noninfectious), most frequently viruses.

Epidemiology and Clinical Illness

Acute aseptic meningitis occurs sporadically and in outbreaks, but is not a nationwide notifiable disease in the United States. The incidence rate of aseptic meningitis during 1950–1981 was approximately

11 per 100,000 person-years, based on a large retrospective study of cases in Olmsted County, Minnesota.³ Reports of aseptic meningitis outbreaks in the United States are not uncommon and echoviruses have been linked to several recent outbreaks.^{4–6}

Aseptic meningitis typically produces symptoms of fever, headache, nausea, photophobia, and stiff neck, as a consequence of the meningeal inflammation. In young children, the meningitis often presents as fever and irritability. During 1988–1999, viral meningitis resulted in an estimated average of 36,000 hospitalizations per year in the United States for an annual average of 175,000 hospital days.⁷ Fortunately, the illness is usually self-limiting and seldom results in death.^{2,8,9} In cases of viral aseptic meningitis, symptoms of fatigue and headaches may sometimes linger for many days, particularly in adults.

Etiologic Agents

Nonpolio enteroviruses account for most aseptic meningitis cases in which an etiologic agent is identified, and represent over 90% of such cases in children.^{3,9–11} Of the 61 serotypes of nonpolio enteroviruses, echovirus types 9, 11, 13, and 30, and coxsackievirus group B types 2 through 5 accounted for the bulk of cases.^{9,10} However, the predominant serotypes in circulation change over time and several additional serotypes are capable of causing the illness. The rarely encountered echovirus type 13 emerged suddenly on multiple continents during 2000–2002 to cause numerous aseptic meningitis outbreaks; this virus strain was genetically distinct from the echovirus 13 strains recovered prior to 2000.^{4,12} Echovirus type 18, another enterovirus rarely detected in previous years, was linked to an aseptic meningitis epidemic in Maryland in the summer of 2001.¹³ During 2002–2004, echovirus types 9 and 30 were in wide circulation and linked to several aseptic meningitis outbreaks across the United States.¹⁴ In temperate climates, the increase in enterovirus circulation from June through October accounts for the summer-fall seasonality in cases of aseptic meningitis. Young children, especially infants, are at greater risk for the infection and the illness.

Enterovirus is shed in saliva and stool of infected persons. It is spread person-to-person through the fecal-oral or oral-oral routes and through respiratory droplets and fomites. Contaminated swimming or wading pool water may occasionally facilitate aseptic meningitis outbreaks, as exemplified by an echovirus 9 meningitis outbreak in summer 2003 among recreational vehicle campers who were more likely to have used a campground swimming pool lacking sufficient chlorine.⁶

Aseptic meningitis has a variety of other infectious and noninfectious causes. Herpes simplex virus (HSV), usually type 2, may rank only below enteroviruses in frequency of causing aseptic meningitis in adults.¹⁵ Aseptic meningitis is the primary manifestation in 16–40% of patients hospitalized with West Nile virus (WNV) disease, though enteroviruses can still be the leading cause of aseptic meningitis cases even in areas with a WNV epidemic in birds.¹³ Aseptic meningitis may also be indicative of the acute retroviral syndrome of primary HIV infection. Other possible viral etiologies include varicella-zoster virus, lymphocytic choriomeningitis virus (LCMV), poliovirus, mumps virus, and additional arboviruses (e.g., St. Louis encephalitis and California encephalitis group viruses). Aseptic meningitis can also be caused by nonviral pathogens, such as rickettsia, ehrlichia, *Mycoplasma pneumoniae*, and the spirochetes causing Lyme disease, syphilis, and leptospirosis. Noninfectious causes of aseptic meningitis include systemic lupus erythematosus, Behçet's syndrome, sarcoidosis, and meningeal carcinomatosis. Certain therapeutic agents (e.g., nonsteroidal anti-inflammatory agents, intravenous immunoglobulin, and trimethoprim-sulfamethoxazole) also infrequently cause the syndrome.

Diagnosis

CSF pleocytosis denotes an abnormally high number of mononuclear cells (e.g., lymphocytes) or neutrophils in the CSF and provides evidence of meningeal inflammation. In viral meningitis, a predominance of neutrophils among the CSF white blood cells is common early in the course of the illness, but typically gives way to predominance of lymphocytes in the first 48 hours of illness.^{2,9,16} However, the following caveats are worth mentioning: (a) children with enteroviral infections and symptoms for 24 hours or less commonly already have CSF lymphocyte predominance, (b) a CSF neutrophil predominance is not always confined to the early stage of symptoms for all cases of viral meningitis, (c) antibiotic treatment of bacterial meningitis can mimic the results of viral infection by shifting CSF pleocytosis from neutrophil to lymphocyte predominance, and (d) CSF pleocytosis may be absent in infants less than 30 days of age.^{2,9,13,16–19}

Elevation in CSF protein concentration is a common and non-specific finding. A CSF glucose concentration remaining in the normal range (≥ 40 mg/dL) is characteristic of viral meningitis, but mildly low CSF glucose concentrations are occasionally observed in infections involving mumps, LCMV, HSV, and poliovirus.

The advent of polymerase chain reaction (PCR) for detection of the genomes of prominent viral pathogens has greatly enhanced the ability to diagnose viral aseptic meningitis. PCR-based assays require only a small amount of clinical specimen and are rapid, sensitive, and specific. Because enteroviruses share a common genomic sequence, PCR testing for this conserved sequence enables detection of nearly all of the nonpolio enterovirus serotypes. PCR is superior in sensitivity to culture methods for detection of enterovirus and HSV in CSF.^{16,20,21} The rapid availability of PCR results (5–24 hours) for diagnosing enteroviral meningitis decreases length of hospitalization and unnecessary use of antimicrobial agents and diagnostic tests.²⁰ Of CSF samples with pleocytosis submitted for enteroviral PCR testing in the St. Louis area during 2001–2003, enterovirus was found in approximately 75% of infants less than 2 months, 65% of infants and children aged 2 months to 18 years, and 25% of patients older than 18 years.²² PCR is also useful for detection of varicella-zoster virus (VZV), LCMV, and arboviruses in CSF, and for detection of HIV in serum of persons with acute retroviral syndrome. However, PCR for WNV in CSF or serum is inferior in sensitivity for establishing the diagnosis of WNV meningitis or encephalitis compared to assays for WNV-specific antibodies.²³ Presence of WNV-specific IgM in CSF or serum is evidence of recent WNV infection.

Treatment and Prevention

There are no antiviral drugs and vaccines available for treatment and prevention of infections caused by the nonpolio enteroviruses.⁹ Attention to hygienic precautions (e.g., wash hands thoroughly after toilet use and avoid sharing drinks and utensils) decreases risk for enteroviral spread. HSV meningitis, usually due to HSV-2, is self-limiting and can be attenuated or, if recurrent, prevented by use of acyclovir-like drugs.

► ENTEROVIRUSES

The human nonpolio enteroviruses are the focus of this chapter. They are members of the *Enterovirus* genus in the family of Picornaviridae that co-opt humans as their only natural host. Human nonpolio enteroviruses comprise 61 distinct antigenic types (known also as serotypes) classified in the group A coxsackieviruses (types 1–24), group B coxsackieviruses B (types 1–6), echoviruses (types 1–33), or the newer enteroviruses (types 68–71).^{10,24} The diversity among these members is also demonstrated by variations in tissue and cell type tropisms, the epidemiology, and clinical syndromes.

Etiologic agents and Immunity

Enteroviruses are non-enveloped RNA viruses.^{24,25} Stomach acid and various disinfectants (e.g., 5% Lysol, 70% alcohol, and 1% quaternary ammonium compounds, and some detergents) do not fully render them noninfectious.^{10,24} They are destroyed by autoclaving and variably inactivated by chlorine and drying. Most types of nonpolio enteroviruses can be grown in cell culture systems, whereas certain types of coxsackie A viruses require inoculation into suckling mice for viral growth. Culture of clinical specimens permits laboratory diagnosis of presumptive enteroviral infection when a characteristic viral cytopathic effect is observed in the appropriate cell lines. The diagnosis is confirmed by a method of enterovirus-specific detection using an antibody broadly reactive to a conserved enteroviral epitope.^{10,24}

Immunity to enteroviruses is type-specific, resulting from development of antibodies with specificity only against the infecting enterovirus type. Natural infections generate lifelong immunity and are usually self-limiting. Infection may actively persist in persons unable to produce functional antibodies because of abnormal or missing B lymphocytes. While T lymphocytes add little to the control of enteroviral infection, they are thought to contribute importantly to pathogenesis of the disease.

Epidemiology

Nonpolio enteroviruses are distributed worldwide and the predominant virus types in circulation vary with geographic region and time.^{10,14,24,26} Infection occurs sporadically and in regional outbreaks, while large epidemics emerge infrequently. The isolation of several enteroviral types during a community outbreak is not unusual. Infection rate varies in relation to season, geographic region, socioeconomic condition, and age of the population.^{10,24,26} In temperate climates, the number of infections peak in summer and autumn months because of maximal circulation of the viruses during these seasons; this seasonality is not observed in tropical climates. Enteroviral infections are more prevalent and acquired at earlier ages in populations living in lower socioeconomic conditions. The majority of infections occur in children, with infants under one year of age having the highest infection rates. Approximately 16–20% of infections in the United States involve persons over 20 years of age.²⁶

Enteroviruses are primarily spread person-to-person through the fecal-oral or oral-oral routes and through respiratory droplets and fomites.^{10,24} Contact with infectious virus shed from the gastrointestinal and upper respiratory tracts account for most of the transmission. Transmission risk is greatest during the maximal viral shedding that attends the early phase of infection. Viral shedding lingers at low levels well beyond the end of illness, with duration of shedding from gut exceeding that from respiratory tract. Virus is recovered from stool for many days to several weeks, depending on virus type and host factors. Certain enteroviral types are more apt to be spread through respiratory droplets or fomites. Coxsackievirus A21 is spread principally by respiratory secretions. Fingers and fomites, including contaminated ophthalmologic instruments, transmit enterovirus 70 to cause acute hemorrhagic conjunctivitis.

Secondary attack rates in susceptible family members are approximately 75% for coxsackieviruses and less than 50% for echoviruses.^{10,27} The incubation period for enteroviral illness is usually 3–5 days, but ranges from 2 days to 2 weeks.^{10,24}

Clinical Illnesses

The vast majority of enterovirus infections do not cause symptoms.^{9,10} When symptoms occur, they commonly present as a nonspecific febrile illness, occasionally accompanied by cold-like symptoms, that last for a few days. However, the enteroviruses are also well recognized for producing distinct diseases, which include aseptic meningitis, encephalitis, paralysis, exanthems (e.g., rubelliform, roseoliform, herpetiform, or petechial rashes), hand-foot-and-mouth disease, herpangina, pleurodynia, hemorrhagic conjunctivitis, and myocarditis. While each of the diseases may be caused by multiple enteroviral types, certain clinical syndromes are commonly associated with certain virus types. Examples of

such associations include hand-foot-and-mouth disease and coxsackievirus A16, encephalitis and enterovirus 71, and acute hemorrhagic conjunctivitis and enterovirus 70 or coxsackievirus A24. Pleurodynia, acute hemorrhagic conjunctivitis, and myocarditis develop more often in adolescents and young adults, whereas the other clinical syndromes occur more frequently in children.

Young infants are prone to enteroviral infection and its complications, though most infections are asymptomatic.^{20,25,28} Neonatal sepsis is a life-threatening complication of this infection that often adversely involves brain, heart, liver, and lung; echoviruses are usually the cause. Most neonatal infections are acquired through vertical transmission during the perinatal period. Infected mothers and health-care workers are infrequently the sources of enterovirus outbreaks in neonatal nurseries, where viral spread has been inadvertently facilitated by hands of personnel in direct contact with an infected neonate.

Diagnosis

The definitive diagnosis of enteroviral infection generally requires the detection of the virus in cerebrospinal fluid (CSF), throat washings, or feces.^{10,20,24} Although most enterovirus types can be recovered by standard cell culture methods, viral culture is substantially less sensitive for viral detection compared to PCR-based methods. PCR testing for a conserved segment of the viral RNA genome shared by nearly all of the enterovirus types permits rapid and accurate detection of these viruses in a variety of clinical specimens. PCR-based molecular typing of the viruses from clinical samples or after viral isolation has become a valuable epidemiological tool, adding to information gleaned from the classical methods of serotyping.^{14,29,30} While PCR of stool specimens obtained from adults with enteroviral meningitis is suggested to have the highest clinical sensitivity, these results can provide only a presumptive diagnosis unless causation is established by detection of the virus in the CSF.³¹ Serological testing is not clinically useful for making the diagnosis of enteroviral infections.^{10,20,24}

Treatment and Prevention

The management of enteroviral infections is supportive.^{20,24} Neither antiviral drugs nor vaccines are currently available. Passive immunization is only considered in exceptional circumstances, such as in a virulent nursery outbreak or in susceptible persons with profound B-cell immunodeficiency. In the hospital setting, practice of standard precautions, hand washing, and appropriate disposal of infected secretions and feces are usually sufficient to prevent transmission. More rigorous precautions are applied to infected infants and young children who are in diapers or incontinent.³² These children should be isolated in a private room or together, and persons in direct contact with them should wear gloves and gowns.

Epstein-Barr Virus and Infectious Mononucleosis

Jeffrey L. Meier

Epstein-Barr Virus (EBV) is a member of the Herpesviridae family that causes a lifelong infection in humans, its only natural host. Newly acquired EBV infections of infants and children usually go unnoticed, whereas such infections of adolescents and adults commonly result in acute infectious mononucleosis. EBV persistence is harmless for the vast majority of persons infected worldwide. However, persons having major defects in cellular immune responses to EBV-infected B-cells are at risk of developing lymphoproliferative diseases. EBV infection is also strongly associated with nonkeratinizing nasopharyngeal carcinoma and the African form of Burkitt's lymphoma.

The Agent and its Pathogenesis

EBV is an enveloped virus that contains double-stranded DNA.¹ The virus infects B lymphocytes (B cells) via a specific interaction with the cell surface receptor CD21, which normally binds to the C3d component of complement. Naso- and oropharyngeal epithelial cells are also sites of viral infection.^{2,3} Production of viral progeny requires the sequential expression of viral immediate-early, early, and late genes. The early antigen (EA) and viral capsid antigen (VCA), expressed from viral early and late gene groups respectively, elicit the immune system to produce antibodies, the key serological markers of EBV infection. The initial phosphorylation of acyclovir-like

compounds by the virally produced thymidine kinase, an early gene product, inhibits EBV DNA synthesis during the lytic phase of infection.

EBV is shed into saliva, and close oral contact with the saliva can transmit infection.³⁻⁵ Primary infection is thought to begin in mucosal epithelial cells and spread to B cells in closely associated lymphoid tissues.³ EBV establishes latency in the B cells, and its genome persists in the form of circular extrachromosomal DNA.¹ The growth promoting program of EBV latency, one of four latent viral gene expression programs, drives B-cell proliferation to generalize the infection.^{3,6} The latent viral genome replicates in concert with the cell cycle and is passed on to dividing B cells, in a manner not inhibited by acyclovir or related drugs.³ EBV-specific cellular immune responses develop and are vital for controlling the EBV-induced B-cell proliferation. Neutralizing antibodies also develop to limit the spread of cell-free virus. In lymphoid tissues, as the EBV-infected B cells engage in the germinal-center reaction, the same growth promoting viral latency program induces infected cells to differentiate into long-lived resting memory B cells.^{6,7} In the EBV-infected germinal center and peripheral blood memory B cells, a switch to other EBV latency programs takes place and partly functions to tightly restrict viral gene expression to help evade immune responses.⁶ Inevitably, EBV persists latently in a small population (one in 10⁵ to 10⁶) of memory B cells in all healthy viral carriers. The repertoire of antibodies that develop against latency-associated Epstein-Barr nuclear antigens (EBNA) does not eliminate the virus, but are of value in serological testing for EBV infection. EBV reactivates to produce infectious virus in pharyngeal lymphoid tissues after the latently infected memory B cells are induced to differentiate into plasma cells.^{3,6,8} Neighboring epithelium may then be reseeded and shed virus into saliva, which occurs even in long-term viral carriers.^{2,3,6}

Acute infectious mononucleosis is an immunopathologic response to primary EBV infection. Its clinical manifestations result from release of proinflammatory cytokines and vigorous expansion of the activated T-cell population, which produces atypical lymphocytosis in blood and hyperplasia of lymphoid tissues.³ In blood, between 25% and 50% of the expanded CD8⁺ T-cell population is directed against defined EBV lytic cycle peptides.^{3,9} Delays in homing of EBV-specific CD8⁺ T cells to pharyngeal lymphoid tissues might explain why viral shedding in saliva remains high for several months.⁹ Only about 0.1–1% of circulating B cells contain EBV, regardless of whether illness occurs.³ Heterophile antibodies, the serological hallmark of infectious mononucleosis, are polyclonal antibodies made by infected B cells. These antibodies do not bind to EBV-specific antigens and their titers do not correlate with severity of illness.^{4,5} Heterophile antibodies characteristically agglutinate sheep and horse red blood cells, lyse beef red blood cells, and fail to bind to guinea pig kidney cells.

Nonkeratinizing nasopharyngeal carcinomas and African Burkitt's lymphomas usually contain clonal copies of the latent EBV episome displaying restricted gene expression.^{3,4} The malignant characteristics of these cells are mostly conferred by chromosomal abnormalities in the host's cell. In Burkitt's lymphoma, for example, there is chromosomal translocation leading to dysregulation of the cellular oncogene *c-myc*. EBV's role in promoting these kinds of malignancies is unclear.

Epidemiology

EBV is spread by close oral contact with infectious saliva.^{3-5,10} Although the virus has also been detected in genital secretions, the epidemiologic association of EBV infection with sexual intercourse might be a result of EBV transmission through deep kissing.¹¹ Blood products or donor tissues containing latent EBV can occasionally be the source of transmission. Persons with acute infectious mononucleosis continuously shed high concentrations of EBV into saliva for many months, despite resuming normal levels of activity.^{4,5,12} However, secondary spread of EBV to susceptible household contacts is infrequent.⁵ Susceptible roommates of college students with infectious mononucleosis acquire EBV no more frequently than other

students. Infectious EBV is also shed intermittently into saliva of healthy viral carriers; and the viral shedding increases in persons with underlying malignancy or cellular immune deficiency. EBV has not been cultured from fomites, reflecting its instability in the ambient environment.

Serological surveys conducted nearly worldwide have shown that EBV is ubiquitous. Almost 95% of all persons, regardless of gender, acquire EBV infection by the end of their third decade of life.^{4,5} Persons living in resource-limited countries or in low socioeconomic conditions where personal hygiene is often substandard usually acquire EBV in childhood. For example, EBV seroprevalence among children five years or younger was found to exceed 95% in Africa and China, 80% in the Amazon Basin, and 90% on the Aleutian Islands.⁵ In persons living in developed countries or among an affluent population, EBV infection is more likely to be delayed until adolescence or early adulthood, when sexual intimacy becomes a greater factor in EBV transmission. A published report from 1971 of a prospective serologic study of college freshmen at Yale University found antibodies to EBV in only half of the students at the time of enrollment, but 13% of susceptible students acquired infection within nine months.¹³ In another study from this era, 63.5% of cadets entering the United States Military Academy were EBV seropositive;¹⁴ the annual seroconversion rates among susceptible cadets during the ensuing four years were 12.4%, 24.4%, 15.1%, and 30.8%. In 1999 and 2000, 2,006 university students volunteered for a study of EBV infection: 75% were EBV seropositive on entry into Edinburgh University, United Kingdom;¹¹ of the 510 EBV seronegative students, 46% experienced seroconversion for EBV in 3 years and 25% of these seroconversions resulted in infectious mononucleosis.

Infectious mononucleosis results from a primary EBV infection, following a 30- to 50-day incubation period. It occurs most often in adolescents and young adults with ages ranging from 15 to 25 years.^{5,15,16} This is because infants and children usually do not exhibit an illness telling of primary EBV infection and most older adults are no longer susceptible to EBV, although they retain the ability to develop the illness. Accordingly, the incidence of infectious mononucleosis largely depends on the number of EBV-seronegative adolescents and young adults in a given population. The incidence of infectious mononucleosis in the United States is 45–100 cases per 100,000 persons.^{15,16} Roughly, 25–50% of young adults with primary EBV infection will experience infectious mononucleosis.

Clinical Features and Diagnosis

The diagnosis of acute infectious mononucleosis is made when the characteristic findings are present: fever, pharyngitis, cervical lymphadenopathy, absolute peripheral lymphocytosis, atypical lymphocytosis greater than 10% of the differential, and heterophile antibodies.^{3,4,17} The probability that EBV is the cause of a mononucleosis-like illness decreases as these criteria are relaxed. Unusual presentations of primary EBV infection are more likely to occur in infants, young children, older adults, and immunosuppressed persons.^{4,18} In these cases, the diagnosis of acute EBV infection can be established with EBV-specific serological testing.

Acute infectious mononucleosis commonly produces symptoms of sore throat, mild headache, painful lymph nodes, sweats, fatigue, and malaise.^{4,10,17} Most of the symptoms subside within 1–2 weeks, but the postinfectious fatigue and malaise often take longer to resolve. In a recently conducted study, self-assessed failure to completely recover was reported by 38% of patients at two months after the acute illness and by 12% at six months; those failing to recover were not distinguished by objective measures of physical examination or laboratory assessment.¹⁹ Notably, chronic fatigue syndrome is rarely linked to EBV infection; but more commonly, misinterpreted EBV-specific serological tests incorrectly suggest such an association. Common signs of acute infectious mononucleosis include exudative tonsillopharyngitis, anterior and posterior cervical lymphadenopathy, splenomegaly, and fever less than 40°C. Rash is infrequent unless evoked by ampicillin or amoxicillin. Laboratory

studies often reveal mild hepatitis and thrombocytopenia that gradually resolve.

Infectious mononucleosis runs a self-limited course usually without incident, but severe complications can occur.^{4,10,17} Airway obstruction from extremely large tonsils or rupture of an enlarged spleen are complications of excessive lymphoid hyperplasia. Induction of autoantibodies may result in severe hemolytic anemia, neutropenia, or thrombocytopenia. Deaths are very rare and largely result from encephalitis, hepatic failure, myocarditis, splenic rupture, or bacterial infection associated with neutropenia. Infectious mononucleosis may evolve into life-threatening lymphoproliferative diseases in persons with profound acquired or congenital cellular immunodeficiency.^{4,20} Fulminant infectious mononucleosis occurs as a rare hereditary disorder of young males, termed the X-linked lymphoproliferative disorder, who have inherited a defective gene for SAP (signaling lymphocytic-activation molecule-associated protein).^{8,20} Survivors of the acute illness may develop aplastic anemia, dysgammaglobulinemia, and lymphoma. Chronic active EBV infection is a very rare and unrelenting complication that manifests as interstitial pneumonitis, marrow failure, dysgammaglobulinemia, Guillain-Barré syndrome, uveitis, and massive lymphadenopathy and hepatosplenomegaly.⁴

In 90–95% of typical episodes of infectious mononucleosis, heterophile antibodies develop; these are only seldom seen in viral hepatitis, primary HIV infection, and lymphoma. They resolve in 3–6 months following the onset of infectious mononucleosis and do not reappear. The appearance of EBV-specific anti-VCA immunoglobulin (Ig)M substantiates the diagnosis of primary EBV infection. When patients present with infectious mononucleosis, these antibodies are usually detectable, disappear in weeks to months and do not reappear. Because anti-VCA IgG titers are usually near their peak when patients present with infectious mononucleosis, a comparison of paired acute and convalescent anti-VCA IgG titers is less helpful in diagnosing acute EBV infection. These antibodies persist for life and can serve as markers of past EBV infection. Anti-EA antibodies are often induced in infectious mononucleosis and their amounts wane over time. The persistence of these antibodies at low titers has no clinical significance. Anti-EBNA antibodies are not detected by the immunofluorescence assay during acute infectious mononucleosis, but appear in convalescence and persist thereafter. Caution should be used when comparing EBV-specific antibody titers, since results generated at different times, in different places, or with different assays may be misleading.

The differential diagnosis of a mononucleosis-like syndrome also includes primary infections with cytomegalovirus, toxoplasma, HIV, rubella, viral hepatitis (e.g., hepatitis A and B viruses), as well as streptococcal pharyngitis.²¹ While each of these other causes may have distinguishing clinical features, their definitive diagnosis usually rests on the results of specific laboratory tests. EBV ought not to be forgotten as a potential cause of heterophile-negative mononucleosis.

EBV infection is associated with a variety of other disorders.^{4,10,20} In persons living with HIV/AIDS, EBV is responsible for an exophytic

growth of epithelial cells of the tongue and buccal mucosa that is called oral hairy leukoplakia. EBV is associated with a variety of B-cell lymphoproliferative diseases in persons having gross defects in cellular immune responses to EBV-infected B cells.^{6,8,20} For example, high levels of immunosuppressive therapy for organ transplantation and primary EBV infection during this therapy are risks for developing EBV-associated posttransplant lymphoproliferative disorders. In persons with AIDS, about one-third of all B-cell lymphomas contain the EBV genome, while this frequency approaches 100% for such tumors originating in the brain. In persons from Africa, EBV is also associated with Burkitt's lymphoma, as over 95% of tumors contain EBV genomes; however, the virus is present in only 20% of Burkitt's lymphomas in persons from the United States. Virtually all nonkeratinizing nasopharyngeal carcinomas, which are prevalent in persons from southern China and certain Native Americans, contain EBV genomes. EBV is also implicated in producing smooth-muscle tumors in children who have AIDS or received organ transplantation; and its role in causing Hodgkin's disease is suggested by the presence of EBV genomes in 40–65% of tumors and increased incidence of this disease in the 5 years following infectious mononucleosis.^{6,8}

Treatment and Prevention

Infectious mononucleosis is managed with general supportive care, such as rest, hydration, antipyretics, and analgesics.^{4,21} Activity is restricted in proportion to the degree of symptoms. Contact sports are suspended for one month or until the absence of splenomegaly is confirmed. The use of glucocorticoid or empiric antibiotic is not warranted for treatment of uncomplicated infectious mononucleosis. Glucocorticoids are beneficial in treating selected complications such as protracted severe illness, autoimmune hemolytic anemia and thrombocytopenia, and impending airway obstruction from tonsillar enlargement.^{4,22} Throat cultures containing *S. pyogenes* should be treated with 10 days of penicillin or erythromycin, since as many as 30% of such cases later exhibit serologic evidence of streptococcal infection. Ampicillin and amoxicillin cause rash in more than 85% of persons with infectious mononucleosis and should not be used for treatment of a concomitant bacterial infection. Acyclovir effectively suppresses viral shedding, but does not appreciably attenuate the acute illness or decrease its complications.^{4,10,21} Treatments of the other EBV-related disorders are beyond the scope of this text.

A vaccine to prevent EBV infection or its diseases is not available, although candidate vaccines are in development. Restricting intimate contact should decrease EBV transmission, but is usually impractical and may delay virus acquisition to an age when symptoms are more likely. Such restriction can be considered when the consequences of infection would be devastating. Use of irradiated blood products and EBV-negative tissues can also decrease risk of EBV transmission. The practice of standard precautions and hand-washing is sufficient to prevent nosocomial transmission of EBV. Therefore, persons with infectious mononucleosis generally need not be placed in isolation.²³

Herpes Simplex Virus

Richard J. Whitley

Herpes simplex virus (HSV) is one of the most common infections encountered by humans worldwide. As a member of the herpesvirus family, it shares the unique biologic characteristic of being able to exist in a latent state and recur periodically, if not chronically, serving as a reservoir for transmission from one person to another.

Herpes simplex virus exists as two distinct antigenic types, HSV-1 and HSV-2. HSV-1 is usually associated with infections above the belt, namely involving the oropharynx and lips; however, increasing numbers of genital infections attributed to this virus have been recognized. HSV-2 infections more commonly cause infection below the

belt, involving the genitalia, buttocks, and infrequently the lower extremities. In addition, HSV-2 is a cause of infection of the newborn. The spectrum of disease caused by HSV ranges from benign and nuisance infections to those that can be life-threatening.¹

Epidemiology

Herpes simplex virus infection is transmitted by direct contact. The epidemiology of infection can best be defined according to seroprevalence of HSV-1 and HSV-2. By adulthood, the majority of adults have experienced HSV-1 infections (70–90%).² Primary HSV-1 infections usually occur in the young child, under five years of age, and are most often asymptomatic. The prevalence of HSV-1 infection increases to a peak in the seventh decade of life, affecting approximately 80% in the United States. Geographic location, socioeconomic status, and age influence the occurrence of HSV infection, regardless of the mode of assessment. In developing countries and in lower socioeconomic communities, primary infection occurs early in life. In some areas of the world, the seroprevalence to HSV-1 is in excess of 95%, as is the case in Spain, Italy, Rwanda, Zaire, Senegal, China, Taiwan, Haiti, Jamaica, and Costa Rica. As noted, most of these infections are asymptomatic.

Acquisition of HSV-2 usually occurs in association with onset of sexual activity. Acquisition of HSV-2 is a function of the number of lifetime sexual partners. Overall, seroprevalence to HSV-2 in the United States was approximately 25% in the mid-1990s, reflecting a 30% increase since the early 1980s. Among heterosexual men, the seroprevalence approaches 80% for individuals with more than 50 lifetime sexual partners.² In contrast, for women with a similar number of sexual partners, the prevalence of HSV-2 exceeds 90%. In general, women acquire HSV-2 infection more frequently than do men, irrespective of the number of partners. For pregnant women, approximately 1% will excrete virus at the time of delivery. Nevertheless, the incidence of neonatal HSV infection is only approximately 1 in 2500 to 1 in 5000 liveborn infants in the United States, implying a relative degree of protection of the newborn.

Nosocomial HSV infection has been documented both in newborn nurseries as well as in intensive care units.¹ In addition, the occurrence of herpetic whitlow as a consequence of exposure has been documented.¹

Pathogenesis

The pathogenesis of HSV infections is dependent upon the requirement for intimate contact between a person who is shedding virus and a susceptible host. After inoculation of HSV onto the skin or mucous membrane, an incubation period of 4–6 days is required before there is evidence of clinical disease. Herpes simplex virus replicates in epithelial cells. As replication continues, cell lysis and local inflammation ensue, resulting in characteristic vesicles on an erythematous base. Regional lymphatics and lymph nodes become involved; viremia and visceral dissemination may develop, depending upon the immunologic competence of the host. In all hosts, the virus generally ascends peripheral sensory nerves and reaches the dorsal root ganglia. Replication of HSV within neural tissue is followed by retrograde axonal spread of the virus back to other mucosal and skin surfaces via the peripheral sensory nerves. Virus replicates further in the epithelial cells, reproducing the lesions of the initial infection, until infection is contained through both systemic and mucosal immune responses.

Latency is established when HSV reaches the dorsal root ganglia after anterograde transmission via sensory nerve pathways. In its latent form, intracellular HSV DNA cannot be detected routinely unless specific molecular probes are used.

Rarely HSV can infect the central nervous system and cause encephalitis.³ The focality and temporal lobe affinity suggest direct extension of virus along neural tracts. Encephalitis caused by HSV is characterized by necrosis of the inferior medial portion of the temporal lobe, initially unilaterally and then contralaterally. This necrotic process accounts for the high morbidity and mortality of infection. Infection of the neonate is usually the consequence of direct contact

with infected maternal genital secretions, accounting for approximately 85% of cases of neonatal herpes. The remaining 15% are caused by in utero infection, secondary to viremia, or postnatal acquisition whereby the baby comes in contact with infectious virus in the environment.

Clinical Manifestations

Mucocutaneous Infections.

Gingivostomatitis. Mucocutaneous infections are the most common clinical manifestations of HSV-1 and HSV-2. Gingivostomatitis is usually caused by HSV-1 and occurs most frequently in children under five years of age. It is characterized by fever, sore throat, pharyngeal edema, and erythema, followed by the development of vesicular or ulcerative lesions of the oral or pharyngeal mucosa. Recurrent HSV-1 infections of the oropharynx frequently manifest as herpes simplex labialis (cold sores), and appear on the vermilion border of the lip. Intraoral lesions as a manifestation of recurrent disease are uncommon in the normal host but do occur frequently in the immunocompromised host.

Genital Herpes. Genital herpes is most frequently caused by HSV-2 but an ever increasing number of cases are attributed to HSV-1.⁴ Primary infection in women usually involves the vulva, vagina, and cervix. In men, initial infection is most often associated with lesions on the glans penis, prepuce, or penile shaft. In individuals of either sex, primary disease is associated with fever, malaise, anorexia, and bilateral inguinal adenopathy. Women frequently have dysuria and urinary retention due to urethral involvement. As many as 10% of individuals will develop an aseptic meningitis with primary infection. Sacral radiculomyelitis may occur in both men and women, resulting in neuralgias, urinary retention, or obstipation. The complete healing of primary infection may take several weeks. The first episode of genital infection is less severe in individuals who have had previous HSV infections at other sites, such as herpes simplex labialis.

Recurrent genital infections in either men or women can be particularly distressing. The frequency of recurrence varies significantly from one individual to another. Approximately one-third of individuals with genital herpes have virtually no recurrences, one-third have approximately three recurrences per year, and another third have more than three per year. By applying polymerase chain reaction to genital swabs from women with a history of recurrent genital herpes, virus DNA can be detected in the absence of culture proof of infection.⁵ This finding suggests the chronicity of genital herpes as opposed to a recurrent infection.

Herpetic Keratitis. Herpes simplex keratitis is usually caused by HSV-1 and is accompanied by conjunctivitis in many cases.⁴ It is considered among the most common infectious causes of blindness in the United States. The characteristic lesions of herpes simplex keratoconjunctivitis are dendritic ulcers best detected by fluorescein staining. Deep stromal involvement has also been reported and may result in visual impairment.

Other Skin Manifestations. Herpes simplex virus infections can manifest at any skin site. Common among health-care workers are lesions on abraded skin of the fingers, known as herpetic whitlows. Similarly, because of physical contact, wrestlers may develop disseminated cutaneous lesions known as herpes gladiatorum.

Neonatal Herpes Simplex Virus Infection

Neonatal HSV infection is estimated to occur in approximately 1 in 2500 to 1 in 5000 deliveries in the United States annually.⁶ Approximately 70% of cases are caused by HSV-2 and usually result from contact of the fetus with infected maternal genital secretions at the time of delivery. Manifestations of neonatal HSV infection can be divided into three categories: (a) skin, eye, and mouth disease; (b) encephalitis; and (c) disseminated infection. As the name implies,

skin, eye, and mouth disease consists of cutaneous lesions and does not involve other organ systems. Involvement of the central nervous system may occur with encephalitis or disseminated infection and generally results in a diffuse encephalitis. The cerebrospinal fluid formula characteristically reveals an elevated protein and a mononuclear pleocytosis. Disseminated infection involves multiple organ systems and can produce disseminated intravascular coagulation, hemorrhagic pneumonitis, encephalitis, and cutaneous lesions. Diagnosis can be particularly difficult in the absence of skin lesions. The mortality rate for each disease classification varies from zero for skin, eye, and mouth disease to 15% for encephalitis and 60% for neonates with disseminated infection. In addition to the high mortality associated with these infections, morbidity is significant in that children with encephalitis or disseminated disease develop normally in only approximately 40% of cases, even with the administration of appropriate antiviral therapy.

Herpes Simplex Encephalitis

Herpes simplex encephalitis is characterized by hemorrhagic necrosis of the inferomedial portion of the temporal lobe. Disease begins unilaterally, then spreads to the contralateral temporal lobe. It is the most common cause of focal, sporadic encephalitis in the United States today and occurs in approximately 1 in 150,000 individuals. Most cases are caused by HSV-1. The actual pathogenesis of herpes simplex encephalitis is unknown, although it has been speculated that primary or recurrent virus can reach the temporal lobe by ascending neural pathways, such as the trigeminal tracts or the olfactory nerves.

Clinical manifestations of herpes simplex encephalitis include headache, fever, altered consciousness, and abnormalities of speech and behavior. Focal seizures may also occur. The cerebrospinal fluid formulae for these patients is variable, but usually consists of a pleocytosis of monocytes. The protein concentration is characteristically elevated and glucose is usually normal. Historically, a definitive diagnosis could be achieved only by brain biopsy, since other pathogens may produce a clinically similar illness. However, the application of polymerase chain reaction (PCR) for detection of virus DNA has replaced brain biopsy as the standard for diagnosis.⁷ The mortality and morbidity are high, even when appropriate antiviral therapy is administered. At present, the mortality rate is approximately 30% one year after treatment. In addition, approximately 70% of survivors will have significant neurologic sequelae.

Herpes Simplex Virus Infections in the Immunocompromised Host

Herpes simplex virus infections in the immunocompromised host are clinically more severe, may be progressive, and require more time for healing. Manifestations of HSV infections in this patient population include pneumonitis, esophagitis, hepatitis, colitis, and disseminated cutaneous disease. Individuals suffering from human immunodeficiency virus infection may have extensive perineal or orofacial ulcerations. Herpes simplex virus infections are also noted to be of increased severity in individuals who are burned.

Diagnosis

The diagnosis of HSV infections is usually predicated on clinical evaluation of mucocutaneous manifestations. However, confirmation of the diagnosis requires isolation of HSV in appropriate cell culture systems or the detection of viral gene products or, alternatively, the detection of viral DNA by PCR. Herpes simplex virus grows readily in tissue culture, producing cytopathic effects within a few days in a wide variety of mammalian cell lines. The routine typing, namely distinguishing HSV-1 from HSV-2, of the isolate is not usually required unless epidemiologic studies are being performed.

Polymerase chain reaction has become a useful method for diagnosing HSV infections, particularly those involving the central nervous system, specifically neonatal HSV infection and herpes simplex encephalitis. The detection of HSV DNA by PCR in the CSF has

replaced brain biopsy as a method of diagnosis of central nervous system infections.

Type-specific serologic assays are not commercially available. The utilization of immunoblot detection of specific glycoproteins that distinguish HSV-1 from HSV-2, namely, glycoprotein (g) G-1 and gG-2, are available in research laboratories for determining prior exposure to HSV-1 and HSV-2 infections. Likely, in the near future, a commercially available assay that distinguishes HSV-1 from HSV-2 will become available.

Historically, Tzanck smears have been used to diagnose HSV infections. Tzanck smears are not sensitive enough for routine diagnostic purposes. However, immunofluorescent staining of cell trap preparations from lesions is both sensitive and specific for the diagnosis for HSV infections.

Treatment

Infections due to HSV are the most amenable to therapy with antiviral drugs. Acyclovir has proved useful for the management of specific infections caused by HSV. Intravenous acyclovir is the preferred therapy for individuals with life-threatening disease, including herpes simplex encephalitis, neonatal herpes, and complications of genital herpes. However, valacyclovir and famciclovir, prodrugs of acyclovir and penciclovir, respectively, have replaced acyclovir in the management of mucocutaneous HSV infections. Immunocompromised individuals with mucocutaneous HSV infections that are not life-threatening can be given oral valacyclovir or famciclovir. Caution must be exercised when acyclovir is used intravenously, because it may crystallize in renal tubules when administered too rapidly or to dehydrated patients.

Topical therapy with one of several antiviral ophthalmic preparations is appropriate for HSV keratoconjunctivitis. However, the treatment of choice is viroptic or trifluorothymidine. Secondary choices include vidarabine ophthalmic or topical idoxuridine.

Prevention and Control

At the present, there is no licensed vaccine for the prevention for HSV infections. However, one glycoprotein vaccine remains in development.⁸ This vaccine includes glycoproteins to one of the major immunodominant glycoproteins of HSV, namely, gD. Currently a 20,000-person volunteer study will assess efficacy. If any vaccine will be successful, it will likely be one that is attenuated and genetically engineered. As a consequence, the prevention of HSV infections resides in the most part on knowledge of the mechanisms of transmission, both person to person as well as in the hospital environment. Individuals with known recurrent HSV infections should be counseled on the possibility of transmission of infection while lesions are present. The use of condoms for individuals with recurrent genital herpes is encouraged in that detection of HSV DNA by PCR can occur even in the absence of lesions. Similarly, for individuals who have recurrent herpes labialis, kissing should be discouraged.

There is a risk of nosocomial transmission of HSV within the hospital environment. Since many individuals excrete HSV in the absence of clinical symptoms, it is impossible to exclude all workers from the hospital environment who could transmit infection. Thus, many authorities simply recommend strict handwashing and covering of lesions, should they exist.

Finally, no data exist on the prevention of neonatal HSV infection. It has been theorized that anticipatory administration of acyclovir to babies delivered through an infected birth canal may prove of value, particularly for women who have first episode genital herpetic infection. However, no data exist to substantiate this hypothesis. Since over 1% of all women at delivery excrete HSV and the rate of neonatal HSV infection is only 1 in 2500 to 1 in 5000 liveborn infants as noted earlier, the routine administration of acyclovir to all children born to HSV-positive women is not reasonable. Alternative approaches, namely administration of acyclovir to known HSV-2-infected women is gaining acceptance.⁹ This latter study, at least, will consider the consequences of acyclovir administration on cesarean section and its complications.

Cytomegalovirus Infections

Anne Blaschke • James F. Bale Jr.

Human cytomegalovirus (CMV), a member of the human herpesvirus family, can produce serious, life-threatening disease when the virus infects the developing fetus or persons with immunocompromising medical conditions.^{1–5} Studies worldwide indicate that 0.4–2.5% of infants excrete CMV at birth, indicating intrauterine infection, and most adults over 40 years of age have serologic evidence of previous CMV infection. Fortunately, the majority of infected persons do not experience serious complications of CMV infection.

Approximately 30–40% of the pregnant women who develop primary CMV infection transmit the virus to their fetuses.⁶ In addition, women occasionally experience reactivated CMV infections or recurrent CMV infections with new CMV strains⁷ and also transmit the virus to their fetuses. Of the infected newborns, 5–10% have a multi-system disorder, labeled “CMV disease,” characterized clinically by petechial rash, jaundice, hepatosplenomegaly, microcephaly or chorioretinitis; the remaining infants have silent infections. Infants who survive CMV disease have a 90% risk of neurodevelopmental sequelae, consisting of visual dysfunction, epilepsy, cerebral palsy, motor and intellectual delays, and sensorineural hearing loss.⁸ Silently infected infants have a 6–23% rate of sensorineural hearing loss, but have very low rates of other neurodevelopmental or visual sequelae.^{9,10}

Acquired CMV infection of children or adults can cause an infectious mononucleosis-like syndrome that resembles disease caused by the Epstein-Barr virus.⁴ Infected persons have malaise, low-grade fever, lymphadenopathy, pharyngitis, hepatitis, or occasionally, pneumonitis. Although the course of CMV-induced mononucleosis can be prolonged, immunocompetent persons typically recover without sequelae.

By contrast, CMV can be a virulent pathogen in immunocompromised hosts, causing pneumonitis, severe gastroenteritis, necrotizing retinitis, polyradiculopathy, or disseminated encephalitis.^{2,3} Conditions associated with potentially severe CMV infections include congenital immunodeficiency disorders, immunosuppression for solid organ or stem cell transplantation, chemotherapy for malignancy or connective tissue disorders, and human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS). CMV infections can develop in 30–60% or more of transplant recipients as a result of primary infection, reactivated latent infection, or reinfection.² During the first decade of the pandemic, CMV disease appeared in as many as 40% of persons with HIV/AIDS, making CMV one of the most frequent opportunistic infections in such patients.³

In infected persons CMV can be detected in urine, saliva, circulating leukocytes, breast milk, semen, or cervical secretions. Ingestion of CMV-infected breast milk or contact with the saliva or urine of infected playmates or family members accounts for most acquired infections in infants and young children. After puberty, sexual contact with infected persons contributes to transmission.¹¹ Infected persons excrete CMV in saliva or urine for prolonged periods, several years after congenital infections or one year or more after acquired infections. Shedding occurs intermittently throughout life in infected individuals and plays a substantial role in CMV transmission. Reinfections with new CMV strains also occur.^{12,13}

CMV can be acquired through transfusion of blood products or transplantation of organs or tissues from CMV-seropositive donors. The risk of infection after blood transfusion, greatest when patients receive blood from multiple donors, ranges from 0.14–2.7% per unit of blood transfused.¹⁴ Solid organs, bone marrow, or skin from seropositive donors can transmit CMV, with seronegative recipients being at greatest risk for CMV infection and invasive disease.^{2,15}

In the past, culturing urine or other body fluids using the shell vial assay was the most widely used assay to diagnose or confirm CMV infection.¹⁶ While urine culture is still used, particularly to diagnose

congenital CMV infection,¹⁷ antigenemia (CMV pp65 antigen detected in leukocytes) or nucleic acid testing has become the most rapid and reliable means to diagnose and monitor CMV disease.^{17–19} The most common nucleic acid tests for CMV are polymerase chain reaction (PCR) tests, which can detect CMV nucleic acids in the blood or other body fluids.²⁰ PCR can be used not only to diagnose CMV infection or disease, but can allow disease monitoring through quantitative testing. PCR and other molecular tests can also be used to compare CMV strains or to identify DNA mutations that confer resistance to ganciclovir or foscarnet.²¹ Serologic testing, or detection of CMV-specific antibodies, can be used as supportive evidence of recent infection, particularly when symptoms are subsiding and virus shedding has ceased.¹⁶ Serologic methods can be used to determine serostatus of transplant donors and recipients, but these methods have no role in the diagnosis of CMV disease post-transplant.^{18,22}

Prevention and Therapy

Congenital or acquired CMV infections cannot currently be prevented by immunization. Several candidate vaccines, including subunit and whole-unit preparations, have been studied during the past two decades.^{4,23} Although some induce cellular, humoral, or neutralizing immune responses against CMV, none have progressed beyond clinical trials.

When compared with many infectious pathogens, CMV is not highly contagious. Because transmission requires contact with fresh, CMV-infected fluids, simple hygienic measures can prevent transmission of CMV in certain settings. Attention to handwashing, avoidance of oral contact, and adoption of standard precautions diminish the risk of CMV transmission. Transmission from children to pregnant women can be interrupted by hand washing, glove use, and avoidance of intimate contact with young children.²⁴ Condoms reduce the risk of sexual transmission.

Fomites contribute to CMV infection in environments, such as childcare centers or nurseries, with high virus loads or many infected children.²⁵ The potential for CMV transmission can be reduced by prompt disposal of soiled diapers or decontamination of environmental surfaces. In childcare environments, mouthing toys can be disinfected by immersion in a bleach and water solution, prepared fresh daily, by adding 1/4 cup of household bleach to one gallon of water.²⁶ Items that cannot be immersed in water should be air-dried thoroughly.

Young, toddler-aged children who attend group childcare centers have high rates of CMV infection and frequently transmit CMV to their playmates, parents, or adult care providers.^{27–29} Although child-to-child transmission of CMV poses minimal risk to healthy young children, transmission to a pregnant woman places her at risk of having a congenitally-infected infant. Thus, women who have contact with young children and intend to become pregnant should attempt to reduce their risk of CMV infection by washing their hands after contact with diapers or body fluids, avoiding oral contact with young children, and refraining from sharing food or eating utensils with young children, including their own. Although the risk of CMV infection is greatest in seronegative women, transmission to seropositive women, indicating reinfections with new CMV strains, can occur.⁷

In seronegative bone marrow or solid organ transplant recipients, the risk of primary CMV infection, the most serious form of infection, can be reduced by transfusing CMV seronegative or leukocyte-depleted blood products.^{30,31} CMV seronegative or leukocyte-depleted blood products should also be administered to premature infants or infants undergoing large volume exchange transfusions, as well as CMV seronegative persons with HIV. Matching of seronegative recipients with organs from seronegative donors is an effective way of preventing primary CMV

infection, however this cannot be accomplished easily due to the limited availability of CMV seronegative organ donors.³¹

A CMV seronegative organ recipient is at high risk for primary CMV infection from a CMV seropositive donor, blood products, or other exposures while immunosuppressed. Seropositive recipients are also at risk for CMV disease, through reactivation during immunosuppression.^{22,32} In the past decade there have been substantial advances in the diagnosis and treatment of CMV disease in the transplant population, and the disease has come under much better control. The optimal approach to management, however, remains controversial.^{19,22,33,34}

One of two strategies is commonly used for prevention of CMV disease after solid organ or bone marrow transplant.^{18,19,22} In the first, “universal prophylaxis,” all at-risk patients are given antiviral therapy, usually ganciclovir or valganciclovir, at the time of transplant for a defined period of time, most commonly 100 days.^{18,19,22} This strategy is preferred by some for seronegative recipients of CMV seropositive tissues, because 70% or more of such patients experience CMV infection within the first three months post-transplant if not prophylaxed.³⁵ This strategy may also prevent organ-based CMV disease that may not be detectable by serum testing, as well as the reactivation of other herpesviruses that are susceptible to ganciclovir.¹⁸ Risks include those associated with antiviral exposure to large numbers of patients, many of whom might never have CMV disease, and the possibility of drug resistance.³³

The second strategy, “preemptive therapy,” may have advantages for seropositive recipients or the seronegative recipients of seronegative organs.^{18,19,22} With this strategy patients are closely monitored with PCR or antigenemia testing to detect early evidence of CMV replication prior to the development of clinical disease. Patients with laboratory detection of CMV replication are then treated with antiviral medications to prevent progression to CMV disease. The advantages of this approach include reduced exposure to antiviral medications and their toxicities.³³ The intensive laboratory monitoring required for this approach can be problematic, however, and some evidence suggest that any level of CMV infection may affect the risk of bacterial and fungal infections, as well as organ rejection.^{34–36}

While both management strategies have significantly reduced the burden of CMV disease in transplant patients, controversy remains regarding optimal therapy due to the absence of large, well-controlled trials. A large meta-analysis of selected trials of prophylaxis and preemptive treatment showed similar benefits of both strategies in reducing the overall risk of CMV disease, as well as the episodes of acute rejection.³⁶ Universal prophylaxis was shown to reduce bacterial and fungal infections as well as overall mortality. However the universal prophylaxis trials were larger and better powered to detect differences.^{34,36}

A relatively new problem in transplantation medicine is the development of late-onset CMV disease after the cessation of prophylactic therapy.^{37,38} There is concern that prophylactic, and less commonly, preemptive, treatment for CMV impairs the development of a CMV-specific T-cell response in transplant patients, leaving them unprotected by natural immunity upon discontinuation of antiviral therapy. Late-onset CMV disease may be more likely to be tissue-invasive, and such disease is more likely to be caused by drug-resistant CMV strains.^{37,38} Strategies to reduce the incidence of late-onset disease are under investigation.

Another group at risk for CMV disease are seronegative persons infected with HIV, particularly those with advanced immunosuppression.³⁹ Most men who have had sexual contact with other men are presumed CMV seropositive; serologic screening is recommended to identify the CMV serostatus of HIV-infected children and adolescents. If seronegative, they can be counseled to use only CMV negative blood products and avoid other potential sources of CMV exposure. Oral ganciclovir can be considered for seropositive patients with CD4 counts less than 50 cells/mL, but cost and toxicity are important considerations. Early recognition of symptoms, particularly visual symptoms that might suggest CMV retinitis, is essential.

Acyclovir, and its valine-ester, valacyclovir, have been used as primary prophylaxis for CMV, particularly in the hematopoietic stem

cell transplant population, due to the substantial bone marrow suppressive effects of ganciclovir.^{19,32,40} Acyclovir has been shown to be ineffective, however, in the treatment of CMV disease, and other drugs should be used for preemptive therapy or treatment of established disease.^{19,32} Ganciclovir (9-[[1,3-dihydroxy-2-propoxy]methyl]guanine [DHPG]), valganciclovir, and foscarnet (trisodium phosphonoformate) have been used to both prevent and treat CMV infections, although foscarnet is usually reserved for patients intolerant to ganciclovir or those infected with ganciclovir-resistant CMV strains.^{41,42}

Ganciclovir, a 2'-deoxyguanosine analog, inhibits CMV DNA synthesis. The standard adult dose is 5 mg/kg intravenously (IV) every 12 hours, but the dose should be decreased in patients with renal impairment.⁴³ Ganciclovir has efficacy when used to treat CMV pneumonitis, retinitis, or neurologic complications in a wide range of immunocompromised patients.⁴¹ Results for CMV-induced gastrointestinal disease have been variable. Treatment is generally given for two weeks. Among HIV-infected patients with CMV retinitis recurrence is the rule, and secondary prophylaxis is recommended for life or until significant immune-reconstitution occurs and is sustained for 6 months.³⁹ The valine ester prodrug of ganciclovir, valganciclovir, has significantly increased oral bioavailability, with drug levels approaching that of IV ganciclovir.⁴³ Oral valganciclovir has been shown to be as effective as IV ganciclovir in treating CMV retinitis in HIV-infected patients.³⁹ IV ganciclovir is still the drug of choice for established CMV disease in transplant recipients, although future trials may show that valganciclovir is equally effective.³²

The side effects of ganciclovir, nephrotoxicity, and bone marrow suppression, particularly neutropenia, can limit its use. Neutropenia is particularly common in hematopoietic stem cell transplant patients, and can lead to increased mortality.^{19,32} For this reason, high-dose acyclovir or valacyclovir is sometimes chosen for primary prophylaxis in this population. Other side effects of ganciclovir include hemolysis, nausea, infusion site reactions, diarrhea, rash and fever.⁴¹ Hematologic parameters and renal function should be monitored closely in patients on ganciclovir.

Ganciclovir has also been used to treat congenitally-infected infants with CMV disease.^{44,45} In a randomized trial involving severe congenital CMV disease and CNS involvement more than 80% of those treated with 12 mg/kg/day of ganciclovir intravenously for six weeks had improved hearing or maintained normal hearing between baseline and six months versus 59% of the control infants.⁴⁴ More importantly, none of the ganciclovir-treated infants had worsening in their hearing between baseline and six months versus 41% of the control patients. The primary side effect of the prolonged treatment was neutropenia, and this sometimes necessitated granulocyte-colony stimulating factor or drug discontinuation. Pancreatitis and catheter-associated bacteremia were additional complications. Improved outcome for ganciclovir-treated infants has also been suggested in smaller, uncontrolled studies.^{46,47} Ongoing trials are evaluating longer therapy with valganciclovir to improve on the modest benefit to risk ratio of the current regimen.

Foscarnet is generally reserved for patients intolerant to ganciclovir, or those with ganciclovir-resistant virus.^{42,43} Foscarnet inhibits CMV replication by binding with the viral DNA polymerase. Foscarnet has been shown to be effective in preemptive therapy in transplant patients as well as treatment of invasive CMV disease and retinitis.^{19,22,39} Foscarnet can also be used for secondary prophylaxis after CMV retinitis in HIV.³⁹ The main side effects of foscarnet are nephrotoxicity, anemia, seizures, and alterations in calcium homeostasis.⁴² Foscarnet is usually dosed at 60–90 mg/kg two to three times daily for induction, and must be given with adequate hydration for renal protection.⁴³ The maintenance dose is 90–120 mg/kg given once daily. Foscarnet must be used cautiously in patient receiving other potentially nephrotoxic drugs and the dose must be adjusted in renal failure. Combined resistance to both ganciclovir and foscarnet can develop, especially among patients with AIDS. Cidofovir, an acyclic nucleotide, is effective as third line therapy in this situation. Cidofovir's utility is limited by the potential for severe nephrotoxicity and the complicated administration protocol involving forced hydration and the use of probenecid.

Group A Streptococcal Diseases

Susan Assanasen • Gonzalo M.L. Bearman

► INTRODUCTION

Group A β -hemolytic *Streptococcus* (GABHS), also known as *Streptococcus pyogenes* or group A *Streptococcus* (GAS), appears as gram-positive cocci arranged in pairs and chains. This organism is the most common cause of acute bacterial pharyngitis and rapidly progressive soft tissue infections.^{1,2} GABHS also causes cutaneous and systemic infections such as pyoderma, erysipelas, cellulitis, scarlet fever, bacteremia, puerperal sepsis, and streptococcal toxic shock syndrome (streptococcal TSS).³ Bacteremic spread of the GABHS may result in a variety of metastatic infections including septic arthritis, endocarditis, meningitis, brain abscess, osteomyelitis, and liver abscess.⁴ In the U.S. there are millions of cases of GABHS pharyngitis causing billions of dollars loss from medical expenses and absenteeism from work.⁵ Furthermore, approximately 10,000 to 15,000 cases of invasive GABHS infections, including necrotizing fasciitis and streptococcal TSS occur annually, with an overall 10–13% mortality rate.⁶ For streptococcal TSS, the reported mortality rate is as high as 45%. The important nonsuppurative sequelae of GABHS include acute rheumatic fever (ARF) and acute poststreptococcal glomerulonephritis (APSGN). Early treatment of streptococcal pharyngitis can relieve sore throat and also prevent acute rheumatic fever and peritonsillar abscess. Presumed GABHS pharyngitis is one of the most common causes of antimicrobial prescription. The widespread use of empiric antibiotics for presumed GABHS pharyngitis is of concern given the potential for promoting both drug hypersensitivity and the emergence of drug-resistant microorganisms in the community.⁷

► HISTORY OF STREPTOCOCCUS PYOGENES AND INFECTION CONTROL

In 1847, Dr. Ignaz Semmelweis, “father of infection control,” observed that pregnant women delivered by physicians and medical students had a much higher rate (13–18%) of post-delivery mortality from puerperal fever than women delivered by midwife trainees or midwives (2%). Semmelweis concluded that the higher infection rates were due to the transfer of pathogens to women in labor by physicians and medical students. These providers frequently attended deliveries following autopsies or other patient care duties without washing their hands. After the initiation of a mandatory handwashing policy with chloride of lime solution, maternal mortality in women delivered by physicians and medical students fell to the same level as those of mothers delivered by midwives.^{8–10}

In 1874, Theodor Billroth, the Viennese surgeon, first introduced the term *streptococci* for chain-forming cocci that he observed microscopically in cases of erysipelas and wound infections.¹¹ In 1879, Louis Pasteur isolated cocci in chains (*microbe en chapelet de grains*) from the blood of a patient dying of puerperal sepsis at the Sorbonne in Paris. Four years later, Fehleisen also isolated chain-forming organisms in pure culture from erysipelas lesions and then demonstrated that these organisms could induce typical erysipelas in humans.⁴ In 1884, Rosenbach first introduced the name *Streptococcus pyogenes* (*pyogenes*, Greek for pus-begetting) to this organism that was also the principal cause of puerperal infection.¹² Joseph Lister, a British surgeon, introduced practical aseptic techniques for the prevention of surgical infection. Before long, these techniques were introduced in the delivery rooms, thereby reducing the risks of childbearing in hospitals. In the twentieth century, the prevalence and

morbidity of puerperal sepsis from GABHS showed a significant decline, probably due to proper aseptic techniques and antibiotics.¹⁰

► BASIC CLASSIFICATION OF STREPTOCOCCUS

Members of the genus *Streptococcus* are round or slightly oval catalase-negative gram-positive cocci arranged in pairs and chains with variable lengths.¹³ Some streptococci are fastidious and require complex media for optimal growth. Most of these organisms are facultative anaerobes, growing both aerobically and anaerobically, but some strains need carbon dioxide for better growth and others may be strictly anaerobic.¹⁴

The taxonomic classification of genus *Streptococcus* is historically complicated.¹⁵ In 1903, Schötmüller described the blood agar technique for differentiating hemolytic from nonhemolytic streptococci. Streptococci producing clear zone of lysis around the colony in media containing blood were called *Streptococcus hemolyticus*.¹⁶ In 1919, streptococci were classified by J.H. Brown into α -hemolytic streptococci, β -hemolytic streptococci, and γ -hemolytic streptococci on the basis of the capacity of the bacterial colony to hemolyze erythrocytes in the sheep blood agar medium.¹⁷ The production of soluble hemolysins such as streptolysin S and O from β -hemolytic streptococci results in a transparent zone around their colonies on blood agar. Alpha-hemolytic streptococci produce partial hemolysis, causing a green or grayish zone surrounding colonies. Besides, nonhemolytic organisms are classified as γ -hemolytic streptococci including most enterococci.¹⁸ The typical GABHS colony is a gray-white color with zone of β -hemolysis, excluding rare strains of *S. pyogenes*, which are non-hemolytic.

In 1933, Dr. Rebecca Lancefield developed the serogroup classification of β -hemolytic streptococci on the basis of cell wall polysaccharide antigenicity difference. Under this scheme streptococci were identified as groups A through H and K through V.¹⁹ Most human pathogenic strains belong to serogroup A (*S. pyogenes* or Group A β -hemolytic *Streptococci*).

In the twentieth century, newer phenotypic characteristics were also examined, leading to various genera and groups, such as *Enterococcus* genus, *Lactococcus* genus, *Leuconostoc* genus, *Pediococcus* genus, *Abiotrophia* genus, *Granulicatella* genus, and five groups of viridans streptococci (*S. milleri* group, *S. mutans* group, *S. salivarius* group, *S. sanguinis* group, and *S. mitis* group).¹⁵ On the basis of molecular studies of 16S rRNA gene sequence similarities, approximately 40 species constituting the genus *Streptococcus* commonly isolated from humans have been subdivided into seven major species groups, including pyogenic group, anginosus group, mitis group, salivarius group, bovis group, mutans group, and sanguinis group (Table 12-7).^{15,20–22}

► COMMON VIRULENCE FACTORS OF THE GABHS

Despite intensive investigation in experimental animal models, the pathogenesis of GABHS infections remains poorly understood. Multiple studies have focused on the interaction between host and streptococcal pathogen.^{23–26} A large number of surface components and extracellular products have been identified as the virulence factors of GABHS.^{4,23}

TABLE 12-7. CLASSIFICATION OF COMMON STREPTOCOCCI

Species	Common Lancefield Antigen(s)	Hemolytic Reaction(s)	Phylogenetic Groups ^a
<i>S. pyogenes</i>	A	β	Pyogenic
<i>S. agalactiae</i>	B	β, γ	Pyogenic
<i>S. dysgalactiae</i> subsp. <i>equisimilis</i>	C, G, occasionally A	β	Pyogenic
<i>S. dysgalactiae</i> subsp. <i>dysgalactiae</i> ^b	C, L	α, β, γ	Pyogenic
Bovis group	D	α, γ	Bovis
Viridans Streptococci			
<i>S. milleri</i> group ^c	A, C, F, G or no detectable antigen	α, γ, β ^d	Anginosus
<i>S. mutans</i> group	ND	α, γ, occasionally β	Mutans
<i>S. salivarius</i> group	ND	α, γ	Salivarius
<i>S. sanguinis</i> group ^e	ND	α	Sanguinis ^f
<i>S. mitis</i> group	ND	α	Mitis
<i>S. pneumoniae</i>	No detectable antigen	α	Mitis ^g
<i>S. suis</i>	R, S, T, occasionally D	α, β ^h	None ⁱ
<i>Enterococcus</i>	D	γ, α, occasionally β ^j	Enterococcus

ND: not useful for differentiation.

^aBased on 16S rRNA gene sequence similarities.

^bAnimal isolates

^cSuch as *S. anginosus*, *S. constellatus*, and *S. intermedius*.

^dSmall colony-forming β-hemolytic strains.

^eFormerly known as *S. sanguis* group.

^fPreviously classified within Mitis group.

^g*S. mitis*, *S. oralis*, and *S. pneumoniae* have over 99% 16s rDNA gene sequence similarities.

^hα-Hemolytic on sheep blood agar, but some strains may be β-hemolytic on horse blood agar.

ⁱNo group name is finally proposed, due to high phylogenetic diversity of some *S. suis* serotypes.

^jCytolysin producing *E. faecalis* strains and some *E. durans* strains. However, these strains may be non-β-hemolytic on sheep blood agar plates.

The most extensively studied virulence factor of *S. pyogenes* is surface M protein, identified by Dr. Rebecca Lancefield in the 1920s.²⁷ From an electron microscope, M protein can be seen protruding from the cell wall like the fuzzy fibrils.⁴ The M protein is heat-stable, trypsin-sensitive filamentous proteins consisting of dimer of α-helical coiled-coil structure.²⁸ This structure is comprised of four portions: (a) a hypervariable N-terminus (distal portion), (b) a conserved region, (c) a proline and glycine-rich region intercalating M protein into cell wall, and (d) a hydrophobic membrane anchor region.^{11,29} M protein producing GABHS is resistant to phagocytosis by polymorphonuclear (PMN) leukocytes, promotes adhesion to human skin epithelial cells, and facilitates entry into host cells (internalization).^{30,31} As such, this protein plays a major role in both infection and colonization. The hypervariable region (HVR) or N-terminal of M protein contains type-specific epitopes of the GABHS strains. Antibodies directed against the HVR are also type-specific protection for GABHS strain and may persist for years. Occasional heterologous protection can be demonstrated. Nevertheless, some patients may remain colonized in spite of protective antibody levels.³¹ The risk of GABHS disease appears to decrease during adult life due to the development of immunity against the prevalent serotypes.

Although GABHS produces numerous extracellular products, only a limited number of these factors have been characterized. Streptolysin O or oxygen-labile streptolysin is toxic to a wide variety of cells such as erythrocytes, PMN leukocytes, platelets, tissue culture cells, lysosomes, and isolated mammalian and amphibian hearts. Streptolysin O is a strong immunogen, but is irreversibly inhibited by cholesterol.¹³ Streptolysin S is a hemolysin produced by streptococci growing in the presence of serum, and has the capacity to damage the membranes of PMN leukocytes, platelets, and some organelles. Most strains of *S. pyogenes* and some strains of group C and G β-hemolytic streptococci can produce these two hemolysins. Unlike streptolysin O, streptolysin S is not immunogenic and not inactivated by oxygen.⁴

Deoxyribonuclease (DNase) is produced by group A streptococci at least four different antigenic variants, designated A, B, C, and D. Most strains produce the B type. Anti-streptolysin O (ASO) and Anti DNase B antibodies can be used as indicators of recent streptococcal infection. However, these antibody responses may be depressed in patients receiving early antibiotic treatment for the infection.

Numerous toxins are generated by GABHS. The streptococcal pyrogenic exotoxins (Spe) have been described as SpeA, SpeC, SpeF, SpeG, SpeH, SpeI, SmeZ, and mitogenic factor (MF). Currently, SpeB is known to be a constitutive cysteine protease. Also, SpeE and MF are identical.³² Spe are associated with scarlet fever, streptococcal TSS,³³ and act as superantigens.³⁴ Conclusively, GABHS induces serious human diseases by three major mechanisms: (a) suppuration, as in pharyngitis, pyoderma, or abscesses; (b) toxin elaboration, as in scarlet fever, or streptococcal TSS; and (3) autoimmune process, such as ARF and APSGN.^{11,35}

► METHODS TO TYPING GABHS

Typing of GABHS is reserved for epidemiologic studies and outbreak investigations. Currently, there are two major approaches to typing GABHS.

Phenotypic Methods to Typing GABHS

GABHS is generally classified into specific serotypes on the basis of differences in cell wall antigens and enzymes. Conventional typings were developed on the basis of T-protein agglutination reactions and M-protein precipitin reactions.^{36–38} GABHS strains specifically express only single M-type antigen, but may carry one or more T antigens. GABHS has been categorized into more than 100 M serotypes. Some M proteins have been found to correlate with the particular GAS diseases, whereas the T-protein function is unknown. Hence, most epidemiological studies use M typing.^{1,4,39} Other phenotypic methods, such as detection of streptococcal serum opacity factor (SOF) production, R typing, phage typing, bacteriocin typing, pyrolysis mass spectrometry, and multilocus enzyme electrophoresis, have also been described.

Genotypic Methods to Typing GABHS

The standard molecular typing of GABHS was established on the basis of nucleotide differences in 160 bases of the *emm* gene encoding the type-specific portion of M protein.^{40,41} The *emm* gene amplification by two highly conserved primers described by the Centers for Disease Control and Prevention (CDC) results in more than 160 distinct *emm*

genotypes.^{5,42} Other genotypic characterizations, including detection of *sof* gene (encoding SOF), *sof* gene sequence typing, ribotyping, pulsed-field gel electrophoresis (PFGE), fluorescent amplified fragment length polymorphisms (FAFLP), multilocus sequence typing (MLST), and streptococcal inhibitor of complement gene typing (M1 strains), are useful for examining clusters and undertaking population genetic studies. However, some techniques such as PFGE are less specific to differentiate GABHS strains of the same M type.¹³⁰ According to several studies, horizontal gene transfer of virulence factors between GAS strains is not uncommon and leads to various clinical manifestations caused by only one strain.^{43–47} For these reasons, the GABHS typing in epidemiologic studies is still problematic.

► GABHS CARRIERS

S. pyogenes is a worldwide human pathogen, rarely infecting other species.¹¹ Besides strain virulence, other factors in development of streptococcal diseases include the patient's age, season of the year, and contact history.¹ GABHS carrier rates vary with geographic location and season of the year. In children, the average rates of pharyngeal colonization is 10–20% and is common in winter and spring.⁴ In adults, the carrier rates are considerably lower. Skin carriage is usually infrequent, except patients who have skin diseases, such as eczema, psoriasis, and wounds. Nevertheless, skin colonization rates may be as high as 40% during the epidemics of streptococcal pyoderma.¹³

► COMMON GABHS DISEASES

Streptococcal Pharyngitis

The major cause of sore throat in adults is acute infectious pharyngitis, accounting for 1–2% of ambulatory visits in the United States.⁴⁸ GABHS causes approximately 15–30% of acute pharyngitis in children, but only 5–10% in adults.^{49,50} Streptococcal sore throat is most prevalent in the 5–15 years of age group with the peak incidence at 8 years, and during late autumn, winter, and early spring.^{51,52} Seasonal variation is fairly constant, but fluctuations between years have been noted. Infants have very low incidence of GABHS infections, probably due to transplacental acquisition of type-specific antibodies.¹

The uncommon causes of bacterial pharyngitis are groups C and G β -hemolytic streptococci, *C. diphtheriae*, *Arcanobacterium haemolyticum*, and *N. gonorrhoeae*. However, two-thirds of acute pharyngitis are caused by viruses, such as rhinovirus, coronavirus, adenovirus, HSV, parainfluenza virus, and influenza virus.⁵³ Due to low prevalence (<1%) of non-streptococcal bacterial pharyngitis, the clinical decision is whether the GABHS is the attributable cause of the pharyngitis.

GABHS pharyngitis is spread via droplets of nasal secretions or saliva from GABHS infected or colonized persons.⁴ Children with streptococcal pharyngitis may excrete the organism in their feces or carry it in the perianal region or vagina.^{1,13} Food-borne epidemics of GABHS pharyngitis from salad, eggs, and cheese prepared by infected or colonized food handlers have been reported.^{54–58} There is little evidence that *S. pyogenes* is transmitted from environment. Susceptibility to streptococcal pharyngitis is closely related to crowded living conditions, but is not related to gender, ethnicity, geography, or nutritional status.¹¹ Spread among family members and classmates is common and gives rise to pharyngeal carriage rates 50%.¹³ Unlike group G streptococci, pets are rarely reservoirs of GABHS.¹¹ Recurrent streptococcal sore throats or skin infections may develop, probably due to the reservoirs in their household, organism virulence, or inadequate treatment.

The incubation period of GABHS pharyngitis is 2–4 days. Typical features include sudden onset of sore throat accompanied by fever and malaise. Headache, nausea, vomiting, and abdominal pain may also be present in children.⁵⁹ Unlike viral pharyngitis, cough, rhinorrhea, conjunctivitis, hoarseness, anterior stomatitis, discrete ulcerative lesions, and diarrhea are usually absent in GABHS pharyngitis.

Typical physical findings include a temperature 101°F or more, erythema of the posterior pharynx, enlarged and hyperemic tonsils with patchy discrete exudates, palatal petechiae, enlarged, tender lymph nodes at the angles of the mandibles, and a scarlatiniform rash.⁴ However, these findings are not specific for GABHS pharyngitis. The ability of physicians to predict positive throat cultures for GABHS is limited, with estimated sensitivity ranging from 55% to 74% and estimated specificity ranging from 58% to 76%.^{60–63}

The most widely used clinical predictor of GABHS pharyngitis is the Centor criteria.⁶¹ These criteria include tonsillar exudates, tender anterior cervical lymphadenopathy, absence of cough, and history of fever. The positive and negative predictive values (PPV and NPV) of the Centor criteria depend on the prevalence of GABHS pharyngitis in the population. According to studies in U.S. populations, the positive predictive value of GABHS pharyngitis in adults who have one Centor criterion is only 2–3%. If three or four of Centor criteria are met, the PPV is approximately 40–60%.^{50,61} The absence of three or four criteria has the NPV of 80%. Both sensitivity and specificity of three or four Centor criteria are 75%.^{64,65} Inaccuracy in clinical criteria is likely due to the broad overlap of signs and symptoms between streptococcal and non-streptococcal pharyngitis. In addition, patients with group C or G β -hemolytic streptococcal pharyngitis, which are the second and third most common causes of bacterial pharyngitis, may have the same clinical findings as patients with GABHS. Of these, 45% will also meet three or four of the Centor criteria.^{66,67} Because of low PPV of Centor criteria, expert panels recommend the antimicrobial treatment of pharyngitis only in patient with laboratory confirmed GABHS.^{68–73}

Throat swab culture on a sheep-blood agar plate described by Breese and Disney in 1954⁷⁴ has been accepted as the “gold standard” for diagnosing GABHS pharyngitis.⁷¹ Throat swab specimens should be obtained directly from both the tonsils and the posterior pharyngeal wall.⁷⁵ The sensitivity of single swab culture is 90%, while the specificity ranges from 95% to 99%.^{76,77} If the patient has not received antibiotics prior to the throat swab collection, a negative culture eliminates the therapy.^{60,78} A major disadvantage of throat culture is the delay (overnight or up to 48 hours) in obtaining the result. If patients have severe symptoms with a high clinical suspicion for GABHS pharyngitis, a throat culture should be obtained and empiric antimicrobial therapy can be initiated. If the diagnosis is subsequently not confirmed by culture, then antibiotic therapy should be discontinued.

Since 1980s, commercial rapid antigen detection tests (RADTs) have been developed for the diagnosis of GABHS pharyngitis. RADTs use enzyme or acid extraction of antigen from throat swabs followed by latex agglutination, coagglutination, enzyme linked immunoabsorbent assay (ELISA), optical immunoassay (OIA), or chemiluminescent DNA probe procedures to demonstrate the presence of GABHS.⁷⁹ The diagnostic accuracy is highly variable. Compared with the throat culture, RADTs have reported sensitivities of 65–91% and specificities of 62–100%, depending on the type of test and the clinical setting.^{80–83} Neither throat culture nor RADTs can discriminate between acutely GABHS pharyngitis and asymptomatic streptococcal carriers with viral pharyngitis. Although RADTs are more expensive than throat cultures, they provide faster results. Most currently available RADTs have an excellent specificity of 95% or more,⁷⁷ so a positive result obviates the need for a throat culture. Unfortunately, the overall sensitivity of RADTs is still lower than that of the conventional throat culture. At present, most expert panels recommend that a negative RADT in suspected cases of group A streptococcal pharyngitis should be confirmed with standard throat culture.^{50,71,73}

In adults, GABHS causes only 5–10% of acute pharyngitis. Additionally, the risk of ARF is extremely low, even in untreated episodes of streptococcal pharyngitis.^{84–86} Newer RADTs including OIA and chemiluminescent DNA probes have higher sensitivity of 80–90%.⁸⁷ Consequently, the use of the Centor criteria and new generation RADTs without throat culture confirmation has recently been accepted for the management of pharyngitis in adults.^{7,50,71}

GABHS pharyngitis is generally a self-limited disease and constitutional symptoms disappear within 3–5 days. Most signs and other symptoms subside within one week, although the tonsils and lymph nodes will return to previous size within several weeks later. The

rationale for treatment of GABHS pharyngitis falls into four categories: preventing acute rheumatic fever (primary prophylaxis), preventing suppurative complications, shortening duration of illness, and reducing risk of transmission. Despite the widespread use of antibiotics for GABHS pharyngitis, there is no definite evidence that APSGN can be prevented by treatment of the antecedent GABHS infection.⁸⁸

Antimicrobial therapy initiated within the first 48 hours of onset hastens symptomatic improvement by only 1–2 days.^{78,89,90} Because of its efficacy in the prevention of ARF, safety, narrow spectrum, and low cost, penicillin V is currently recommended as a first-line oral medication for GABHS pharyngitis.^{7,71–73} Benzathine penicillin G is indicated for noncompliant patients or those with nausea, vomiting, or diarrhea. Patients with severe complications such as severe scarlet fever, mastoiditis, ethmoiditis, streptococcal bacteremia, pneumonia, or meningitis should be treated with parenteral antibiotic.¹ Drainage and anti-anaerobic antibiotics should be considered in patients with suppurative cervical lymphadenitis, peritonsillar or retropharyngeal abscesses.

The alternative regimens for the treatment of GABHS pharyngitis are amoxicillin, amoxicillin-clavulanate, erythromycin, azithromycin, clarithromycin, and oral cephalosporins. Although clindamycin is effective for eradication of the GABHS carrier state, the routine use for treatment of acute pharyngitis is not advocated because of its side effects, especially pseudomembranous colitis.⁹¹ Most oral antibiotics must be administered for the conventional 10 days to achieve maximal rates of pharyngeal eradication of group A streptococci. Currently, it has been reported that clarithromycin, cefuroxime, cefixime, cefitibuten, cefdinir, cefpodoxime proxetil, and azithromycin (60 mg/kg per course) are also effective in the eradication of GABHS from pharynx when administered for five days or less, but the cost is more expensive.^{4,71,92} Despite these alternatives, most authorities still recommend penicillin as the drug of choice.^{93,94}

The GABHS is generally susceptible to macrolides, azalides (azithromycin), and clindamycin. However, the surveillance study in the United States found that erythromycin resistance increased steadily from 3.8% to 6.8% and 8.4% in 2002–2003, 2003–2004, and 2004–2005, respectively.⁹⁵ Cross-resistance among these drugs was also observed. Physicians should monitor the local antimicrobial resistant patterns, if non-penicillin antibiotics are prescribed.⁹⁶

Clindamycin, amoxicillin-clavulanate, or benzathine penicillin G with or without rifampicin should be considered in patients with recurrent episodes of GABHS pharyngitis.^{71,92} Tonsillectomy is only indicated in severely affected children with more than six GABHS pharyngitis in a single year or 3–4 episodes in each of two years.^{97,98} Although tonsillectomy may decrease the frequency and severity of infections, there is currently no firm evidence that it can reduce the incidence of rheumatic fever.

Routine throat culture after treatment is generally not recommended except for persistent symptoms, frequent recurrences, and high-risk circumstances such as patient or family member with history of rheumatic fever. Persistence of streptococci after a complete course of penicillin occurs approximately 5–40% and may be due to poor compliance, reinfection, presence of β -lactamase-producing oral flora, tolerant streptococci, or presence of a carrier state.

Most patients with streptococcal pharyngitis are less communicable within 24 hours of appropriate antimicrobial therapy.⁷⁸ In untreated patients, GABHS may persist for several weeks, then gradually declines during convalescence.⁴ The type-specific protective antibodies of GABHS are generally detectable in 4–8 weeks. Children should not return to school until they have had completed 24 hours of antibiotic therapy. Although approximately 25% of asymptomatic household contacts of known cases of streptococcal pharyngitis will harbor GABHS in their upper respiratory tracts, these individuals are at low risk of developing ARF.^{71,99,100} As such, asymptomatic carriers are not treated unless they are associated with treatment failure and recurrent pharyngitis in a close-contact index patient.

Scarlet Fever

Scarlet fever results from infection with an erythrogenic toxin producing GABHS. However, scarlet fever has been linked with group

C and G β -hemolytic streptococcal infections. The primary foci of GABHS infections are usually pharyngeal infections, wound infections, and puerperal sepsis.

Scarlet fever is characterized by fever, chill, vomiting, headache, and diffuse erythematous rash over trunk, neck, and limbs, except palms, soles, and face. The generalized sunburn-linked exanthema is often first noted over the upper chest on the second day and then spreads to the other parts.⁴ Cheeks appear flushed with marked circumoral pallor. The rash is usually blanchable and petechiae may also occur on the distal limbs. Areas of unblanchable hyperpigmentation such as skin folds of the neck, axillae, groin, elbows, and knees may appear as lines of deeper red, particularly in the antecubital fossae (Pastia's lines).¹ In some patients, the skin may feel like coarse sandpaper. Pharynx is inflamed and tonsils may be covered with gray-white exudates. Palate and uvula are red and covered with hemorrhagic spots. Tongue may be edematous and initially covered with a yellowish-white coat through which may be seen the red papillae ("white strawberry tongue"). After several days the white coat desquamates, leaving a beefy red tongue spotted with prominent papillae ("red strawberry tongue or raspberry tongue").¹ Desquamation of skin begins on face at the end of first week and continues over trunk, lasting for several weeks. Extensive desquamation can be seen on palms and soles.¹³ Severe and rare forms of scarlet fever such as septic scarlet fever (local and hematogenous spread) and toxic scarlet fever (profound toxemia) are characterized by high fever and marked systemic toxicity. The course may be complicated by arthritis, jaundice, and hydrops of the gallbladder.⁴ Untreated patients with scarlet fever from pharyngitis usually recover within 5–7 days. Early antibiotic treatment may alleviate the clinical sequelae. The mainstay of treatment is penicillin and β -lactam antibiotics.

Streptococcal Pyoderma

Pyoderma or impetigo is a discrete purulent superficial skin infection caused by β -hemolytic streptococci and/or *Staphylococcus aureus*.^{101,102} *S. pyogenes* pyoderma is more prevalent in children aged between two and five, particularly in summer and fall.¹¹ Pyoderma also markedly occurs in children who live in humid tropical climates and have lower levels of hygiene and it may also occur in older children and adults who have the abrasions or wound from recreational activities or occupation.^{103,104} There is no gender or racial predilection.

Pyoderma is often spread by direct contact, with initial normal skin colonization. Skin colonization commonly precedes the infection with an average interval of 10 days. Subsequent skin injuries such as abrasions, scratches, minor trauma, insect bites, or varicella lesions cause intradermal inoculation and contribute to develop pyoderma.⁴ Then, GABHS on the patient's skin usually transfer to their nose and/or throat within 2–3 weeks. Due to highly contagious skin lesions, GABHS can spread to the immediate environments such as clothing, sheet, and mattress, causing the indirect transmission.¹³

Topical mupirocin is as effective as systemic antibiotics^{105–107} and may be used when lesions are limited in number. The other agents such as bacitracin and neomycin are considerably less effective than mupirocin. Patients who have numerous lesions or who are not responded to topical agents should receive oral antibiotics against both *S. aureus* and *S. pyogenes* such as penicillinase-resistant penicillins and first-generation cephalosporins. Cutaneous infections with nephritogenic strains of GABHS are the major antecedent of APSGN. ARF has never occurred after streptococcal pyoderma. No conclusive data indicate that treatment of pyoderma prevents APSGN.⁸⁸

Erysipelas

Erysipelas is an acute, well-demarcated superficial skin infection spreading rapidly through cutaneous lymphatic vessels. It occurs mostly in infants, young children, and older adults. It is usually caused by GABHS, but similar lesions are also caused by group B, C or G β -hemolytic streptococci, and rarely *S. aureus*.⁴ Erysipelas typically involves the butterfly area of face and lower limbs.¹⁰⁸ Surgical incisions, trauma, abrasions, dermatologic diseases such as psoriasis, and local fungal infections may be served as portals of entry of GABHS.

Classically, erysipelas is a fiery red, tender, painful plaque with well-demarcated edge and then spreads rapidly with advancing red margin. It is usually associated with lymphangitis, lymphadenopathy, and systemic symptoms such as fever, rigors, nausea and vomiting.² Generally, erysipelas is a mild disease, but approximately 10% of cases may progress to deeper skin infections such as cellulitis and necrotizing fasciitis. Its differential diagnoses include early herpes zoster, contact dermatitis, giant urticaria, and erysipeloid. Penicillin is the drug of choice.⁴

Invasive GABHS Diseases

Invasive group A streptococcal disease (iGAS) is defined as an infection associated with the isolation of GABHS or *Streptococcus pyogenes* from a normally sterile body site.^{109,110} Clinical manifestations are divided into three categories including necrotizing fasciitis, streptococcal TSS, and miscellaneous types of severe infections. Necrotizing fasciitis is characterized by extensive local necrosis of subcutaneous soft tissues and skin. Streptococcal TSS is differentiated from other types of iGAS by occurrence of shock and multi-organ system failure early in the course of the infection. The third group is a severe infection in patients not meeting the criteria for streptococcal TSS or necrotizing fasciitis, such as bacteremia, meningitis, pneumonia, spontaneous gangrenous myositis, peritonitis, and puerperal sepsis.⁶

Preexisting conditions for sporadic iGAS include age over 65 years, heart disease, diabetes, cancer, HIV infection, high dose steroid use, injecting drug use, chronic lung disease, alcohol abuse, skin trauma, and those infected with varicella virus.⁶ The relation between the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and the subsequent development of iGAS is controversial. Prolonged contact of patients with iGAS (during the period from 7 days prior to the onset of symptoms to 24 hours after the initiation of appropriate antibiotic) more than 24 hours per week or more than 4 hour per day on average in the previous 7 days have been reported as a significant risk factor of streptococcal transmission.^{111,112}

Necrotizing Fasciitis

Necrotizing fasciitis is an infection of deeper subcutaneous tissue and fascia, characterized by extensive and rapidly progressive destruction of tissue, systemic signs of toxicity, and a high rate of mortality. Generally, necrotizing fasciitis is categorized into types I and II. Type I necrotizing fasciitis is typically a polymicrobial infection caused by aerobic and anaerobic bacteria and occurs most commonly in patients with diabetes, decubitus ulcers, peripheral vascular disease, and recent surgical procedures. Type II necrotizing fasciitis refers to a monomicrobial infection caused by GABHS and occurs in all age groups and in patients without complicated medical comorbidities. Necrotizing fasciitis from GABHS can present with erysipelas, cellulitis with or without myonecrosis. Almost 50% of necrotizing fasciitis case will develop streptococcal TSS.

Unexplained progressive pain, frequently disproportionate to clinical findings, may be the first manifestation of GABHS necrotizing fasciitis.¹¹⁰ During the first 24 hours, flu-like symptoms such as fever, malaise, anorexia, myalgias, vomiting, and diarrhea may also be present. Within 24–48 hours, erythema develops to a reddish-purple color, and frequently leads to localized blisters, bullae, and areas of skin necrosis. Once the bullous stage is reached, patients usually exhibit fever and systemic toxicity and may progress to strep TSS.

Successful management of necrotizing fasciitis calls for early recognition. General clues for distinguishing necrotizing fasciitis from cellulitis are: (a) severe, constant pain that is disproportionate to physical findings; (b) violaceous bullae; (c) ecchymosis or skin necrosis; (d) gas in the soft tissues especially in mixed infections or Clostridial gas gangrene; (e) edema that extends beyond the margin of erythema; (f) the hard or wooden induration of the subcutaneous tissue, extending beyond the area of apparent skin involvement; (g) cutaneous anesthesia; (h) systemic toxicity or multiple organ failure; and (i) rapid spread of infections, despite receiving antibiotic therapy.¹⁰⁵

Clinical judgment is the most important element in diagnosis. Surgical exploration should proceed rapidly if necrotizing fasciitis is highly suspected. The goals of surgical exploration are to establish a

diagnosis, to perform aggressive surgical debridement, and to obtain material for microbiological diagnosis. CT scan or MRI may be used to locate the site and depth of necrotizing fasciitis, but cannot exactly differentiate necrotizing fasciitis from cellulitis and preexisting inflammatory process, such as muscle tear, hematoma, and prior surgery except if there is gas in the affected tissue.

Treatment of necrotizing fasciitis consists of early and aggressive surgical debridement of necrotic tissue, antibiotic therapy, and hemodynamic support. In a mouse model of GABHS necrotizing fasciitis and myonecrosis, clindamycin is more effective than penicillin because it is not affected by inoculum size or the stage of bacterial growth, and it also suppresses toxin production.^{113,114} Although there are no data from clinical trials establishing the benefit of combined therapy in human, most expert panels recommend the administration of penicillin G (4 million units intravenously every four hours in adults >60 kg in weight and with normal renal function) in combination with clindamycin (600–900 mg intravenously every eight hours).¹⁰⁵ There is few clinical data that support the use of intravenous immune globulin (IVIg) as an adjunctive therapy in severe iGAS.^{115–119} Despite optimal antibiotic treatment and intensive care support, the mortality rates of GABHS necrotizing fasciitis in patients with hypotension and multi-organ failure are 30–80% and 50–70%, respectively.^{120–122}

Streptococcal Toxic Shock Syndrome

Streptococcal TSS is defined as a severe streptococcal infection associated with shock and multi-organ system dysfunction, such as renal impairment, coagulopathy, hepatic abnormalities, adult respiratory distress syndrome (ARDS), and soft-tissue necrosis.¹²³ All age groups may be afflicted. This syndrome mostly occurs in immunocompetent hosts, although some have diabetes and alcoholism.^{124–126} The most common causes of streptococcal TSS are GABHS skin and soft tissue infections, either from traumatic injury or post surgical procedures.

Twenty percent of streptococcal TSS patients may begin with an influenza-like prodrome characterized by fever, chill, myalgia, nausea, vomiting, and diarrhea that precedes the hypotension by 24–48 hours.¹²¹ Progressive pain at the portal of entry without clinical evidence of localized infection may be present in the initial phase of streptococcal TSS. Alteration of consciousness may be present in 55% of cases. Nearly half of patients are normotensive on initial presentation, but become hypotensive within 4–8 hours after admission. A diffuse, scarlatina-like erythema occurs in only 10% of cases. Renal dysfunction is usually present within 48–72 hours. Serum creatinine concentration is frequently elevated, and precedes hypotension in 40–50% of cases. ARDS occurs in approximately 55% of patients.¹²¹

Treatment of streptococcal TSS includes aggressive source control, antimicrobial treatment, and hemodynamic support. Prompt broad-spectrum antimicrobial therapy to cover possible pathogens is mandatory. Given its association with toxin production, clindamycin (900 mg intravenously every 8 hours) should be included in the initial antimicrobial regimen. If GABHS is the causative organism of TSS, combination therapy with high-dose penicillin and clindamycin should be given. The IVIg role in the treatment of streptococcal TSS remains controversial.¹¹⁵ Generally, mortality rates of strep TSS are very high and have varied from 30–70%.^{121,126,127}

► PREVENTION OF SUBSEQUENT INFECTIONS AMONG HOUSEHOLD CONTACTS OF PERSONS WITH INVASIVE GABHS DISEASE

Practice guidelines for management of close community contacts of iGAS vary.^{128–131} The risk of subsequent streptococcal infection among household contacts is estimated to range between 0.66–2.94 per 1000 or 19–200 times higher than the risk among the general population.^{6,130} The subsequent infection usually occurs within 1–3 week(s) following exposure.

Currently, no clinical trials have evaluated the actual risk reduction following antimicrobial prophylaxis.^{132–135} Even without chemoprophylaxis, subsequent invasive GAS infections in household contacts

are still rare.^{112,136-138} Moreover, antibiotics may have potential undesirable effects and may contribute to the emergence of antimicrobial resistance. For these reasons, most experts do not recommend either routine testing for GAS colonization or routine administration of chemoprophylaxis to all household contacts of persons with iGAS.¹²⁹⁻¹³¹ To minimize antibiotic use and maximize its benefit, chemoprophylaxis may be recommended in household contacts who are at high risk for developing iGAS or death from subsequent infection (targeted antibiotic prophylaxis). High-risk individuals include persons aged over 65 years, children with recent onset of varicella infection within two weeks, intravenous drug abusers, either the mother or child in the neonatal period, and those with comorbid conditions such as HIV infection, heart disease, cancer, systemic corticosteroids use, and diabetes.^{112,130,131}

The choice chemoprophylaxis varies between countries: Canada (first-generation cephalosporins, erythromycin, clarithromycin or clindamycin); the U.S.A. (benzathine benzylpenicillin plus rifampicin, clindamycin, or azithromycin); and the UK (oral penicillin, or azithromycin). The doses for chemoprophylaxis are summarized in Table 12-8. Clusters of asymptomatic GABHS carriers among household contacts are common. Thus, physicians giving chemoprophylaxis for high-risk household contacts should prescribe drugs for all household contacts.¹³¹ All household contacts of patient with iGAS should be informed about the clinical manifestations of GABHS infection and should seek immediate medical assessment if they develop symptoms within 30 days after the diagnosis of an index patient.^{131,137-139}

► IMPORTANT NONSUPPURATIVE SEQUELAE OF GABHS INFECTIONS

Several diseases are associated with the immune response to prior streptococcal infection. The classical sequelae of GABHS infections are ARF and APSGN.

Acute Rheumatic Fever

ARF is a multisystemic autoimmune disease in children and adolescents involving heart, joints, skin, and central nervous system.

Pharyngitis is the only GABHS infection associated with ARF. The attack rate of ARF in untreated pharyngitis ranges from 0.4% to 3%.^{60,140} One third of ARF cases occur after asymptomatic streptococcal infection. The initial signs and symptoms of ARF usually develop between one week and five weeks, with an average of 19 days, after the preceding GABHS pharyngitis.¹⁴¹ ARF is seen predominantly in children aged between five and 15 during late fall and winter.¹⁰³ First episode commonly occurs around age of 11, but rarely occurs in children younger than age of 5 and adults older than age of 35.¹⁴²⁻¹⁴⁴ Generally, there is no gender predilection. In patients with mitral stenosis and Sydenham's chorea, the prevalence is higher in females than in males.¹⁴² Traditionally, ARF is highly prevalent in lower socioeconomic groups where crowded conditions, poor hygiene, and limited access to health care still persist. A higher incidence has been reported in blacks versus whites.¹⁴⁵ Certain ethnic groups, such as Aboriginal children in Australia, Pacific Islander children in New Zealand, and Maori populations, have extraordinarily high rates of ARF and rheumatic heart disease (RHD).^{142,146}

At the beginning of the twentieth century, ARF was a significant cause of morbidity and mortality worldwide and the annual incidence rate of ARF in the United States was 100–200 per 100,000 population.¹⁴⁷ By the 1940s, this annual incidence rate dropped to 50 per 100,000.¹⁴¹ In the early 1980s, the annual incidence rate of ARF in the United States ranged from 0.23 to 1.88 patients per 100,000 population.¹⁴⁸ This accelerated decline has also been observed in other developed countries. The explanation of the decline in incidence of acute rheumatic fever (ARF) is still unclear. During the preantibiotic era, the decline was attributed to improvements in living conditions. After 1950, the declining ARF rate was possibly attributed to increased antibiotic use driven by intensive, school-based sore throat screening programs.^{149,150} Furthermore, recent studies revealed a decline in streptococcal rheumatogenic strain prevalence. In the 1960s, 49.7% of streptococcal pharyngeal isolates were rheumatogenic, while only 17.9% of streptococcal pharyngeal isolates were rheumatogenic in 2000–2004.^{151,152} Thus, the declining incidence of ARF may also be attributed to the replacement of rheumatogenic strains by non-rheumatogenic strains.

Unexpected outbreaks associated with rheumatogenic strains were documented in several geographical locations of the United

TABLE 12-8. SUMMARY OF CHEMOPROPHYLAXIS DOSAGES AGAINST INVASIVE GABHS DISEASES

Drugs	Dosage(s)	Duration
Benzathine penicillin G plus Rifampin*†	Benzathine penicillin G 600,000 U im for patients weighing <27 kg or 1,200,000 U im for patients weighing ≥27 kg Plus Rifampin: 20 mg/kg/day po in 2 divided doses (max. daily dose, 600 mg)	1 dose 4 days
Cephalexin‡	25–50 mg/kg/day po in 2–4 divided doses (max. daily dose, 1,000 mg) Adults: 250mg po q6h or 500 mg po q12h	10 days
Penicillin V	25–30 mg/kg/day po in 4 divided doses (max. daily dose, 2,000 mg) Adults: 250–500 mg po q6h	10 days
Clindamycin§	8–20 mg/kg/day po in 3–4 divided doses (max. daily dose, 900 mg) Adults: 150 mg po q6h or 300 mg po q8-12h	10 days
Azithromycin¶	12 mg/kg/day po in a single dose (max. daily dose, 500 mg) Adults: 500 mg po q24h	5 days
Erythromycin¶	20–30 mg/kg/day (estolate* suspension) po in 4 divided doses 20–30 mg/kg/day (base) po in 2 divided doses (max. daily dose, 1,000 mg) Adults: (base) 250 mg po q6h or 500 mg q12h	10 days
Clarithromycin*¶	15 mg/kg/day po in 2 divided doses (max. daily dose, 500 mg) Adults: 250 mg po q12h	10 days

NOTE. max., maximum

*Not recommended for pregnant women

†Not recommended for women who currently use oral contraceptive pills for contraception.

‡First-generation cephalosporins are more effective than penicillin in eradicating GABHS from pharyngeal carriers in most studies.

§Preferred for health care workers who are rectal carriers of GABHS.

¶Sensitivity testing is recommended in areas where macrolide resistance is unknown or known to be ≥ 10%.

States during the late 1980s and early 1990s.¹⁴¹ Smaller clusters of ARF were reported in 1984 to 1988.^{153–156} Unlike the usual high-risk profile, these outbreaks surprisingly involved white middle-class children living in suburban with access to health care. Other outbreaks occurred among recruits at both the San Diego Naval Training Center in California and the Fort Leonard Wood Army Training Base in Missouri.^{157,158} Fortunately, the resurgence of acute ARF was localized and not nationwide. ARF remains highly prevalent in some developing countries and RHD is still the most common cause of severe valvular heart diseases in pediatric and adult populations.

The pathogenesis of ARF is not entirely clear. The leading theory is molecular mimicry. In this theory, an autoimmune response is induced by the similarity of certain streptococcal antigens to a wide variety of human tissue antigens. This is an important step in the initiation of the tissue injury.^{159–161} Molecular mimicry is supported by: (a) the latent period between GABHS infection and ARF; (b) the immunologic cross-reactivity between some epitopes of GABHS components from rheumatogenic strains (such as M-types 1, 3, 5, 6, 14, 18, 19, and 24) and specific human tissues such as cardiac myosin, tropomyosin, laminin, lysoganglioside, and calcium/calmodulin dependent (CaM) protein kinase II.^{161–163} Both humoral and cell-mediated immunologic responses are responsible for the pathogenesis of ARF.

Even during epidemics of GABHS pharyngitis, only a small percentage of infected persons ultimately developed ARF. Thus, host genetic factors may also influence the susceptibility to ARF. Several studies have reported genetic associations with ARF. An association of HLA-DR4 and HLA-DR2 among white and black patients with RHD has been described in the US.^{164,165} However, several studies from other populations have shown conflicting results.^{166,167} The D8/17 alloantigen, a non-HLA B-cell marker, was also associated with ARF patients in North America, the Caribbean, Israel, Russia, Mexico, and Chile.¹⁴⁶

In 1944, T. Duckett Jones proposed guidelines to assist in the diagnosis of ARF. In 1992, the most recent revision of the Jones criteria was conducted by the American Heart Association. Currently, this revision is still used to diagnose an initial attack of ARF.¹⁶⁸ There are five major and four minor criteria. The major criteria include carditis, polyarthritides, chorea, erythema marginatum, and subcutaneous nodules. The minor criteria include fever, arthralgia, prolonged PR interval on electrocardiogram (ECG), and elevation of the acute-phase reactants in the blood such as C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR). In diagnosis of ARF, the patient must have: (a) at least two major criteria, or one major plus two minor criteria; (b) the evidence of recent GABHS infection. Two major criteria are more specific than one major plus two minor criteria. Arthralgia or a prolonged PR interval cannot be used as minor criteria in the presence of arthritis or carditis, respectively.

Most rheumatic attacks begin with migratory polyarthritides, occurring in 75% of ARF. It generally involves larger joints, particularly knees, ankles, wrists, and elbows. However, monoarticular arthritis has been reported in 17% of patients with ARF.¹⁶⁹ Arthritis is more severe in young adults than in children. There is often an inverse relationship between severity of arthritis and the risk of developing carditis. Joint pain may appear disproportionate to findings on physical examination. Each inflamed joint usually improves spontaneously within 1–3 days.¹⁶² Arthritis usually subsides within four weeks, leaving no residual articular damage.

Carditis and RHD are the most serious manifestations of ARF. It most frequently occurs in young children typically within three weeks after the onset of ARF. Carditis can be found in 48–65% of ARF cases on clinical examination and 70–90% of ARF cases on echocardiography.^{147,170,171} Endocarditis is the most frequent site of rheumatic carditis, whereas pericarditis is the least common cardiac finding. Cardiac manifestations include heart murmurs especially mitral regurgitation, tachycardia out of proportion to fever, arrhythmias and heart block, cardiac enlargement, congestive heart failure, pericardial friction rubs, and pericardial effusion. Intractable heart failure is rare and, when present, probably due to acute valvular regurgitation rather than myocarditis. The diagnostic accuracy of echocardiography in differentiating valvular regurgitation between acute rheumatic carditis and

nonrheumatic disorder is uncertain, and the prognosis of “silent” rheumatic valvular regurgitation is unknown. For these reasons, expert panels currently do not recommend that subclinical carditis diagnosed by echocardiography be added to the Jones criteria.¹⁷² However, echocardiography still has some benefits in differential diagnosis and management of ARF and RHD.¹⁷³ Although the diagnostic sensitivity of right ventricular endomyocardial biopsy is only 27%, it may be used to confirm rheumatic recurrence in patients who presented with unexplained congestive heart failure and elevated ASO titers.¹⁷⁴ Signs of mild carditis disappear rapidly in weeks, but those of severe carditis may last for 2–6 months. Approximately 60–70% of patients with carditis significantly improve within six months.^{175,176} By serial echocardiography, 41% of valvular regurgitation disappear after 6 months.¹⁷⁷

Sydenham’s chorea or “St. Vitus dance” is a neuropsychiatric disorder, consisting of abrupt, purposeless, nonrhythmic involuntary movements, hypotonia, and psychiatric symptoms such as emotional lability, hyperactivity, separation anxiety and obsessions-compulsions.¹⁷⁸ About 10–16% of ARF patients develop chorea after a latent period of 1–8 months (average 4 months), while ESR, CRP, or ASO titers may have already return to normal.^{147,179} Chorea is usually a self-limited illness and improves within 2–7 months, but some reports showed that complete recovery might take as long as 17 months. Relapses of chorea may infrequently occur and exacerbate by stress, pregnancy, oral contraceptives, and intercurrent illnesses.¹⁸⁰ Surprisingly, 20–25% of ARF patients with Sydenham’s chorea may subsequently develop RHD.¹⁴¹

Erythema marginatum is seen in less than 10% of patients with ARF, and is usually associated with carditis.¹⁴⁷ It is a nonpruritic, nonpainful erythematous serpiginous macular eruption with central pale clearing, which is usually seen on trunk and the proximal aspects of limbs and accentuated by skin warming.¹⁴¹ Erythema marginatum can appear at any time during the course of ARF. Individual lesions may appear and disappear in minutes to hours. These symptoms may go on intermittently for weeks to months.

Subcutaneous nodules are the least frequent manifestations of ARF, occurring less than 7% of cases.^{147,148} They are associated with severe carditis, and tend to occur several weeks after onset of ARF. The nodules are firm and painless and vary in size from 0.2 mm to 2.0 cm. They are usually found over bony prominences and extensor surface of tendons such as elbows, knees, wrists, ankles, Achilles tendons, occiput, or spinous processes of the vertebrae.¹⁶²

Evidence of preceding streptococcal infection includes positive throat culture or RADTs for GABHS, rising serum anti-streptococcal antibody titer, and recent scarlet fever. Throat culture or RADTs are positive in only 10–30% of cases and up to 50% of culture-positive patients may be chronic pharyngeal carriers.^{147,181} Therefore, anti-streptococcal antibody tests are commonly used for diagnosing ARF. These include ASO, anti-DNase B, anti-group A streptococcus carbohydrate (GAS CHO), anti-group A carbohydrate, anti-hyaluronidase, and antistreptokinase. Due to the variation of ASO level, “upper limit of normal” (ULN) value of the titers should be established for each age group and population. Generally, 80–85% of patients with ARF have positive result from single antibody test, but the sensitivity of multiple tests may increase up to 92–98%.¹⁸²

ASO response can typically be determined after 1 week, and peaks at 3–6 weeks after GABHS infection or the second or third week of ARF. Thus, two serum samples are required at an interval of 2–3 weeks.¹⁸³ Anti-DNase B titer usually begins to rise by the second week after infection and peaks at 6–8 weeks.¹⁸²

Most patients with recurrent rheumatic fever fulfill the Jones criteria; however, polyarthritides, chorea, and carditis may recur independently. Therefore, a recurrent rheumatic fever should be considered in prior ARF or RHD patients who have the evidence of recent GABHS infection with only one major or two minor criteria.^{168,184} Lack of sensitivity of the Jones criteria is also a recognized problem.¹⁶⁹ Proposed guidelines to supplement the Jones criteria are developed in 2006 to increase the sensitivity for detection of ARF in the areas with high rates of ARF and RHD.¹⁸⁵

The goals of ARF treatment are symptomatic relief, eradication of GABHS in pharynx, and prophylaxis against subsequent GABHS

infection to prevent further cardiac damage. Analgesics without anti-inflammatory properties are recommended for patient with mild disease or questionable migratory polyarthritis. Anti-inflammatory therapy, especially aspirin (60–100 mg/kg/day), leads to dramatic improvement in fever, arthritis, and arthralgia and is the mainstay of therapy in ARF. Without anti-inflammatory therapy, the average duration of a rheumatic attack is approximately three months; fewer than 5% of cases may persist for longer than six months.¹⁶² Patients with moderately severe carditis such as congestive heart failure, significant cardiomegaly, or third-degree heart block should receive corticosteroid therapy as well as other supportive cares. However, the advantage of corticosteroid treatment over aspirin in preventing valvular heart disease from ARF is unclear.¹⁸⁶ Prednisolone can be used as an alternative in patients who have serious side effects from NSAIDs or uncontrolled inflammation. Although IVIg might hasten recovery from chorea, it has no proven effect on cardiac outcome in ARF.¹⁷⁷ Mild Sydenham's chorea typically is not treated. The traditional management of chorea includes reassurance, and moving of the patient to a quiet, calm environment. Patients with moderate-to-severe chorea or refractory to conservative management may benefit from valproic acid, carbamazepine or haloperidol.¹⁸⁷ Sedative therapy, such as Phenobarbital, diazepam, or chlorpromazine may also be helpful in the early course of chorea.

At the time of diagnosis, all patients presented with ARF should receive either 10-day oral penicillin or 10-day erythromycin or a single intramuscular injection of benzathine penicillin (primary prophylaxis) to eradicate of possibly persistent GABHS in upper respiratory tracts, regardless of culture results. However, these regimens have not been shown to alter cardiac outcome after one year in controlled studies.^{188,189}

Without antibiotic prophylaxis, three-quarters of patients with ARF have one or more recurrence(s) during their lifetime. The long-term sequelae of rheumatic fever are limited to the heart. Patients with carditis during the first episode of ARF are likely to have recurrent episodes of carditis. The long-term sequelae of recurrent rheumatic carditis is typically chronic progressive valvular stenosis with or without valvular insufficiency.^{190,191} Symptomatic rheumatic valvular heart disease usually occurs 10–20 years after the initial rheumatic attack. Prevalence of RHD peaks at age between 25 and 34.¹⁴⁶ Mitral valve, especially mitral stenosis, is more commonly involved than aortic valve.

In patients with a history of ARF or RHD, secondary prophylaxis aims to prevent subsequent episodes of GABHS pharyngitis, which may trigger recurrent ARF, development or deterioration of RHD. Prophylaxis should begin immediately after completing of the initial course of antibiotic therapy. Prophylactic regimens include intramuscular benzathine penicillin G every 3–4 weeks, twice daily oral penicillin, sulfadiazine, or erythromycin.¹⁹²

The duration of secondary prophylaxis is not well defined. The decision to discontinue prophylaxis should be made after careful consideration of potential risks and consequences of recurrent ARF. The highest risk of recurrence is within a few years after the initial attack. The risk declines with age, and the number of years after the most recent attack.

Patients with persistent rheumatic valvular heart disease should continue prophylaxis for 10 years after the last attack, or at least until 40 years of age (whichever is longer). Some guidelines recommend lifelong prophylaxis in patients with severe carditis or severe valvular heart disease, as rheumatic fever can recur as late as the fifth or sixth decades of life.^{72,184} Patients with a previous history of rheumatic carditis but without residual heart disease by echocardiography should continue prophylaxis for 10 years after the last attack, or at least until 25 years of age (whichever is longer).^{72,184} For patients without proven carditis, prophylaxis should continue for five years after the last attack, or at least until 18–21 years of age (whichever is longer).^{72,184,193} Patients having history of rheumatic fever or RHD who develop acute pharyngitis should be evaluated and treated promptly.

In 1997, the guidelines from the American Heart Association (AHA) recommended endocarditis prophylaxis for invasive dental procedures in all patients with rheumatic valvular heart diseases (moderate-risk patients).¹⁹⁴ However, it is postulated that cumulative bacteremia over one year from chewing, and tooth brushing is six mil-

lion times greater than bacteremia from a single dental extraction.^{195,196} Currently, there is little evidence to support the use of prophylactic antibiotics for the prevention of endocarditis in patients with rheumatic valvular heart disease undergoing invasive dental procedures.¹⁹⁷ Recent guidelines from the British Society for Antimicrobial Therapy does not recommend endocarditis prophylaxis for invasive dental procedures in patients with rheumatic valvular heart disease, except when deemed high risk.¹⁹⁸ High-risk factors include patients with a prior history of endocarditis, prior valve replacement surgery, and surgically constructed systemic or pulmonary shunts or conduits. Due to limited evidence, endocarditis prophylaxis for invasive dental procedures in patients with rheumatic valvular diseases remains controversial.

Acute Poststreptococcal Glomerulonephritis

Acute poststreptococcal glomerulonephritis (APSGN) is an acute inflammatory disorder of renal glomeruli associated with a recent pharyngeal or skin infection by nephritogenic strains of GABHS. M-types 1, 2, 3, 4, 12, 15, 18, and 25 of GABHS may be associated with postpharyngitis glomerulonephritis, and M-types 49, 52, 55, 57, 59, 60, and 61 of GABHS are frequently associated with postpyoderma glomerulonephritis.^{13,39,162} APSGN is characterized pathologically by diffuse proliferative glomerulonephritis.

The attack rate of APSGN after an infection with nephritogenic strains is 10–15%.¹⁹⁹ The epidemiologic characteristics of APSGN significantly correlate with the antecedent group A streptococcal infection. Approximately 60% of APSGN occurs in children between 2 years and 12 years of age.³⁹ Pyoderma-associated APSGN usually occurs in summer and early autumn, whereas pharyngitis-associated APSGN occurs in winter and early spring, coinciding with peak of ARF.¹⁰³ Concomitant presence of ARF and AGN in the same patient after pharyngitis is rare.^{200,201}

The latent period of pharyngitis-associated APSGN is about 10 days,²⁰² while the latent period of pyoderma-associated APSGN is about three weeks or longer.^{199,203} Renal injury in APSGN results from the deposition of antigen-antibody complexes within the glomerular basement membrane.^{204,205} These complexes lead to complement activation, cytokine release, and infiltration by inflammatory cells. The possible streptococcal antigens in these immune complexes include endostreptosin, streptokinase, streptococcal pyrogenic exotoxin B, and nephritis-associated plasmin-receptor (NAP1r).^{206–210} In addition, molecular mimicry between human glomerular components, such as vimentin, basement membrane, and certain epitopes of the M protein, may also lead to autoantibodies and subsequent immune complexes.^{211–213}

Typical clinical findings include oliguria, hematuria, proteinuria, edema, hypertension, and hypocomplementemia. Edema and hematuria are the most common presentations of APSGN. Edema is typically first noticed in periorbital area after arising in the morning, and also involves dependent areas such as feet, legs, scrotum, and sacrum. Children also have systemic symptoms such as lethargy, anorexia, fever, nausea, and abdominal pain.

Although oliguria is often seen in children, anuria and renal failure are uncommon. Nearly all children with APSGN have microscopic hematuria, and approximately 30–50% have gross hematuria. Laboratory findings include a mild normochromic-normocytic anemia, elevated ESR, slight hypoalbuminemia, hypercholesterolemia, hyperlipidemia, and elevated blood urea nitrogen and serum creatinine levels. In the first two weeks of APSGN, serum levels of total hemolytic complement and C3 are markedly reduced in most children. Approximately 90–95% of patients with pharyngitis-associated APSGN have elevations of both ASO and anti-DNAse B. The streptolysin O molecule binds with free cholesterol in the skin, so ASO response is relatively weak after GABHS pyoderma. In pyoderma-associated APSGN, anti-DNAse B titer is elevated in 90–95% of cases.³⁹

APSGN is usually self-limited. Spontaneous diuresis, loss of edema, and improvement in hypertension occur within 1 week.^{214–216} The serum creatinine usually returns to baseline level within 3–4 weeks. Microscopic hematuria usually resolves within 3–6 months, but the degree of proteinuria declines much more slowly.^{217,218}

Death from APSGN is rare. Severe and irreversible renal failure may occur in 0.5–2% of hospitalized children with APSGN.^{219,220} Because recurrent episodes of APSGN are rare, long-term antibiotic prophylaxis is unnecessary. Although antibiotic therapy cannot prevent the APSGN or shorten the course of illness, it might reduce the risk of transmission of nephritogenic GABHS to close contacts.^{88,202,221,222}

► IMMUNIZATION

Due to high burden of GABHS diseases, there have been ongoing efforts to develop a safe and effective vaccine for more than seven decades. In the 1960s, two parenteral vaccines were conducted in clinical trial: (a) vaccine consisting of partially purified M protein and (b) vaccine consisting of cell wall preparations with high M protein content. Both vaccines were unacceptably reactogenic and inconsistently immunogenic.²²³ Several studies in the 1970s showed that subcutaneous or mucosal (intranasal or pharyngeal) administration of purified M protein vaccine evoked immune responses with partial protection in humans, and had no host-reactive antibodies.^{224–227} Patients receiving mucosal vaccines had fewer rates of pharyngeal acquisition of GAS, which were associated with reduced rates of symptomatic infection, than those of parenteral vaccines. In the 1980s, further structural analyses of the M protein revealed that *N*-terminal region of the M protein was responsible for type-specific opsonic antibodies.²⁹

In the late 1990s, development of a group A streptococcus vaccine used recombinant peptides of *N*-terminal region of M protein, and then constructed a multivalent fusion protein vaccine. This vaccine was safe, immunogenic, and protective in rabbits and mice.^{228,229} A hexavalent recombinant fusion peptide GAS vaccine, containing *N*-terminal M protein fragments from serotypes 1, 3, 5, 6, 19, and 24, was studied in a phase I trial of healthy adults. This vaccine was found to be well tolerated and highly immunogenic against six serotypes of group A streptococcus without eliciting antibodies that cross-react with host tissues.²³⁰ A 26-valent GABHS vaccine, consisting of 80–90% of serotypes causing common GABHS infections in North America, was studied in a phase I and II trial of healthy adults.^{231–233} This vaccine revealed no evidence of rheumatogenicity or nephritogenicity, did not induce the formation of human tissue-reactive antibodies, and had no serious adverse events. Also, it was found to be highly immunogenic, eliciting an antibody response to the majority of group A streptococcus serotypes. However, there is currently no FDA-approved vaccine for the prevention of GABHS infections.²³⁴

Besides *N*-terminal region of M protein based vaccine, other vaccine candidates include *C*-terminal region of M protein,^{235–239} C5a peptidase,^{240–244} cysteine protease,²⁴⁵ fibronectin binding proteins,^{246,247}

group A carbohydrate (GAS CHO),^{248,249} and lipoproteins.²⁵⁰ These candidates are active against different serotypes of streptococci because the determinants conserved in most GABHS strains. Although new vaccines are efficacious in the prevention of GABHS colonization and infection in animal models, few studies have demonstrated immunity in humans.^{251,252} Despite these advances, further studies are needed to better understand the pathogenesis of GABHS infections, and to develop a cost-effective GABHS vaccine.

► DISEASE REPORTING

In the U.S., streptococcal TSS and iGAS have been designated as nationally notifiable diseases since 1995.^{253,254} Due to a decline in sequelae of streptococcal pharyngitis and the increased workload of surveillance, GABHS pharyngitis and ARF have been deleted from the national notifiable disease list since 1971 and 1995, respectively.²⁵³ Disease reporting to state health departments is mandated by legislation at the state and local levels. However, reporting of nationally notifiable diseases to CDC by the states is voluntary.^{255,256} Currently, automated laboratory-based reporting should be used instead of data collected manually in an attempt to improve accuracy, completeness, and timeliness of the surveillance.^{257–262} Furthermore, the real-time collection of electronic data may result in rapid detection of clusters or potential outbreaks.²⁶³

For hospitalized patients, all iGAS or streptococcal TSS cases should be reported to the institution's infection control team.^{129,130} Any patient with suspected or proven iGAS or streptococcal TSS should be admitted to a single room. Isolation is required for at least 24 hours after the initiation of appropriate antibiotic therapy.²⁶⁴ According to CDC recommendations, enhanced surveillance should be performed if one case of iGAS is detected in postpartum, post-surgical, long-term care, and day care populations.¹³¹ Enhanced surveillance includes review of microbiology records and autopsy reports and/or review of operative, labor and delivery, and medical records from the previous six months for the definite and probable cases of iGAS. GABHS isolates from the index case and any additional cases should be stored for at least six months to allow for the strain comparison. If two or more cases of iGAS are detected in health-care facilities within a six-month time frame, and if these are found to be clonal, an outbreak investigation must be performed.^{129,131}

► ACKNOWLEDGMENT

The authors wish to thank Ms. Laura Boehmer for her assistance in the preparation of this manuscript.

Meningococcal Disease

Montse Soriano-Gabarró • Nancy Rosenstein

Vieusseux provided the first definite description of epidemic cerebrospinal meningitis as it occurred in Geneva, Switzerland, in 1805. In 1887, Weichselbaum demonstrated that *Neisseria meningitidis* was the cause of this disease. The high mortality and epidemic potential of meningococcal disease has led to intensive study of means for its control and prevention since the early part of this century.^{1,2}

Note: The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Bacteriology

N. meningitidis is a nonmotile, nonsporeforming gram-negative coccus. The organisms usually are arrayed in pairs that are flattened along the axis joining them. Isolation of diplococci from the nasopharynx in Mueller-Hinton agar is facilitated in addition of vancomycin, colistin, and nystatin, to which they are resistant. Addition of blood or other detoxicants in agar also facilitates growth, as does incubation in 5% of 10% CO₂. All *Neisseria* species are oxidase positive. The meningococcus can be differentiated from other *Neisseria* by its fermentation of glucose and maltose but not of sucrose or lactose, by its lack of pigmentation, and by its failure to grow at room temperature.

Strains of *N. meningitidis* are serologically classified based on immunologic reactivity of their capsular polysaccharides (serogroup), which are the basis for currently licensed meningococcal vaccines. Meningococci are further classified on the basis of their class 1 outer membrane proteins (OMP) (serosubtype), class 2 or 3 OMP (serotype), and lipooligosaccharides (immunotype).³ Other strains lack capsular polysaccharide and cannot be serogrouped. Molecular subtyping with the use of multilocus sequence typing, pulsed-field gel electrophoresis, or DNA sequence analysis allows estimates of genetic relatedness between strains of meningococci.⁴ Studies using this method have demonstrated that highly related, or clonal, groups of meningococci are responsible for epidemics of meningococcal disease.⁵ Meningococci also have the capacity to exchange the genetic material responsible for capsule production and thereby switch from serogroup B to C or vice versa.⁶ Capsule switching may become an important mechanism of virulence with the widespread use of vaccines that provide serogroup-specific protection.

Clinical Characteristics

N. meningitidis is most commonly found asymptotically in the oropharynx or nasopharynx. Specific immunity may be induced, but carriage is not eradicated by the serological response.

In less than 5% of people, meningococci penetrate respiratory epithelium and cause bacteremia. Persons who lack or have a deficiency of antibody-dependent, complement-mediated immune lysis (bactericidal activity) are most susceptible to meningococcal disease. Immune defects that confer a predisposition to invasive meningococcal infection include asplenia (functional or anatomical), deficiency of properdin, and deficiency of terminal complement components.⁷ The role of genetic immune defects in altering the susceptibility to meningococcal disease is not yet well understood. Antecedent viral infection, household crowding, chronic underlying illness, and both active and passive smoking also are associated with increased risk for meningococcal disease.

Clinical manifestations of meningococcal disease vary according to the intensity of bacteremia, the organs seeded from the blood, and perhaps the strain involved. Overwhelming septicemia (meningococemia) occurs in 5–20% of patients and can cause death within 2–8 hours of the first symptoms; meningococemia is associated with vasculitis, irregular petechial, purpuric, or maculopapular skin eruption, cutaneous infarction, and bilateral adrenal hemorrhage (Waterhouse-Friderichsen syndrome).

Meningeal infection, resulting from hematogenous spread, occurs in about 50% of patients, and its clinical presentation is similar to other forms of acute purulent meningitis.⁷ The incubation period is often difficult to assess but apparently ranges from 2 to 10 days. Symptoms of meningitis include sudden onset of malaise, followed rapidly by fever, headache, nausea, vomiting, and stiff neck. Arthritis, pericarditis, and pneumonia constitute other systemic manifestation of meningococcal disease. In infants, meningeal infection may have a slower onset, with nonspecific signs, a bulging fontanelle and without stiffness of the neck.

The diagnosis of acute fulminant meningococemia often can be made clinically. Specific diagnosis of meningococcal disease can be made by recovery of meningococci from blood, cerebrospinal fluid (CSF), or other normally sterile sites or by detection of capsular polysaccharide in those sites by latex agglutination. Polymerase chain reaction (PCR) analysis offers the advantages of detecting serogroup-specific *N. meningitidis* DNA and of not requiring live organisms for a positive result. This approach is widely used in the United Kingdom (UK) where more than half of meningococcal cases are confirmed with PCR.⁸ Newer molecular-based subtyping techniques also allow further characterization of *N. meningitidis* from PCR-derived products.

Many antimicrobial agents, including penicillin, are active against *N. meningitidis*. The low prevalence of resistance to penicillin, as well as uncertainty about the clinical relevance of intermediate resistance, supports the continued use of penicillin to treat

meningococcal infections for persons who are not allergic to it.⁹ Up to 20 million units per day (300,000 U/kg/d for children) may be given intravenously in divided doses. Clinical isolates with intermediate resistance to penicillin (MIC, 0.1–1.0 ug/mL) have been isolated in Europe, South Africa, and the United States (US), although its clinical relevance is unclear.^{9,10} For patients who have inadequate clinical response to penicillin therapy, strains should be tested for susceptibility to penicillin. Because the clinical presentation of meningococcal meningitis may be similar to meningitis caused by other bacteria (e.g., *S. pneumoniae*), empirical therapy should be directed at the most likely pathogen, on the basis of epidemiological data. Empirical management of meningitis in children who are one month of age or older should include vancomycin plus cefotaxime or ceftriaxone, given the high prevalence of penicillin-resistant *S. pneumoniae*.⁹

In developing countries, the need to treat a large number of patients makes repeated injections with penicillin or even ceftriaxone impractical. A single intramuscular dose of an oily suspension of chloramphenicol has been shown to be as effective as a five-day course of crystalline penicillin in the treatment of meningococcal meningitis.¹¹

Carriers

Pharyngeal carriage of meningococci is common. The proportion of carriers varies from 5% to 40% depending on the population, season, age, and living conditions.¹² Carriage tends to be greatest under crowded conditions, such as among military recruits. Rates of meningococcal carriage vary with age. Very low carriage rates are reported in children under the age of four years; in most studies, carriage rates are highest among adolescents and young adults.^{13,14} The increase in carriage among adolescents may be a consequence of behavior and social interactions that promote spread of meningococci among people.

Carriage generally persists between three weeks and three months. The carriage rate in a population is of little value in predicting whether an outbreak will occur, probably because of the great variation in virulence of strains, susceptibility of the population, and the difficulty in assessing incidence of infection from a prevalence measurement, such as the carriage rate.

Immunity

Immunity to the meningococcus is mediated primarily by bactericidal antibodies directed against capsular or noncapsular antigens. Goldschneider and colleagues showed that bactericidal antibody probably resulted most commonly from asymptomatic meningococcal infection in the nasopharynx.¹⁵ The presence of serum bactericidal antibodies is common in neonates, reflecting transplacental transfer of maternal antibodies, and decreases rapidly in the first three months of life, increasing again toward the end of the first year. The prevalence of bactericidal antibodies thus mirrors the incidence of meningococcal disease. Following asymptomatic infection or disease, antibodies commonly develop to capsular polysaccharide—although less strikingly to serogroup B than to other serogroup antigens—and to OMP antigens. The presence of complement is necessary for the full protection of bactericidal antibody.

Transmission

N. meningitidis is found only in humans and is spread from the nasopharynx, probably by respiratory droplets. *N. meningitidis* carriage may be introduced into the household by an adult and spreads first to older children and then to infants.¹⁶ In sub-Saharan Africa, where seasonal epidemics are typical, disease occurs primarily in the dry season and decreases abruptly with the first rains. However, transmission of carriage does not seem to be seasonal and likely occurs during both the dry and rainy seasons.¹⁷ Transmission is most intense in closed, crowded conditions—in the home, barracks, or jail.¹⁸ Most disease is due to transmission from asymptomatic carriers but patients with *N. meningitidis* transmit more efficiently. The risk of meningococcal

disease is increased 400-800-fold among household contacts of a person with meningococcal disease.¹⁹

Occurrence

In the U.S. meningococcal disease occurs endemically at a rate of 0.9–1.5 cases per 100,000 population per year, or 2500-3000 cases per year with a peak in late winter and early spring.^{7,20,21} The rates of disease are highest among infants in whom protective antibodies have not yet developed; the rates drop after infancy and then increase during adolescence and early adulthood.²¹ The proportion of cases among adolescents and young adults increased in the 1990s; in the United States during the period from 1992 to 1996, 28% of affected persons were between 12 years and 29 years old.^{20,21}

Globally, serogroups B and C have been responsible for most endemic disease, although variations in the proportion of disease due to each serogroup are observed. In the United States, the number of cases involving serogroup Y has increased; from 1996 to 1998, one-third of cases were due to serogroup Y.²¹ Serogroup B is relatively more common in cases in young infants.

Most large epidemics of meningococcal disease are caused by serogroup A, although epidemics of serogroup B or C have been reported. During the past years, serogroup W-135 has caused meningococcal disease epidemics in Saudi Arabia and Burkina Faso^{22,23} and more recently serogroup X has been identified as cause of disease and outbreaks in some parts of Africa.

Epidemics may be community-wide or confined to only parts of the population. In the latter situation, crowded or impoverished groups seem particularly susceptible, for example, military recruits and prisoners. Until 1945, major meningococcal epidemics occurred about every 10 years in the U.S. For unknown reasons, these major epidemics stopped; small outbreaks of meningococcal disease, primarily due to serogroup C, have been occurring more frequently in the U.S. since 1980s, and a serogroup B outbreak began in Oregon in 1994.²⁴⁻²⁶ Periodic large epidemics continue to occur in sub-Saharan Africa, where incidence rates may be as high as 1000 cases per 100,000 population during epidemic periods. Introduction of new strains into a susceptible population as well as concurrent viral infections, smoking, and crowding may be important risk factors for epidemics.^{7,27-29}

Prevention

Antimicrobial chemoprophylaxis among close contacts of sporadic cases of meningococcal disease is the primary means for prevention of meningococcal disease in the United States.³⁰ Close contacts include household members, day care center contacts, and anyone directly exposed to the patient's oral secretions (e.g., through kissing, mouth-to-mouth resuscitation, endotracheal intubation, or endotracheal tube management). Because the risk of secondary disease among close contacts is highest during the first few days after the onset of disease in the index patient, chemoprophylaxis should be administered as soon as possible.³⁰

Antibiotics that effectively eliminate nasopharyngeal carriage of *N. meningitidis* include rifampin, ciprofloxacin, and ceftriaxone. Rifampin is administered twice daily for two days (600 mg bid for adults, 10 mg/kg bid for two days for children over one month of age, and 5 mg/kg bid for 2 days for neonates). Ciprofloxacin is administered as a single dose (500 mg orally). Ceftriaxone is recommended as an intramuscular dose of 250 mg for adults and 125 mg for children.³⁰ Although secondary cases in hospital contacts are rare, standard and droplet precautions should be considered to reduce the risk of transmission of disease during hospitalization (<http://www.cdc.gov/ncidod/hip/ISOLAT/isopart2.htm>).

Meningococcal purified polysaccharide vaccines have been widely used since the development in 1969 of a highly immunogenic vaccine for serogroups A and C by Gotschlich et al.³¹ The serogroup A and C components have good efficacy in adults and children as young as two years of age.³²⁻³⁴ The serogroup A polysaccharide induces antibodies in some children as young as three months of age although a response comparable to adults is not achieved until four or

five years of age; the serogroup C component is poorly immunogenic in children less than 18–24 months of age.³⁵ Duration of protection is likely only 5 years and is substantially shorter in young children.³⁵⁻³⁶ In addition, the polysaccharide vaccine does not provide sustained protection from nasopharyngeal carriage and thus does not include long-lasting herd immunity.

In the United States, a licensed meningococcal polysaccharide vaccine for serogroups A, C, Y, and W-135 (tetravalent) is available. Because its relative ineffectiveness and short duration of protection in children aged less than two years of age, the tetravalent vaccine is not recommended for routine infant immunization. However, the vaccine is recommended for use in control of localized outbreaks known to be due to serogroups included in the vaccine.^{30,37} For serogroup C meningococcal disease outbreaks, it is recommended that when 3 or more confirmed cases of serogroup C meningococcal disease occur in a defined community or organization over three months or less and result in an attack rate of greater than 10 cases per 100,000 population (about 20 times greater than endemic rate of serogroup C disease in the United States), mass vaccination of the affected population should be considered.³⁷

College freshmen, particularly those living in dormitories or residence halls, are at modestly increased risk for meningococcal disease compared with persons of the same age who are not attending college. Therefore, it is recommended that students and their parents are educated about the risk for disease and about the vaccine so they can make individualized, informed decisions regarding vaccination.³⁸

Routine vaccination with the tetravalent vaccine is recommended for certain high-risk groups, including persons who have terminal complement component deficiencies and those who have anatomic or functional asplenia. Research, industrial, and clinical laboratory personnel who are exposed routinely to *N. meningitidis* in solutions that may be aerosolized also should be considered for vaccination.³⁹

A serogroup A/C (bivalent) meningococcal polysaccharide vaccine is licensed in Europe and is used for control of outbreaks in other parts of the world, including epidemic meningococcal meningitis in African meningitis belt countries, where reactive mass vaccination campaigns with the vaccine are conducted following WHO recommendations.³⁹ In 2003, a serogroup A/C/W-135 (trivalent) meningococcal polysaccharide vaccine was also licensed for use in Africa, to respond to the potential emergence of serogroup W-135 meningococcal disease epidemics in that Region.³⁹

In the past 10 years, a major effort has been to enhance the immunogenicity and protective efficacy of A and C polysaccharides in infants and young children, methods similar to those used for *Haemophilus influenzae* type b conjugate vaccines have been applied to produce conjugate A and C meningococcal vaccines.⁴⁰⁻⁴² This is protein conjugation of bacterial polysaccharides converting a T-cell-independent immune response onto a T-cell-dependent response, and resulting in increased antibody titers and polysaccharide-specific immunological memory in infants and young children.

Serogroup C polysaccharide conjugate vaccines are already licensed for use in infants and children in Europe and Canada. Studies in the UK have reported that these vaccines are safe and immunogenic in infants and children, and can decrease transmission, thus protecting unvaccinated individuals by inducing herd immunity. In 2000, after introduction of the vaccine in the UK, the vaccine was shown to be highly efficacious and resulted in a dramatic decline in the number of serogroup C meningococcal disease cases.⁴³ The vaccine also reduced carriage of serogroup C meningococci and induced herd immunity.⁴⁴

The meningococcal serogroup C conjugate vaccine program in the UK has successfully controlled the incidence of serogroup C meningococcal disease. However, recent data suggest that duration of protection may be short among young infants vaccinated at 2, 3, and 4 months through routine immunization programs; however, vaccine effectiveness remained high in children aged 5 months to 18 years. A booster dose or a different schedule may solve the challenge of waning immunity in infants, but these findings continue to raise concerns about whether immunological memory is sufficient to provide long-term protection.⁴⁵ Since 2006, the UK has incorporated a

booster dose of Men C conjugate combined with a Hib conjugate vaccine (Hib Men C conjugate). Surveillance is ongoing to monitor disease trends.

A serogroup A/C/Y/W-135 (tetravalent) meningococcal conjugate vaccine has recently been licensed in the U.S. since January 2005 for persons between the ages of 11 years and 55 years based on safety and immunogenicity, and⁴⁶ CDC's Advisory Committee on Immunization Practices (ACIP) made a recommendation is for its use in May 2005.^{45a} This vaccine and other similar vaccines with different formulations and combination of antigens such as the Hib Men C conjugate vaccine currently used in the UK, have been or may be licensed for use among young children in subsequent years.

Because the serogroup B capsular polysaccharide is poorly immunogenic in humans, vaccine development for serogroup B meningococci have focused on other common proteins, including the outer membrane proteins (OMP) of specific epidemic strains. OMP vaccines have shown good efficacy in older children and adults, but

efficacy in young children, in whom rates of disease are highest, has not been shown.⁴⁷⁻⁵⁰ In addition, the variability in OMP strains causing endemic disease will likely limit their usefulness in the United States.⁵¹

Because of the potential limitations of these vaccines, other new approaches to serogroup B vaccines are being pursued including the conjugation of a modified serogroup B polysaccharide (after substitution of the *N*-acetyl group with a *N*-propionyl group) to a recombinant serogroup B meningococcal porin protein. While this vaccine is immunogenic in mice and nonhuman primates, there is concern that the vaccine may not be safe.⁵² In addition, with the recent sequencing of the serogroup B meningococcal genome, several new genes and encoding putative membrane proteins have been identified suggesting potential new targets for serogroup B vaccines.⁵³⁻⁵⁴ The availability of new meningococcal conjugate vaccines as well as the pursuit of new vaccine strategies should lead to substantial improvements in control and prevention of meningococcal disease in both the United States and globally.

Tuberculosis

Douglas B. Hornick

Tuberculosis (TB) has been an affliction of humankind since before recorded history. TB inspired writers such as John Bunyan to aptly describe this deadly and mysterious disease in 1660 as "the captain of all these men of death that came against him to take him away, was the consumption for it was that brought him down to the grave."¹ As with classic works of literature, tuberculosis endures. In spite of the much heralded medicinal cures developed in the 1940s and 1950s, tuberculosis still devastates populations throughout the world. Aspects of the pathogenesis of this disease remain shrouded in mystery. Even more disturbing, *Mycobacterium tuberculosis*, the agent of TB, has become increasingly resistant to antimycobacterial medications, and travels with and has been especially virulent among those suffering from acquired immunodeficiency syndrome (AIDS). These trends keep tuberculosis at the forefront among the deadly infections of humankind.

The Microbiology of *M. tuberculosis*

M. tuberculosis is classified within the *M. tuberculosis* complex. Closely related members of the *M. tuberculosis* complex are *Mycobacterium bovis*, and two very uncommon species *Mycobacterium microti* and *Mycobacterium africanum*.² *M. tuberculosis* and *M. bovis* along with *Mycobacterium leprae* cause communicable disease, which sets these species apart from the more than 50 other species of *Mycobacteria*, which are referred to as nontuberculous mycobacteria (NTM).

M. tuberculosis organisms exhibit a bacillary morphology and produce an impervious waxy cell wall. The cell wall, composed mostly of a beta-hydroxy fatty acid, mycolic acid, excludes most antimicrobial agents and is resistant to alkali and acid. The latter property is taken advantage of by the acid-fast stains (e.g., Ziehl-Neelsen, Kinyoun, fluorochrome). *M. tuberculosis* organisms can be killed relatively easily by ultraviolet (UV) light at 254-nm wavelength, sunlight, heat, and specific disinfectants such as tricresol and phenol. Modern molecular techniques applied to *M. tuberculosis* have resulted in sequencing and annotation of entire genome, comprising about 4000 genes, and allow many labs to routinely take advantage, for strain identification, of the unique restriction digest patterns created by the GC-rich repetitive sequences and major polymorphic tandem repeats that account for 10% of the genomic DNA while not yet knowing these genes function.³

Mycobacteria divide every 18–24 hours compared to every 1–2 hours for most other bacterial pathogens. Mycobacteria have traditionally been cultured on egg-potato-based solid media, Lowenstein-Jensen (L-J) slants, or Middlebrook 7H10 or 7H11 agar-based solid media. Following a 3- to 4-week incubation, an array of biochemical tests and additional growth on artificial media have been necessary traditionally to distinguish *M. tuberculosis* from the other multiple species of mycobacteria.² Final identification by these methods accounts for the 6–8 week delay in diagnosis, historically. Modern laboratory techniques that shorten the time to identification are described later.

Antimycobacterial Resistance. Mutations producing resistance to the first-line medications such as isoniazid (INH) and rifampin occur spontaneously. Genetic data have shown that at least two mechanisms account for INH resistance: deletion of *katG*, the gene encoding for catalase or mutation in *inhA*, a gene involved in the synthesis of mycolic acid.^{4,5} Rifampin resistance results from mutations within the *ropB* gene which encodes for β subunit of RNA polymerase.⁶

The probability of spontaneous resistance is estimated at 10^{-6} for isoniazid and 10^{-8} for rifampin, and the probabilities for resistance to the other first-line medications fall within the same range.⁷ The occurrence of these mutations is an unlinked phenomenon, so the probability that a single organism will be resistant to both INH and rifampin is the product of the probability of each mutation or 10^{-14} . The estimated burden of organisms in a patient varies as follows: 10^3 bacteria for a latent infection, 10^4 – 10^5 bacteria per gram of tissue for non-cavitary pulmonary disease, and 10^9 – 10^{11} organisms per gram of tissue for cavitary pulmonary disease. The use of INH alone in a patient with latent TB infection is not believed to risk selection of resistant strains. The use of INH alone in a patient with cavitary pulmonary disease, however, allows spontaneously resistant strains to grow selectively. Resistance to multiple medications can develop with time if other antimycobacterial medications are added sequentially. Resistance that develops in this fashion is defined as *acquired* (or *secondary*) *drug resistance*.

Primary drug resistance is drug resistance discovered in an isolate from a patient who has not previously received antituberculous

medications. Primary resistance usually is found in patients who have been infected by transmission from another individual with drug-resistant TB. *M. tuberculosis* isolates that exhibit simultaneous resistance to at least INH and rifampin are referred to as *multidrug-resistant tuberculosis* (MDR-TB).^{8,9} The rationale for this specific definition is that treatment outcomes are compromised significantly when the two most potent first-line medications, INH and rifampin, are ineffective. Unfortunately, the new millennium has brought an even more ominous strain, the *extensively drug-resistant tuberculosis* (XDR-TB). These organisms are not only resistant to INH and rifampin, but at least three out of six main classes of the second-line antimycobacterial drugs (fluoroquinolones, aminoglycosides, cycloserine, para-aminosalicylic acid, polypeptides, thioamides).¹⁰

Pathogenesis and Transmission of *M. tuberculosis*

M. tuberculosis infects the human host following inhalation of small infectious particles called *droplet nuclei*.^{11,12} At least three possible consequences result if the organisms are not killed and cleared immediately: progressive development of active infection (*primary TB*), *latent tuberculosis infection* (LTBI) that persists throughout the life of the host, or disease that activates many months or years after the initial infection (*reactivation TB*).

Infectious droplet nuclei measure approximately 1–5 µm in diameter, deposit in the terminal bronchioles and alveoli of the host, and theoretically may contain as few as one viable organism. The bacteria may multiply briefly at the site of deposition but eventually are ingested by pulmonary macrophages. Following phagocytosis, *M. tuberculosis* inhibits phagolysosomal fusion, allowing the organism to survive and multiply intracellularly within lysosomes.¹³

The infected macrophages then initiate the cellular immune response that in most individuals eventually contains the infection. During this initial phase of infection and multiplication, the inflammatory response can be of sufficient intensity to cause a localized pneumonitis. In general, the host is asymptomatic or minimally symptomatic. During this phase, also, the organisms are carried into the regional lymphatics, then into the hilar and mediastinal lymph nodes.¹⁴ Lymphohematogenous dissemination occurs with deposition of the bacteria at multiple extrapulmonary sites, where further multiplication can continue. During dissemination, specific-cell-mediated immunity matures and further multiplication and dissemination of the organism is halted in the majority of healthy individuals. Subsequently the infection remains contained or latent.¹⁵ The immune response produces granulomas known as *tubercles* with characteristic caseous necrosis seen microscopically within the lung, mediastinal lymph nodes, and other tissues. When the cell-mediated immune response is overwhelmed (approximately 5% of all infected individuals), rapidly progressive infection or primary TB results. Human immunodeficiency virus (HIV) infected patients, due to impaired cellular immunity, are very likely, compared to normal hosts, to develop primary TB after exposure.

Reactivation TB (approximately 5% of all infected individuals) results when previously contained organisms begin uncontrolled proliferation. This may occur in the non-immunosuppressed host within approximately two years of the initial infection, accounting for roughly half of the cases of reactivation TB. The other half arises after two years, spontaneously in some and in others when cell-mediated immunity is compromised, during the remaining years of life.

The cell-mediated immune response takes approximately 4–8 weeks to mature in the naive host,¹⁶ and it is manifested in the human host by the *Tuberculin Skin Test* (TST) response. The response results from an intradermal injection of *tuberculin*, a purified protein derivative of *M. tuberculosis* culture extract.

Factors listed in Table 12-9 consist of disease states that weaken cell-mediated immunity, and situations that reflect an increased burden of latent organisms and result in more risk for active tuberculosis.¹⁷ The rate of progression among HIV patients is 8–10% annually, much higher compared with all others hosts.^{18,19} HIV coinfection

TABLE 12-9. RISK FACTORS FOR DEVELOPING ACTIVE TB FROM LATENT TB INFECTION

HIV or AIDS
One or more of the following medical conditions:
Intravenous drug users that are HIV negative
Diabetes mellitus
Silicosis
Renal failure and those on chronic hemodialysis
Immunosuppressive therapy:
Steroids (>15 mg/day for >1 month)
TNF antagonist treatment
Chemotherapy
Hematologic malignancy (e.g., leukemia, Hodgkin's disease)
Head and neck malignancy
Chronic malabsorption syndrome or body weight 10% below ideal
Intestinal bypass or gastrectomy
TB infection documented in the previous 2 years
Healed prior pulmonary TB
History of active TB in the past, but treatment incomplete or inadequate

increases the risk of progression by greater than 100-fold.²⁰ Recent data have shown that selective immunosuppressant agents, TNF antagonist therapies (e.g., infliximab, etanercept) increase the risk of reactivation TB by a rate yet to be determined.^{21,22} The other factors listed increase risk for progression to active disease between 3- and 7-fold.^{23,24}

Transmission of Tuberculosis. Transmission of tuberculosis to other human hosts is strictly via droplet nuclei. *M. tuberculosis* within secretions or droplet nuclei that have deposited on a surface lose the potential for infection. Patients with pulmonary or laryngeal TB produce infectious droplet nuclei.^{25,26} Those with extrapulmonary tuberculosis do not, unless the site of TB infection is manipulated in such a way that an aerosol is generated (e.g., wound irrigation, autopsy). Data from the Centers for Disease Control and Prevention (CDC) show that approximately 21–23% of individuals in close contact to patients with infectious tuberculosis become infected. Transmission of infection to another human host is generally a function of the concentration of infectious droplet nuclei, duration of contact with the infectious case, and the susceptibility of the host exposed.

Classic experiments attempting to quantify TB transmission and identifying key factors in droplet nuclei concentration were done in the late 1950s and early 1960s by Riley and investigators in the Baltimore City veterans hospital.¹² In these studies, air from a room containing patients with active pulmonary tuberculosis was diverted to either a UV light chamber, then a control group of guinea pigs, or directly past a test group of guinea pigs. By monitoring the rate of guinea pig infections and the volume of air circulated over the study period, the average concentration of infectious units was calculated at approximately 1 per 15,000–20,000 cubic feet of air. If an adult person inhales approximately 18 cubic feet of air per hour, the probability of infection for an hour of exposure would be approximately 1 in 800 to 1000, which is comparable to risk data from other studies examining nosocomial tuberculosis transmission. The guinea pig investigations also demonstrated significant variation in the concentration of infectious units or droplet nuclei.²⁷ The variation depended upon clinical characteristics of TB in the source patient (e.g., cavitary vs. non-cavitary lung disease). In addition, transmission dropped rapidly after the source patient was started on antimycobacterial treatment.

Factors affecting transmission can be related to the source case, the environment, the recipient host and/or the organism. Most source cases with active pulmonary disease produce droplet nuclei within aerosols produced by coughing, sneezing, or speaking. The behavior of the infectious patient also affects the concentration of droplet

nuclei released. When a patient with active pulmonary disease cooperates by covering their nose and mouth when coughing or sneezing, or by wearing an ordinary surgical mask, the large droplets with the potential to form infectious droplet nuclei are captured and inactivated.²⁵ The effect as a physical barrier rather than the filtration properties is what is important with such techniques. In addition, cavity disease increases the probability of infection among contacts because of the large number of organisms in the sputum from these patients. A study from Finland even suggested that the probability of active tuberculosis was also higher among contacts of patients who produced sputum smears that contained a high number of organisms.²⁸ At the other end of the spectrum, patients who produce a low concentration of organisms in sputum, those who are smear-negative, but culture-positive, are the least likely to transmit infection, yet transmission does occur at low levels.²⁹

Environmental factors also affect the concentration of droplet nuclei in the air.²⁵ The volume of air common to the source and the recipient host is one such factor. The smaller the room, the more concentrated the droplet nuclei. The amount of outside air ventilated into a room is another factor, since fresh air will dilute the number of droplet nuclei. Modern buildings are engineered for air recirculation. The closed heating and air conditioning systems increase the concentration of droplet nuclei since not much outside air is introduced into such a system. Engineering controls that reduce contamination include passage of recirculated air across a UV light source or across high-efficiency particulate air (HEPA) filters.

Duration of exposure and immune status of the recipient host (also referred to as a *close contact*) of an infectious case also affect the probability of transmission. The longer the duration of exposure, the greater the probability the close contact will inhale a critical number of droplet nuclei and exceed the threshold for infection. Naive hosts who are immunosuppressed or at the extremes of age (under 5 or over 65) are more likely to become infected when they are in close contact with a patient with a positive sputum smear. In contrast, close contacts who have been infected previously, demonstrable by a positive TST, are unlikely to be reinfected as long as immune and health status is intact.^{30,31} However, reinfection has been documented for non-immunosuppressed individuals where TB prevalence is high.³²

Recent studies from New York City using DNA fingerprinting methodology to precisely track the *M. tuberculosis* isolates have shown that TB strain-specific characteristics related to transmissibility remain incompletely understood.³³

Clinical Aspects of Tuberculosis

Active TB must be suspected in specific clinical settings. The confirmation of active TB relies on the acquisition of sputum or infected tissue followed by identification of the organism. The promise of new and faster diagnostic tests, however, is more tangible now than in years past.

Characteristics of Patients with Tuberculosis. The majority of primary infections (approximately 90%) result in healing and granuloma formation. The organism then becomes dormant and the infection remains latent. Individuals with latent tuberculosis infection (LTBI) are completely asymptomatic and are only detected by a positive TST. These individuals cannot transmit tuberculosis to others and represent the most prevalent form of tuberculosis.

Active tuberculosis in the non-immunocompromised host is frequently infectious because it presents as a pulmonary infection in 85% of the cases. Symptoms are insidious in onset and develop over several weeks or months. The typical pulmonary symptoms are a productive cough of small or scant amounts of a non-purulent sputum, hemoptysis, and vague chest discomfort. Patients also have systemic symptoms such as chills, night sweats, fever, easy fatigue, loss of appetite, and/or weight loss. A physical examination of patients with active pulmonary tuberculosis usually contributes little to the diagnosis of tuberculosis.

Patients with active tuberculosis and HIV or AIDS coinfection present differently than the non-immunosuppressed patient. Atypical chest findings or extrapulmonary disease are far more common in HIV hosts. Extrapulmonary disease can occur in up to 70% of patients.³⁴ The probability of an atypical presentation increases as the CD4+ T-cell count falls. Sputum samples and TST also are less reliable adjuncts to diagnosis. The reaction to the TST is often blunted and as many as 40% of HIV patients with active TB will not react to the TST.³⁵ One study showed that 100% of AIDS patients with CD4+ T-cell counts below 100 and active TB had a negative TST.³⁶ Furthermore, histologic samples from patients infected with TB may not demonstrate a mature granuloma. In general, specific diagnosis of tuberculosis in patients with AIDS often requires a high index of suspicion, a comprehensive search for site of infection, and biopsy to demonstrate and identify the organisms in the tissue site.

Culture of Clinical Specimens. Developments in culture techniques and DNA technology have cut the time for culture and identification down to approximately 2–3 weeks. Currently, clinical mycobacteriology labs utilize as selective liquid media, Middlebrook 7H12, which facilitates rapid growth. The media contains a growth detection marker (e.g., fluorescence, radiometric) for automated detection of the growth index. The growth index is monitored and at a well-defined threshold, usually achieved within 14–20 days, enough DNA can be harvested from the cultured organisms for hybridization with a DNA probe for *M. tuberculosis* complex. Antibiotic susceptibilities for the first-line medications have been adapted to this rapid culture process so that notification of resistant isolates can be available in as little as 5 additional days.

Sputum Examination. The standard sputum acid-fast smear is less sensitive and not specific compared to culture for detecting *M. tuberculosis*. To detect organisms in a sputum smear, the concentration needs to exceed approximately 10,000 organisms/mL.^{37,38} Only 50–80% of patients with active pulmonary TB will have a positive acid-fast smear. Acid-fast smears also cannot distinguish *M. tuberculosis* from acid-fast staining NTM.

The latest technology for interpreting sputum smears use nucleic acid amplification (NAA) techniques, which are becoming less cost prohibitive and more generally available. These techniques are applied directly to sputum smears and improve the specificity and sensitivity. The Food and Drug Administration (FDA) has approved two commercial NAA kits: *M. tuberculosis* direct test (MTD) (Gen-Probe, San Diego, Ca) and Amplicor TB test (Roche Diagnostic Systems, Inc, Branchburg, NJ). The MTD test uses transcription mediated amplification of ribosomal RNA followed by hybridization with a specific *M. tuberculosis* probe. This test has been approved for smears of respiratory specimens when acid-fast bacilli are not detectable by microscopic examination. The Amplicor TB test is only approved for acid-fast bacilli smear positive specimens. These techniques enhance the diagnostic value of the sputum smear, by improving sensitivity (MTD test), providing immediate *M. tuberculosis* confirmation, and impacting treatment decisions (*M. tuberculosis* vs. NTM).^{39,40}

Chest Radiography. The chest x-ray in active pulmonary tuberculosis typically demonstrates infiltrates within the apical and/or posterior segments, and often the infiltrates contain variably sized cavities. In immunocompromised and particularly HIV patients, the chest x-ray may be normal, exhibit only hilar or mediastinal adenopathy or infiltrates in any lung zone. Also, cavities within infiltrates are uncommon.

The Tuberculin Skin Test. The Mantoux or standard TST requires intradermal injection of 5 tuberculin units (TU). The test identifies persons infected by *M. tuberculosis* that have developed the specific cellular immune response. Infected individuals will develop induration at the site of injection at 48–72 hours. The diameter of induration is measured to determine whether the test is positive or negative. The

modern classification of a positive Mantoux tuberculin skin test depends upon the pretest probability that the person was infected with *M. tuberculosis*.^{17,41}

False-positive reactions rarely arise from subclinical infection by other similar organisms such as NTM, which express antigens that cross-react with *M. tuberculosis*. False-positive results have the greatest impact in populations with a low incidence of tuberculosis. For persons living in regions of low tuberculosis incidence, such as those in rural parts of the United States, a higher cut point set at 15 mm of induration minimizes the possibility of a false-positive test misidentifying someone as having tuberculosis.

The established cut point is at 5 mm of induration for those persons with a high probability of being infected, who may also exhibit an attenuated cellular immune response. HIV-infected persons, close contacts of an active case of tuberculosis, and individuals with a chest x-ray compatible with old or healed tuberculosis lesions are those in which the smaller reaction is still considered positive.

The standard cut point of 10 mm of induration effectively identifies all other patient populations where the incidence of TB is significant. These groups include foreign-born persons (Africa, Asia, Pacific Islands, Eastern Europe, and Central and South America), medically underserved and low-income populations, intravenous drug abusers, residents of long-term care facilities, and individuals with medical conditions (other than HIV) known to increase the risk of TB (Table 12-9).

Pitfalls in TST Interpretation. The *booster phenomenon* should be considered when screening congregate populations, particularly those containing a significant proportion of elderly people. A person infected in the distant past may exhibit an insignificant skin test reaction, because the cellular immune response to *M. tuberculosis* wanes with time. Within a week, however, a boosted reaction can be seen upon placing a second TST. The first TST induces a recall of the immune response so that the second test should be classified as a true-positive result. The boosted response can last up to a year, so that it potentially can be confused with a TST conversion. Therefore, two tests separated by 1–2 weeks, or *two-step* testing, is recommended for screening populations that contain a significant number of persons infected in the distant past (e.g., at a long-term care facility).²⁵

TB vaccination (bacillus Calmette-Guérin [BCG]) is used in many parts of the world and may confound the interpretation of the TST reaction when screening foreign-born populations for tuberculosis infections. Prior BCG vaccination can induce a TST reaction ranging from 0 mm to 19 mm of induration. A larger reaction cannot be used reliably to differentiate those also infected with *M. tuberculosis*.⁴² Recent data indicate that a positive TST remains the best tool for finding those infected by *M. tuberculosis* among individuals who were previously vaccinated and have immigrated from parts of the world where TB is prevalent. Thus, the CDC recommends that a significant skin test reaction be considered indicative of *M. tuberculosis* infection in an individual from a high TB prevalence area regardless of whether they were previously vaccinated with BCG.^{17,43}

Blood Analysis for M. tuberculosis (BAMT). BAMT kits assay interferon- γ release from sensitized blood monocytes and are used increasingly instead of the TST for detecting LTBI. In the United States, the QuantiFERON TB Gold (QFT-G; Cellestis LTD, Carnegie, Australia) kit, approved by FDA May 2005, measures the concentration of interferon- γ released from blood monocytes after exposure to an antigen specific for *M. tuberculosis* and not expressed by either NTM or BCG organisms. Data comparing the QFT-G to the TST show several advantages: reduced false-positive rates, no booster effect, and a result after only one visit. The limitations of the QFT-G kit are not insurmountable, but include: requirement that the blood be processed within 12 hours, higher cost and incomplete long-term and multiple population data.⁴⁴

Genotyping M. tuberculosis isolates. Advancing molecular biology technology introduced genotyping strains originally to enhance

epidemiologic research,^{45,46} but the techniques have transferred to routine use for understanding more precisely the transmission dynamics in outbreaks. Restriction fragment length polymorphism (RFLP) analysis of the insertion sequence IS6110 produces a unique fingerprint and is the basic method of genotyping strains.⁴⁷ The CDC has established the National TB Genotyping and Surveillance Network which has the capacity for genotyping all isolates from culture positive cases.⁴⁸ Furthermore, the CDC has committed recently to supplement the IS6110-based RFLP analysis with newer, more rapid, and discriminatory methods using two polymerase chain reaction-based tests, spoligotyping, and mycobacterial interspersed repetitive units analysis, for selected cases.⁴⁹

Reporting a Verified Case of Tuberculosis. Every active tuberculosis case and associated epidemiological data must be reported to the local or state health department as part of ongoing public health surveillance. National results are reported annually by the CDC. Specific criteria have been established to generate a valid report of a verified case of tuberculosis (RVCT).^{50,51} Case definition for an RVCT relies on laboratory and clinical criteria. The laboratory criteria for diagnosis of *M. tuberculosis* require any of the following: isolation by culture followed by DNA probe, demonstration by NAA test, or acid-fast bacilli on smear when a culture has not been or cannot be obtained. In the absence of laboratory data, a valid case must meet the following clinical criteria: (a) a positive TST, (b) signs and symptoms compatible with active TB (e.g., clinical evidence of active disease, changing chest x-ray), (c) treatment with two or more antituberculous medications, and (d) completed diagnostic evaluation.

Treatment of Tuberculosis

Treatment of tuberculosis requires distinguishing patients with active TB from those with a LTBI. The current approach to treatment of active TB reflects the emphasis on ensuring adherence to treatment to head off the development of secondary resistance. The updated recommendations for LTBI screening and treatment focus on patients most likely infected and/or at higher risk for developing active TB. In the United States, detailed diagnosis and treatment guidelines can be found in consensus documents which are regularly updated and provide ratings for the quality of evidence supporting recommendations.^{52,53}

Treatment of Active Tuberculosis. The basic principles of therapy are to provide a safe, cost-effective medication regimen in the shortest period of time. The initiation phase of treatment involves use of multiple drugs to rapidly reduce the number of viable organisms. Additionally, steps are taken to ensure adherence to treatment.

To treat pulmonary and most forms of extrapulmonary tuberculosis in non-immunosuppressed patients as well as those coinfecting with HIV, four first-line medications are used during the first two months: isoniazid, rifampin, pyrazinamide, and ethambutol.⁵² Ethambutol may be stopped before the end of the initial two-month phase if microbiology data indicate that the organism is susceptible to all first-line medications. Following the multidrug initial phase, INH and rifampin are given for an additional 4 months. This four-medication regimen has been shown to be highly effective. CDC data for the United States indicate that 95% of patients treated by this regimen will receive at least two drugs to which the infecting organism is susceptible. Also, patients who default before completing this regimen are more likely to be cured than those receiving fewer medications at the onset.

The duration of airborne infection isolation for a patient who has started on treatment remains a contentious issue. It is known from the guinea pig studies cited earlier that once treatment is started the risk of transmission of infection rapidly diminishes, and by approximately two weeks of effective treatment, the risk approaches zero.²⁷ The sputum smear and culture from patients on therapy, however, may remain positive well beyond two weeks. For example, in the study by Cohn et al,⁵⁴ which achieved a 98.4% cure rate, the median time to culture negativity was 4.6 weeks, and 25% of the

patients had sputum samples still culture positive at eight weeks. The persistently positive sputum often raises concern for continued contagion. Practical recommendations for certifying an outpatient low risk for contagion are as follows: documented adherence to recommended multidrug TB therapy for 2–3 weeks, low risk for MDRTB, and evidence for clinical improvement (eg, less cough, reduced organism load in sputum smear). More conservative recommendations are suggested for patients within a health-care setting. One would require the above criteria, but rather than release isolation upon demonstration of reduced organism load on sputum smear, continue airborne infection isolation until three consecutive sputum samples (8–24 hours apart and at least one early morning sample) are negative for acid-fast bacilli.⁵⁵

Most patients with active tuberculosis are not severely ill, and treatment can be initiated safely in the outpatient setting. Temporary hospitalization for isolation of an active pulmonary case may be necessary while treatment is initiated, if household members include highly susceptible contacts such as HIV-positive individuals or children less than five years of age. Miliary tuberculosis and tuberculous meningitis are examples of serious extrapulmonary TB that require inpatient management. Enforcement of adherence for a patient who has been repeatedly nonadherent with treatment as an outpatient is another reason to use the inpatient setting for treatment.

INH-resistant bacteria can be treated successfully with the four-medication regimen noted above.^{52,54,56} MDRTB strains, however, pose a more complicated treatment problem. The treatment is generally extended much longer than six months. At least three medications to which the organism is susceptible need to be provided. Often second-line medications are required, which are generally less effective and carry a higher side effect and intolerance profile.

Treatment Adherence Issues for Patients with Active TB. Adherence to therapy is essential to ensure a successful outcome and to prevent the development of resistance. Nonadherence to tuberculosis therapy is common with self-administered regimens. Approximately 25% of patients with active tuberculosis fail to complete the six-month standard regimen by 12 months. In homeless and substance-abusing patients, the number approaches 90%.⁵⁷ In addition, the ability of physicians to predict nonadherence is generally poor.⁵⁸ A study in a tuberculosis clinic showed that only 68% of all patients nonadherent to therapy were identified.

Physicians can improve upon their ability to anticipate nonadherence through continuing education that teaches them the most reliable predictors. A history of poor adherence to therapy, for example, has been shown to be among the best predictors. Other predictive factors include homelessness, substance abuse, emotional disturbance, and lack of family and social support.⁵⁹ Cultural factors also influence adherence to tuberculosis therapy. For example, Hispanic patients with active TB risk rejection by their families.

The current approach to tuberculosis treatment incorporates supervised or directly observed therapy (DOT) to improve patient adherence. The advantages of DOT have been proven in several studies. A prospective study in Tarrant County, Texas, demonstrated that DOT, compared to standard self-administered therapy, decreased relapse rates and decreased incidence of drug-resistant strains of *M. tuberculosis*.⁶⁰ In New York City, prior to introducing a DOT program, a dismal 35% of the patients returned for follow-up appointments, with an overall 11% adherence to therapy. After a DOT program was introduced, 88% of patients were adherent to treatment and all sterilized their sputum. Relapses became rare and occurred only in those with primary drug resistance.⁶¹ Data such as these have led to strong recommendations that DOT be the core management strategy for all patients with active pulmonary tuberculosis.^{41,52}

Treatment of Latent Tuberculosis Infection. Approximately 10% of patients with LTBI progress to active TB in their lifetime.²³ U.S. evidence-based consensus guidelines recommend targeted TB skin testing for individuals at risk for reactivation TB and populations in whom active TB is prevalent.⁵³ These individuals form the reservoir

from which new cases of active TB arise and treatment reduces the rate of active TB cases within these populations. INH daily for 6–9 months is 65–80% effective in treating a non-immunosuppressed individual with LTBI.^{17,62} INH treatment in an HIV patient with LTBI reduces the risk of developing active TB from 4.7 to 1.6 cases per 100 patient-years.⁶³ An equally efficacious and more convenient two-month regimen for LTBI, consisting of rifampin and pyrazinamide, is no longer recommended due to an unanticipated high rate of fatal and severe liver toxicity.⁶⁴

The targeted skin testing paradigm focuses public health efforts on those who benefit from treatment and reduces waste of valuable resources on groups at low or no risk for reactivation TB. The highest priority group targeted for TST screening are the following: HIV patients, patients whose HIV status is unknown but suspected, IV drug abusers who are HIV negative, close contacts of a newly diagnosed person with tuberculosis, persons exhibiting recent tuberculosis skin test conversion from negative to positive (less than two years), persons with old fibrotic lesions on chest x-ray consistent with prior pulmonary TB, and persons with certain non-HIV medical conditions that are known to increase the risk for developing active tuberculosis (Table 12-9).⁵³ A recent review of all published data quantified more precisely lifetime risk for reactivation TB among persons with a positive TST. Individuals with either HIV infection or evidence of old healed TB on chest x-ray were the highest risk populations, each more than 20%. Population groups within a 10–20% lifetime risk included the following: those recently infected (less than two years), those receiving tumor necrosis factor antagonist treatment and under 35 years old with a TST more than 15 mm, and those under five years old and demonstrating a TST more than 5 mm.⁶⁵

Also targeted for TST screening and treatment are individuals in whom TB is more prevalent: immigrants to the United States from high TB prevalence countries, medically underserved individuals, residents of long-term care facilities, and staff of schools and correctional, health, and child care facilities.⁵³

Recent estimates for the general risk of hepatitis from INH treatment vary between 0.1% and 0.15%, which is lower than previous data indicated.⁵³ A U.S. public health department seven-year study involving 11,141 patients receiving INH in which nurses performed monthly symptom surveys and intervention revealed only 11 cases of clinical hepatitis, one of which required hospitalization and none resulted in death.⁶⁶ In general, the risk of INH hepatotoxicity increases in the following clinical situations: age greater than 60 years, preexisting liver disease, pregnancy plus early postpartum period, and heavy alcohol consumption.⁵³

Efficacy of the BCG Vaccine. An *M. bovis* strain was continuously subcultured by Calmette and Guérin from 1908 to 1922 to produce the live attenuated strain named for them, bacillus Calmette-Guérin (BCG). BCG has been used as the basis for the live attenuated vaccine against tuberculosis since 1922. BCG vaccine remains the best available TB vaccine today and is used in many parts of the world.

Assessment of efficacy of the BCG vaccine has been clouded by multiple variables, which include the variability of BCG strains from which vaccines have been prepared, method and route of administration, characteristics of populations studied, and endpoints selected. Two recent meta-analyses of best studies dating back to 1950 indicate that the vaccine's efficacy is more than 80% in preventing TB meningitis and miliary TB in children.^{67,68} These meta-analyses were unable to unravel the disparate data regarding prevention of pulmonary TB in adults. It is likely that the BCG vaccine does not prevent infection in adults, but possibly decreases the probability of reactivation TB. A recent report showing efficacy over a 60-year period among Alaskan natives as well as progress toward improving the BCG vaccine through recombinant technology has boosted enthusiasm for continuing research toward a broader and more effective immunization against TB.^{69–71}

The CDC continues to recommend that the current BCG vaccine be used rarely because of questions surrounding its efficacy, the issues relative to TST interpretation, and the overall low risk for TB exposure in the United States. Infants and young children at high risk

of repeated TB exposure are the main indication for BCG vaccine use in the United States.⁴³

Epidemiology of Tuberculosis

Crowded conditions, poverty, and host susceptibility facilitate the spread of this disease within populations. These situations have evolved over the past millennium and over the past decade, affecting the trends in TB incidence in the United States, the rest of the world, and specific subpopulations.

Tuberculosis Trends Through History. Evidence for tuberculosis in ancient civilizations has come from the remains of ancient Egyptians, early Hindu writings referring to a disease called consumption, and ancient Greek medical literature referring to tuberculosis as phthisis. Also, documentation comes from granulomata found in a 1000-year-old pre-Columbian Peruvian mummy containing DNA compatible with *M. tuberculosis* by nucleic acid amplification studies,⁷² as well as spinal and psoas abscesses, and a lung granuloma containing acid-fast staining bacilli found in another Peruvian mummy dated to 700 AD.⁷³

Initial theories logically speculated that *M. bovis* may have been the evolutionary precursor of *M. tuberculosis*.⁷⁴ *M. bovis* was known to be endemic within bovine and other animal populations before humans evolved. After humans evolved, particularly once cattle were herded and in close contact with humans, *M. bovis* could have been transmitted from animals causing the most ancient forms of human tuberculosis. More recent phylogenetic analysis of genomic deletions in the DNA from *M. tuberculosis* complex strains, however, indicates that *M. tuberculosis* and *M. bovis* evolved separately within human and bovine ancestors long before cattle and humans were in close contact through domestication.^{75,76}

Tuberculosis became widespread after 1600 AD, with the onset of the Industrial Revolution in Europe.^{74,77} Crowded conditions, poor sanitation, and poor nutrition were all features of rapidly expanding cities. Conditions were ideal for transmission of tuberculosis and it became epidemic. At its peak, 100% of western European urban dwellers may have been infected and the mortality rate was extremely high.⁷⁴ Tuberculosis struck predominantly young people. Those that survived to reproductive age are believed to have had a selective advantage. After several generations, a degree of natural immunity and a greater prevalence of chronic infection developed. The higher prevalence of chronic infection, however, facilitated transmission of infection. TB naturally followed the Europeans to the Americas, where the immunologically naive Native Americans were extremely susceptible to tuberculosis upon first exposure. The same can be said for the peoples in the interior of Africa, where the disease arrived with western culture around 1910. Similar transmission to naive populations occurred in New Guinea in 1950 and in the deep Amazon region of South America in the 1970s.⁷⁸

During the twentieth century before the development of effective anti-tuberculosis medications in 1945, TB mortality in the United States and Europe continuously declined, probably in part because of the continued development of natural immunity. In the United States from 1900 to 1945, the number of new cases dropped from 194 to 40 per 100,000.⁷⁹ Improved socioeconomic conditions and public health interventions are other factors that likely contributed to the decline in incidence.⁷⁷ Public health interventions for finding active cases included the widespread use of fluorography, skin testing, and chest x-ray for patients with a positive TST. The patients with active disease were removed from society and placed into sanatoria, which helped break the transmission cycle. Sanitaria-focused care was state-of-the-art for tuberculosis management prior to the development of effective antimycobacterial medications. In the sanatoria, patients received rest and fresh air therapy supplemented by surgical lung collapse and resection. Mortality remained as high as 50%.

Widespread use of effective drug treatment finally reduced TB mortality to nearly zero in the United States during the 1950s through the early 1980s. The decline in incidence of TB disease continued over the same period, but the rate of decline did not change or accelerate.

The most plausible explanation is that socioeconomic conditions and public health measures have had the predominant effect on TB incidence, while treatment improvements have affected mortality rates. It is disconcerting to realize that in many parts of the world over the last decade, the incidence of tuberculosis has risen and antituberculosis drugs are becoming less effective.

Modern Tuberculosis Trends Within the United States. In 1984, the incidence of new cases of tuberculosis had declined to 9.4 per 100,000 and mortality was low at 0.7 per 100,000. Federal funding for TB control was also declining rapidly, and different public health needs had moved to the forefront, diverting money away from TB programs. City and state governments downgraded their TB control and treatment supervision programs. With this decline in attention, there was an unanticipated upswing in TB incidence from 1985 to 1992. Incidence peaked at 10.5 cases per 100,000 population and there were 51,700 excess new cases of tuberculosis.^{35,80} Other factors contributing to the resurgence in tuberculosis, besides the failure of public health system, included the exponential growth in the AIDS epidemic, the development of drug-resistant strains of tuberculosis, the influx of immigrants from countries with high TB prevalence, the increase in homelessness in urban centers, and the increase in substance and drug abuse.

The combination of AIDS and drug-resistant TB made treatment and control of infections more difficult and allowed for more prolonged transmission of infection. The greatest upswing in cases were in geographically restricted, congested urban centers such as New York City, Miami, and San Francisco, where AIDS and drug-resistant tuberculosis were most prevalent.⁸¹ The drug resistance problem in particular was a by-product of the failing public health system (e.g., poor case management, poor patient compliance with treatment), and the importation of drug-resistant *M. tuberculosis* with immigrants.

By 1993, the infusion of money from the U.S. government for TB control programs had increased substantially and was targeted to the urban centers where the most significant outbreaks were occurring. The trend in the incidence of new cases has been downward since. In 2004, the incidence of new cases was down to 4.8 per 100,000.⁸² Success has been due to reduced TB transmission through improved containment of active cases and adherence with prescribed treatment (e.g., widespread DOT). Although the annual U.S. TB rate continues to decrease, the proportion of cases accounted for by foreign-born individuals increases steadily (see section: TB in Foreign-Born Immigrants) and focuses national policy on screening and treating LTBI among high-risk immigrants.⁸²

HIV and Tuberculosis in the United States. HIV impairs cell-mediated immunity and the host's ability to resist tuberculous infection. The resurgence of TB in the United States during 1986–1992 was closely interwoven with the HIV epidemic,^{83,84} which is supported by the following: approximately 57% of the excess cases of tuberculosis were attributable to HIV coinfection;⁸⁵ the AIDS epidemic and the resurgence of TB followed similar time courses, persons in the 25–44 age group exhibited the highest increase in TB and included the majority of AIDS cases;^{86,87} and the geographic distribution of the two epidemics correlated closely on state-by-state analysis as well as within specific urban TB clinics (eg, New York City, Newark, and Miami), where prevalence of HIV among TB cases was approximately 30% and as high as 58%.⁸⁶

Many persons within populations with a high incidence of HIV are independently at high risk for exposure to tuberculosis.^{20,84} For example, many HIV-positive individuals living in urban areas in the eastern United States are more likely to be exposed to others with active TB. Generally, a positive TST in these areas is more likely to represent recent infection.⁶³ In addition, AIDS patients with active tuberculosis will acquire a new infection exogenously, which is uncommon in the nonimmunocompromised host. Investigators monitored the RFLP patterns of *M. tuberculosis* isolates from patients with AIDS and active tuberculosis who were responding poorly to antituberculosis treatment.⁸⁸ The data indicated that relapses (during

or after successful completion of therapy) in a significant proportion of the group were caused by infection with a new *M. tuberculosis* strain. Thus, infectious TB patients who also have AIDS not only require isolation for public health reasons, but also to be protection from others with active TB.

Current data about the HIV status of TB patients in the United States remain incomplete, probably as a result of concerns about confidentiality, reluctance to report HIV status to TB surveillance program staff, and varying interpretation of state and local laws.⁵⁰ The number of TB cases which have been HIV tested has improved from 30% in 1993, when HIV status was added to national TB surveillance database, to 54% in 2004, while the % positive rate has fallen from 15% to 9% in 2004. Among the 25–44 year age group, the HIV testing rate improved to 67% in 2004, while the % positive fell from 29% in 1993 to 16% in 2004.⁸⁹ Consistent with earlier data, a few states and urban areas (New York City, California, Florida, Georgia, and Texas) account for almost 60% of the HIV positive cases.⁵⁰

Effective antiretroviral therapy, essentially restoring normal immune function, has contributed to improved outcomes for TB in HIV patients over the last decade. Restoration of the immune function simultaneous with active TB infection, however, may cause the *immune reconstitution* phenomenon. These patients, due to revitalization of their immune system, will develop high fevers, adenopathy, and advancing pulmonary infiltrates as a result of a marked increase in inflammation within existing TB lesions.⁹⁰ Besides this confusing and paradoxical treatment response, managing antiretroviral along with TB therapy is extremely complex due to many factors such as the necessity for prolonged duration of TB therapy, malabsorption of TB drugs,⁹¹ acquired rifampin resistance,⁹² multiple antiretroviral and TB drug interactions, and high rates of side effects and intolerance. The details for these and other complexities are beyond the scope of this overview and are more extensively summarized elsewhere.⁹³

Despite complexities, the successful treatment of HIV and TB in United States has been realized in many ways. However, troublesome HIV/TB coinfection trends remain in developing countries of the world (see Global Tuberculosis below).

U.S. Data for Drug-Resistant Tuberculosis (Including MDR- and XDR-TB). The threat of drug-resistant tuberculosis arose during the 1990s, and most serious was the emergence of MDR-TB isolates, demonstrating resistance at least to INH and rifampin. Treatment of such cases relies on selecting at least two additional drugs from six main classes of second-line drugs (aminoglycosides, polypeptides, fluoroquinolones, thioamides, cycloserine, and para-aminosalicylic acid), which are less effective, more costly, and toxic. Recently, reports have emerged describing cases of greater threat than MDR-TB, XDR-TB, cases which exhibit not only resistance to INH and rifampin, but also to at least three of the six classes of second-line drugs.¹⁰

Theoretical explanations for how drug resistance develops (see earlier text) have been borne out in epidemiologic data. Patients with cavitory pulmonary TB were four-fold more likely to exhibit resistant isolates compared to those with non-cavitory disease. Also, among *M. tuberculosis* isolates from patients who relapsed after previous treatment, resistance was demonstrated 4.7 times more frequently compared to those with no history of prior treatment. The combination of cavitory disease and prior treatment produced a risk of resistance that was additive.⁹⁴ Errors in prescribing treatment are a too frequent reason for development of drug resistance.⁹⁵ Inappropriate use of monotherapy for active TB, failure to provide an adequate medication regimen at time of TB diagnosis, failure to ensure adherence to treatment, and failure to recognize and treat medication failure are the typical prescribing errors. Patient errors such as taking partial doses or only some of the drugs prescribed are also a significant factor when treatment occurs without supervision.⁹⁶

The greatest and most concerning concentrations of drug-resistant cases have been found in urban populations, particularly New York City and in California. In 1991, the CDC national survey

revealed that single drug resistance was at 14.2% and two or more drug resistance was at 6%. More disturbing was the rapidly emergent trend for MDR-TB, present in 3.5% of all cases surveyed.⁹⁷ The New York City region accounted for 63% of these MDR-TB cases, while only 1% of the other counties surveyed reported MDR-TB. The New York City TB Control Bureau reported in 1991 that 26% of *M. tuberculosis* isolates exhibited resistance to INH and 19% exhibited multidrug resistance.⁹⁸ Subsequent aggressive efforts to ensure appropriate treatment, compliance, and effective isolation of infectious TB cases led to reduced rates of resistant *M. tuberculosis* strains.⁹⁹ Yet in New York City, reports of outbreaks of cases infected by a particularly resistant MDR-TB, strain W (resistant to INH, rifampin, ethambutol, streptomycin and several second-line drugs) persisted throughout the 1990s.^{100,101} In 2004, however, U.S. rates for MDR-TB remained low at 1%, while New York City reported its lowest rate (2%), and California reported the largest total number of MDR-TB cases at a stable rate of 1.4%, largely attributable to foreign-born immigrants.^{50,102,103} Management of MDR-TB cases remains difficult, costly, and more likely to be fatal, making close surveillance and aggressive containment an ongoing focus.⁸²

Recent data from a survey of isolates gathered from 2000 to 2004 at a worldwide laboratory network suggests that XDR-TB accounts for 2% and that the proportion among MDR-TB cases in industrialized nations (including the U.S.) has increased from 3% in 2000 to 11% in 2004. The emergence of XDR-TB heightens concern since recent data demonstrate that rates of death or therapeutic failure are 54% more likely compared to the already poor outcomes recorded for MDR-TB cases.¹⁰

Global Tuberculosis. Since 1994, the World Health Organization (WHO) has been annually updating and publishing worldwide tuberculosis surveillance data and marking the magnitude of the problem, as well as the uncertainty in the data, the large financial resources needed to follow-through with the newest strategies for worldwide TB control and where small incremental gains have been made.¹⁰⁴ Approximately one-third of the world's population is infected with tuberculosis (2 billion persons with LTBI). The annual growth in global incidence of new TB cases is below 1%. The world incidence of TB is 140 per 100,000 population and the number of new tuberculosis cases in the year 2004 was 9 million of which 2 million died.¹⁰⁴ The figures for tuberculosis incidence and mortality among developing countries, however, are even more staggering. Two-thirds of the population within developing countries, twenty-two of these the WHO refers to as the high burden countries (HBC), are infected with tuberculosis.^{104,105} Ninety-five percent of the world's tuberculosis cases and 98% of the tuberculosis deaths occur in developing countries.¹⁰⁵ Although five of the six WHO designated regions (Africa, Americas, Eastern Mediterranean, Europe, Southeast Asia, Western Pacific) show stable or falling case rates, data not seen easily in the overall reports are that TB rates are still rising in a substantial number of countries of the former Soviet Union (European region). More evident is that the African (24%), Southeast Asian (35%), and Western Pacific (24%) regions account for most of the new tuberculosis cases and the countries in the African region continue to show the number of new cases is rising at a mean of about 4% per year. Eleven of the fifteen HBC with the highest TB incidence can be found in the African region. The highest rates reported are from Swaziland, at an estimated rate more than 1200 per 100,000 population. Indeed, the highest rates of tuberculosis in the world occur within the sub-Saharan region of Africa. Deaths from tuberculosis continue to rise in all of Africa, but particularly within the sub-Saharan region and represent a substantial fraction of avoidable adult deaths in these countries. Analogous to Western Europe during the Industrial Revolution, those under the age of 50, the most productive fraction of the population have been hit hardest.^{104,106}

HIV infection is a major contributing factor to the increases in tuberculosis in the HBC of the world. Since 1994, the estimated worldwide prevalence of HIV has increased from 13 million to 40 million individuals in 2003.^{104,107} Most of the world's AIDS cases

occur in developing countries and mostly affect young adults and children. The impact of AIDS and HIV, therefore, is greatest on the same population in whom tuberculosis prevalence is the greatest. The rate of progression to active disease from a latent infection in persons coinfecting with HIV worldwide is about 8–10 % annually. There were 11.4 million cases of TB/HIV coinfection in 2003. The majority, 8 million or 70%, were in sub-Saharan Africa, and represented 31% of the new TB cases in that region. Southeast Asia contributed the next largest number of TB and HIV coinfections at 2.3 million or 20%.^{104,106} HIV has become the most important predictor of tuberculosis incidence in HBC.¹⁰⁸ Furthermore, case fatality rates are increased significantly among TB cases with HIV coinfections. For example, in sub-Saharan Africa, approximately 30% of TB and HIV coinfecting cases die within 12 months of starting a treatment regimen that is highly effective for tuberculosis cases without HIV.¹⁰⁹

The prevalence of drug-resistant tuberculosis is another important factor contributing to the increase in TB worldwide. Drug resistance prevalence correlates inversely with the level of good tuberculosis control practices. Overall, global prevalence for MDR-TB remains difficult to measure due to inconsistent reporting, but current estimates show that MDR-TB accounts for 2.3% of new tuberculosis cases and 16.4% of previously treated cases. Hong Kong, Thailand, and the United States have produced decreasing rates due to effective national TB programs that achieve high adherence and cure rates. The highest prevalence of new cases of MDR-TB are in former Soviet Union countries (eg, Kazakhstan 14.2%, Tomsk Oblast 13.7%, Uzbekistan 13.2%, Estonia 12.2%), Israel (14.2%), China (Liaoning Province 10.4%, Henan Province 7.8%), and Ecuador 6.6%.¹⁰⁶

The WHO in 1993 declared that tuberculosis is a global health emergency. Strategies for control were developed and were published in 1994.¹⁰⁷ This document established the following two main targets for tuberculosis control: to cure 85% of newly detected smear-positive tuberculosis cases, and to find at least 70% of existing cases by the year 2000. In 2005, the WHO continues to report shortfalls: the goal for 85% treatment success was at 82% based on selected cohort of 1.7 million patients diagnosed in 2003 and the goal for case detection was only at 60%. The key elements in the WHO control programs emphasize the administration of the standard short-course regimen with a very strong effort toward supervised treatment (referred to as DOTS, directly observed treatment, short course), adequate drug supplies, and effective program management and evaluation. Further enhancements include an expanded scope of interventions in regions of high HIV prevalence, development of the DOTS-Plus and PPM-DOTS programs. The DOTS-Plus program expands treatment for MDR-TB in regions of high MDR-TB prevalence. The PPM-DOTS program actively brings private practitioners into compliance with universal application of DOTS and has been rolled out into regions where tuberculosis patients are more likely to seek care from private practitioners than from public health services. Unfortunately financial constraints within the WHO and the HBC continue to be the major obstacle to widely instituting these effective and well-intentioned programs.¹⁰⁴

Tuberculosis in Foreign-Born Immigrants to the United States. Given the problems controlling tuberculosis globally, it is not surprising to find that foreign-born immigrants are having an increasing impact on the new cases of tuberculosis in the United States. The proportion of United States TB cases that is comprised of the foreign-born population increased from 22% to 54% over the period of 1986–2005.^{82,110} Mexico (25%), the Philippines (11%), Vietnam (8%), India (7%), and China (5%) are the top five countries and account for more than half of the tuberculosis cases among new immigrants. Tuberculosis rates for these countries are many times greater than the U.S. rate, ranging from 31 (Mexico) to 320 (Philippines) per 100,000 per year.¹⁰⁴ Also, progression from latent to active tuberculosis among these immigrants is as high as 100–200 times the U.S. rate.¹¹¹ Another potential contributor to the tuberculosis rate, which is difficult to measure, are the millions of nonimmigrant, foreign arrivals per year that are in the United States as tourists, business

visitors, and students.¹⁰⁵ Many do not receive any sort of screening for tuberculosis before they arrive.

Most cases of tuberculosis in the foreign-born population have occurred in Hispanic (40%) and Asian (40%) immigrants.⁸² Approximately 35–53% of these individuals are TST-positive upon arrival in this country.^{112,113} The case rate for active tuberculosis among these persons after they arrive in the United States is about 22 per 100,000 or almost nine times the rate for U.S.-born individuals (2.5 per 100,000). Most of the foreign-born cases of active tuberculosis (55%) are diagnosed during the first 5 years in the United States.⁸²

Active tuberculosis in the foreign-born population most often arises from activation of a prior infection.¹¹⁴ Drug resistance is a greater problem than HIV coinfection in the immigrant population. The main reason is that HIV screening removes many before seeking immigration to the United States.¹¹⁵

Nosocomial Transmission of Tuberculosis. The major causes of tuberculosis transmission within hospitals are from those cases where it is not suspected, the diagnosis is delayed, or respiratory isolation procedures break down.^{116,117}

The following unusual example of extrapulmonary tuberculosis aptly illustrates these aspects of nosocomial transmission.¹¹⁸ A deep thigh abscess, not suspected to be tuberculous, was surgically debrided in an Arkansas hospital, then irrigated daily for approximately two weeks using a Water Pik-type device. Eventually, of the 70 health-care workers (HCWs) either directly exposed to or working on the same hallway as this patient, 63% became infected and 14% developed active tuberculosis between 9–12 weeks after the exposure. The high rate of transmission resulted from the combined effect of the following factors: (a) unsuspected, high concentration of *M. tuberculosis* in the abscess tissues; (b) unrecognized generation of aerosol densely contaminated with *M. tuberculosis* because of wound irrigation (perhaps further facilitated by the high intensity of the water stream produced by the irrigating device); and (c) unanticipated positive air pressure in the patient's room so that the contaminated air circulated outside the room and up and down the hallways.

Medical students, pathologists, and assistants working in an autopsy room exhibit a higher risk for tuberculosis infection and active disease.^{119,120} The autopsy suite stands out as one of the hospital sites where the heaviest exposure to tuberculosis may occur for several reasons. An aerosol with a high density of bacteria will likely be generated when cutting infected lung or bone with a knife or oscillating saw. Recent data show that the concentration can be as high as 1 infectious unit per 3.5 cubic feet of air,¹²¹ a far more dense concentration when one considers that on a tuberculosis ward the concentration measures approximately 1 infectious unit per 24,000 cubic feet of air.¹² Also, autopsy workers are more frequently exposed to patients unsuspected of having tuberculosis antemortem, increasing the risk that adequate respiratory protection may be neglected.

The extensive MDR-TB outbreaks that occurred during the late 1980s in eight hospitals and a New York state prison displayed overlapping chains of transmission and illustrated unfortunate, but common characteristics of nosocomial transmission.^{8,9,18,19,122} Delayed diagnosis, delay in effective treatment, lack of effective isolation procedures, and a high proportion of patients with severe AIDS (CD4+ lymphocytes less than 100/mL) were all common features. Severe AIDS altered the clinical picture of active TB and contributed significantly to the delayed diagnosis. The laboratory confirmation of *M. tuberculosis* was also delayed for several of the following reasons: TB went unsuspected, so confirmation tests were not done; acid-fast bacilli present on smears of clinical specimens were assumed to be *M. avium* complex instead of *M. tuberculosis*; and the mean time between specimen collection and identification of *M. tuberculosis* was six weeks. The realization that the *M. tuberculosis* strain isolated was drug resistant was further delayed because the task of susceptibility testing required at least an additional six weeks. All of these factors together resulted in extended opportunities for transmission of MDR-TB in the hospitals, outpatient clinics, and among the prisoners. Approximately 300 individuals developed active MDR-TB and

most were coinfecting by HIV. A high attack rate, short incubation time, and rapid progression to active disease and death were among the most striking characteristics and were a function of the high prevalence of patients with AIDS and MDR-TB. The mortality rate in most of the hospitals approached 100%, with a median time from diagnosis to death of four weeks. Over 150 HCWs were directly exposed and 27% became infected. Seventeen of these developed active MDR-TB, eight were coinfecting with HIV, and four of those persons died from MDR-TB. Three others died, one of whom may also have been immunosuppressed because of a malignancy.

Both the irrigated tuberculous abscess and the extensive MDR-TB outbreak in upstate New York demonstrated clear and dramatic evidence for overlapping chains of nosocomial transmission and the danger to health-care workers and patients when active cases go unsuspected. The upstate New York outbreak in particular provided the motivation behind subsequent government efforts to tighten isolation procedures for health-care facilities (discussed below).

Guidelines for Protection of Health-Care Workers. The resurgence of tuberculosis, and in particular the lessons learned from the MDR-TB outbreaks reviewed above, drove the process for reevaluating the 1990 CDC guidelines for tuberculosis containment in the hospital environment.^{123,124} These efforts culminated in detailed, broad guidelines published by the CDC and the National Institute for Occupational Safety and Health (NIOSH) at the end of 1994 and introduced the three-tier control hierarchy within hospitals: administrative controls, environmental controls, and respiratory protection.¹²⁵ The changes in the recent update to these guidelines (2005), fortunately, were not driven by dramatic tuberculous outbreaks in the years since 1994. Rather the new guidelines recognize that the risk for health-care associated tuberculosis transmission has decreased, that health-care practices have changed since 1994, and that better scientific data regarding transmission and control can be applied.¹²⁶ The essential structure based on the three-tier control hierarchy continues with the latest iteration. Among the biggest changes is that the guidelines have been rewritten to include much more practical and detailed information and it encompasses the entire health-care arena, beyond hospitals, including chronic care facilities, outpatient settings, laboratories, and nontraditional settings.

The administrative control portion of the plan assigns the responsibility for developing, installing, and maintaining TB infection control as well as identifying how it should be coordinated with the public health department. The administrative controls also include a detailed local risk assessment worksheet and annual reassessment plan. Based on local risk assessment, the rate and intensity for screening, training, and educating HCW for and about tuberculosis can be established. The updated guidelines make clearer which HCWs should be included in screening programs, describes how BAMT tests may be substituted for TST, and allows low-risk institutions exemption from annual TST screening altogether.¹²⁶

The environmental controls portion of the guidelines aims to control the source of infection by reducing the concentration of droplet nuclei within the patient's room, adjacent rooms, and hallway. Expanded information includes detailed specific information about designing negative pressure *airborne infection isolation* (AII) rooms, room air circulation, cleaning air by use of HEPA filtration (minimum efficiency 99.97% for particles > 0.3 μm diameter), and UV germicidal irradiation.¹²⁶

The respiratory protection measures described in the current guidelines spell out the details for use of the N95 disposable respirator, fit testing, and user training, and even includes how to train patients in proper respiratory hygiene and cough techniques.¹²⁶

Appropriate respiratory protection historically has been a contentious issue particularly around the appropriate respirator and the issue of fit-testing health-care workers.¹²⁴ In 1992, NIOSH took the stance that the risk to HCWs had to be completely eliminated and therefore all who were at risk for exposure to TB patients should wear HEPA-filtered, powered, personal respirators and participate in a

mandatory respirator fit-testing program. These recommendations were put forward even though there was no specific data to support the necessity of such a drastic upgrade from the standard surgical masks. Subsequent revision of the guidelines released a year later in the *Federal Register* by both the CDC and NIOSH recommended HEPA-filtered disposable particulate respiratory protection and fit-testing, yet adequate data to support this recommendation was still not available. After reviewing the extensive public criticism (2700 responses) to those revised guidelines, CDC and NIOSH agreed to accept the use of disposable personal particulate respirators that met the less stringent specifications of 95% efficiency at filtering 1- μm particles (N95 classification). Fit-testing was still recommended to ensure that the appropriate-size mask works properly in at least 90% of individuals at risk for exposure.¹²⁵ The Occupational Safety and Health Administration (OSHA) were left to develop and enforce regulations. Initially, hospitals were required to conform to the 1987 OSHA Respiratory Protection Standard, which required initial fit-testing but not annual testing. In 1998, OSHA revised the Respiratory Protection Standard (29 CFR 110.134) to require initial and annual fit-testing but excluded TB until December 30, 2003. The most recent salvo in this ongoing battle came from the U.S. Congress, which enacted an amendment to the spending bill, which prevents OSHA from using tax money to enforce the Respiratory Protection Standard for tuberculosis.

Several classic studies have demonstrated that administrative and environmental portions of infection control plans most successfully arrest nosocomial transmission. For example, a study by Wenger et al¹²⁷ demonstrated that strict implementation of the least stringent 1990 CDC tuberculosis control guidelines substantially reduced transmission of MDR-TB to HCWs and among HIV-positive inpatients. However, multiple factors were tested simultaneously, making it difficult to determine which component of the infection control practices was most essential. Blumberg et al¹²⁸ evaluated a broad upgrade of administrative controls, engineering controls, and respiratory protection. The administrative controls specifically were an expanded isolation policy mandating discharge from isolation only after three sputums were acid-fast bacilli smear negative, an expanded infection control department, increased HCW education, and more frequent TST screening of workers at risk for TB exposure. The engineering controls included simply introducing negative-pressure ventilation via a window fan installation in isolation rooms so that air was vented directly to the outdoors. And for respiratory protection, the hospital switched to a disposable personal particulate respirator from the standard surgical mask. The result of these changes was a significant reduction in nosocomial transmission. Maloney et al¹²³ demonstrated that the combination of early isolation and treatment of patients with tuberculosis, the use of techniques more rapid for identifying *M. tuberculosis* in specimens, configuration of isolation rooms with negative-pressure ventilation, and molded surgical masks for HCWs greatly reduced transmission within the hospital studied. Taken together these studies confirm that stricter adherence to standard infection control measures greatly reduce nosocomial transmission of tuberculosis, but do not provide data to evaluate the impact of individual control measures. Subsequent surveys of hospital TB control plans instituted in the 1990s show that TST conversion rates fell or remained low more as a result of administrative and environmental controls than respiratory protection.^{129–132} These results and the lack of data for added protection produced by expensive high filtration respirators and fit-testing continue to fuel debate.

Tuberculosis in Correctional Institutions. A correctional institution is a congregate setting that is ideal for transmission of tuberculosis between inmates and/or the correctional workers. Also, evidence indicates that prisoners released into the communities extend transmission, particularly to children in the home.^{133,134} Further compounding the problem, more people are in jail, and recidivism occurs at a greater rate, than ever before.¹³³ The number of people incarcerated increased from about 500,000 people in 1980 to more than 2 million in 2004.¹³⁵

Tuberculosis is more prevalent in prison populations compared with its prevalence in the general population. Fourteen to twenty-five percent of inmates have a positive TST.^{136,137} The probability of tuberculosis infection increases directly with the length of incarceration, which indicates that transmission of tuberculosis must occur in prisons.^{134,138} The rate of tuberculosis in prisoners compared with that in the general population varies depending on the prison location. For example, in New York State, the rate of TB in the prisons has been reported 6.3 times the rate for that state's general population, whereas in New Jersey and California the values have been found even higher at 11- and 10-fold, respectively.^{133,139}

Multiple factors contribute to the high rates of tuberculosis in correctional institutions.¹³³ Many state and federal facilities operate well above design capacity. Overcrowding, coupled with poor ventilation typical in the prison environment, facilitates aerosol transmission of tuberculosis. The high rate of HIV infection is another factor, which is highlighted by a study showing that the HIV-seropositive rate in the prison population was approximately 50 times greater than that in a matched population of military recruits.⁸⁰ In the absence of HIV infection, a history of intravenous drug abuse is associated with a higher risk of tuberculosis. In a survey of 20,000 state and federal prisoners from 45 states, 25% of the inmates had a history of IV drug abuse. Also, the prison population represents a lower socioeconomic group, a segment of the population that is more commonly infected with tuberculosis. All of these factors taken together help explain the higher rates of tuberculosis among individuals housed in correctional institutions.

Tuberculosis in IV Drug Abusers. The IV drug abuse population has a higher incidence of tuberculosis than does the general population in areas of the United States where tuberculosis is prevalent.¹⁴⁰ Higher rates of HIV coinfection within the IV drug abuse population increase the risk of a tuberculosis infection and the development of active disease in this population. The data are somewhat conflicting regarding whether drug abuse in absence of coinfection with HIV is an independent risk factor for tuberculosis.^{141,142} Data suggest that non-HIV-infected drug abusers may exhibit lower levels of cellular immunity, and the TST is less reliable in this population.¹⁴³

Other risk factors for tuberculosis are prevalent among populations of drug abusers. Drug abusers as well as alcohol abusers have a poor record of compliance with tuberculosis therapy.¹⁴⁴ They frequent similar locations, so they are more likely to transmit to others within the cohort. They are a mobile population that is difficult to hold onto in tuberculosis treatment programs. Thus they are also at higher risk for acquired drug resistance because they often do not complete therapy or take therapy on an irregular basis.

Tuberculosis in the Elderly. Analogous to that in the foreign-born population, the majority of tuberculosis cases in the elderly population are a result of activation of a prior infection, and only approximately 10–20% of active cases are due to primary infection.^{145,146} In the 1930s, approximately 80% of the U.S. population was infected by tuberculosis once they reached the age of 30. The oldest of this cohort are still alive today. In a study of 43,000 nursing home residents from Arkansas, it was found that the rate of positive TST was 13.2%.¹⁴⁷

Pulmonary infection occurs in 75% of active cases in the elderly in contrast to 85% of a younger cohort.¹⁴⁵ A higher proportion of elderly patients present with disseminated tuberculosis, tuberculous meningitis, and skeletal tuberculosis. Signs can be nonspecific and the TST may be nonreactive.¹⁴⁸ Consequently, active tuberculosis in the elderly has a greater probability of going undiagnosed for an

extended period of time with the increased risk of transmission to other individuals.

Transmission of Tuberculosis During Airline Flights. The risk of *M. tuberculosis* transmission to other passengers during commercial airline flight is not greater than in any other confined spaces. Several studies have even shown that passengers with documented cavitary pulmonary disease did not infect other passengers.^{149,150} These data may have been confounded by the fact that the investigations were initiated many weeks to months following the flight, which limited contact finding and the effectiveness of the tuberculosis skin test to detect conversions.

Airplane ambient air is relatively sterile.^{151,152} The fresh air is compressed and passed through the jet engines, where it is heated to 250°C and then cooled at high pressures (450 pounds per square inch). Since the 1980s, however, airplanes have not used 100% fresh air circulation. About 50% of the air is recirculated. The air is introduced as vertical laminar sheets from the top of the cabin to the floor and is recirculated every 3–4 minutes. This is more frequent than the standard of 5–12 minutes that is seen in offices and homes. In newer aircraft, the recirculated air passes across a HEPA filtration unit. Investigators have shown that the usual bacteria contamination of this air is less than 100 colony-forming units (CFUs) per 160 L, which is significantly less than the approximately 1000 CFUs per 160 L found in city buses, shopping malls, or even airline terminals. These data suggest that transmission risk may be lower within airplanes.

The CDC identifies three critical factors necessary to increase the probability that others may be infected during flight.^{149,153} Clear-cut evidence of infectiousness at the time of the flight (e.g., cavitary disease, laryngeal TB, evidence of household transmission prior to flight), prolonged flight time (probably exceeding 8 hours), and proximity to the active case (risk is measurable within 15 rows of the active case).

Bovine Tuberculosis

M. bovis most commonly causes extrapulmonary disease such as lymphadenitis, genitourinary tract infections, or bone and joint infections, but it may also cause pulmonary infection.¹⁵⁴ *M. bovis* is closely related to *M. tuberculosis*. DNA from *M. bovis* is almost 100% homologous to DNA from *M. tuberculosis*. Clinical laboratories using nucleic acid probes can have difficulty distinguishing *M. tuberculosis* from *M. bovis*. Distinguishing one from the other has clinical relevance because *M. bovis* is normally resistant to pyrazinamide, one of the first-line medications for tuberculosis.

Pulmonary infection due to *M. bovis* is clinically indistinguishable from pulmonary tuberculosis. Up to 3% of the mycobacteria respiratory isolates in San Diego were previously reported to be *M. bovis*, and most were from Hispanic adult immigrants to the United States.¹⁵⁴ This form of bovine tuberculosis probably results from livestock (usually a cow)-to-human and human-to-human aerosol transmission and indicates that bovine tuberculosis has not been effectively eliminated from domestic cattle herds. In fact, *M. bovis* remains endemic in beef and dairy cattle herds in many regions of Mexico and Central America.

The cervical lymphadenitis form of *M. bovis* is also clinically indistinguishable from *M. tuberculosis*.¹⁵⁵ Cervical adenitis due to *M. bovis* occurs more often in children and usually results from the ingestion of unpasteurized milk from contaminated cows.

In general, the problem of bovine tuberculosis can be solved by removing the infected cows from the herd and pasteurizing the milk.

Leprosy

Kenrad E. Nelson

Leprosy (also called Hansen's disease) is a chronic infectious disease involving primarily the peripheral nervous system, skin, eyes, and mucous membranes. It is endemic in many countries in Asia, Africa, the Pacific Islands, Latin America, southern Europe, and the Middle East. There are endemic areas of infection in the United States as well, particularly in Louisiana, Texas, and California. The major sequelae of leprosy are physical deformities involving the extremities, face, and eyes due primarily to damage to the sensory nerves from *Mycobacterium leprae* infection and the immune reaction to the organism. The resultant deformities often lead to stigmatization that continues after the infection becomes inactive and the patient is noninfectious.

Since several effective antileprosy drugs are now available, new cases of leprosy can be treated effectively and rendered noninfectious. Leprosy should not pose a significant public health problem once treatment is instituted. In fact, despite the recognized importation of 100–320 cases annually in the United States for the last few decades, the development of clinical leprosy among the contacts of these imported cases has not been documented.¹

Etiologic Agent

Leprosy is caused by *M. leprae*, a weakly acid-fast organism. The organism can be found in tissues using a modified acid-fast stain, the Fite-Faraco stain. The bacterium was originally identified in 1873 by Gerhard Henrik Armauer Hansen, but it has not yet been successfully cultivated in vitro. *M. leprae* has one of the slowest replication cycles of any known bacteria: it divides only every 10–12 days during the log phase of growth. The organism replicates in mouse footpads,² in thymectomized mice or rats, nude mice, severe combined immunodeficient (SCID) mice, the nine-banded armadillo, and in several non-human primate species.³ Naturally occurring leprosy infections have been documented in nine-banded armadillos,⁴ chimpanzees, and sooty mangabeys.⁵ The complete genome sequence of an armadillo-derived Indian isolate of *M. leprae* has been reported.⁶ The genome contained 3.3 million base pairs compared to 4.4 million base pairs in the *M. tuberculosis* genome. However, in contrast with the *M. tuberculosis* genome, less than half of the *M. leprae* genome encodes functional genes, but pseudogenes with intact counterparts of *M. tuberculosis* are common. Gene deletion and decay eliminated many important metabolic activities, including part of the oxidative and most of the microaerophilic and anaerobic respiratory chains and numerous catabolic systems and regulatory circuits in *M. leprae*. The reductive evolution indicated by the *M. leprae* genome's structure explains its slow growth and limited metabolic activity.⁶

Throughout the world *M. leprae* strains are remarkably similar.⁸ *M. leprae* has very little genetic diversity with single nucleotide polymorphism (SNPs) only every 28,000 base pairs; however, genetic analysis has identified four subtypes.

Clinical Manifestations

The clinical manifestations of leprosy are variable. The clinical presentation and course of the disease depend on the interactions between the *M. leprae* bacterial load and the host's immune system, especially the cellular immune system. The most widely used system for clinical-immunologic classification of leprosy was developed by Ridley and Jopling,⁸ which subdivides leprosy into five general classes: polar lepromatous leprosy (LL), borderline lepromatous (BL) leprosy, midborderline (BB) leprosy, borderline tuberculoid (BT) leprosy, and polar tuberculoid (TT) leprosy. In addition, a very early form of leprosy, not readily classified into the above groups, is called

indeterminate (I) leprosy. Indeterminate leprosy is the earliest clinical evidence of infection and often resolves spontaneously without specific therapy; however, it may progress to one of the five classes. Leprosy is often divided into only two groups: multibacillary leprosy (MB), consisting of LL, BL, and BB leprosy, and paucibacillary leprosy (PB) consisting of BT and TT leprosy. These broader groupings are useful for therapeutic decisions.

There is a good correlation between the clinical appearance, the number of organisms and distribution and type of skin lesions, and the patient's classification according to the Ridley-Jopling criteria. Patients with paucibacillary leprosy have well-defined macular skin lesions with distinct borders, that are few in number and distributed asymmetrically. Lesions increase in number, and become more diffuse and smaller as the disease moves toward the lepromatous end of the spectrum. Patients with BL or LL leprosy have ill-defined, sometimes nodular, skin lesions without clear borders. Loss of eyebrows or hair and deformities caused by infiltration of the pinna of the ear are common in patients with lepromatous disease. Another characteristic of leprosy is anesthesia of the skin lesions. Leprosy skin lesions generally spare the body's warmer intertriginous areas. Enlargement and nodularity of the peripheral nerves, especially the ulnar, posterior tibial, and great auricular nerves, are characteristic. Patients may have corneal anesthesia and keratitis or lagophthalmos due to involvement of the facial nerve. Damage to the hands, feet, and eyes is characteristic of lepromatous disease. Trophic ulcers and resorption of digits may result from the sensory nerve damage and the repeated trauma that these patients undergo. Early involvement of large sensory nerves is characteristic of tuberculoid leprosy.

An important clinical feature of leprosy is leprosy reactions, which are of two types. Type 1 are reversal (or downgrading) reactions that represent increased (or decreased in the case of downgrading reactions) cell-mediated immune responses to the organisms. Type 2 are erythema nodosum leprosum (ENL) reactions, believed to be mediated largely by humoral immune responses to *M. leprae*, leading to immune complexes. Nearly half of all leprosy patients experience a reaction during the first few years after their diagnosis.⁹ Type 1 (reversal) reactions can occur in any patient with borderline (BL, BB, or BT) leprosy; they are not seen in patients with polar lepromatous or tuberculoid leprosy. Type 2 (ENL) reactions are characteristic of and limited to patients with multibacillary leprosy. Clinically, type 1 reactions consist of acute inflammation of preexisting leprosy lesions, including superficial nerves, with fever and systemic symptoms that begin gradually and have a natural course of several weeks or months. Early recognition and aggressive therapy of type 1 reactions is especially important to prevent irreversible deformity from nerve damage. Type 2 reactions consist of the sudden appearance of crops of tender (erythematous skin nodules that did not previously have leprosy lesions) along with fever, malaise, and sometimes acute neuritis, arthritis, orchitis, iritis, glomerulonephritis, myalgia, and peripheral edema. Typically, type 2 reactions have a sudden onset and may subside in several days to a few weeks, though they may cause severe nerve damage in that time. Type 2 reactions may recur over the course of a year or more, especially in patients treated with anti-inflammatory agents, after these drugs are withdrawn or tapered.

Diagnosis

The diagnosis of leprosy is usually made clinically. Characteristics of leprosy are skin lesions that are anesthetic to light touch, enlarged nerves to palpation, lagophthalmos, and distal stocking-glove anesthesia. The diagnosis should be confirmed by skin biopsy and slit-skin

smears whenever possible. When taking a punch biopsy, it is important to include specimens of the entire dermis at a lesion's active border, because the organisms are often located deep in the skin, but not found in the epidermis, and in multibacillary disease there may be a "clear zone" at the dermal-epidermal junction. The histopathologic features of leprosy correlate well with the disease's clinical presentation. Patients with lepromatous disease have many organisms in their lesions and lack a well-developed granulomatous response due to their ineffective cellular immunity to the organism. In contrast, tuberculoid patients have few (or no detectable) organisms with a well-organized granulomatous infiltrate. In patients with tuberculoid leprosy, the leprosy granulomas are infiltrated with cells of the CD4+ T-helper memory phenotype and macrophages with a ring of CD8+ cells around the periphery. In contrast, in lepromatous lesions CD4+ T cells of the naïve phenotype and CD8+ suppressor cells are scattered randomly throughout the lesions.^{10,11} Consultation for the interpretation and classification of skin biopsies or for therapeutic decisions can be obtained from the National Hansen's Disease Center at Baton Rouge, Louisiana (Phone: 504-642-4740), or the Armed Forces Institute of Pathology, Washington, DC.

The Mitsuda lepromin skin test is not useful in making a diagnosis of *M. leprae*. The main use of the lepromin test is to classify patients once the diagnosis has been made. Patients with polar lepromatous leprosy will have no induration at 3–4 weeks after the intradermal injection of Mitsuda lepromin. Patients with tuberculoid leprosy, and many with no history of clinical leprosy or exposure to leprosy, will have a positive Mitsuda skin test.¹² The Mitsuda skin test measures the response to *M. leprae* antigens, hence its usefulness in classifying patients with leprosy.

A phenolic glycolipid that is antigenic and specific was isolated from the *M. leprae* cell wall.¹³ However, serodiagnosis is not sensitive enough to be a routine diagnostic adjunct, because not all untreated multibacillary patients and only 20–30% of paucibacillary patients are antibody positive.¹⁴

Distribution

Leprosy has existed in eastern Mediterranean and Asian populations since ancient times. During the Middle Ages, leprosy became widespread in Europe. It declined in most of Europe after the sixteenth century but peaked in Norway during the nineteenth century, followed by a rapid decline during the late nineteenth and early twentieth centuries. The last known endemic case in Norway had onset about 1950.¹⁵ The disease was introduced into the northern United States and Canada by European settlers from Norway, France, and Germany. It persisted in several clearly defined foci and within certain family groups for several decades and then disappeared.¹⁶

Currently the disease is primarily epidemic in certain tropical countries in Africa, Southeast Asia, India, some Pacific Islands, and Latin America; it remains a significant endemic problem in 27 countries worldwide. However, six countries, namely, India, Brazil, Myanmar, Madagascar, Nepal, and Mozambique, accounted for over 80% of the new cases registered with the World Health Organization (WHO) in 2000. In these six countries, the annual incidence of new cases has increased between 1995 and 2006.¹⁷ Furthermore, children comprise 15% of incident cases indicating that active transmission still occurs in these endemic countries. The prevalence rates declined substantially in the last 25 years, because in 1981 the WHO recommended that the disease be treated with a course of multiple drugs.¹⁸ The WHO recommended the routine treatment of all active cases with multidrug therapy (MDT) containing dapsone, rifampin, and clofazimine for a fixed time period, rather than indefinite treatment with dapsone alone, as was common practice until then.

In 1982, over 12 million leprosy cases were estimated to exist worldwide, and in 1992 there were an estimated 3.1 million cases.¹⁹ The 2001 estimate was 700,000–1,000,000 cases. However, these figures are not nearly comparable, since the more recent figures only include new active patients receiving treatment.¹⁷ The substantial decline in the global numbers of leprosy cases is probably in part

related to the widespread use of supervised MDT, in accordance with WHO recommendations for the treatment of active cases. Multidrug therapy renders most leprosy cases noninfectious sooner after the start of therapy, in comparison to the previous monotherapy with dapsone, a bacteriostatic drug to which many *M. leprae* were resistant. Some experts believe that stricter compliance with shorter drug regimens may have decreased the rates of relapse, as well as interrupted the transmission cycle.²⁰ However, another factor that clearly reduced the current estimated prevalence of leprosy is the acceptance of a defined course of therapy for patients on MDT and the release of patients from the registry of active cases after this therapy is completed. Previously, dapsone monotherapy was recommended for life for multibacillary cases, and patients were never dropped from the registry even after they became inactive, or "cured." So, the decreased leprosy prevalence rates are due in part to a change in the definition of what constitutes an "active case."²¹

Apparently, leprosy was introduced into the Americas through African and European immigration. A genetic study of 175 strains of *M. leprae* found rare single nucleotide polymorphisms that allowed sub-classification of the organism into four subtypes. These genetic data suggested that *M. leprae* originated as a human pathogen in East Africa or the near East.⁷ Leprosy was reported in French Polynesia as the eighteenth century ended. Trade links among these islands, Easter Island, and Hawaii probably helped spread the disease.²² North American endemic foci are now limited to Louisiana, Texas, and California. New cases in North America now occur primarily among immigrants, which occur 5–10 times more commonly than infections acquired among U.S. residents. Many cases in the United States come from Southeast Asia, and some come from Mexico and other countries in Latin America or Africa where leprosy is endemic.

One of the most impressive epidemics of leprosy was reported from the island of Nauru, in the South Pacific.²³ A single case of leprosy was introduced into a population of approximately 1200 persons in 1912 and this led to an epidemic that eventually affected 30% of the population over the next 30 years. It is of interest that nearly all of the leprosy cases on Nauru were of the tuberculoid type, and only about 1% was multibacillary. The marked predominance of tuberculoid leprosy in hyperendemic populations led Newell to suggest that lepromatous leprosy occurs only in persons with specific genetic immunological deficiencies in controlling infection with this organism, a view subsequently supported by several genetic studies.²⁴ It is believed that only 1–5% of the human population is susceptible to leprosy.¹⁰

Epidemiology

Transmission. *Mycobacterium leprae* is believed to be transmitted from person to person by close contact. However, some debate continues about the exact means of transmission. Only about 15–30% of patients with clinical leprosy who live in endemic areas have a history of close personal or household contact with a known leprosy case.²⁵ However, the indolent nature and the long incubation period of the disease could have led to failure to recognize or recall this exposure in many cases.

In contrast with tuberculosis, a primary site of infection in the respiratory tract has not been documented. Nevertheless, many experts believe that the infection is most often transmitted from contact with the nasal secretions of an infectious case. Studies of the nasal discharge of multibacillary cases have estimated that 10⁷ bacilli per day may be contained in these secretions.²⁶ Recently investigators used the polymerase chain reaction (PCR) to amplify *M. leprae* DNA, confirming the presence of the organism in the nasal secretions of leprosy cases and their household contacts.^{27–29} One study of 1228 persons living in two villages in Indonesia where leprosy was endemic found 7.85 healthy persons to have nasal smears that were PCR positive.²⁹

In contrast with these findings, the organism is not found in the epidermis of the intact skin, although it may be present in ulcerated lesions, usually in much lower numbers than found in nasal secretions. The organism was also found in high concentration in the blood

of lepromatous cases³⁰ and in the breast milk of patients with active disease.³¹ Some investigators speculate that *M. leprae* may be infectious by direct skin contact. The more common occurrence of the initial leprosy lesions on exposed skin is sometimes cited as evidence for this site of entry of the organisms.³² However, since the organisms are known to grow better in cooler, exposed skin, this could influence the distribution of lesions. There are reports of inoculation of *M. leprae* by tattooing or bacillus Calmette-Guérin (BCG) injection, leading to clinical leprosy at the site of inoculation, many years later.²⁵ Some special exposures in some populations (e.g., Micronesia) in which leprosy is epidemic, such as sharing of bamboo sleeping mats with an active case, could result in the transmission of *M. leprae* by direct inoculation of organisms from an infectious case into the skin (J. Douglas, personal communication).

Reservoir. Viable *M. leprae* have been recovered from arthropods including mosquitoes and bed bugs who have fed on lepromatous patients.³³ Cochrane noted that, even when malaria prevalence was equal in adjacent villages in India, leprosy prevalence differed significantly, suggesting that, at least anopheline transmission of *M. leprae* was not important.³⁴ It is also possible that organisms could enter humans through the gastrointestinal tract, like *Mycobacterium avium* complex organisms, but no evidence for this route of entry is published. Some investigators suggested that the original site of *M. leprae* entry could condition the host immune response to the organism; skin or upper respiratory penetration could more readily provoke a TH-1-type lymphocyte response, whereas the lower respiratory or oral route could lead to a TH-2-type lymphocyte response and progression of infection to lepromatous disease.³⁵

Infectious human cases almost certainly are the only important reservoir of *M. leprae* for human infections. Nevertheless, there are reports of isolation of noncultivable mycobacteria resembling *M. leprae* from several environmental sites, including soil, sphagnum moss, and thorns;³⁶ also, leprosy infections are endemic in feral armadillos.³⁷

Prevalence and Incidence. The prevalence of leprosy varies widely in different populations but generally involves 0.01–2.0% of the population in areas where the disease is endemic. Although leprosy may occur in infants and young children, it is rare in children under seven years old; this is likely due to the long incubation period between exposure and the onset of clinical symptoms. The incubation period was estimated through military personnel and missionaries who returned to the United States or Europe from endemic areas. These data indicate that the incubation period is longer for lepromatous (median of 8–12 years) than it is for tuberculoid disease (median of 2–5 years).³⁸ These studies are also the basis for the estimate that only approximately 5% of the adult population may be susceptible.

The incidence of leprosy peaks between the ages of 10 years and 29 years.^{25,39,40} The rates of new cases are at least five- to tenfold higher in persons with a close contact in the household.^{25,39,40} Leprosy incidence rates rarely exceed 2 per 1000 persons per year, except in persons with a household contact with an active case. A recent prospective study in Malawi found the incidence to be 1.2 per 1000 persons per year and the rates were significantly higher (RR=1.65) in persons who had not had BCG vaccination.⁴¹

Household crowding and a population's low socioeconomic status are important factors promoting *M. leprae* transmission and the development of clinical leprosy. A recent prospective study in Malawi found a lower incidence of leprosy in persons with less household crowding and higher levels of education.⁴² Improving the standards of living may have been critical in the spontaneous disappearance of leprosy from several countries, such as Norway, where the disease had been endemic in the nineteenth and early twentieth centuries.⁴³

It is likely that genetic susceptibility may be one of the important factors contributing to the risk of leprosy and in the type of leprosy that develops after exposure. A twin study found higher concordance rates for leprosy among 62 monozygotic twin pairs (60%) than among

40 dizygotic twin pairs (20%).⁴⁴ However, this important study may have been affected by recruitment bias, since more monozygotic than dizygotic twins were studied. Several studies of human lymphocyte antigen (HLA) distributions of leprosy patients found significant associations with certain HLA haplotypes.^{45–48} A segregation analysis of leprosy in families with multiple cases suggested that the genetic susceptibility may differ between tuberculoid and lepromatous disease.⁴⁹ More recent studies linked leprosy susceptibility to the human NRAMP1 gene⁵⁰ and to the Parkinson's disease susceptibility genes PARK2 and PRCRG on chromosome 6.⁵¹

Depending on geographic location, the proportion of multibacillary and paucibacillary leprosy cases in different populations varies considerably. A much higher proportion of lepromatous cases was observed in Southeast Asia than in Africa, where most cases are tuberculoid.⁵² Whether these differences are due to host differences (such as genetic or nutritional factors), epidemiological factors influencing the route or age at the time of exposure, the size of the inoculum, or to differences in the strains of *M. leprae* in different areas of the world is not known. However, as noted above, *M. leprae* strains from different areas of the world have very little genetic diversity. The inability to culture the organism and the lack of a good animal model that develops a disease similar to that seen in humans has hindered investigations of these important scientific questions.

Interaction of HIV and Leprosy. The pandemic of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) has markedly increased the incidence of several mycobacterial infections, particularly *Mycobacterium tuberculosis* and *Mycobacterium avium-intracellulare*. This has led to concerns that HIV infection might also increase the rates of leprosy in areas of the world where both HIV and *M. leprae* are epidemic. Immunosuppression from HIV could affect the transmission of *M. leprae* by increasing the prevalence of multibacillary forms of leprosy, which could be more readily transmitted. Theoretically, the interaction between HIV infection and leprosy could produce a higher proportion of multibacillary cases, a greater incidence, and more frequent relapses after a course of therapy.⁵³

Several studies of the interaction between HIV and *M. leprae* were reported recently from areas of the world where both leprosy and HIV infections are common. Most of these studies have not found HIV infections to have a significant impact on leprosy.^{54–55} Case-control studies in Malawi,⁵⁶ Uganda,⁵⁷ and Yemen⁵⁸ failed to show a significantly higher HIV antibody prevalence among leprosy patients than in control subjects. Also, these studies did not find a higher proportion of multibacillary leprosy cases among patients infected with HIV than in those who were HIV uninfected. However, a small hospital-based study in Zambia found a higher HIV prevalence rate in leprosy patients than control subjects.⁵⁹ A larger community-based case-control study in Tanzania, in which leprosy cases and control subjects were matched by their geographic areas of residence, found an association between HIV infection and leprosy in those from rural areas and in those with multibacillary leprosy.⁶⁰

The different findings in these studies could be explained by several factors. The HIV epidemic in different countries varies in duration and severity. It is possible that the effect of HIV immunosuppression on leprosy might be manifest at more severe levels of immunosuppression than for tuberculosis. Also, the rates of leprosy are higher in rural populations, whereas HIV infections often are concentrated among urban populations. Therefore, overlap between the epidemics of leprosy and HIV/AIDS may not have occurred yet in some countries where both diseases are epidemic. While the effects of HIV infection certainly are not as evident for leprosy as they have been for tuberculosis, further evaluation of this interaction is warranted before definite conclusions are drawn.

There is no evidence that active leprosy accelerates HIV progression, as has been reported in tuberculosis patients.⁶¹ One intriguing study⁶² in rhesus monkeys who were inoculated with *M. leprae* suggested that those monkeys who were coinfecting with Simian Immunodeficiency Virus (SIV) were more likely to progress to

lepromatous leprosy. Nevertheless, the published studies did not report a significant interaction between HIV and *M. leprae*.

Treatment and Rehabilitation

Antileprosy Drugs. At present, three drugs are commonly used for the treatment of leprosy: dapsone, rifampin (Rifadin), and clofazimine (Lamprene). The use of ethionamide-prothionamide (Trecator) was abandoned due to its hepatotoxicity and the availability of better alternative drugs. Dapsone and clofazimine have weak bactericidal activity against *M. leprae*, and rifampin has potent bactericidal activity against nearly all strains of the organism. However, a few strains of *M. leprae* that are resistant to rifampin have been reported. Other drugs were recently shown to have good antibacterial activity against *M. leprae*. Included are ofloxacin (Floxin), sparfloxacin, minocycline (Minocin), and clarithromycin (Biaxin). Isoniazid (INH), an important first-line drug for treating tuberculosis, is ineffective for treating leprosy.

Dapsone. The usual dose is 100 mg daily for adults and 1.0 mg per kg per day for children. It is a safe, cheap, and effective drug for treating all types of leprosy. Strains of *M. leprae* that are fully sensitive to dapsone have a minimal inhibitory concentration (MIC) of about 0.003 mg per mL, as determined in the mouse footpad assay. Although doses of 100 mg per day of dapsone exceed the MIC by a factor of nearly 500-fold, the increasing prevalence of mild, moderate, or complete resistance to dapsone among *M. leprae* organisms, either in untreated leprosy (primary resistance) or emergence of resistance during treatment (secondary resistance), and the relatively weak bactericidal action of the drug have dictated the current recommendation for treatment at the 100-mg daily dosage. Because of the problem of dapsone resistance, the drug should always be used in combination with rifampin and/or clofazimine for treating active leprosy¹⁸ (Table 12-10).

The most common side effect of dapsone therapy is anemia. However, this is usually very mild and well tolerated, unless the patient has a complete glucose-6-phosphate dehydrogenase (G6PD) deficiency, in which case the anemia may be more severe. Therefore, it is useful to screen patients for complete (G6PD) deficiency prior to instituting therapy with dapsone. More serious but, fortunately, very rare side effects of dapsone include agranulocytosis, exfoliative dermatitis, hepatitis, and a syndrome termed the “dapsone syndrome,” which includes hepatitis and a generalized rash and can progress to exfoliation. Since these more serious toxic effects generally occur soon after initiation of therapy, patients should be seen periodically, and complete blood counts and liver enzymes should be measured after therapy has begun.

TABLE 12-10. WORLD HEALTH ORGANIZATION RECOMMENDATIONS FOR MULTIDRUG THERAPY FOR LEPROSY

Drug	Dose
■ Multibacillary Leprosy*	
Rifampin	600 mg once a month, supervised
Dapsone	100 mg/day, self-administered
Clofazimine	300 mg once a month, supervised
Clofazimine	50 mg/day, self-administered
Therapy should be continued for 2 years or until leprosy is inactive.	
■ Paucibacillary Leprosy	
Rifampin	600 mg once a month, supervised
Dapsone	100 mg/day, self-administered

*Any of the following three drugs can be substituted for one of the above drugs in cases of drug intolerance: Ofloxacin 400 mg/day, minocycline 100 mg/day, or clarithromycin 500 mg/day.

Rifampin. Because of its excellent bactericidal activity against *M. leprae*, rifampin is included in the therapy of leprosy patients. Patients with lepromatous leprosy who are treated with a drug regimen that includes rifampin will become noncontagious after only 2–3 weeks of treatment, or less. The usual adult daily dose is 600 mg; children should be treated with 10–20 mg per kg, not to exceed 600 mg per day. The cost of daily administration of rifampin is sometimes prohibitive for leprosy control programs in the developing world; however, the very slow replication of *M. leprae* permits administration of the drug once monthly. The alternative regimen recommended by WHO for leprosy control programs in developing countries includes administration of 600 mg of rifampin at monthly intervals as directly observed therapy. This regimen of monthly administration of rifampin was shown to be equivalent to daily doses. The major toxic side effect of rifampin is hepatotoxicity. Generally, rifampin should be discontinued if the alanine transaminase (ALT) (SGPT) or aspartate transaminase (AST) (SGOT) levels increase to more than 2.5–5.0 times the upper limit of normal. Rifabutin, a drug licensed for therapy of *M. avium* complex infections, also has bactericidal activity against *M. leprae*.

Clofazimine. Clofazimine is an iminophenazine dye with antimycobacterial activity roughly equivalent to that of dapsone. It is a useful drug for controlling leprosy reactions, since it also has some anti-inflammatory activity. The usual adult daily dose is 50–100 mg. Higher doses of 200–300 mg daily have more pronounced anti-inflammatory activity but are more likely to lead to gastrointestinal toxicity with chronic use. Also, clofazimine has been used in doses of 100 mg three times weekly for the chronic treatment of leprosy. The drug is deposited in the skin and slowly released, thus providing a repository effect in chronic therapy.

The most frequent side effect of clofazimine therapy is reddish-black pigmentation of the skin. The degree of pigmentation is dose related. However, in many patients the pigmentation tends not to be uniform but is concentrated in the areas of the lesions, producing a blotchy pigmentation that many patients consider to be unsightly. Since virtually all fair-skinned patients will have some pigmentation with clofazimine therapy, it also serves as a useful marker of drug compliance. The pigmentation is slowly cleared 6–12 months or more after therapy is discontinued.

Aside from pigmentation, the major side effects of clofazimine therapy involve the gastrointestinal tract. Patients may develop abdominal cramps, sometimes associated with nausea, vomiting, and diarrhea. On high doses of clofazimine (over 100 mg daily), these symptoms are common after more than 3–6 months of therapy. Radiographic studies of the small bowel may show a pattern compatible with malabsorption. Fortunately, these symptoms usually are reversible when the drug is discontinued.

Other side effects include anticholinergic activity, which may result in diminished sweating and tearing. Since lepromatous leprosy can cause autonomic nerve involvement, patients commonly have ichthyosis from their decreased sweating, and this problem may be intensified by clofazimine.

Ofloxacin. A number of fluoroquinolones have been developed; many of these drugs, such as ciprofloxacin, are not active against *M. leprae*. Among those that are active against *M. leprae* are ofloxacin^{63,64} and sparfloxacin.⁶⁵ These drugs interfere with bacterial DNA replication by inhibiting the enzyme DNA gyrase. They were shown, in animal and short-term human experiments, to have good bactericidal activity against *M. leprae*. Ofloxacin is absorbed well orally and generally given in a dose of 400 mg once daily. A trial is currently under way to determine whether a combination of rifampin and ofloxacin, with or without minocycline, can significantly reduce the treatment period of multibacillary leprosy (i.e., to 1–3 months).^{66,67}

Minocycline. Minocycline is the only member of the tetracycline group of antibiotics that has significant bactericidal activity against *M. leprae*⁶⁸ The standard dose is 100 mg daily, which gives a peak

serum level that exceeds the MIC of minocycline against *M. leprae* by a factor of 10–20. Clinical trials are under way to determine optimal usage of the drug. Although the drug is tolerated relatively well, in some patients vestibular toxicity was reported.

Clarithromycin. Among the macrolide antibiotics, clarithromycin (Biaxin) is the only drug shown to have significant bactericidal activity against *M. leprae*. When given in a daily dose of 500 mg to patients with lepromatous leprosy, 99% of bacilli were killed within 28 days and 99.9% were killed by 56 days.⁶⁹ The drug is relatively nontoxic, however gastrointestinal irritation, nausea, vomiting, and diarrhea are the most common side effects.

Treatment Regimens. The standard therapy for leprosy should include MDT for all forms of the disease.¹⁸ Prior to the early 1980s, patients were often treated with dapsone alone. This led to the emergence of dapsone resistance and rendered further dapsone therapy ineffective in many areas. In 1981, a WHO study group met to recommend new treatment regimens for leprosy control programs. The WHO study group reviewed the data on both the resistance of *M. leprae* organisms to dapsone and their sensitivity to rifampin and clofazimine and recommended that multidrug therapy be used to treat all active cases of leprosy (Table 12-10). The WHO recommended the treatment of patients with paucibacillary disease with 100 mg (1–2 mg per kg) of dapsone daily, unsupervised, and 600 mg of rifampin once a month as directly observed therapy for 6 months. Patients with multibacillary leprosy are to be treated with dapsone 100 mg daily, clofazimine 50 mg daily, both self-administered, and rifampin 600 mg once monthly and clofazimine 300 mg once monthly, both supervised for at least two years or until the disease becomes inactive. Patients in whom acid-fast organisms were identified on their slit-skin smears or skin biopsies prior to treatment should be treated with the regimen for multibacillary disease. Also, patients with currently “inactive” leprosy, who have had only monotherapy with dapsone, should be given MDT to prevent relapse. In patients who were successfully treated, relapse rates of 1.0% or less were reported in the 5–9 years after completing these regimens.

However, relapse rates have varied from 20 per 1000 person-years among patients in India with multibacillary leprosy who were treated for two years to 10 per 1000 person-years in persons treated until they were smear negative.⁷⁰ Higher relapse rates have been reported in patients with a high bacterial index (BI \geq 4.0). In lepromatous patients with high BI relapses have occurred in some patients as long as 15 years after completing treatment.⁷¹

Patients should be followed at frequent intervals after treatment is started. Follow-up should include examination for new skin lesions, new areas of anesthesia, new motor deficits, enlargement or tenderness of nerves, and clinical evidence of reactions. In addition, annual skin biopsies are useful in documenting changes in disease status. Slit-skin smears are helpful in estimating the bacillary load of acid-fast organisms remaining in the skin. These smears are done by pinching the skin to reduce bleeding, cleaning with alcohol, and making a superficial skin slit through the epidermis with a scalpel blade and transferring the subepidermal fluid to a circular area 5–6 mm in diameter on a clean glass slide. Slit-skin smears are taken from six or more sites (e.g., earlobe, eyebrow, trunk, elbow, thigh, and knee) at 6- to 12-month intervals and stained using the Fite-Faraco acid-fast stain. The bacteriologic index (BI) is a semiquantitative logarithmic estimate of the number of organisms in the skin (Table 12-11). With effective therapy of lepromatous patients, the average BI should decrease at a rate of about $1/2$ –1 log each year. Failure of the BI to fall suggests poor compliance with therapy or infection with drug-resistant organisms. The National Hansen’s Disease Center at Baton Rouge, Louisiana, will stain and examine slides prepared by the slit-skin smear technique. Inactive leprosy is defined as a BI of zero on slit-skin smear, no active lesions on skin biopsy, and no clinical evidence of disease activity for at least one year. In cases of intolerance to one of the primary drugs (i.e., dapsone, clofazimine, or rifampin) or drug-resistant organisms, one of the other

TABLE 12-11. THE BACTERIAL INDEX

BI	Number of Organisms
0	No bacilli in 100 OIF*
1+	1–10 bacilli per 100 OIF
2+	1–10 bacilli per 10 OIF
3+	1–10 bacilli per OIF
4+	10–100 bacilli per OIF
5+	100–1,000 bacilli per OIF
6+	Over 1,000 bacilli per OIF

*OIF, oil immersion fields

antileprosy drugs can be substituted (i.e., ofloxacin, minocycline, or clarithromycin).

Treatment of Reactions. Reactions are common during leprosy treatment and complicate the outcome of therapy. Educating patients to recognize and seek prompt treatment for reactions is essential for a successful therapeutic outcome. Such reactions, especially those involving major nerves or the eyes, can cause permanent incapacitation if they are not promptly recognized and properly treated.

Type 1 Reactions. The most important goals in treating type 1 reactions (reversal reactions) are to prevent nerve damage, control severe inflammation, and prevent necrosis of skin lesions. Antileprosy chemotherapy should not be interrupted during the reaction. In mild reactions, especially those without neuritis or facial lesions, treatment with analgesics and anti-inflammatory agents and close observation may suffice. However, any reaction where there is evidence of acute neuritis with pain, tenderness, or loss of nerve function should be treated with steroids, starting with prednisone in doses of 40–60 mg per day. It should be noted that the metabolism of prednisone is accelerated in patients who are also receiving rifampin. The patient may need hospitalization and should be closely observed with frequent voluntary muscle tests (VMTs) to evaluate nerve weakness. The dose of prednisone may be reduced by 5–10 mg every 1–2 weeks until a maintenance dose of 20–25 mg is reached. It can then be reduced slowly over the course of six months or more while repeating VMT and watching for the reaction to recur. Careful management of type 1 reactions is essential to prevent long-term sequelae.

Type 2 Reactions. Although type II (ENL) reactions are important because of their frequency and potential for organ damage, mild ENL reactions can sometimes be managed with anti-inflammatory agents, such as salicylates or nonsteroidal anti-inflammatory agents. However, severe or persistent ENL often requires therapy with corticosteroids, thalidomide, or clofazimine singly or in combination. Commonly, prednisone in doses of 40–60 mg are given and the patient is started on 400 mg per day of thalidomide. Steroids can be reduced or withdrawn, and the ENL can be controlled in some cases with thalidomide alone. Although thalidomide is often effective in controlling ENL reactions, it cannot be given to women of child-bearing age, unless they are following a fool-proof method of contraception, since the drug is highly teratogenic. Clofazimine in doses of 100–300 mg per day has anti-inflammatory effects, but gastrointestinal toxicity is common when the drug is continued at this dose for more than 2–3 months. Some patients will require chronic steroid therapy to suppress their ENL reaction, which can persist for several months.

Iridocyclitis. Iridocyclitis commonly accompanies type II reactions and may cause blindness in leprosy. Another cause of visual damage in leprosy is keratitis secondary to facial nerve damage causing lagophthalmos. Acute iridocyclitis should be treated with mydriatics, such as 1% atropine or 0.25% scopolamine, and anti-inflammatory drugs, such as 1% hydrocortisone.

Other Complications. Important complications of leprosy, such as neuritis, iridocyclitis, orchitis, and glomerulonephritis, may occur during reactions. Therefore it is important that leprosy patients be carefully monitored at frequent intervals, especially while the disease is active. If available, baseline slit lamp examination of the eyes is recommended.

Patients should be trained to avoid injuries to anesthetic areas and to report injuries promptly, even in the absence of pain. Sensory loss (to the point of compromised protective sensation) is often more severe than is generally appreciated.⁷² In addition to sensory loss, many leprosy patients experience neuropathic pain.⁷³ Frequent inspection of the feet and hands and special footwear constructed to prevent permanent damage to deformed and anesthetic feet are important aspects of the care of leprosy patients. Reconstructive surgery, such as tibialis posterior muscle transfer to correct footdrop and temporalis muscle transplant to correct lagophthalmos, may be important in treating some patients. Patients who have ocular problems should be seen by an ophthalmologist.

Control and Prevention

Three basic approaches have been used to control and prevent leprosy, namely:

1. Early detection and supervised chemotherapy of active cases, as described above
2. Preventive treatment of household contacts, especially children, of infectious cases
3. Immunization with BCG

Active searching for cases is an important for controlling leprosy where the disease is endemic. Especially important is periodic screening and follow-up of household contacts of newly diagnosed cases. In leprosy endemic areas, it is important to train health-care professionals to recognize and treat leprosy. Health-care facilities, such as general or skin disease clinics, can provide screening and appropriate leprosy therapy in an atmosphere that is not stigmatizing. Screening of special populations, such as school children, laborers, or military populations can be useful in detecting early leprosy in some highly endemic populations.

Prophylaxis with dapsone, 50 mg daily for three years, has been recommended for persons under the age of 25 who have a household contact with a patient with active multibacillary leprosy.⁷⁴ Children with close contact with someone with paucibacillary (tuberculoid) leprosy are also at some increased risk; however, their risk is less, so they should be examined every 6–12 months for several years after this exposure, and biopsies should be obtained of any suspicious lesions in order to detect and institute treatment soon after clinical disease appears. The rate of leprosy in household members in the 10 years after close household contacts with someone with untreated

lepromatous leprosy was reported to be about 11% after 10 years follow-up in careful studies by Worth and Hirschy in Hawaii⁷⁵ and Hong Kong.⁷⁶ When the index case had tuberculoid leprosy, the incidence in household contacts was reported to be 0.5%. A study of 80,000 disease-free persons in a rural district of northern Malawi found 331 incident cases of leprosy on follow-up in the 1980s.⁷⁷ Persons having dwelling contact with a multibacillary case had an eight-fold higher incidence and those whose contact was with a paucibacillary case had a twofold greater incidence than those without household contact. However, only 15% of new leprosy cases occurred in those who had household contact with leprosy. A randomized controlled study of dapsone prophylaxis, using a 50-mg daily dose for three years in household contacts, found a 52.5% reduction in leprosy in the 12 years after exposure in those who received dapsone.⁷⁸

BCG and Leprosy Vaccines

The initial experimental evidence for the possible preventive efficacy of BCG was reported by Shepard in 1966.⁷⁹ He found that vaccinating mice with BCG prevented experimental infection from footpad inoculation with viable *M. leprae*. Subsequently, several randomized trials of BCG in human populations were done. A trial in Uganda, where most leprosy is tuberculoid, showed an 80% protective efficacy of BCG;⁸⁰ another trial in Karimui, New Guinea, found 48% efficacy;⁸¹ and a third trial in Burma found an efficacy of 20% (however, the efficacy was 38% in children from 0 to 4 years of age and when a second more immunogenic lot of freeze-dried BCG was used).⁸² A more recent trial of BCG in Malawi found that the incidence of leprosy was reduced by 50% after a second inoculation of BCG, but no additional efficacy was associated with including heat-killed *M. leprae* with BCG.⁸³ In summary, these controlled studies of BCG, together with several case-control studies,^{84,85} suggest that BCG affords significant but incomplete protection against leprosy in several populations. However, vaccines prepared from heat-killed *M. leprae* were not efficacious.¹⁰

In recent years, the widespread use of effective multidrug therapy for leprosy under direct supervision, the earlier diagnosis of leprosy, the reduction of the stigma previously associated with this disease in many societies, and the routine use of BCG in many leprosy endemic countries led to a decline in new leprosy cases.^{86,87} Many experts are cautiously optimistic that this trend will continue in the future and that the public health importance of leprosy will continue to decline,^{87,88} as long as the effort to control this disease persists. The long-term outlook for controlling leprosy as a public health problem is good, as long as the effective prevention efforts are not abandoned prematurely. However, many experts are concerned that leprosy control efforts might be abandoned prematurely by assuming that a prevalence rate of under 1 per 10,000 population signifies that leprosy has been “eliminated” permanently as a public health problem.^{10,17,89}

Acute Gastrointestinal Infections

Victoria Valls

► OCCURRENCE AND SCOPE OF GASTROINTESTINAL INFECTIONS

Gastrointestinal infections are caused by a wide variety of microorganisms including viruses, bacteria, protozoa, and helminths that produce diarrhea and vomiting induced by the causative organisms themselves or by the toxins that they produce. Although most cases only require supportive management and are self-limited, diarrheal diseases

remain the fifth leading cause of death among the global population. In spite of the existence of effective preventive measures, gastrointestinal infections produced during 2001 almost 1.8 million deaths worldwide and accounted for 3.2% of overall casualties, most of them taking place in developing countries and most of them happening in children under five.¹ Nevertheless, within the last decades global mortality due to diarrheal diseases has shown a steady decline from figures of 4.8 million deaths per year estimated before 1980

to 3.3 million and 2.6 million for the 1980–1990 and 1990–2000 periods, respectively. This negative trend is probably a consequence of the improvement on case management and infant and children nutrition.

Scarce and contradictory information exist about global incidence because of the limited support existing in many countries to collect systematic data. In addition, differences on how data are gathered, analysed, or resumed make comparisons difficult. In developing countries, 3.2 episodes per child and year in 2003 were estimated,² a figure that has not changed much since the 1990s.^{1–3} In the United States, 211–375 million cases are estimated to occur each year (1.4 episodes per person) producing more than 900,000 hospital admissions and 6000 deaths.^{4,5} Similar data have been reported from European countries.⁶

Frequency of gastrointestinal infection is highly related to environmental conditions and social and economic development. Living circumstances often reflect the socioeconomic situation and are major determinants of environmental risk of exposure. In addition, human behaviour and collective interactions are involved (Table 12-12). Children, especially the very young, show the highest risk. The reasons may be age-related changes affecting children's specific immunologic development, endogenous microbial flora, mucus, and cell-surface factors.⁷ Personal hygiene habits determine how many organisms are ingested. Therefore, breaks of hygiene practices, which are often observed among children, favour spread of pathogenic agents.⁸

Diminished socioeconomic status is strongly related to an unhygienic environment and the number of diarrheal episodes especially for children. Poverty is associated with poor housing, crowding, dirty floors, lack of access to sufficient clean water or to sanitary disposal or fecal waste, cohabitation with domestic animals that may carry human pathogens, and a lack of refrigerated storage for food.¹ It also influences the ability to provide age-appropriate nutritional balanced

diets or to modify diets when diarrhea develops. Therefore, children may suffer repeated episodes of infection, which may increase malnourish. Moreover, the number of diarrheal episodes suffered in childhood may have long-term consequences on psychomotor and cognitive development,⁹ which combined with malnutrition itself may reduce physical fitness and work productivity in adults.

► MAJOR CLINICAL SYNDROMES

Acute gastrointestinal illness is defined as a syndrome of vomiting, diarrhea, or both that begins abruptly in otherwise healthy person. However, the consistency of normal faeces varies from person to person, day to day, and stool to stool. By convention, diarrhea is present when three or more stools (or at least 200 g of stool) are passed in 24 hours and are liquid to adopt the shape of the container in which they are placed.

Three major diarrhea syndromes exist: (a) watery acute diarrhea lasting less than 14 days, (b) bloody diarrhea, which is a sign of damage caused by inflammation, and (c) persistent diarrhea that lasts for more than 14 days. The clinical syndrome is not specifically linked to the causative agent. However, the clinical syndrome provides important clues on the aetiology and may be relevant for epidemiological investigations and outbreak management. Acute watery diarrhea is due to enterotoxins or mucosa superficial invasion. The pathogenic mechanism consists in a shift in bi-directional water and electrolyte fluxes within the small bowel. As there is not mucosa inflammation, leukocytes are not found in faeces. This syndrome usually presents during infections produced by toxin-producing organisms like *E. coli*, *S. aureus*, *C. difficile*, or vibrio species. Infections produced by virus or protozoa like giardia or cryptosporidium also produce this type of diarrhea. Most of infections due to these organisms require ingestion of high quantities of cells to develop. However, watery diarrhea may produce huge environmental contamination, which therefore may favour spread.

The second type of clinical presentation, bloody diarrhea, is due to intestinal damage and use to be associated with malnutrition and often with secondary sepsis. The clinical syndrome is the result of inflammatory destruction of the intestinal mucosa. Increased leukocyte counts and lactoferrin excretion is observed. This syndrome, commonly referred as dysentery, presents during infections due to some shigella, salmonella, and *E. coli* species. It can also be observed during infections produced by *Campylobacter jejuni*, *Vibrio parahaemolyticus*, and *Entamoeba histolytica*. Contamination of soil and dry environments seldom happens. However, spread may occur through exposure to contaminated food or water as most of the involved organisms may produce disease after ingestion of low quantities of cells.

Persistent diarrhea is typically associated with malnutrition either preceding or resulting from the infectious illness itself. Persistent diarrhea poses a mortality risk three times higher than acute episodes.¹⁰ When malnutrition is severe, mortality risk may increase by 17 times.¹¹ Main clinical and epidemiological features of gastrointestinal infections are summarized in Table 12-13 and Table 12-14. For better understanding of text, a glossary of terms is shown at the end of this chapter. Specific reviews on aetiology, patient evaluation, and therapy are published elsewhere.^{5,12,13}

► RISK OF CONTAGION

Agents that cause diarrheal diseases may enter the gastrointestinal tract by ingestion of common food or water, which may serve as primary source or may have been contaminated by contact with either an infected human or animal, or a carrier.^{14–16} Infection may also result from exposure to contaminated environments via hand-to-mouth transmission and from direct contact among humans.¹⁷

Gastrointestinal agents do not universally share routes of transmission. Organisms that multiply in food like Salmonella, typically produce foodborne outbreaks¹⁸ while others like Campylobacter, which

TABLE 12-12. FACTORS THAT INCREASE THE RISK OF CONTAGION

■ Risk of Exposure (Usually Related to the Environment)

- Living or travelling to areas with poor sanitary infrastructure (lack of access to sufficient clean water or to sanitary disposal of fecal waste)
- Living or travelling to areas with poor hygiene compliance
- Lack of refrigerated storage for food
- Cohabitation with domestic animals
- Work with asymptomatic or clinically infected humans
- Work with asymptomatic or clinically infected animals
- Work in clinical or research microbiologic laboratories or industries

■ Risk of Transmission

- Quantity of organisms excreted by faeces or urine
- Quantity of inoculum ingested
- Characteristics of faeces (liquid faeces possess more risk)
- Duration of shedding
- Ability to survive and replicate within different environments
- Human behaviour: poor compliance with hygiene practices

■ Risk of Infection/Disease

Related to the Host

- Age and genetic predisposition
- Gastric pH
- Intestinal motility
- Normal enteric microflora
- Intestinal immunity

Related to Organism

- Enterotoxins
- Cytotoxins
- Attachment and invasiveness

TABLE 12-13. GASTROINTESTINAL INFECTIONS MOST COMMON CAUSATIVE AGENTS

■ CLINICAL FEATURES				
Causative Agent	Usual Symptoms	Incubation Period	Duration of Symptoms	Diagnosis
Norovirus (Norwalk-like & small round-structured virus)	Voluminous diarrhea & vomiting	1–2 d	1–3 d	Routine RT-PCR
Rotavirus	Voluminous diarrhea & vomiting	1–3 d	3–9 d	EIA, latex agglutination
Bacillus (<i>B. cereus</i> & <i>B. subtilis</i>)	Watery diarrhea. (<i>B. cereus</i> may produce vomiting without diarrhea)	6–24 h for diarrhea syndrome	3–7 d	Fecal cultures do not routinely identify the organism
<i>Campylobacter jejuni</i>	Watery diarrhea (may be bloodstained), fever	1–7 d	1–7 d	Routine fecal culture; requires special media
<i>Clostridium difficile</i>	Watery diarrhea to pseudomembranous colitis	Not relevant	Variable; requires discontinuation of previous antibiotics and therapy with metronidazole or vancomycin	Toxin identification.
<i>Clostridium perfringens</i>	Watery diarrhea.	4–24 h	1–3 d	Fecal culture and toxin identification, quantitative cultures required
Enterohaemorrhagic and other Shiga toxin <i>E. coli</i> (STEC O157)	Severe/bloody diarrhea, Haemolytic-uremic syndrome may happen	3–4 d	5–10 d	Fecal cultures, requires special techniques
Enterotoxigenic <i>E. coli</i>	Watery diarrhea	10–72 h	3–7 d	Fecal cultures, requires special techniques
<i>Salmonella nontyphi</i> (<i>S. enteritidis</i> & <i>S. typhimurium</i>)	Diarrhea, vomiting, fever	24 h	2–4 d	Routine fecal culture
<i>Salmonella typhi</i>	Diarrhea in the context of systemic disease.	5–14 d	3–4 w	Routine fecal culture/ blood culture
Shigella (<i>S. sonnei</i> , <i>S. boydii</i> , <i>S. dysenteriae</i> , & <i>S. flexneri</i>)	<i>S. sonnei</i> : mild diarrhea; other species: bloody diarrhea with mucous & pus, fever, systemic disease	1–2 d	2–6 d	Routine fecal culture
<i>Vibrio</i> spp (no-cholerae)	Watery diarrhea	4–30 h	2–5 d	Fecal cultures, requires special techniques.
<i>Vibrio cholerae</i>	Profuse watery diarrhea	24–72 h	3–7 d	Fecal cultures, requires special techniques.
Cyclosporidium (<i>Cyclospora cayetanensis</i>)	Watery or mucoid diarrhea	7–11 d	May be remitting and relapsing over weeks to months	Specific feces microscopical examination
Cryptosporidium	Watery or mucoid diarrhea	1–10 d	May be remitting and relapsing over weeks to months	Specific feces microscopical examination
<i>Entamoeba histolytica</i>	Bloody diarrhea (dysentery syndrome)	2–4 w	Weeks to months	Specific feces microscopical examination
<i>Giardia duodenalis</i>	Mild diarrhea, no fever	1–2 w	1–8 w	Specific feces microscopical examination

TABLE 12-14. GASTROINTESTINAL INFECTIONS MOST COMMON CAUSATIVE AGENTS

■ Epidemiological Features

Causative Agent	Sources	Transmission	Outbreaks	Inoculum Required	Duration of Shedding	Precautions ^{13,62}
Norovirus (Norwalk-like & small round-structured virus)	Humans	P-to-P (exposure to environmental spillage or vomiting contamination), ^{66, 67} Airborne, ⁶⁸ Ingestion (contaminated food or water) ⁶⁹	Nosocomial ^{70,71} & community-acquired: All-aged/ Families Seldom foodborne disease	Low ($<10^3$ ufc)	1–7 d, including 48 h after recovery	Enteric (until 48 h normal stool). Private room & no transfer should be recommended within hospitals. Resistance to common cleaning agents. Bleach 1:10 diluted for contaminated hard, non-porous, surfaces or steam cleaning of contaminated soft furniture in a 2-m radio. ⁷²
Rotavirus	Humans	P-to-P (exposure to environmental spillage or vomiting contamination), ⁷³ Ingestion (contaminated food or water) ⁷⁴	Nosocomial ⁷⁵ & community-acquired: Infants/Families ³⁸	Very low ($<10^2$ ufc)	2–7 d	Enteric (until 48 h normal stool). Private room & no transfer should be recommended within hospitals. Resistance to common cleaning agents. Bleach 1:10 diluted for contaminated hard, non-porous, surfaces or steam cleaning of contaminated soft furniture in a 2-m radio. ⁷²
Bacillus (<i>B cereus</i> & <i>B subtilis</i>)	Dry environment Cereal products, herbs & spices, meat & meat products ⁷⁶	Ingestion of contaminated cooked food with inadequate post-cooking temperature control ^{77, 78}	Community-acquired: Foodborne disease ⁷⁹	High ($>10^6$)	Symptomatic period	Enteric (until 48 h normal stool). Contacts: no action required.
Campylobacter	Birds and mammals (poultry, milk) & tap water C does not multiply on food ¹⁹	Ingestion of contaminated food or water ⁸⁰ Seldom P-to-P	Seldom	Low ($<10^4$ ufc)	50% up to 3 w	Enteric (until 48 h normal stool). Contacts: clinical surveillance.
<i>Clostridium difficile</i>	Humans environment around symptomatic cases	Antibiotic-associated endogenous infection ⁸¹ Gross environmental contamination ^{23, 24} P-to-P through fecal-oral route ⁸²	Nosocomial: Hospitals and nursing homes ^{83–86}	Variable	Symptomatic period	Enteric (until 48 h normal stool). Contacts: clinical surveillance (elderly and patients receiving antibiotics).
<i>Clostridium perfringens</i>	Food animals dry environment	Ingestion of contaminated cooked meat and poultry with inadequate post-cooking temperature control ⁸⁷ P-to-P does not occur	Community-acquired: Foodborne disease ^{88–90}	High ($>10^5$ ufc)	Symptomatic period	Enteric (until 48 h normal stool). Contacts: no action required.

Enterotoxigenic <i>E. coli</i>	Humans & animals	P-to-P transmission in day care units & nurseries Ingestion of contaminated food & water	Community-acquired: Foodborne disease	High (>10 ⁵ ufc)	Symptomatic period	Enteric (until 48 h normal stool). Private room while in hospital. Contacts: clinical surveillance.
Enterohaemorrhagic and other Shiga-toxin <i>E. coli</i> (STEC O157)	Food animals (cattle, sheeps goats)	P-to-P transmission among household contacts & nurseries. Ingestion of contaminated food & water	Community Foodborne disease	High (>10 ⁵ ufc)	Symptomatic period	Enteric (until 48 h normal stool) Contacts: no action required. Microbiological clearance for cases (Groups A–D) & household contacts: 2 fecal cultures 48 h apart.
<i>Salmonella non-typhi</i>	Birds, mammals, reptiles and amphibians multiply on many kinds of foods	Ingestion of contaminated food or water after cross-contamination ^{91,92} P-to-P associated with poor hygiene compliance ⁹³	Community-acquired & Nosocomial: Foodborne or waterborne; ^{94–96} Pt-to-HCW may occur ⁹⁷	Low (10 ² –10 ³ ufc)	4–5 w (10 w for children <5 y) Chronic carriage (>1 y) 0.2–0.6% adults ⁹⁸	Enteric (until 48 h normal stool). Contacts: clinical surveillance.
<i>Salmonella typhi</i>	Humans	Secondarily contaminated food or water ^{22,99,100} Identification of one case should prompt to find the source person P-to-P if poor hygiene ²⁶	Seldom; Community-acquired: Foodborne disease associated to food handling ^{101,102}	High (10 ⁵ ufc)	Chronic carriage (>1 y) 1–4% adults ¹⁰³	Enteric. Private room should be recommended within hospitals. Contacts: clinical & microbiological surveillance. Microbiological clearance required for cases, excretors & carriers: 6 (group C) or 3 (groups A, B & D) fecal cultures one week apart. Two fecal cultures for contacts, 48 h apart.
Shigella	Humans	P-to-P, usually children involved ¹⁰⁴ Day care centers: poor standard precautions compliance ^{8,25}	Community-acquired: close institutions & day care centers	Very low (<10 ² ufc)	Long-term carriage <1%	Enteric. Handwashing supervising within day care centers. Contacts: clinical & microbiological surveillance. Microbiological clearance required for high risk contacts of shigella species other than <i>S. Sonnei</i> : cultures 48 h apart. 2 fecal
<i>Vibrio</i> spp (no-cholerae)	Aquatic environments	Ingestion of seafood or contaminated water ^{20,105,106}	Community-acquired: Foodborne disease	High (10 ⁵ ufc)	Not relevant	Enteric (until 48 h normal stool). Contacts: clinical surveillance.
<i>Vibrio cholerae</i>	Aquatic environments	Ingestion of contaminated water, shellfish, raw food or food washed with contaminated water ¹⁰⁷	Community-acquired in developing countries ^{21,108,109}	High (10 ⁵ ufc)	Not relevant	Enteric (until 48 h normal stool). Patients should be admitted to an infectious disease unit. Contacts: clinical surveillance. Microbiological clearance for cases: 2 fecal cultures 24 h apart.

TABLE 12-14. GASTROINTESTINAL INFECTIONS MOST COMMON CAUSATIVE AGENTS (Continued)

■ Epidemiological Features

<i>Causative Agent</i>	<i>Sources</i>	<i>Transmission</i>	<i>Outbreaks</i>	<i>Inoculum Required</i>	<i>Duration of Shedding</i>	<i>Precautions</i> ^{13,62}
<i>Cyclosporidium (Cyclospora cayetanensis)</i>	Humans	Ingestion of contaminated food or water (soft fruits or leafy veg) Unlikely direct P-to-P	Seldom. Community-acquired: Foodborne disease	Very low (<10 ufc)	Not relevant	Enteric (until 48 h normal stool).
<i>Cryptosporidium spp</i>	Humans and animals	Ingestion of contaminated water ¹¹⁰ P-to-P in households, health care and nurseries ¹¹¹ Cysts resist standard water chlorination ¹¹²	Community-acquired: Public and private water supplies, swimming pools ^{40,113,114} Wildlife & farm parks ^{115,116} Nosocomial: Hospitals and nursing homes ^{117,118}	Very low (<10 ufc)	1–2 w ¹¹⁹	Enteric (until 48 h normal stool). Cases: should avoid using swimming pools for 2 w after normal stool. Contacts: clinical surveillance.
<i>E. histolytica</i>	Humans	Secondarily contaminated food or water Cysts resist standard water chlorination	Seldom. Community acquired: Waterborne disease	Very low (<10 ² ufc)	Asymptomatic carriage may exist	Enteric (until treatment is completed). Household contacts: microbiological screening. Microbiological clearance for food handlers & attending health and social care staff: One stool one week after finishing treatment.
<i>Giardia duodenalis</i>	Humans	P-to-P (families & children). Eventually food contamination due to food handlers or water contamination within recreational parks	Seldom. Community-acquired	Low (<10 ² ufc)		Enteric (until 48 h normal stool). Household contacts: microbiological screening.

do not multiply in food,¹⁹ produce sporadic cases. On the contrary, there are foods that favour growing of specific agents as happens with vibrio no-cholerae species, which characteristically produce gastrointestinal illness after ingestion of oysters.²⁰ Contaminated water is the most common source of vibrio cholerae, the agent responsible for cholera, a highly dehydrating disease, which may produce massive outbreaks in developing countries.²¹ Contamination of water has also been associated with large outbreaks produced by organisms like *Salmonella typhi* which otherwise are direct person-to-person transmitted.²² There are organisms like *C. difficile* that heavily contaminate case surrounding environment, which may become a secondary source of infection. Examples of this route have been observed in hospitals and day care centers outbreaks where environment played an important role in spreading the agent.^{23,24} Until recently, transmission through human contact was thought to be restricted to some specific agents. However, human contact is currently considered the most important route of transmission within developed countries, where sporadic cases and family outbreaks account for most cases.

The relative importance of these different routes of spread varies among countries depending on their sanitary and environmental conditions and on the extension of their food and water supplies control. In the United States, it is expected to be 76 million cases per year of foodborne infections, 13 million cases of waterborne illness, and up to 122 million cases of person-to-person transmission.^{6,17}

Risk of transmission is related to the number of organisms present in food, water, or environment, which is linked to the number of organisms excreted by faeces or urine and to the organism's ability to survive and replicate. However, there are significant differences between organisms referred to the amount of cells required to produce infection. Exposures to cryptosporidium or shigella species are among the most risky situations, as less than 100 cells are required to produce infection.²⁵ On the contrary, a person must ingest more than 10^5 *S. typhi* cells to develop typhoid fever.²⁶ The intrinsic infectivity of species and specific strains and probably the age and the immune status of the host will then determine the severity of the disease.²⁷

Overall risk of contagion is strongly linked to environmental factors. It is well known that likelihood of exposure to contaminated food or water is going to be higher for persons travelling from an area of more highly developed hygiene and sanitation infrastructure to a less developed one. On the other hand, risk of exposure to person-to-person directly transmitted agents will increase within health-care and social-care institutions,⁸ where either infectious patients are attended or breaks on hygiene practices are common. Risk of spreading is also going to play an important role to increase the overall risk of contagion. Four groups of persons with high risk of spreading gastrointestinal organisms have been proposed¹³ (Table 12-15). Spread risk category must be taken into account when controlling an outbreak.

Host Factors

Susceptibility to gastrointestinal infections is highly related to the integrity of host natural barriers, such as gastric acidity, intestinal motility, and intestinal immunity. In addition, age and genetic factors may play an important role.

Gastric acid pH is normally less than 4, which kills more than 99.9% of coliform bacteria within 30 minutes. However, in achlorhydric stomachs there is no reduction on bacterial counts ingested with food.

TABLE 12-15. PERSONS WITH HIGH RISK OF SPREADING GASTROINTESTINAL ORGANISMS¹³

GROUP A	Any person suspected of having poor compliance for hygiene practices or unsatisfactory toilet, handwashing or hand-drying facilities at home, work, or school
GROUP B	Children who attend pre-school groups or nursery
GROUP C	People who prepare or serve unwrapped foods not subject to further heating
GROUP D	Health- and social-care workers who have direct contact with highly susceptible persons

Therefore, patients suffering conditions or receiving therapies that decrease or neutralize gastric pH present higher rates of gastrointestinal infections.^{28,29}

Intestinal motility plays an important function in providing protection against enteric pathogenic organisms. Increased gut motility associated with diarrhea is a highly effective defense mechanism that acts to excel host offending pathogens as does cough in pulmonary infections. Another physical barrier is offered by gastrointestinal mucus, which binds organisms and toxins that are then eliminated as mucus is removed and renewed.

Enteric normal microflora also provides resistance to gastrointestinal infections. The fact that patients treated with oral antibiotics are highly susceptible to gastrointestinal pathogens has been known for a long time. Infection due to *C. difficile* is the most representative condition, although antimicrobial therapy has also been associated to acquisition of other gastrointestinal pathogens.³⁰ Therefore, novel therapies, consisting of replacement of indigenous microbes with probiotics (lactobacillus and other intestinal organisms) are being developed, although their efficacy is still controversial.^{31,32}

Protection against gastrointestinal pathogens is also enhanced by enteric immunity, which is composed of phagocytic, humoral, and cell-mediated elements. The importance of intact phagocytic immunity becomes evident in neutropenic patients who may develop gram-negative rod infections that usually originate in the gastrointestinal tract.³³ Specific active humoral intestinal immunity arises either from a leakage of serum immunoglobulin (IgM and IgG) or from the formation of IgA by plasma cells located in the lamina propria. Intestinal antibodies may be directed at many different bacterial antigens such as endotoxins, capsular material, or exotoxins and may have bactericidal, opsonic, or neutralizing effects. Selective IgA deficiency, which has been associated with respiratory tract infections, has nevertheless little effect on gastrointestinal infections, as its deficit is often compensated with an increment in IgM levels.⁷

Microbial Factors

Enteric pathogens produce diarrheal diseases by altering the normal intestinal absorptive function in different ways.⁷

Some organisms produce enterotoxins (toxins that have a direct effect on intestinal mucosa to elicit net fluid secretion). The classic enterotoxin, cholera toxin, causes fluid secretion by increasing the concentration of cyclic adenosin monophosphate (c-AMP). This same mechanism has been described for other vibrios and *E. coli* species, which produce antigenically similar toxins. Another mechanism of bacterial toxins is cytoskeletal disruption, which has been the mechanism observed for *C. difficile* and *B. fragilis* infections.

Several enteric pathogens excrete cytotoxins that are responsible of mucosa destruction, resulting in inflammatory colitis. Enterohaemorrhagic *E. coli*, *C. perfringens*, and *S. aureus* are among the most representative cytotoxin producer's pathogens, although this mechanism is also supposed for *C. jejuni* and *H. pylori*.

Attachment and invasiveness are other capacities that will facilitate the pathogenic action of enteric pathogens. The ability to adhere and to colonize the mucosa has been observed in enterotoxigenic *E. coli* infections. Other organisms like shigella or enteroinvasive *E. coli* penetrate into and destroy the epithelial cells of the intestinal mucosa, which produces inflammatory or dysenteric diarrhea.

In addition to enterotoxin production, adherence, or invasiveness ability, other virulence traits may affect the organisms' capacity to produce disease. Among these, motility, chemotaxis and mucinase production have been demonstrated to influence *V. cholerae* virulence.³⁴

► EPIDEMIOLOGICAL APPROACH

General Considerations

To manage the problem of gastrointestinal infections effectively, four major questions should be considered: Who, What, Where, and When. "Who" is related to the patient's characteristics: age, sex, health status, therapies, living conditions, profession, etc. "Who" also refers

TABLE 12-16. GASTROINTESTINAL INFECTIONS DESIGNATED AS NOTIFIABLE AT NATIONAL LEVEL IN UNITED STATES**■ Bacterial Diseases**

 Giardiasis

All suspected foodborne disease and outbreaks should be notified. Specific reporting requirements are available from: Council of State and Territorial Epidemiologists. (www.cste.org/nndss/reportingrequirements.htm) And from: Centers for Disease Control and Prevention. (www.cdc.gov/epo/dphsi/phs/infdis2006.htm)

to the relationships among cases (sporadic case vs. outbreak associated case). “What” describes the clinical syndrome. “Where” is related to the setting: developed versus developing country and community versus health-care or social-care institution. As noted previously, risk of exposure to certain pathogens is highly related to the environmental characteristics of the place where the person lives, works, or travels. In addition, “Where” must evaluate place clustering. The last question “When” considers seasonal variations of potential pathogenic agents and time dependent disease’s characteristics such a suspected incubation period, which may guide to a possible source and agent. “When” must also explore time clustering.

All this information will lead one to (a) suspect what organism may most probably be implicated, (b) perform initial microbiological evaluations, (c) initiate case specific therapy if required, (d) anticipate most probable evolution of the problem, and (e) start implementation of contention measures.

In a preventative approach, all cases of diarrheal disease should be considered potentially infectious and should be recommended to avoid attending work, school, or any other social or institutional activity.

Sporadic cases should be differentiated from outbreak-related cases; for the latter, an epidemiological investigation through a case-control study must be urgently conducted in order to determine and avoid causal factors. Therefore, all diarrheal diseases are statutorily notifiable if thought to be foodborne or waterborne, as are some organisms that possess special risk of spreading (Table 12-16). In the United States, national reporting requirements are determined by the Council of State and Territorial Epidemiologists and CDC. State and territorial laws and regulations may also mandate additional reporting requirements.

Outbreak related cases might be suspected by gathering place- and time-clustering information (Table 12-17). Thereafter, specific

TABLE 12-17. INFORMATION TO BE GATHERED FOR PLACE/TIME CLUSTERING INVESTIGATION

Has the patient suffered similar symptoms before?
 Has the household been experiencing similar symptoms within the previous week?
 Has the patient been in contact with anyone other than households with similar symptoms within the previous week?
 Does the patient know about some one else experiencing similar symptoms?
 Has the patient travelled in the month prior to the onset of illness?
 If yes, where?
 Has the patient been in contact with pet reptiles or farm animals or visited petting zoos in the week prior to the symptoms onset?
 Did the patient swim in recreational water parks or swimming pools in the month prior to the symptoms onset?

microbiologic investigations may be required. The characteristics of illness, the epidemiological setting, and the public health implications help to determine whether and what types of fecal testing are appropriate.⁵

Antimicrobial prophylaxis is not recommended after exposures to gastrointestinal pathogens. Nevertheless, clinical or microbiological surveillance of contacts may be required (Table 12-14).

Three different scenarios may be described: gastrointestinal infections observed in the community, gastrointestinal infections acquired while or related to traveling, and gastrointestinal infections acquired in or related to a health-care system. Within them, each characteristic scenes may be pictured which may be useful for a starting approach (Table 12-18 and Table 12-19).

Gastrointestinal Infections Within the Community

Most gastrointestinal infections that occur within the community in developed countries are sporadic or family cases. In this setting, calicivirus and rotavirus are the most common cause of infection. Patients of all age groups may be affected, although rotaviruses predominate in infants. Adenovirus types 40 and 41 and astrovirus may also be implicated. Caliciviruses, of which norovirus (Norwalk-like and small-rounded-structure virus) is the prototype, are thought to be responsible of up to 90% of outbreaks in the United States, where the number of cases per year has been estimated to range from 23 million³⁵ to 74 million.¹⁷ On the contrary, prospective studies identified bacteria in less than 6% of fecal samples.³⁶ The propensity of norovirus to cause emesis and voluminous stools, and the low inoculum required to produce infection could explain the high attack rates observed.¹⁷

Within families, young children, whose hygiene is not as good as that of adults and who are dependent, easily spread acute gastrointestinal infections. Day care centers have reported outbreaks of gastrointestinal infections where both children and attending staff were affected.^{37,38} Again, rotavirus and norovirus are the most common agents, as prevalent risk factors are the same than those described for families.⁸

Foodborne and/or waterborne illness may also happen within the community in developed countries. Foodborne/waterborne gastrointestinal infections may be acquired by ingestion of either contaminated food or contaminated water, which may happen in any point along the alimentary chain, from the source to the dish. Most of foodborne/waterborne diseases are due to viral and bacterial agents among which norovirus, enterotoxigenic *E. coli*, and campylobacter are the most frequently isolated.

The Foodborne Diseases Active Surveillance Network (FoodNet) of the CDC’s Emerging Infections Program collects data from 10 U.S. states regarding diseases caused by enteric pathogens transmitted commonly through food. In its last report,³⁹ comparison of 2005 data with baseline data from the period 1996–1998 shows a decline on the incidence of bacterial outbreaks. In fact, incidence of infections caused by campylobacter, listeria, salmonella, enterotoxigenic *Escherichia coli*, shigella, and yersinia has declined, and campylobacter and listeria incidences are approaching levels targeted by national health objectives, whereas vibrio infections have increased, indicating that further measures are needed to prevent foodborne illness.

Diarrheal disease may affect children or adults attending recreational water parks or private or public swimming pools, if water is contaminated with cryptosporidium, an intestinal protozoa, which cysts resist standard chlorination procedures.⁴⁰ Ingestion of less than 10 cysts may produce infection. This fact facilitates spread even if minimal contamination has happened.

In developing countries, vibrio, enteropathogenic *E. coli*, and protozoa cause the majority of cases of acute gastrointestinal illness, while viral infections are thought to be infrequent.¹⁷

Travelers’ Diarrhea

Travelers’ diarrhea is defined as the clinical syndrome resulting from microbial contamination of ingested food and water that

TABLE 12-18. SCENES OF COMMUNITY-ACQUIRED GASTROINTESTINAL INFECTIONS

Who	What	Where/ When	Suspected Problem	Recommendations
Previously healthy child or adult	Watery diarrhea	Sporadic or family clustered Winter months	P-to-P transmission of rotavirus (children) or norovirus (adults)	Home: enteric precautions Avoid attending work, school or any other social or institutional activity
Previously healthy child or adult	Mild bloody & mucoid diarrhea Fever & myalgia	Place and time clustered There are cases among persons have share an activity	Food-waterborne GI Most common pathogens: enterotoxigenic <i>E. coli</i> , salmonella, campylobacter	Notifiable condition Home: enteric precautions Avoid attending work, school, or any other social or institutional activity Clinical surveillance of exposed contacts
Previously healthy child or adult	Watery to mucoid diarrhea No fever	Sporadic and place/time clustering are possible Summer months The patient has visited a recreational park, swimming pool, or farm	Waterborne disease Most common pathogens: cryptosporidium or giardia	Notifiable condition Home: enteric precautions Avoid attending public or private recreational water facilities Clinical surveillance of exposed contacts

occurs during or shortly after travel.⁴¹ It is most commonly observed among people travelling from an area of more highly developed sanitation infrastructure to a less developed one. There are regional differences in both the risk and the aetiology of travellers' diarrhea. Low-risk countries include North America, North and western Europe, Japan, Australia, and New Zealand. Intermediate-risk countries are those in eastern Europe and South Africa, Argentina, Chile, and some Caribbean islands, whereas high-risk areas include most of Asia, the Middle East, Africa, and Central and South America. It has been estimated that on the average up to 30–50% of travellers to high-risk areas will develop diarrhea during a one- to two-weeks stay.⁴² Classically, bacteria have been responsible for most of the cases,³¹ though protozoa are being increasingly recognized.⁴³ The most common bacterial travellers' diarrhea is produced by enterotoxigenic *E. coli*. It requires ingestion of high inoculums of the organism to produce disease, which may occur when there is a breakdown in sanitation. Enteroaggregative *E. coli* and *Campylobacter jejuni* are also frequent causes of travellers' diarrhea. Both

pathogens may be observed in patients suffering bloody diarrhea, although campylobacter must be suspected if the patient proceeds from Asia.⁴³ On the contrary, patients complaining for mild and long lasting (more than seven days) diarrhea may be suffering a protozoa infection, most commonly due to giardia or cryptosporidium.⁵ Contaminated water is the major source of these organisms, which are usually acquired through ingestion of the water itself or of the products washed with it without boiling it. Low inoculums of the organisms may produce disease.

Passenger Ships' Diarrhea. A special scene of traveller' diarrhea is that represented by infections acquired within or related to shipping. During the last decade, extended outbreaks of diarrhea disease on passenger ships have been reported^{44–47} which has attracted public attention. Cruise ships have long been sites for outbreaks because they place large cohorts of people at risk by living together in confined spaces, eating from one food supply, and drinking from one water supply. These outbreaks are of particular public health importance due

TABLE 12-19. SCENES OF GASTROINTESTINAL INFECTIONS WITHIN OR RELATED TO HEALTH CARE

Who	What	Where / When	Suspected Problem	Recommendations

to the large number of people exposed. The International Council of Cruise Lines estimated that almost 9.8 millions people sailed on a cruise ship in year 2000, and this number was forecast to grow to 20.7 million by 2010.⁴⁸

Rooney et al^{49,50} recently reviewed outbreaks of foodborne and waterborne diseases on ships. The authors identified 50 foodborne outbreaks reported from January 1, 1970 to June 30, 2003. Ten thousand people were affected. *Salmonella spp* were most frequently associated with outbreaks although *Shigella spp*, enterotoxigenic *E. coli*, *Vibrio parahaemolyticus*, and norovirus were observed in 50% of outbreaks. Inadequate temperature control of food or an infected food handler were the most frequently found risk factors. During the same period, 21 waterborne outbreaks were identified, which involved 6400 people. Enterotoxigenic *E. coli* and norovirus were the most common causative agents. In this study, waterborne outbreaks were mostly associated to water uplifted from unsafe sources, contamination of water tank, and defective back-flow preventers.

Gastrointestinal Infections Within Health-Care Settings

Health-care related and hospital-acquired gastrointestinal infections are eventually observed. The most frequent picture in this setting is that of a patient who has been hospitalized for more than 72 hours, who develops watery diarrhea not present on admission and who is receiving antibiotics. Neither time or place nor attending staff associations are observed. Testing for pathogens other than *C. difficile* is discouraged except in an outbreak or in patients over 65 years or with preexisting medical conditions.⁵

Outbreaks of gastrointestinal infections may also happen in health-care institutions. Viruses, like norovirus and rotavirus, are the first leading cause. As previously cited, *C. difficile* may produce heavy environmental contamination, which may become a source of secondary cases. Viruses and *C. difficile* infections may all present like watery diarrhea and, within the first days of the epidemic, place-clustered cases might be limited to a specific ward or unit. A viral etiology must be suspected when the index case is not health-care-related, whereas *C. difficile* might be assumed if the index case presents a health-care-related gastrointestinal infection and has been receiving antibiotics.

Health institutions are not free of suffering foodborne or waterborne outbreaks. The etiologic agent may be any of those causing outbreaks within the community, as the causal factors are the same as those described for community-acquired foodborne outbreaks. The existence of time-clustered cases in the absence of place-clusters is an important clue to suspect a foodborne or waterborne outbreak.

► PREVENTION STRATEGIES

Universal Measures

Universal measures are those that when applied to general population reduce the extent of morbidity or mortality due to gastrointestinal infections. With these objectives, The Disease Control Priorities In Developing Countries supported by the World Health Organization^{1,51} recommended seven interventions (Table 12-20). Exclusive breast-feeding for infants less than six months with appropriate complementary food practices thereafter are keystones to improve global infant mortality as they protect children from both foodborne diarrhea and malnutrition. These measures must be accompanied by immunizations programs, which will decrease morbidity in illness not always linked to food or water contamination. Rotavirus and measles vaccinations are the only ones currently recommended for global gastrointestinal illness prevention. Other gastrointestinal pathogens vaccines lack enough effectiveness to be universally promoted or are under development. Improvement of water and sanitary facilities and promotion of personal and domestic hygiene should be among the first measures to implement, as they are important risk factors for acquisition of foodborne, waterborne, and person-to-person transmitted gastrointestinal illnesses. Unfortunately, these latter activities

TABLE 12-20. PREVENTION STRATEGIES FOR DEVELOPING COUNTRIES^{1,51}

Promotion of exclusive breast-feeding
Improved complementary feeding practices
Rotavirus immunization
Cholera immunization
Measles immunization
Improved water and sanitary facilities and promotion of personal and domestic hygiene
Improvement of case management (new oral rehydration solutions, zinc supplementation, and proper management of bloody diarrhea)

require not only behaviour change interventions but also construction and maintenance of sanitary infrastructure, which can be costly and within some settings even impossible.

Promotion of Exclusive Breast-Feeding and Improvement on Complementary Diets

Exclusive breast-feeding means no other food or drink except necessary medications or vitamins or mineral supplements. Exclusive breast-feeding protects the infant in two ways: first, breast milk contains antimicrobial factors that will protect the child against many pathogens and provides all the nutrients the child needs. Second, breast-feeding reduces the risk of exposure to contaminated food or water, which is known to be high in many areas. In addition, if breast-feeding is continued when the child suffers diarrhea it will help to decrease the negative impact of the disease on nutritional status, which is a risk factor for subsequent episodes of diarrhea and will affect future child development.

Exclusive breast-feeding is currently considered one of the most effective measures on reducing global mortality due to gastrointestinal infections, both for developing and developed countries. It has been estimated that up to 13% of overall cause-mortality in children fewer than five years may be prevented.⁵² In addition, infants who are breast-fed are six times less likely to die of diarrhea than those who are not breast-fed.⁵³ When breast-feeding is continued after weaning—up to the age of two years—the benefits on children nutritional and immunological status are maximized and up to 800,000 deaths could be saved.⁵² Therefore, exclusive breast-feeding is currently recommended within the first six months of life. Thereafter, breast-feeding must be maintained associated with complementary foods for children less than two years. Zinc and vitamin A supplementation may also help to reduce mortality by decreasing the incidence of severe diarrheal episodes.¹

A special situation is that of children born from HIV positive mothers. Since the beginning of HIV epidemic, breast-feeding was thought to be a potential risk factor for HIV transmission and it was discouraged. Recommended alternatives included heat-treated breast milk, HIV-negative wet nurses, uncontaminated donor milk, or exclusive breast-feeding for six months and rapid discontinuation thereafter.⁵⁴ However, some of these practices are seldom affordable within developing countries, where in addition, high rates of HIV infection may be associated with lack of access to HIV testing. Recent reports have shown that HIV transmission through breast-feeding is not easy to happen,⁵⁵ whereas high risk of mortality is undoubtedly associated with replacement feeding. Therefore, exclusive breast-feeding is considered for all women regarding their HIV status.⁵⁶

Rotavirus Immunization

Rotavirus is one of the most frequent causes of diarrheal disease. Within developing countries, rotavirus is estimated to produce up to 500,000 deaths per year among children under five.² Within developed countries, appropriate nutritional and hydration management of gastrointestinal diseases keep mortality rates into anecdotal numbers (20–60 cases per year). However, in United States, rotavirus is responsible for 55,000–70,000 hospitalizations and 200,000–270,000 visits to

emergency departments per year.⁵⁷ In addition, rotavirus infection is not linked to sanitation facilities and improvements on water supplies or hygiene practices are unlikely to further decrease infection rates.

A routinely vaccination of U.S. children was started in 1998 with a rhesus-based tetravalent rotavirus vaccine, which was administered at ages two, four, and six months. One year after, this vaccine was withdrawn because of an increased risk of intussusception, a condition in which the intestine telescopes on itself. Recent research suggests a that risk of intussusception was age-dependent and that the relative risk for intussusception associated with the first dose increased with increased age at vaccination.⁵⁸

Recently two new formulations have been marketed. The first one is a monovalent vaccine based on an attenuated human rotavirus strain (RotaRix, GSK biological, Belgium) that has been licensed and is currently in use in countries within Europe, Central America, Africa, and Asia. The second one is a live oral vaccine that contains five reassortant rotaviruses developed from human and bovine parent rotavirus strain (RotaTeq) and it is licensed for use within the United States since 2006. Both vaccines have been tested in phase III trials and neither intussusception nor other severe adverse effects increased risks were noted. Efficacy of RotaTeq after completion of a 3-dose regimen was 74% against any rotavirus disease and 98% against severe rotavirus gastroenteritis. Currently this vaccine is proposed for universal vaccination for U.S. children at ages two, four, and six months.⁵⁹ First dose should be administered between ages 6 weeks and 12 weeks and subsequent doses should follow at 4–10 week intervals. Any clinically significant or unexpected adverse effect that occurs after administration of this vaccine should be reported to the Vaccine Adverse Events Reporting System (VAERS), which may be electronically accessed at <http://vaers.hhs.gov>.

Measles Immunization

Measles-induced immunodeficiency is a risk factor for diarrheal disease. It was estimated that up to 3.8% of diarrheal episodes and 26% of diarrheal deaths could be prevented if global measles vaccination achieved a 90% coverage rate.⁶⁰

Measles vaccine contains live, attenuated measles virus. It is available as a single-antigen preparation or combined with live, attenuated mumps or rubella vaccines, or both. Combined measles, mumps, and rubella (MMR) vaccine is recommended whenever one or more of the individual components are indicated. Within developed countries, combined MMR vaccination is administered to infants at the age of 12–15 months. A second routinely dose is recommended at age of 4–6 years. Severe adverse events are scarce, however fever and rash occurring 7–12 days after vaccination may be observed in up to 5% of vaccines.⁶¹

Improved Water and Sanitary Facilities and Promotion of Personal and Domestic Hygiene

Improved access to sanitation facilities may reduce overall child mortality by an average of 55% and promotion of handwashing may trim down diarrhea episodes by a 33%. However, the greatest effect of these interventions will be in areas of high population density and if the entire community adopts the intervention rather than single households.¹

Promotion of personal and domestic hygiene may help to reduce potential contamination of foods and person-to-person transmission. Education of caregivers on hygienic practices, improving home food storage and knowledge on simple domestic methods to reduce pathogen contamination should be conducted.

Enteric Precautions

Enteric precautions are those that address limiting the spread of gastrointestinal pathogens, once an infected or colonized patient, who may become a source, has been identified. Gastrointestinal infections may spread through both direct and indirect person-to-person transmission, which always imply contact and physical transfer of organisms from the source person to a susceptible person or to a vehicle

(food, water, and environment). Therefore, enteric precaution should include contact precautions, which consist of improving handwashing practices, proper disposal of excretions and soiled materials, and management of spillages. Education of patients and households is important to assure compliance. In addition, for patients admitted to a hospital, use of gloves and gowns, and specific recommendations for patient placement and transport and patient-care equipment may be required. Detailed information about contact precautions within hospitals can be obtained from the Centers for Disease Control and Prevention's Guideline for Isolation Precautions in Hospitals,⁶² which can be electronically accessed at <http://www.cdc.gov/ncidod/dhqp/guidelines.html>.

Handwashing

This is the most important measure to avoid transfer the organisms. Hands must be washed after dealing with sick people, handling their clothes or bedding, having contact with their room equipment, and after removing disposable gloves. Every one must wash their hands after going to the toilet and after changing babies' nappies. Towels should not be shared, and within the hospital, must be replaced by disposable paper devices. Liquid soap instead of soap tablets is encouraged. Antiseptic soaps and alcohol-based solutions may be recommended for some instances.

Disposal of Excretions and Soiled Materials

Excretions may be eliminated normally to the toilet. Excretions containers, when required, should be washed with hot water and detergent. Gloves and aprons should be worn to handle contaminated containers or any other contaminated materials. Soiled clothing and bed linen should be washed separately from other clothes at the highest temperature they will tolerate. Contaminated solid waste should be eliminated to a plastic bag, and after sealing, placed with the other solid waste.

Spillages

Spillages should be cleaned with absorbent materials. Thereafter, contaminated surfaces should be cleaned with hot water and detergent while wearing gloves and aprons. Careful handwashing should be done after removing disposable gloves.

Specific Interventions

Contact Evaluation

Contact evaluation refers to clinical and/or microbiological surveillance of a person who had been exposed to a gastrointestinal infection that may be transmitted through person-to-person direct or indirect contact. The exposed person may develop the disease, which may be health threatening, but may also become the index case for secondary cases, which may happen by being an excreter during the symptomatic period, or by being an asymptomatic carrier. Furthermore, some persons who had been exposed to transmissible gastrointestinal pathogens may be food handlers or caregivers, which may increase the risk of transmission (Table 12-15).

All asymptomatic persons who might have been exposed during an ongoing outbreak should be recommended to consult their physicians if they develop symptoms. However, clinical surveillance should be explicitly done when the person was exposed to *C. difficile*, salmonella, shigella, vibrio, or cryptosporidium. In addition, microbiological studies should be required after exposures to typhoid fever, shigellosis, amebiasis, or giardiasis (Table 12-14).

Vaccines

Rotavirus is the only gastrointestinal agent for which infant vaccination has been scheduled. However, there are licensed vaccines against salmonellosis and cholera. These vaccines are currently recommended for travellers under special circumstances. Vaccination against typhoid fever is recommended for persons travelling to tropical areas where sanitation facilities are thought to be poor.

Two typhoid vaccines are currently available for use in the United States: an oral live, attenuated vaccine (Vivotif Berna vaccine, manufactured from the Ty21a strain of *S. Typhi* by the Swiss Serum and Vaccine Institute) and a Vi capsular polysaccharide vaccine (ViCPS) (Typhim Vi, manufactured by Aventis Pasteur) for intramuscular use. Both vaccines have been shown to protect 50–80% of recipients. Revaccination might be required after five years and two years, respectively.⁶³

Cholera vaccination is considered only for those persons working in relief or refugee settings or for those who will be travelling in cholera-epidemic areas and who will be unable to obtain prompt medical care. These constrained uses are both because of the lack of maintained immunogenic stimulation and the low risk of exposure expected as cholera is restricted to some world specific areas. In addition, cholera diarrhea may be efficiently controlled by administering liquid rehydration. Nevertheless, a killed whole-cell cholera vaccine combined with the recombinant B subunit of cholera toxin (rCTB-WC) recently licensed in Europe has renewed the interest.⁶⁴ Because of the similarity between cholera toxin and the heat-labile toxin of *Escherichia coli*, it has been proposed that the rCTB-WC vaccine may be used against travellers' diarrhea. In fact, vaccines primarily addressed against enterotoxigenic *Escherichia coli* (ETEC) are being intensively investigated.⁶⁵

► GLOSSARY

Carrier: a person who has excreted the organism in faeces or urine for more than 12 weeks.

Case: a person with symptoms.

Clinical Surveillance: observation for development of relevant clinical symptoms.

Contact: a person who is likely to have been exposed to an infectious person either through direct contact or through contact with infectious excreta.

Enteric Precautions: measures recommended for limiting enteric spread.

Excreter: a person without symptoms who excretes pathogenic microorganism in faeces or urine for fewer than 12 months. The person may have had the disease or may have been asymptomatic infected.

Foodborne Infection: any infection caused by or thought to be caused by the consumption of food. Infections acquired after water consumption are also considered foodborne infections. Symptoms of intestinal irritation or damage may not necessarily be present.

Food handler: person who prepares or serves unwrapped foods.

Gastrointestinal Infection: any infection, from whatever source, of the digestive tract. Symptoms of intestinal irritation or damage must be present.

Index Case: first case that develops an infectious disease and who is supposed to be the origin of an outbreak in a person-to-person (P-to-P) transmitted infection.

Microbiological Clearance: reduction of the excretion of the pathogenic organisms to undetectable levels by conventional diagnostic methods.

Outbreak: two or more cases associated in place and or time.

Standard Precautions: Barrier measures used to take care of patients within hospitals given the possibility of a transmission mechanism.

Waterborne Disease: any infection caused by or thought to be caused by the ingestion of water. Infections may be acquired after consumption of drinking water (foodborne) or after accidental ingestion in recreational water parks or swimming pools.
