CHAPTER 13

Transfusion Therapy and Blood Conservation

Leonard Y. Lee • William J. DeBois • Karl H. Krieger • O. Wayne Isom

With the development of cardiac surgery in the 1950s to correct congenital heart defects came the need for large-volume blood transfusions. In the 1960s and 1970s, the introduction of valve prostheses and direct grafting of coronary arteries made the correction of acquired heart disease a possibility. These landmarks, along with the liberal use of homologous blood transfusion therapy, led to rapid growth of the field. Commensurate with the growth of cardiac surgery as a field was an increasing incidence of transfusion-transmitted hepatitis in the 1970s, ultimately alerting the public and treating physicians to the concept of blood conservation. The emergence of infection by human immunodeficiency virus (HIV) greater heightened the interest in this area, leading to the current practices of blood conservation therapy in cardiac surgery.

Historically, open-heart surgery has been associated with a high usage of blood transfusion. Some reports suggest that up to 70% of this patient population requires blood transfusions, resulting in an average of two to four donor exposures per patient.[1,2] It has been reported that 10% of all red blood cell units transfused in the United States are administered during coronary bypass surgery.[3] Almost all patients received blood transfusion in the early days of cardiac surgery. However, with an increased awareness of blood-borne infectious diseases, lack of donors, great cost to both the patient and the institution, allergic reaction, blood-type mismatch, and the needs of special populations such as Jehovah's Witnesses, a greater effort has been made to perform open-heart procedures without blood transfusions even in high-risk patients. Advances in perioperative medications that minimize blood loss; greater tolerance of lower hematocrits, especially on bypass; and improvements in surgical techniques resulting in shorter operative times have allowed for these extensive procedures to be performed without significant blood loss.

The high transfusion rates associated with cardiac surgery have been well characterized and are likely due to the coagulopathy, platelet dysfunction, and red cell hemolysis that occur as a result of the cardiopulmonary bypass circuit.[4–6] The introduction of hemodilution using crystalloid pump-priming solution rather than whole blood dramatically reduced the transfusion requirements seen during coronary artery bypass grafting (CABG) procedures.[7] While this technique has reduced the amount of blood transfused during cardiopulmonary bypass (CPB), the resulting hemodilution contributes to the risk of low intraoperative and postoperative hematocrit, especially in patients who weigh less than 70 kg, thereby posing a new risk for transfusion.

Efforts at reducing the use of homologous blood in cardiac surgery began almost 40 years ago. The efforts to decrease allogeneic blood exposures have been a topic of constant review and attention because of the desires of both patients and their physicians to conserve blood during the perioperative period. These joint efforts have affected virtually every aspect of the manner in which heart surgery and CPB are performed. Our experience combined with the experiences of others has led to the development of an integrated, comprehensive blood conservation program that makes the goal of bloodless heart surgery possible.

PAST EXPERIENCE: A REVIEW OF THE LITERATURE

Since the earlier days of cardiac surgery, there have been several reports of minimizing the use of blood and blood products both intraoperatively and postoperatively. While most of these studies have focused on the use of one particular modality or pharmacologic agent, these techniques were applied in the context of an entire set of blood conservation measures. Collectively the results of these reports provide an important body of information that can be used as an aid to evaluating the relative effectiveness of various combinations of the presently available blood conservation techniques. Table 13-1

summarizes the findings of 35 studies of patients undergoing non-CABG or combined procedures requiring CPB.

Table 13-2 similarly summarizes the findings of 41 studies of patients undergoing CABG only. These studies provide information about the techniques applied, as well as outcome measures of patients receiving homologous transfusions. Although preoperative autologous donation was applied only sporadically (12 of 73 studies), nonblood prime was applied almost universally (65 of 73 studies). The majority of studies achieving very low transfusion rates used low to low-moderate transfusion triggers both during and following CPB. Conversely, the studies reporting high rates of transfusion either used higher transfusion triggers or the triggers were not stated, indicating that the investigators likely did not recognize or place enough emphasis on this essential blood conservation measure. Finally, the studies that achieved overall transfusion rates of less than 30% used the cornerstones of blood conservation, namely, pre- or intraoperative autologous blood donation, nonblood priming, return of residual circuit blood to the patient, low or moderately low intra- and postoperative transfusion triggers, and reinfusion of shed mediastinal blood. Several of these studies bear special attention.

The first program to report less than 10% transfusion rates in non–Jehovah's Witness CABG patients was that of Cosgrove and colleagues at the Cleveland Clinic in 1978.[8] This report of 50 patients undergoing elective CABG demonstrated transfusion rates of only 6%, with a mean of 0.06 unit per patient receiving blood. Included in Cosgrove's study were the six principal techniques of blood conservation stated earlier, many of which are still used today in blood conservation programs throughout the world, namely

1. Intraoperative autologous donation
2. Nonblood prime
3. Return of all residual CPB circuit blood
4. Intraoperative salvage
5. Use of the lowest safe level of anemia during CPB as well as in the postoperative period
6. Reinfusion of shed mediastinal blood

Later studies took advantage of pharmacologic developments such as serine protease inhibitors, antifibrinolytics, and erythropoietin. By the early 1990s, these pharmacologic adjuncts to blood conservation had become readily available and could be categorized as agents useful in perioperative stimulation of bone marrow for red blood cell production (e.g., erythropoietin) and agents useful in reducing postoperative bleeding (e.g., serine protease inhibitors and antifibrinolytics).

In 1990, Ovrum and colleagues confirmed the effectiveness of the simple "core" approach to blood conservation.[9] In 121 consecutive elective CABG patients, the authors achieved a transfusion rate of 4.1% and 0.06 unit per patient. In 1991, Ovrum applied these same principles to 500 elective CABG patients and obtained similar low rates of transfusion (2.4% of patients).[10] The authors found this six-step blood conservation program to be simple, safe, and cost-effective.

By the 1990s, there also were some technical advances in CPB designed to minimize the need for transfusions as well as for hemodilution. With better oxygenators came a reduction in the volume of the CPB circuit, accompanied by a reduction in the amount of hemodilution that occurred.[11] Circuit volume could be further reduced by replacing as much of the crystalloid circuit prime as possible with autologous blood drained from the arterial cannula into the circuit immediately prior to CPB, called *retrograde autologous priming* (RAP), as well as displacing the venous side of the crystalloid prime when first initiating CPB.[12] These relatively simple maneuvers can reduce the crystalloid prime to a volume of roughly 200 mL. In addition, technical advances such as leukocyte filters and heparin-bonded circuits reduced the inflammatory response of the body to the blood interface with the CPB circuit, which ultimately can lead to less homologous blood requirement.[13,14]

The addition of newer pharmacologic and technologic advances to the proven "core" conservation measures as established by Cosgrove and Ovrum had the potential to markedly reduce and even eliminate the need for transfusion even in the face of the more difficult patient characteristics increasingly being encountered. This then became the goal of blood conservation programs.

PREOPERATIVE MANAGEMENT

Identification of Patients at Risk

The coagulopathy associated with CPB is related primarily to the interaction of blood components with the artificial surfaces of the CPB circuit, which results in derangements in platelet function, abnormal functioning of the coagulation cascades, and excessive fibrinolysis. The administration of high-dose heparin to prevent coagulation within the CPB circuit and hypothermia achieved during bypass further contribute to hemostatic derangements. Finally, while the use of asanguineous crystalloid prime rather than the whole-blood pump prime used historically has reduced the amount of blood transfused during CPB dramatically, the resulting hemodilution contributes to the risk of low intraoperative and postoperative hematocrit, which can be independent risk factors for transfusion in the postoperative period. Other risk factors can be assessed in the preoperative state that can identify those patients who may be at high risk of bleeding or who have a low red cell mass, both of which may require autologous blood transfusions.

One of the most important predictors of postoperative bleeding in the surgical patient is a personal or family history of any excessive bleeding or documented bleeding disorders. Many disorders can be confirmed with simple laboratory tests demonstrating some level of coagulation derangement. However, in the cardiothoracic patient population, medications and acquired medical diseases and their associated hemostatic defects are likely to be the most common risk for bleeding. Some of the most commonly seen problems are summarized in Tables 13-3 and 13-4. Notably, the use of

Table 13–3.

Medications Associated with an Increased Risk of Bleeding

Drug	Effect on hemostasis
Aspirin	Irreversible platelet inhibition by blocking platelet cyclooxygenase
Heparin	Inhibition of factors II and X, both direct and indirect thrombocytopenia
	Mostly antibody-mediated (HIT)
Coumadin	Multiple factor deficiency by blocking gamma-carboxylation
	Vitamin K–dependent factors
Antibiotics	Multiple factor deficiency owing to vitamin K malabsorption
Multiple drugs	Thrombocytopenia owing to bone marrow inhibition of platelet production

aspirin alone or included in other medications intended for pain relief or treatment of other ailments is very common. The prevalence among patients undergoing unplanned surgery may be as high as 50%, and this may be even higher among patients with previously diagnosed coronary artery disease.[15,16] The currently published data would suggest that this does not represent a significant bleeding risk, and there is little evidence to suggest that bleeding times correlate with operative blood loss in these patients.[17,18]

Herbal Extracts for Cardiovascular Health

The use of herbal extracts and complementary medicine has become popular in the prevention of arterial thrombotic disease. In 1997, an estimated $21 billion was spent in the United States on complementary and alternative therapies.[19,20] Herbs such as thyme and rosemary have been shown to have a direct inhibitory effect on platelets.[21]

Despite the increased potassium contained in fruits and nuts, menu planning for patients on warfarin can

Table 13–4.

Acquired Diseases Associated with an Increased Risk of Bleeding

Condition	Effect on hemostasis
ESRD/uremia	Irreversible platelet dysfunction by platelet inhibitory metabolites
Liver disease	Multiple factor deficiency owing to defective synthesis
	Thrombocytopenia owing to hypersplenism
Malabsorption	Multiple factor deficiency from vitamin K deficiency
SLE	Thrombocytopenia and thrombocytopathy owing to platelet autoantibodies
	Factor deficiency owing to prothrombin deficiency occasionally associated with lupus-type inhibitor
Amyloid	Capillary fragility owing to vascular amyloid infiltration
	Factor X deficiency owing to absorption by amyloid
Malignancy	Thrombocytopenia and anemia owing to chemotherapy
	Thrombocytopenia owing to marrow infiltration of tumor
	Factor deficiency owing to DIC (advanced stages of cancer) as well as some chemotherapeutic agents

include a healthy diet of these foods without compromising the stability of their oral anticoagulation therapy because most fruits are not important sources of vitamin K, with the exception of some berries, green fruits, and prunes.[22] In a case report regarding fish oil supplementation, it was demonstrated that additional anticoagulation could have resulted from an interaction with warfarin therapy. This case reveals that a significant rise in the international normalization ratio (INR) occurred after the dose of concomitant fish oil was doubled. Fish oil, an omega-3 polyunsaturated fatty acid, consists of eicosapentaenoic acid and docosahexaenoic acid. This fatty acid may affect platelet aggregation and/or vitamin K–dependent coagulation factors. Omega-3 fatty acids may lower thromboxane A_2 supplies within the platelet, as well as decrease factor VII levels.[23]

The popularity of herbal additives can be evidenced by the over $700 million spent annually and the continued expected spending on such products.[24] Despite the potential benefits of many herbs with regard to improved well-being, many adverse risks exist. Primarily there is an increased cardiovascular risk among the more commonly used supplements, as seen in Table 13-5.[25]

Health care workers can play a crucial role in identifying possible drug interactions by asking patients taking warfarin about herbal and other alternative medicine product use. Furthermore, the clinical importance of herb-drug interactions depends on many factors associated with the particular herb, drug, and patient. Herbs should be labeled appropriately to alert consumers to potential interactions when used concomitantly with drugs and to recommend a consultation with their general practitioners.

Autologous Blood Donation

One of the primary concerns in blood conservation is the patient's size and preoperative red blood cell volume. Two early reports by Cosgrove and Utley demonstrated these factors in addition to preoperative anemia as independent risk factors for blood transfusion.[26,27] As will be discussed later in this chapter, there are several relatively simple manipulations to the CPB circuit that can be made to reduce the amount of hemodilution that the patient experiences while on bypass to reduce the overall risk of transfusions.

Table 13–5.

Herbs with Adverse Effects

Herb	Adverse effect
Garlic	Increased bleeding
Ginger	Platelet dysfunction Hypertension
Gingko	Increased bleeding Platelet dysfunction
Ginseng	Hypertension
Licorice	Hypertension

Preoperative autologous donation (PAD) is a recognized strategy to reduce the risk of homologous blood transfusion in the perioperative period. Although this technique has been in practice since the 1960s, its use in cardiac surgery did not achieve widespread acceptance until the 1980s, with the advent of HIV, as an effort to reduce homologous blood exposures. Unfortunately, in cardiac surgery, the acuteness of the operations and dealing with an older and sicker patient population often preclude PAD because there must be enough preoperative time for autologous collection as well as for red blood cell mass regeneration prior to arriving in the operating room. However, for that select, elective cardiac surgical patient for whom PAD is possible, it is a good option to reduce homologous blood exposures.

Several preoperative characteristics can identify the cardiac patient who is eligible for PAD. The first criterion is that the patient be able to wait the required time for donation and red blood cell regeneration. This length of time typically varies depending on the type of surgical procedure planned (larger operative procedures likely requiring a larger amount of blood) and patient characteristics (e.g., body size, blood volume, and hematocrit). In general, this time is a minimum of 2 weeks per unit of blood donated to allow for red blood cell regeneration. The second criterion is that the patient be healthy enough to undergo donation. This criterion would preclude patients with severe left main stem stenosis, critical aortic stenosis, congestive heart failure, and idiopathic hypertrophic subaortic stenosis, as well as patients with severe coronary artery disease and ongoing ischemia, given that many of these patients would have been screening failures for the first criterion. The third criterion is that the patient not have active endocarditis. The time between donation and receiving the PAD unit is ample time for bacteria to replicate in the donated unit with resulting bacteremia, which is potentially life-threatening. The fourth criterion is that the patient has an adequate hematocrit and red blood cell mass. A preoperative hematocrit of less than 33% regardless of red blood cell mass is a contraindication to PAD according to the American Association of Blood Banks (AABB) guidelines. A patient with a hematocrit of greater than 33% may be eligible provided that other criteria are met.

Several options exist for patients who historically were not eligible for PAD. Recombinant erythropoietin can be used to accelerate red blood cell production in anemic patients; this strategy is used commonly in Jehovah's Witness patients to increase their red blood cell mass prior to surgery.[21] However, this can be quite costly; as a result, it is usually reserved for patients who are unable to tolerate homologous blood transfusions whether for religious reasons or because they have a rare blood type. An alternative strategy is to stimulate the body to increase the release of endogenous erythropoietin by allowing patients with hematocrits below the traditional cutoff to undergo PAD. The

resulting anemia experienced by the patient in the postdonation period is a strong stimulant for endogenous erythropoietin production, ultimately leading to an increase in red blood cell mass.[28]

Red blood cell mass is related to patient body size.[29] A traditional cutoff of 110 lb had been used for PAD. However, the AABB does make specific allowances for PAD in smaller patients. The current recommendation is that no more than 15% of the patient's effective blood volume should be removed at any given time, which takes into account smaller patient body size. PAD should be pursued aggressively for these small patients with low red blood cell mass and hematocrit because they are at highest risk of receiving a blood transfusion at some time during their hospital stay. The mean rate of red blood cell generation of the studies that provided adequate data is 0.46 unit per week, or slightly less than 1 unit every 2 weeks.[30] In conjunction with PAD, oral iron therapy should be initiated at the time of first donation to ensure adequate iron stores for red blood cell regeneration.

Owing to the relatively acute illness of the population, rarely is there sufficient time for PAD in the cardiothoracic surgical patient. In addition, PAD has been supplanted largely by intraoperative blood salvage techniques for reasons of cost-effectiveness (i.e., blood withdrawal, preparation, storage, and potential erythropoietin therapy add to costs) and because of advances in intraoperative blood salvage techniques such as intraoperative autologous donation (IAD; discussed later in this chapter), retrograde autologous prime of the CPB circuit, use of cell salvage, and regular use of cardiotomy suction.

PHARMACOLOGIC STRATEGIES FOR BLOOD CONSERVATION

A number of drugs have been used to decrease blood loss and the use of blood transfusion associated with cardiac surgery (Table 13-6). Interest has been renewed recently in antifibrinolytics, a relatively old class of drug. Currently, three such medications are used clinically; two are synthetic antifibrinolytics (i.e., epsilon-aminocaproic acid and tranexamic acid), and one is naturally occurring (i.e., aprotinin derived from bovine lung). Linked with the resurgence of interest in these drugs is interest in diminishing homologous blood transfusions related to cardiac surgery.

Epsilon-Aminocaproic Acid

Epsilon-aminocaproic acid (EACA) is a synthetic antifibrinolytic agent first described in 1959 that derives its effect by forming reversible complexes with either plasminogen or plasmin, saturating the lysine-binding sites and thus displacing plasminogen and therefore plasmin from the surface of fibrin. This blockage of plasminogen binding to fibrin blocks plasminogen activation and therefore fibrinolysis. The overall effect is to block the dissolution of the fibrin clot.

Several studies have demonstrated the efficacy of EACA in reducing bleeding following open-heart surgery. Although EACA was first used in situations in which excessive bleeding was encountered, Lambert and colleagues used EACA in 1979 to successfully treat patients with coagulation disorders, who comprise 20% of total primary coronary bypass patients.[32] DelRossi used EACA in 1989 as a prophylactic tool to reduce blood loss in 350 patients undergoing CPB, having an impact on both blood loss and transfusion of autologous blood and blood products.[33]

Tranexamic Acid

The mechanism of action of tranexamic acid (TA) is similar to that of EACA. The significant difference between EACA and TA is that TA is roughly 10 times more potent than EACA. As with EACA, postoperative bleeding and homologous blood requirements were similarly decreased with the use of TA, as shown by Horrow in 1990 in 38 patients undergoing CPB.[34]

Table 13–6.

Antifibrinolytics Used in Cardiac Surgery and Their Mechanism of Action

Antifibrinolytic	Mechanism of action
Epsilon-aminocaproic acid (Amicar)	Forms a complex with plasminogen through lysine-binding sites, thus blocking their adhesion to fibrin
Tranexamic acid (Cyklokapron)	Forms a complex with plasminogen through lysine-binding sites, thus blocking their adhesion to fibrin
Aprotinin (Trasylol)	Serine protease inhibitor with an antifibrinolytic effect carried by the inhibition of plasmin and kallikrein
	Protection of platelet GP Ib, reducing thrombin-mediated consumption of the platelets

Aprotinin

Aprotinin is a low-molecular-weight serine-protease inhibitor with a lysine residue occupying its active center. It is a naturally occurring polypeptide isolated from bovine lung. Reversible enzyme-inhibitor complexes with various proteases are formed that display activity against trypsin, plasmin, streptokinase-plasma complex, tissue kallikrein, and plasma kallikrein. Because aprotinin is a nonspecific serine antiprotease, it intervenes in the coagulation cascade in multiple loci, working to decrease bleeding in CPB patients by its antiplasmin and antikallikrein effects.

Aprotinin was first used in cardiac surgery by Tice and colleagues, who described the administration of 10,000 to 20,000 kallikrein inhibitory units (KIU), resulting in rapid establishment of hemostasis in five patients who had undergone CPB; they also demonstrated increased bleeding and increased fibrinolytic activity.[35] The currently accepted regimen of high-dose aprotinin (5 to 6 million unit average total dose) is reflective of the experiences of the Hammersmith group, which serendipitously saw a reduction in bleeding in patients receiving aprotinin to reduce kallikrein-mediated lung inflammation during CPB.[36] Since this report, multiple reports have emerged citing the efficacy of aprotinin as compared with other antifibrinolytics and controls in reducing bleeding complications, homologous blood transfusions, and inflammation primarily in the reoperative setting.[37–39] Despite these advantages, Mangano and colleagues reported that aprotinin use was associated with an increased risk of renal failure, myocardial infarction, and stroke.[40] In this nonrandomized observational trial of 4374 patients undergoing revascularization, the group concluded that aprotinin use was not prudent in comparison with less expensive alternatives such as aminocaproic acid and TA. Limitations to this study include nonblinded randomization and a significantly higher operative risk in the aprotinin study group that required complicated propensity adjustment to statistically match groups. Randomized, blinded studies need to be performed before definitive recommendations can be made.

Recombinant Activated Factor VII

The use of recombinant factor VII has been shown to induce hemostasis in patients with severe hemophilia A or B with factor specific inhibitors.[41] Recombinant activated factor VII complexes with all available tissue factor to activate factor X directly and induce thrombin generation. This leads to the formation of a tight and stable fibrin plug that is resistant to early fibrinolysis.[42]

Off-label use in cardiac surgery has been indicated when all efforts at conventional hemostasis have been exhausted. These include non–red blood cell product support (e.g., fresh-frozen plasma, platelets, and cryoprecipitate), topical agents, desmopressin, and antifibrinolytics. When hemostasis is still not satisfactory, we have given a recombinant factor VIIa (rFVIIa) dose of between 75 and 100 μg/kg. Efficacy is variable with rFVIIa use, ranging from no difference from standard therapy to causing mortal thrombosis.

Heymann and colleagues reported in a retrospective analysis that rFVIIa was safe with regard to risk of thrombosis, but blood loss and transfusion rates were similar. High mortality rates were seen in both groups in house and at 6 months (approximately 30% and 50%, respectively).[43] Conversely, Raivio reported in a retrospective series that rFVIIa was significantly more effective in restoring hemostasis; however, severe postoperative thromboembolic complications occurred in 25% of the patients.[44] The rFVIIa doses in these two studies ranged from 60 to 80 μg/kg and from 24 to 192 μg/kg, respectively.

Diprose and colleagues compared rFVIIa to placebo in a randomized, double-blind study following complex noncoronary artery cardiac surgery. The group found in this 20-patient study that homologous transfusions were significantly fewer in the study group cohort. There were no differences in regard to adverse events, but this pilot study had limitations that include being underpowered and prone to type I error.[45] Despite the effectiveness that has been demonstrated in single-patient case reports and small-scale studies, we recommend caution when using this product until more prospective, randomized studies are available to determine safety and effectiveness.

TOPICAL HEMOSTATIC AGENTS

The limited efficacy of topical agents such as oxidized cellulose and microfibrillar collagen has led to the development of new products with novel applicator systems that are direct activators of the clotting cascade. Additionally, pericardial lavage with aprotinin or EACA has been shown to be ineffective at reducing transfusion requirements and may enhance mediastinal adhesion formation.[46–48] As a result of the limitations of more traditional agents, the new-generation topical agents have gained appeal owing to their inherent effectiveness as well as their ease of use.

Bioglue (Cryolife, Inc., Kennesaw, GA) is a biologic glue approved initially for use in the repair of aortic dissection. This product is composed of purified bovine serum, albumin, and glutaraldehyde. The action is almost instantaneous because glutaraldehyde exposure leads to the tenuous binding of lysine molecules, proteins, and tissue surfaces. Raanani described the use of Bioglue as an aid in aortic reconstructive surgery, avoiding the use of stiff Teflon felt strips.[49]

Tisseel VH (Baxter Healthcare Corp., Glendale, CA) is a topical protein solution sealer that is sprayed onto hemorrhagic surfaces. This fibrin sealant contains fibrinogen, thrombin, calcium chloride, and aprotinin. When the protein and thrombin solutions are mixed and sprayed topically, a viscous solution that sets rapidly into an elastic coagulum is produced. A study by Rousou demonstrated that fibrin sealant was safe with regard to viral transmission and

Table 13–7.

Antiplatelet Agents

Drug	Binding	Mechanism	Half-life
Clopidogrel (Plavix)	Irreversible	ADP-mediated platelet aggregation	8 h
Abciximab (ReoPro)	Noncompetitive	GP IIb/IIIa inhibition	30 min
Tirofiban (Aggrastat)	Reversible	GP IIb/IIIa inhibition	2.2 h
Eptifibatide (Integrillin)	Reversible	GP IIb/IIIa inhibition	2.5 h

highly effective in controlling localized bleeding in cardiac operations.[50]

The gelatin-based hemostatic sealant FloSeal (Fusion Medical Technologies, Inc., Mountain View, CA) activates the clotting cascade and simultaneously forms a nondisplacing hemostatic plug. A FloSeal kit contains a bovine-derived gelatin matrix, a bovine-derived thrombin component, and a syringe applicator. The gelatinous matrix is biocompatible and reabsorbed in 6 to 8 weeks. In a series of patients undergoing open-heart procedures, the Fusion Matrix Group studied FloSeal versus Gelfoam-Thrombin in procedures in which standard surgical means were ineffective at controlling bleeding.[51] FloSeal stopped bleeding in a significantly higher number of patients than did standard therapy with no differences in adverse events; however, there was no mention of each product's effect on transfusion rates.

PLATELET INHIBITORS AND THEIR EFFECT ON BLOOD USAGE

Platelet inhibition with the relatively new drug class glycoprotein (GP) IIb/IIIa receptor antagonists has greatly reduced the need for emergent CABG in patients undergoing angioplasty or coronary stenting procedures. However, these agents pose a new challenge for the cardiac surgical team for patients referred for surgery in terms of bleeding risk.

The final common pathway of platelet aggregation leading to coronary artery occlusion is the cross-linking of receptor GP IIb/IIIa on adjacent platelets by adhesive plasma proteins (fibrinogen). As a result, receptor blockade of GP IIb/IIIa results in blocking platelet aggregation and subsequent thrombus formation. A population of patients with ischemic heart disease who may be expected to require CABG despite maximal therapy with GP IIb/IIIa inhibitors still remains. Currently, there are no controlled studies of the effect of GP IIb/IIIa inhibitors on patients undergoing CABG. However, the use of these inhibitors may enhance the risk of bleeding compared with elective procedures in patients not receiving these agents. The currently used agents are summarized in Table 13-7. Current guidelines for patients requiring CABG include

1. Stop the GP IIb/IIIa inhibitor.
2. Delay surgery for up to 12 hours if abciximab, tirofiban, or eptifibatide is used, and delay up to 7 days if clopidogrel is used.
3. Maintain standard heparin dosing despite elevated bleeding times.
4. Use ultrafiltration via the zero-balance technique while on CPB.
5. Transfuse platelets as needed as opposed to prophylactically, preferably once off CPB and after protamine administration.[52]

Heparin-Induced Thrombocytopenia and Cardiac Surgery

Heparin-induced thrombocytopenia and thrombosis (HITT) is a serious complication of heparin therapy. This immunologic response develops in approximately 1 to 3% of patients treated with unfractionated heparin (UFH) for 5 to 10 days.[53,54] HITT is a severe prothrombotic condition, with affected individuals having a 20 to 50% risk of developing new thromboembolic events. The mortality rate is approximately 20%; in addition, approximately 10% of patients require amputations or suffer other major morbidity.[55,56] Although there is no best way to anticoagulate these patients, when surgical delay is unavoidable, few options exist. Most reports, however, are limited single case reports with significant morbidity and mortality.

Currently, direct thrombin inhibitors (DTIs) are recommended for HITT (Table 13-8). Limitations of these agents include the lack of a reversal agent and route of clearance.[57]

These agents have several advantages over UFH. Since they do not rely on antithrombin III levels and do not bind to plasma proteins, the anticoagulant effect is more predictable. Also, DTIs inhibit fibrin-bound thrombin as well as fluid-phase thrombin, leading to a greater antithrombotic effect.

Specific recommendations on how to treat patients with HITT cannot be given at this time. Diagnosis of HITT

Table 13–8.

Direct Thrombin Inhibitors for HITT

Drug	Monitored	Excretion	Half-life
Lepirudin (Refludan)	APTT 1.5–2.5 times baseline	Kidney	40–60 min
Argatroban	APTT 1.5–3 times baseline	Liver	45 min
Bivalirudin (Angiomax)	APTT or ACT 1.5–3 times baseline	Kidney	25 min

is difficult because assays vary in both specificity and sensitivity. Second, and key to this dilemma, are the lack of randomized trials. Most data available for treating these patients are derived from single case reports and small retrospective trials. Dosing of the available anticoagulation agents is not fully understood, and there is no reversal agent. Since drug elimination varies for these agents, renal or liver function needs to be fully assessed. Table 13-9 lists information regarding detection and choices of agents when presented with patients with HITT.

Table 13–9.

Cardiac Surgery in Patients with Previous HITT

Clinical pathlogy	Immunologic disorder when IgG antibodies attach to platelet factor IV sites. This leads to activation of both platelets and coagulation system.
Incidence	Up to 50% of post–cardiac surgery patients develop HITT. antibodies. Of these, 7 to 40% lead to in vitro platelet activation. Development of HITT only occurs in 1 to 3% of postoperative cardiac patients despite the high seroconversion rate. However, HITT-related mortality has been reported as high as 28%.
Differntial diagnosis	Unexpected platelet count drop of 50% or greater. Increased risk of venous thrombosis preoperatively and arterial thrombosis postoperatively. Most thrombotic episodes are not seen until at least 5 days because HITT antibodies usually do not develop until higher bypass heparin doses are given.
Laboratory testing	Enzyme immune assays for detecting platelet factor IV–reactive HITT antibodies and platelet activation assays that use washed platelets. Washed assays, however, have greater specificity but take longer to perform
Anticoagulation monitoring during cardiac surgery	When heparin is used, a standard celite activated clotting time (ACT) test can be performed. When using thrombin inhibitors, an alternative but complicated ecarin clotting time (ECT) can be performed. The ECT correlates better than the ACT to drug level, but the ACT has been used successfully
Anticoagulation reversal	When using heparin, standard protamine reversal is sufficient. Direct thrombin inhibitors have no reversal agents at this time. Drug elimination is enzymatically with bivalirudin, renally with other agents such as hirudin, and via the hepatobiliary system for Argatroban. A hemoconcentrator can be used toward termination of bypass or postoperatively.
Anticoagulation better cardiac surgery	Monitor platelet count drops for HITT detection. Nonheparin agents should be used for all patients with HITT history or when antibodies are present. These alternatives include aspirin, wafarin (only if thrombocytopenia is resolved), and direct thrombin inhibitors. Valve prophylaxis can be resumed similar to warfarin therapy.

INTRAOPERATIVE AND POSTOPERATIVE MANAGEMENT

Intraoperative Period

Intraoperative autologous donation (IAD) of whole blood has many advantages over PAD. IAD does not require a delay in surgery; it can be performed efficiently and with minimal additional cost. In addition, the blood product obtained by IAD is whole blood, which is transfused within 2 to 3 hours of collection and therefore contains active platelets and factors. The resulting advantages are the avoidance of coagulopathy frequently seen after CPB and the addition of red blood cell mass capable of oxygen transport. The storage process limits the amount of blood loss during surgery via lap pads and discard suction and spares the damaging effects of the heart-lung machine, which include contact activation of platelets and complement as well as red blood cell hemolysis. Because IAD serves to decrease red blood cell requirements in a volume-dependent manner, the maximum amount of blood should be removed from each individual patient in order to optimize blood conservation efforts. The amount of blood that an individual patient is capable of donating via IAD depends strictly on the patient's own physiologic parameters, estimated blood volume (based on height-weight normogram), pre-IAD hematocrit, and pre-CPB hematocrit.[58]

Minimal hemodilution by red blood cell priming of the CPB circuit is a useful technique in avoiding transfusions. Techniques include low-prime circuitry and retrograde autologous prime (RAP).[59] Up to 90% of the crystalloid prime of the CPB circuit can be displaced with autologous blood using RAP. This technique involves partial priming of the bypass circuit with the patient's own blood from the arterial cannula just prior to instituting CPB. In addition, the venous loop also can be primed in a similar manner when first instituting CPB, displacing the crystalloid prime in the venous loop. The result is the replacement of virtually all the crystalloid prime with autologous blood, thereby reducing the amount of hemodilution the patient experiences on CPB.

TRANSFUSION TRIGGERS

The literature indicates that the anesthetized patient on full CPB at moderate hypothermia can safely tolerate a hematocrit as low as 15%, with the exception of patients at risk for decreased cerebral oxygen delivery, namely, those with a history of cerebrovascular accident (CVA), diabetes, or cerebrovascular disease.[60] These latter patients can tolerate a hematocrit as low as 18% when using moderate hypothermia.[61] Once the patient is warm and being weaned from CPB, these percentage points are raised by 2% each (17% and 20%, respectively) because the relative protective effects of the hypothermia are no longer present. In our institution, once the patient is off CPB, our practice has been to retransfuse all or as much as possible remaining blood in the CPB circuit to the patient and then give all available cell salvage blood, including any blood remaining in the CPB circuit that was not initially given back to the patient, then any IAD blood, and then finally PAD blood if available. Then and only then, if the hematocrit remains unsatisfactorily low, does the patient receive homologous blood.

Once the patient leaves the operating room, we use a transfusion trigger corresponding to a hematocrit of 22% in asymptomatic patients. In patients older than 80 years of age, a trigger of 24% is used. These numbers are meant to serve as guidelines; if a patient is at all symptomatic (i.e., tachycardic, hypotensive, ischemic, or showing any evidence of end-organ hypoperfusion), he or she will receive homologous blood transfusion therapy. To apply minimum transfusion standards safely and appropriately, the cardiac surgeon or anesthesiologist must have an understanding of the lowest safe level of anemia under the variety of conditions encountered by the cardiac surgical patient. This understanding then can be combined with an assessment of the patient's clinical status to determine the true need for red blood cell transfusion.

COST OF BLOOD CONSERVATION

In today's economic environment, it is important to discuss patient treatment modalities in terms of cost. There is no question that some aspects of the blood conservation approach are more costly than others (Table 13-10). However, when taken in the context of the cost of blood products, their use, the potential reduction in the risk of reexplorations, and the reduction or elimination of the risks of homologous blood exposures, these costs may seem a little more reasonable.

CONCLUSION

Historically, cardiac surgery has been associated with a high incidence of blood transfusion, with up to 70% of these patients receiving homologous blood transfusions at some point during their hospital stay. However, with improving technology, awareness of blood conservation techniques, and better pharmacologic agents, a multidisciplinary approach to blood conservation can make "bloodless heart surgery" entirely possible. For the purely elective patient, these techniques are initiated preoperatively with PAD, whereas other patients are eligible for one or all of the remainder of the in-hospital techniques described. Using a team approach that both optimizes and integrates the use of each of these measures, the use of homologous blood can be markedly reduced in a majority of cardiac surgical patients.

Table 13–10.

Relative Costs of Blood Conservation Agents Used in a Single Institution

Agents	Approximate cost
EACA (Amicar)	$30 per case
Tranexemic acid	$25 per case
Aprotinin (Trasylol)	$1200 per case
Erythropoietin (Procrit)	$130 per 20,000-unit dose
Homologous banked PRBCs	$210 per unit
PAD	$340 per unit
Platelets (pheresed only)	$600 per 6 units
FFP	$55 per unit
Cryoprecipitate	$53 per 10 units
Blood irradiation	$16 per bag
Blood CMV testing	$25 per bag

CHAPTER 14

Deep Hypothermic Circulatory Arrest

René Prêtre • Marko I. Turina

Hypothermia is the most efficient measure to prevent or reduce ischemic damage to the central nervous system when blood circulation is reduced. The central nervous system has a high metabolic rate and limited energy stores, which make it extremely vulnerable to ischemia. Because the central nervous system is the most sensitive organ to ischemia, attention has been centered mainly on neurologic outcome when perfusion was reduced, with the indirect assumption that if the brain or the spinal cord could tolerate undamaged the reduced perfusion, the other organs would too. With the introduction of regional cerebral perfusion, many surgeons have shifted their practice from a deep to a moderate systemic hypothermia during repair of the aortic arch. Consideration (that will not be discussed here) then should be given to specific protection of the abdominal viscera when a long period of reduced perfusion is anticipated.

CEREBRAL METABOLIC RATE

Reduction of Metabolism

The brain uses up to 20% of total-body oxygen consumption, with 40% of its energy used in the preservation of cellular integrity and 60% in the transmission of nerve impulses.[1] Hypothermia reduces the metabolic rate of the central nervous system and lengthens the period of ischemia tolerated. The central nervous system almost exclusively extracts its energy through aerobic glycolysis. The uptake of oxygen or glucose consequently is a reliable parameter of the cerebral metabolic rate. Using oxygen and glucose consumption, animal studies showed a drop in the brain metabolic rate of 50% at 28°C, 19% at 18°C, and 11% at 8°C.[2,3] Comparable results using less precise methods of measurement were obtained in humans[4] (Table 14-1). The reduction in metabolic rate in relation to temperature espouses an exponential curve, with a greater drop at high temperatures (about 6% for 1°C around 37°C) than at low temperatures (about 1% at 15°C).[2,4,5] A luxurious perfusion of the brain is rapidly set when the metabolic rate is reduced and perfusion flow rate maintained. The arteriovenous difference of oxygen, glucose, and brain-produced metabolites decreases. The luxurious perfusion is, however, of limited help in view of an ischemic period because additional energetic reserve cannot be stored in neurons. The obvious clinical implication of these findings is that although reduced, the metabolism of the brain is not suppressed by hypothermia and actually remains relatively high at 18°C, a common target temperature in surgical practice. Assuming an ischemic tolerance of 5 minutes at normothermia, the calculated safe period of circulatory arrest for the central nervous system would not exceed 25 minutes at 18°C and 38 minutes at 13°C[4] (see Table 14-1).

Cellular activity, be it mechanical, biochemical, or electrical, is an important determinant of energetic requirement superimposed on basal metabolism.[6] Obtaining a complete suppression of cerebral electrical activity consequently should be an important goal in the strategy of brain protection when a significant period of cerebral ischemia is anticipated. In the clinical setting, electrocerebral silence (as assessed by electroencephalography) is obtained at a mean nasopharyngeal temperature of 17.5°C.[7] Wide variations in the temperature inducing silence, however, exist between individuals and methods of cooling. The variations are also amplified by the fact that the brain temperature is not measured directly. The correlation between nasopharyngeal and jugular bulb venous temperature shows minimal difference during cooling (nasopharyngeal temperature therefore is a reliable surrogate for brain temperature) but a significant underestimation of the brain temperature during rewarming.[8] In one large study, the minimal nasopharyngeal temperature to obtain electrocerebral silence in all patients was 12.5°C; at the classic 18°C, 40% of patients still exhibited electrical activity.[7]

Table 14–1.

Effect of Temperature on Cerebral Metabolic Rate

Temperature (°C)	CMR (% baseline)	Duration of Safe CA (min)	$CMRO_2$ (mL/100 g/min)	pMPFR (mL/kg/min)
37	100	5	1.48	100
32	70 (66–74)	7.5 (6.5–8)	0.82	56
30	56 (52–60)	9 (8–10)	0.65	44
28	48 (44–52)	10.5 (9.5–11.5)	0.51	34
25	37 (33–42)	14 (12–15)	0.36	24
20	24 (21–29)	21 (17–24)	0.20	14
18	17 (20–25)	25 (21–30)	0.16	11
15	14 (11–18)	31 (25–38)	0.11	8

CMR: cerebral metabolic rate; CA: circulatory arrest; $CMRO_2$: cerebral metabolism rate for oxygen; pMPFR: predicted minimal perfusion flow rate.
Data derived from McCullough JN, Zhang N, Reich DL, et al: Cerebral metabolic suppression during hypothermic circulatory arrest in humans. Ann Thorac Surg 1999; 67:1895; and Kern FH, Ungerleider RV, Reves JG, et al: Effect of altering pump flow rate on cerebral blood flow and metabolism in infants and children. Ann Thorac Surg 1993; 56:1366.

Anesthetists often administer cortisone at the beginning of anesthesia to reduce the production of proinflammatory cytokines and barbiturates a few minutes before circulatory arrest to shut down any residual electrical activity.[9] The action of these agents is difficult to establish and remains controversial. Barbiturates, for instance, can have a two-edged–sword effect because they cause cerebral vasoconstriction—with halving of cerebral blood flow[10]—and showed a detrimental effect on preservation of the energy molecules of the brain.[11] Their early administration could result in inappropriate cooling of the brain and disturbed energy states. If ever, they should be administered only when the target temperature is achieved, just before arrest.[12] The evidence supporting the use of high-dose cortisone to reduce postischemic neurologic damage (such as that observed in spinal cord injury[13]) is lacking totally in deep hypothermic circulatory arrest. In view of its immunosuppressive effect,[14] the use of high-dose methylprednisolone cannot be recommended at this time.

Duration of Circulatory Arrest

The duration of safe circulatory arrest at a given temperature should not be seen as a clear cutoff point but as a broad zone during which successive biochemical alterations occur, followed by ultrastructural and finally by structural changes (Fig. 14-1). The potential for recovery exists during the initial phase of biochemical alteration but decreases as ischemia persists and becomes more dependent on reperfusion conditions. The cerebral metabolic rate of oxygen and glucose often has been used as a surrogate for adequate energetic metabolism of the brain and consequently adequate maintenance of cellular homeostasis.[5,15] The recovery of oxygen consumption is already impaired after 15 minutes of ischemia at 18°C,[3] and cerebral-produced lactate (a marker of anaerobic metabolism) is detectable in the effluent blood after 20 minutes of ischemia.[16] Definitive damage to the brain, however, is unlikely if perfusion is reinstituted adequately after this time period.

Monitoring the evolution of intracellular high-energy molecules and pH points out more precisely the moment when the exhaustion of energetic substrates may trigger the cascade of deleterious biochemical reactions. Nuclear magnetic resonance can provide continuous measurements of the relative concentration of phosphocreatine and adenosine triphosphate, the principal energetic molecules of the brain, as well as that of inorganic phosphate (the split product of these molecules) and intracellular pH. The electromagnetic signal of phosphocreatine decreases rapidly, followed by that of adenosine triphosphate, after institution of circulatory arrest.[6] These signals become hardly detectable after 32 to 36 minutes of ischemia at 15°C in animals.[17–19] Parallel to their disappearance, the signals of inorganic phosphate and pH rise progressively within the cells.

DIRECT AND DELAYED ISCHEMIC INJURY

Direct Injuries

Cessation of blood delivery to neurons leads to an immediate reduction in the production of energetic molecules and a

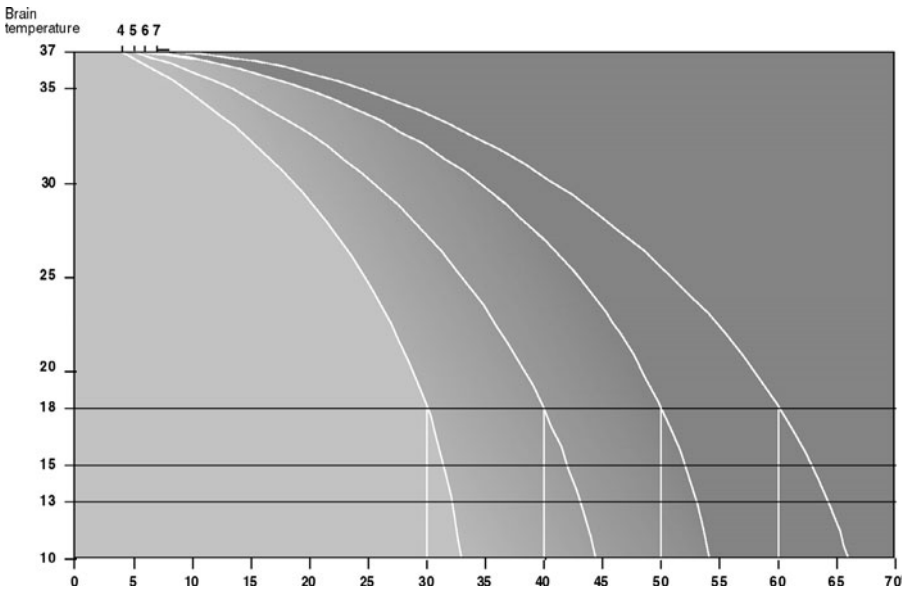

Figure 14-1. Consequences of circulatory arrest in relation to temperature and duration of cerebral ischemia. The dark shading depicts the periods of safe circulatory arrest. The light shading depicts the periods of excessive and damaging circulatory arrest. The transitional area depicts the periods where the risk and extent of brain damage depend on the conduct of surgery and pharmacologic intervention. A dominance of the dark shading is compatible with reversible deficits, whereas a dominance of the light shading is associated with irreversible injuries.

state of progressive energy failure. Cellular injury occurs because of a rapidly occurring intracellular acidosis and a more progressive dissipation of ionic gradient across membranes. The dissipation of ionic gradient initiates a cascade of destructive events that rapidly escape regulatory control.[6] At this stage, accumulation of calcium within cells (which interferes with many fundamental biochemical reactions) and attraction of osmotically obligated water are striking.[20] Mitochondrial swelling with dilatation of the intercristal spaces is the first ultrastructural sign of ischemic injury that progresses eventually to membrane rupture. With low adenosine triphosphate concentration, the massive release of calcium into the cytoplasm initiates necrotic cellular death. If the concentration of adenosine triphosphate is sufficient, the release of mitochondrial proteins, such as cytochrome *c* and apoptosis-inducing factors, induces cellular apoptosis.[21] Other ultrastructural signs of neuronal injury are clumping of chromatin and nuclear rupture, rupture of the endoplasmic reticulum, and detachment of ribosomes with the consequent loss of the ability to synthesize RNA and proteins.

The endothelial cells are also extremely sensitive to ischemia. The continuous activation and production of vasoactive factors, among which nitric oxide plays a central role, are impaired after endothelial ischemia. The endothelial dysfunction results in an increase in cerebral vascular resistance.[18,22] This is exemplified clinically by the loss of diastolic perfusion of the brain in Doppler analysis of the middle cerebral artery after circulatory arrest.[23] Nitric oxide is a potent short-acting vasodilator that regulates online the local vascular tone. The molecule further inhibits the aggregation of platelets and adherence of polymorphonuclear cells (PMNs) to the endothelium, two critical steps in the initiation of reperfusion injury.[24,25] The stimulation of nitric oxide production after circulatory arrest improves cerebral perfusion and accelerates recovery of high-energy phosphate and cerebral metabolism.[18,22]

Delayed Injuries

Delayed injuries occur on and after restitution of perfusion. Reperfusion injuries operate at a cellular and at a vascular level. At the cellular level, the restitution of oxygen provokes the formation of highly reactive free radicals, which are able to disintegrate the membrane structure. At the vascular level, the recirculation of blood in ischemic territories induces a tight aggregation and adhesion of platelets and PMNs to the endothelium. These cellular complexes release potent inflammatory mediators and vasoconstrictor agents. Blood elements slug in small capillaries and can shut down the microcirculation and reestablish ischemia. Although a strong theoretical background supports the mechanisms of reperfusion injuries, their real contribution after deep hypothermic circulatory arrest remains uncertain.[20] At the vascular level, the risk of blood slugging seems greatly attenuated by the hemodilution induced by cardiopulmonary bypass.

Electrical hyperactivity of the brain after ischemia can produce extensive damage because the condition recreates a cellular energetic mismatch and induces the release of toxic neurotransmitters. *Excitotoxicity* is a term applied to the death of cells caused by overstimulation of excitatory amino acids and is believed to be a fundamental process involved in postischemic neuronal cell damage. Compromised synaptic reuptake of excitatory amino acids and membrane depolarization associated with ischemia cause a lethal flood of calcium and sodium into the neuron.[26] The mammalian brain paradoxically is extraordinary vulnerable to its own neurotransmitters when they are released in the extracellular space.[27] Glutamate is the principal excitatory neurotransmitter of the

brain and is found in extremely high concentration within neurons and astrocytes. The death of one cell liberates the neurotransmitter from its extracellular space and puts in danger all the surrounding neurons, especially in the context of reduced defense capacity. A series of events starting with the overexcitation of a neuron and ending in its death propagates rapidly and expands exponentially the brain damage. It is unknown if premature resumption of brain activity (before replenishment of energy stores) can trigger the cascade of harmful events. It is evident, however, that hyperactivity of the brain during the rewarming period and thereafter results in the extracellular release of glutamate.[27] Administration of glutamate antagonists after ischemic injury to the brain has shown a protective effect in animals and humans, already in the absence of cerebral hyperactivity.[28,29] These antagonists could prove valuable in circumscribing brain damage once significant neuronal injury has occurred, especially in case of electrical hyperactivity.

Protracted cellular dysfunction and apoptosis lead to a delayed (after a few days) neuronal death. The prolonged inability of the neuron to restore calcium homeostasis and ensure the turnover of cytostructure proteins is responsible for a progressive loss of cellular function and eventual death.[6,30–32] Apoptosis (programmed cellular death) is an active, energy-dependent process characterized by the silent breakdown and phagocytosis of a cell. A profound or long-lasting ischemia results in cellular necrosis, whereas a less severe ischemia results in apoptosis. The importance of apoptotic cell clearance is not well established but certainly underestimated because of the swiftness of the process and the fact that it leaves no inflammatory traces. Apoptosis often has been documented in zones of borderline ischemia—in zones with moderate energy depletion—such as the penumbra surrounding a focal ischemia.[30,33] In a piglet model of deep hypothermic circulatory arrest (DHCA), the apoptotic process was found to start a few hours after reperfusion and to extend over several days. As expected, caspase 3 and 8, the final pathway of the apoptotic process, and cytosolic cytochrome *c* were significantly elevated in the damaged neurons.[32]

CEREBRAL BLOOD FLOW

Low-Flow and Intermittent Perfusion

Low-flow and intermittent perfusion of the brain are able to maintain, respectively restore, intracellular stores of high-energy substrates, prevent anaerobic glycolysis and intracellular acidosis, and consequently prolong cerebral tolerance to ischemia. Continuous monitoring of high-energy molecules established that the minimal perfusion flow able to maintain metabolic homeostasis in animals at 15°C was 10 mL/kg per minute (a flow corresponding to 8% of full flow).[19] The minimal flow rate in humans, extrapolated from the slope of metabolic rate reduction, is 11 mL/kg per minute at 18°C[34,35] (see Table 14-1). In clinical practice, however, wide ranges of minimal flow rates (ranging from 5 to 30 mL/kg per minute at 18°C) have been determined at a given temperature.[34] The wide variation probably is a consequence of hematologic (e.g., hematocrit, management of carbon dioxide) and hemodynamic (e.g., pulsatility and evolution of the "noncerebral" systemic resistance) factors. These facts argue for the use of a significant residual flow (a flow 50% greater than the predicted minimal perfusion flow rate of Table 14-1 for temperatures above 25°C and 100% greater for temperatures under 25°C) when a low-flow perfusion strategy is adopted. Lower flow rates should not be used without close monitoring of the jugular venous saturation or cerebral oxygenated state.[36] A continuous drop in venous saturation and a reduction in cerebral oxyhemoglobin detected by near-infrared spectroscopy are absolute signs of insufficient brain perfusion.[37]

Intermittent perfusion of the brain also results in the absence of lactate production and rapid resumption of normal cerebral metabolism and perfusion after circulatory arrest.[38,39] Oxygen saturation in the saggital sinus fell tremendously (to 16%) after 60 minutes of noninterrupted circulatory arrest, whereas it remained around 55% with intermittent perfusion.[39] This higher oxygen saturation, in combination with the higher blood pH and lower lactate production, acknowledges the nutritive role of intermittent perfusion at low temperatures. Metabolic homeostasis was maintained throughout when intermittent perfusion was established after a relatively short period of ischemia (after every 20 minutes at 18°C). Extending the ischemic period to 30 minutes resulted in a moderate production of lactate and subsequent impaired oxygen extraction in the brain.[3,38] Concerns that repetitive episodes of reperfusion may result in neuronal damage (as has been documented at normothermia[40,41]) have not been validated in the model of deep hypothermic circulatory arrest. One at least may speculate that reperfusion injuries do not happen if recirculation is established before the occurrence of anaerobic glycolysis.

Pulsatile Flow

Pulsatile perfusion provides hemodynamic advantages over nonpulsatile perfusion that become significant with borderline pressure and perfusion flow.[42,43] Once the perfusion pressure falls under the closing pressure of the precapillary arterioles, the vascular bed shuts down and is no longer perfused. The peak pressure in pulsatile perfusion is able to maintain the microcirculation open with a lower mean perfusion pressure and, consequently, a lower flow rate. The phenomenon is amplified after circulatory arrest.[42] A high perfusion pressure (higher than the pressure needed to maintain a capillary bed open) is necessary to reopen closed vascular beds. The postischemic dysfunction of the endothelial cells (with the loss of the vasodilatation dominance[44]) further increases the critical reopening pressure of the capillaries. The peak pressure in a pulsatile perfusion overcomes this critical pressure more quickly. This results in a swifter and more homogeneous restitution of brain perfusion. Cerebral vascular resistance was reduced and recovery of cerebral

metabolic rate improved with pulsatile perfusion after circulatory arrest.[42,43]

MANAGEMENT OF TEMPERATURE

pH Strategy

Two strategies for blood gas management are possible during hypothermia. Alpha-stat management (the mechanism prevailing in reptiles) aims at maintaining normal pH and blood gases (a pH of 7.40 and a $PaCO_2$ of 40 mm Hg) in the rewarmed (to 37°C) blood. In vivo, the hypothermic blood is alkalic and hypocapnic. pH-stat management (the mechanism prevailing in hibernating animals) aims at maintaining normal values in vivo in the hypothermic blood. When rewarmed to 37°C, the blood becomes acidotic and hypercapnic.

Alpha-stat management preserves autoregulation of brain perfusion and optimizes cellular enzyme activity. Because of the blood alkalosis, the curve of oxyhemoglobin dissociation is shifted toward the right, corresponding to an increased affinity of oxygen for hemoglobin. With the further shift of oxyhemoglobin to the right owing to hypothermia, the availability of oxygen carried by the hemoglobin molecule becomes tremendously reduced. At deep temperature, oxygen diluted in blood represents the major source of oxygen to tissues.

The pH-stat strategy, because of the high level of carbon dioxide, results in a powerful and sustained dilatation of the cerebral vessels. Autoregulation of brain perfusion is lost, and cerebral blood flow is increased greatly. The time for temperature equilibration between blood and brain is shortened, resulting in a quick and homogeneous cooling of the brain. Hypercapnia shifts the oxyhemoglobin dissociation curve to the left and results in an increased availability of oxygen to tissues.

A comparison between the two strategies has been performed mainly in neonates and small animals. In piglets, a pH-stat strategy resulted in improved recovery of cerebral metabolism and better histologic and behavioral scores.[45] In neonates, the same strategy provided superior psychometric scores at midterm evaluation.[46] The superiority of the pH-stat strategy has not been confirmed in adults, however. Prospective studies found no differences[47] or even worse neuropsychological outcomes.[48–51] Because it maintains a physiologic coupling between cerebral blood flow and metabolism, the alpha-stat strategy appears advantageous in adults where the risk of under- or overperfusion within the brain is substantial.[51] Cerebral edema, which can be a consequence of cerebral overperfusion, is less likely to occur. Finally, the preservation of cerebral autoregulation may attenuate the inhomogeneous distribution of blood that is prone to occur in patients with an underlying vasculopathy such as atherosclerosis, hypertension, and diabetes.

Cooling and Rewarming

The time required to obtain equilibration of temperature between blood and tissues depends on the temperature gradient on the one hand and the blood flow in the tissue and a tissue-specific coefficient of temperature exchange on the other. Cooling or rewarming over a short period of time results in wide variations in temperature between organs, as well as within an organ itself. A slow rate of cooling or rewarming and a high blood flow are the two factors ensuring homogeneous changes in body temperature. Occlusive vascular disease and altered vascular reactivity may reduce cerebral perfusion significantly and delay temperature equilibration. Enhancement of cerebral cooling can be achieved by local cooling. Ice packed around the head efficiently reduces the temperature of the brain cortex and subcortical area by heat conduction across the skull.[52]

Oxygen availability is reduced during hypothermia because of the shift to the right of the oxyhemoglobin curve. The parallel decrease in metabolic rate is likely to preserve an appropriate balance between availability of and requirement for oxygen. During rapid cooling, however, the affinity of oxygen for hemoglobin rises sharply, whereas the tissue temperature is not equilibrated with that of blood. This effect, combined with the dilution of blood by the priming volume of cardiopulmonary bypass, may create a temporary state of insufficient oxygen availability.[53] Studies in animals confirmed that expedited cooling associated with excessive hemodilution resulted in an uncompensated consumption of energetic molecules and in the development of cellular acidosis before institution of circulatory arrest. In one study it was demonstrated that an increased concentration of hemoglobin was able to compensate for the decreased oxygen availability related to hypothermia.[54] Intracellular acidosis was not present with a hematocrit of 30%, was mild with a hematocrit of 20%, and was severe with a hematocrit of 10%.[55,56] Using intravital microscopy, these investigators further established that the cerebral capillary flow was maintained despite the increased blood viscosity (that is associated with high hematocrit values).[56,57] These findings support the consensus that cooling should be slowly performed and with an adequate hematocrit.[53,54]

Rewarming represents a critical time period—perhaps the most decisive one—during which any additional harm to cerebral cells might induce permanent injury or precipitate their death. It seems logical to strive to obtain rapidly a stable energetic and biochemical homeostasis to prevent the occurrence of delayed injuries. Once initiated, the pathologic processes are difficult to restrain. Moreover, the final impact of a specific therapeutic action is often uncertain owing to the complexity of interrelated biochemical derangements.

Providing a favorable hematologic environment, ensuring optimal hemodynamic conditions, and avoiding cerebral hyperactivity should set the best conditions for optimal recovery of the energy-depleted brain.[58] It seems, therefore, capital to restart perfusion slowly after circulatory arrest. An initial period of "cold blood low-pressure reperfusion" washes out accumulated metabolites, buffers free radicals, and provides substrates for regeneration of high-energy molecules before the resumption of cerebral electrical activity.[59] A sufficient hematocrit during this reperfusion period

is attractive theoretically because of its buffer, redox, and free-radical scavenging capacity.[53,60] Glycemia should be monitored closely, and hyperglycemia should be treated aggressively. Hyperglycemia, stimulated by the release of endogenous catecholamines, increases intracellular acidosis and can prevent or delay the restitution of metabolic homeostasis.[60] During rewarming, cerebral vascular resistance and energetic metabolism are impaired in proportion to the severity of ischemia.[61,62] Cerebral perfusion is reduced, glucose is derived in part from the less efficient anaerobic pathway, and oxygen coupling with the oxidative phosphorylation is disturbed.[30] This vulnerable period can last for 6 to 8 hours after initiation of reperfusion.[62,63] During this time, an abnormally high extraction of oxygen and glucose is necessary to sustain the cerebral metabolic rate.[62] Jugular venous oxygen saturation is often below 40% during this recovering period.[62] Cerebral autoregulation may become unable to compensate for another reduction in oxygen delivery, which could occur with postoperative events such as acute hypotension, hypoxemia, and anemia.

The temperature of the perfusate during the rewarming phase should be managed carefully. Hyperthermia exacerbates cerebral activity and disturbs cellular metabolism after circulatory arrest.[64] It should be stressed that nasopharyngeal temperature underestimates by 2 to 3°C the brain temperature during rewarming.[8] The perfusate temperature should not be allowed to exceed 37°C, keeping in mind that a relative hypothermia actually might be beneficial for optimal brain recovery.[65] Electrical hyperactivity of the brain can trigger overwhelmingly destructive reactions.[27] The disorder is not uncommon after prolonged circulatory arrest and actually is considered a sign of ischemic injury.[66–68] Detection of increased cerebral activity should prompt immediate therapeutic action, which includes deep anesthesia, appropriate sedation, and reduction of temperature. Monitoring the electrical activity of the brain during the rewarming phase (and thereafter if circulatory arrest has exceeded the safe ischemic period or if signs of abnormal electrical activity are present) could help to limit the extent of secondary damage to the brain.

NEUROLOGIC INJURY AFTER DHCA IN CLINICAL PRACTICE

Neurologic deficit after DHCA encompasses a wide range of disorders ranging from deep coma to subtle, hardly perceptible alterations in cognitive functions or behavioral changes. In the immediate postoperative period, the return of sophisticated neurologic functions often is obscured by the administration of sedative and analgesic agents. Neurologic injury presents at that time mostly as a focal or diffuse deficit. A focal deficit is due to interruption of blood in a terminal vascular territory, usually secondary to embolism of material or gas bubbles. Less frequently, a prolonged subliminal perfusion of the brain can result in a localized necrosis in the transition area between two vascular territories (the so-called watershed lesion). The clinical expression typically is a motor-sensory deficit, aphasia, or cortical blindness. Computed tomographic scanning and magnetic resonance imaging usually are able to detect a sharply demarcated area of necrosis in the brain (Fig. 14-2). The prevalence of a focal deficit in clinical series ranges from 5 to 10% after aortic surgery with the use of deep hypothermic circulatory arrest. Age, atherosclerosis, and manipulation of aorta are more potent risk factors than the duration of circulatory arrest.[52] Retrograde perfusion of the aorta during cardiopulmonary bypass (with the arterial cannula inserted into the femoral or iliac artery) also has been associated with an increased risk of focal deficit. The retrograde flow of blood in the aorta can dislodge floating atheromatous plaques and thrombi loosely attached to the walls of thoracic aortic aneurysms.[69–71]

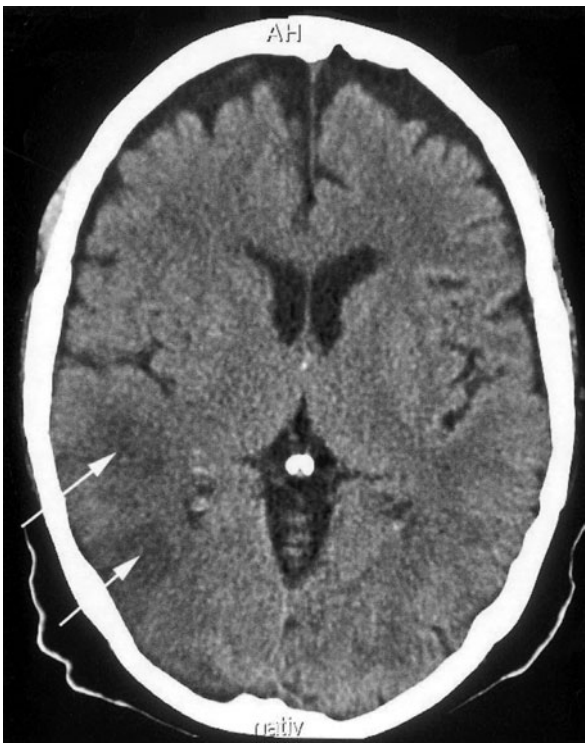

Figure 14-2. Computed tomography performed 2 days after surgery showing multiple focal ischemic lesions of the brain. Areas of demarcated necrosis can be seen (*arrows*) in the temporo-occipital junction of the right hemispheres. The damage was attributed to a retrograde perfusion of the aorta leading to dislodgment and embolization to the brain of mural thrombi.

Diffuse neurologic deficits are due to a global cerebral ischemia that has produced various levels of cellular dysfunction. In the mild forms, the cerebral cells are viable but temporarily unable to function properly. Cerebral areas with reduced perfusion (owing to atherosclerosis) or with increased metabolic activity (such as the hippocampus, which is responsible for the acquisition and treatment of new information) are most vulnerable and affected first by ischemia. The spectrum of neuropsychological disorders ranges from benign and reversible conditions such as transient confusion, stupor, delirium, and agitation to more

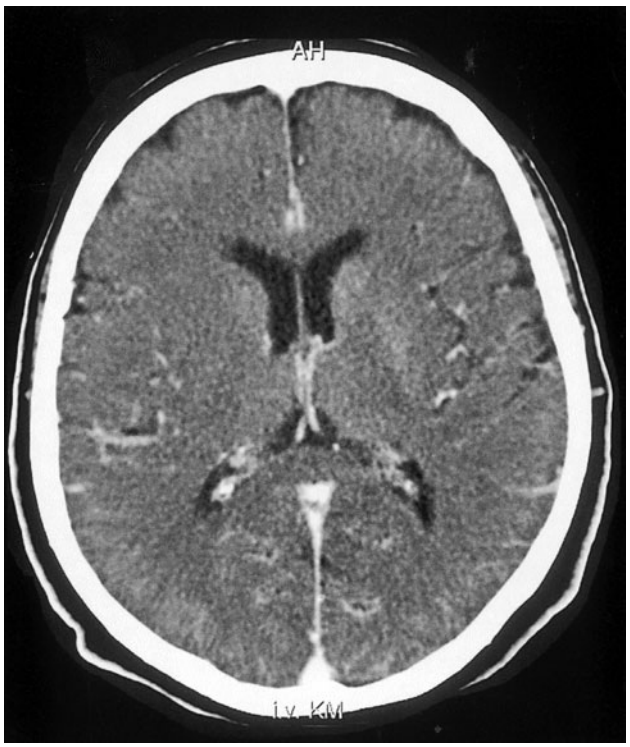

Figure 14-3. Computed tomography with contrast enhancement showing signs of diffuse anoxic lesions of the brain. Of note is the blurred delineation of the cerebral cortex and basal ganglia on the right side.

serious and debilitating ones such as seizures, parkinsonism, and coma. Imaging studies usually are normal, although in the most severe forms, scattered areas of necrosis may appear progressively (Fig. 14-3). The wide range (from 3 to 30%) of prevalence of diffuse deficit after circulatory arrest quoted in the literature reflects the subtle and often unrecognized nature of most deficits. Scrupulous postoperative evaluation of neurologic function discloses a frequency of between 10% and 20%.[67,68,72,73] Age, improper conduct of cardiopulmonary bypass, and prolonged duration of circulatory arrest are recognized risk factors for diffuse deficit. Disorders that impair vascular reactivity and cerebral autoregulation, such as diabetes and hypertension, have been associated sporadically with an increased incidence of diffuse deficit.[74]

For a long time, only relatively coarse and persistent neurologic deficits were accounted for in clinical series. The harm of circulatory arrest was underestimated, and more worrying, the duration of safe circulatory arrest was inferred erroneously. With refinement in neurologic evaluation, including behavioral and cognitive testing, it appears that subtle deficits occur in a much larger proportion of patients after shorter ischemic times. Transient neurologic dysfunction, a condition once not considered a deficit, and postoperative electroencephalographic hyperactivity appear now as definitive markers of long-lasting cerebral injury.[68,72,73,75] One-quarter of patients with transient deficits perform poorly on postoperative neuropsychological testing, and the deficit, affecting mainly memory and fine motor function, persists in many of them after hospital discharge. The risk of transient neurologic deficit starts when deep hypothermic circulatory arrest exceeds 25 minutes.[72,73] The risk initially is linearly related to the duration of circulatory arrest and rises more steeply after 50 minutes of ischemia.[52] Transient neurologic dysfunction may represent the subtlest clinical derangement of the brain that appears first during circulatory arrest.

Based on these findings and accumulated experience, it appears that the great majority of patients can support unharmed a circulatory arrest of 30 minutes at 18°C, provided that electrocerebral silence has been obtained. No deficit or only a transient neurologic dysfunction is expected when the ischemic period extends to 40 minutes, provided that rewarming is performed correctly and hemodynamic stability is maintained postoperatively. With an arrest time of more than 40 minutes, neurologic deficit is prone to occur, particularly in high-risk patients, such as those presenting with diabetes, hypertension, or old age. Further cooling of the brain to 13 to 15°C reduces the risk and makes a deficit again unlikely if the arrest time does not exceed 40 minutes or makes it no more severe than a transient dysfunction if it lasts 50 minutes. In these cases, careful rewarming with close monitoring of cerebral activity, deep anesthesia, and hemodynamic stability are decisive for a favorable outcome.

MEASURES TO PREVENT ISCHEMIC NEUROLOGIC DAMAGE

Reduction of cerebral metabolism and swift surgery are the two fundamental measures able to prevent or reduce brain damage during circulatory arrest. Selective perfusion of the brain has emerged as an important adjunctive protective measure (see Figs. 14-3 and 14-4). The efficacy and safety of selective perfusion has allowed progressive modulation of the level of systemic cooling. When the anticipated ischemic period does not exceed 20 minutes (e.g., as illustrated in Fig. 14-3 for a hemiarch replacement), systemic cooling could be set at 25°C. The duration of cardiopulmonary bypass to equilibrate temperature during cooling and rewarming is greatly reduced. Homeostasis of the blood, in turn, is less disturbed, particularly regarding platelets function and coagulation. When the anticipated ischemic time exceeds 40 minutes (e.g., as illustrated in Fig. 14-4 for a complete resection of the aortic arch), deep systemic hypothermia to 18°C or lower remains the safest measure to protect not only the brain but also the spinal cord and abdominal organs.

Antegrade Cerebral Perfusion

Antegrade perfusion of the brain through cannulas inserted in the innominate artery (or more distally in the right common carotid artery) and left common carotid artery provides the most physiologic and efficient perfusion of the brain.[76] Perfusate temperature is usually set at 18°C and flow

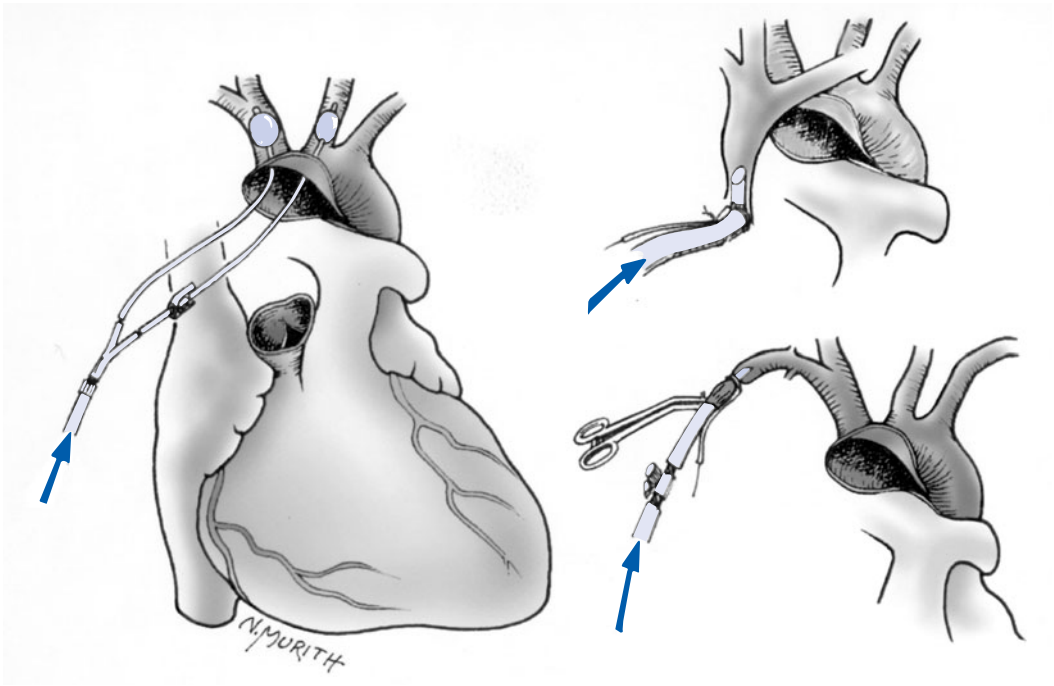

Figure 14-4. Perfusion techniques to reduce ischemic injury to the brain. Bilateral antegrade cerebral perfusion obtained by selective cannulation of the innominate and left common carotid arteries. (*Inset, bottom right*) Regional cerebral perfusion (unilateral antegrade perfusion) via cannulation of the right subclavian artery.

between 10 and 20 mL/kg per minute or adjusted to maintain a pressure of between 40 and 50 mm Hg in the right radial artery. Clinical results, especially regarding swift recovery of cerebral function, have been outstanding with this method of perfusion.[76–81] The need to cannulate relatively small and often diseased arch arteries and the presence of additional cannulas in the operating field constitute the main drawbacks of the technique. Cannulation of the common carotid arteries can result in dissection of the arterial wall and embolism of atheromatous plaque material or air. Furthermore, the flow in the artery depends on a proper position of the tip of the cannula within the vessel. For these reasons, many surgeons rely on a unilateral perfusion of the brain, with sole cannulation and perfusion of the right subclavian artery.[81,82] The right vertebral and right common carotid artery territories are perfused in an antegrade fashion. The blood reaches the left cerebral hemisphere through the circle of Willis and, to a lesser extent, through cervicofascial connections. It is therefore important that the takeoffs of the left common carotid and left subclavian arteries be occluded to avoid a steal of blood down these arteries. Occlusion (usually with an inflatable balloon) of the descending aorta is also a useful maneuver to improve overall body perfusion. Effective somatic perfusion (including the abdominal organs, spinal cord, and lower limb musculature) has been documented with this maneuver.[83] The presence of an aberrant right subclavian artery (also called *arteria lusoria*) obviously is a contraindication to the use of this perfusion method. The aberrant origin of the artery usually is identified readily by computed tomographic scanning or magnetic resonance imaging. The burst of blood from the descending aorta during opening of the aortic arch should alert the surgeon to this anatomic variation and prompt a direct cannulation of the ostium of the right and left common carotid arteries.

Sequential perfusion of the cerebral arteries provides additional safety to unilateral cerebral perfusion and avoids cannulation of small or diseased arch arteries.[37,84] The right subclavian artery remains perfused during the whole procedure. A vascular graft is sewn immediately on a common patch of aortic wall including all the arch vessels,[85] or the second branch of a multiple-arm prosthesis is anastomosed to the left common carotid artery. Perfusion then is instituted through this additional graft and enhances, after a short period of time, cerebral perfusion.

Retrograde Cerebral Perfusion

The value of retrograde cerebral perfusion in protecting the human brain still has not been elucidated clearly. No animal model truly replicates the complex anatomy and physiology of the human brain, and none allows a fine neuropsychological evaluation. Conflicting results and conclusions in clinical and experimental studies therefore have been reported. Accepted facts include a deep and homogeneous cooling of the brain hemispheres (the cooling scalp effect) and the

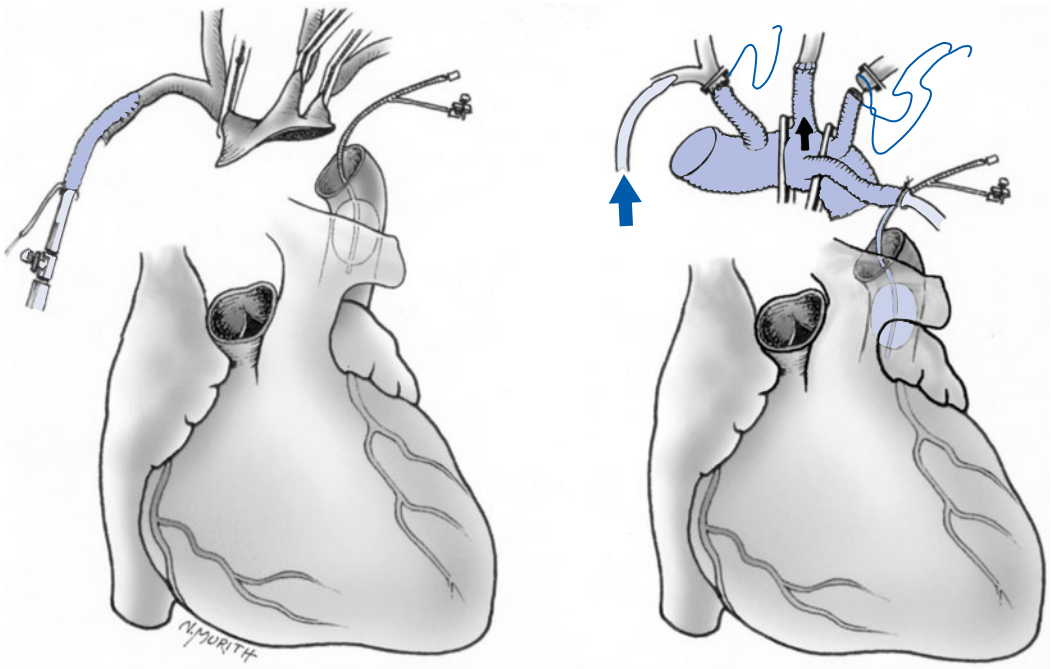

Figure 14-5. Perfusion techniques to reduce ischemic injury to the brain. Sequential bilateral antegrade perfusion of the brain. The branch of a multiple-arm graft is connected initially to the left common carotid artery, allowing rapid establishment of bilateral perfusion of the brain. The other anastomoses are performed thereafter. Perfusion of the right subclavian artery through a graft allows monitoring of the perfusion pressure via the right radial artery.

expulsion of solid particles or gaseous bubbles from the arch arteries. Controversies surround the possible nutritive value of retrograde perfusion.[86] The nutritive value has been demonstrated in rabbits but not in dogs, pigs, or baboons.[87–89] In humans, signs of cerebral perfusion and oxygen uptake have been documented,[90] but the amount of perfusate providing cerebral nutrition is low, corresponding to about 5% of total retrograde flow.[73,88,91] The blood delivered in the superior vena cava flows preferentially in the low-pressure inferior vena cava via the azygos system, the perivertebral venous plexus, and the thoracic wall veins.[92] Even within the brain, the distribution of retrograde flow is inhomogeneous, with a preferential distribution in the saggital sinus and hemispheric veins.[93] The large steal of blood to the inferior venous territory is corroborated by the clinical finding of an extremely small proportion of perfused blood flowing out of the arch arteries. Occlusion of the inferior vena cava to decrease the pressure gradient between the two venous territories effectively reduces the amount of stolen blood but increases the sequestration of fluid in the interstitial tissue.[94] Interstitial edema is another potential problem of retrograde perfusion that can lead to cerebral edema and hypertension, particularly when the perfusion pressure is set above 25 mm Hg.[95] Finally, the finding that the human jugular system may contain competent valves[96] casts definitive doubt regarding the reliability of retrograde cerebral perfusion.

Clinical series, however, have reported encouraging results. A reduction in both mortality and neurologic damage has been documented regularly with the adjunctive use of retrograde cerebral perfusion to classic hypothermia.[80,97–100] Some studies confirmed the limited capacity of retrograde perfusion to sustain cerebral metabolism and stressed the fact that the occurrence of neurologic damage was only delayed.[88,95] Indeed, the risk rises sharply after 60 minutes of deep hypothermic circulatory arrest, perhaps at the extinction of intracellular energy substrates. If most surgeons acknowledge the capacity of retrograde cerebral perfusion to prolong the period of safe circulatory arrest, they consider the method a valuable but not an alternative adjunct to conventional methods when long periods of circulatory arrest are contemplated.[80,97–100]

Integrated Perfusion

Probably the safest approach to a patient requiring a long period of circulatory arrest resides in the integration of complementary methods of perfusion and monitoring.[52,71,85,86] Retrograde perfusion of the aorta through the femoral artery should be avoided in case of thoracic aortic aneurysm in order to reduce the risk of particulate dislodgment with embolization in the brain and myocardium.[69,70] Antegrade perfusion of the aorta is performed with cannulation of the ascending aorta or right subclavian artery. The body is cooled to 18°C. Electroencephalogram and venous jugular saturation are monitored to ensure adequate reduction of cerebral metabolism. Circulatory arrest is established

only after electrocerebral silence has been obtained and jugular venous saturation is greater than 95%. During the 10 to 20 minutes preceding circulatory arrest, the temperature of the perfusate can be lowered to 13°C to further reduce brain temperature and metabolism. The arch arteries are connected to a graft (either with the use of a patch of aortic wall or separately), and antegrade perfusion of the brain is resumed before more extensive resection and repair of the aorta are performed.[71,85] When the risk of particle embolization to the brain is substantial (e.g., in old age or with severe atherosclerosis of the aorta and arch aneurysm with thrombotic material), a short period of retrograde cerebral perfusion can be performed to wash out the arch arteries before antegrade perfusion is reestablished definitively.[52]

CHAPTER 15

Myocardial Protection

Robert M. Mentzer, Jr. • M. Salik Jahania • Robert D. Lasley

The term *myocardial protection* refers to strategies and methodologies used either to attenuate or to prevent postischemic myocardial dysfunction that occurs during and after heart surgery. Postischemic myocardial dysfunction is attributable, in part, to a phenomenon known as *ischemia-reperfusion-induced injury.* Clinically, it manifests by low cardiac output and hypotension and may be subdivided into two subgroups: reversible injury and irreversible injury. The two typically are differentiated by the presence of electrocardiographic abnormalities, elevations in the levels of specific plasma enzymes or proteins such as creatine kinase and troponin I or T, and/or the presence of regional or global echocardiographic wall motion abnormalities. With respect to coronary artery bypass grafting (CABG) alone, 10% of patients may experience myocardial infarction (MI), severe ventricular dysfunction, heart failure, and/or death despite advances in surgical technique. The impact from these complications both on families and on society is enormous. From an economic standpoint, the initial hospital cost of CABG is approximately $10 billion annually; it is likely, then, that complications after CABG consume an additional $2 billion in U.S. health care resources each year.[1] The purpose of this chapter is to review the history of myocardial protection, to update the reader regarding the current protective techniques, to examine the mechanisms underlying ischemia-reperfusion injury, and to discuss several new strategies currently under investigation.

HISTORY

Over the past 50 years, many therapeutic strategies have been developed to protect the heart during surgery (Table 15-1). This concept of shielding the heart from perioperative insult originated in 1950 with the review article by Bigelow and colleagues in which hypothermia was reported "as a form of anesthetic" that could be used to expand the scope of surgery.[2] It was proposed that hypothermia could be used as "a technique that might permit surgeons to operate on the bloodless heart without recourse to extracorporeal pumps and perhaps allotransplantation of organs."[2] Five years later, Melrose and colleagues reported another way to stop and restart the heart reliably by injecting potassium citrate into the root of the aorta at both normal and reduced body temperatures.[3] Soon thereafter, the clinical application of potassium citrate arrest was adopted by many centers. Interest in using the Melrose technique waned, however, with subsequent reports that potassium citrate arrest was associated with myocardial injury and necrosis. Within a short time, many cardiac surgeons shifted from using potassium-induced arrest to normothermic cardiac ischemia (i.e., normothermic heart surgery performed with the aorta occluded while the patient was on cardiopulmonary bypass), intermittent aortic occlusion, or coronary artery perfusion. Experimental and clinical evidence showed, however, that normothermic cardiac ischemia was associated with metabolic acidosis, hypotension, and low cardiac output.[4–6]

As a consequence, there was a renewed interest in discovering ways to arrest the heart. Bretschneider published the principle of arresting the heart with a low-sodium, calcium-free solution.[7] It was Hearse and colleagues, however, who studied the various components of cardioplegic solutions, which led to the development and use of St. Thomas solution.[8] The components of this crystalloid solution were based on Ringer's solution with its normal concentrations of sodium and calcium with the addition of potassium chloride (16 mmol/L) and magnesium chloride (16 mmol/L) to arrest the heart instantly. The latter component was shown by Hearse to provide an additional cardioprotective benefit. In 1975, Braimbridge and colleagues introduced this crystalloid solution into clinical practice at St. Thomas Hospital.[9]

Gay and Ebert showed experimentally that lower concentrations of potassium chloride could achieve the same degree of chemical arrest and myocardial protection

Table 15–1.

Therapeutic Innovations for Myocardial Protection

Reference	Year	Innovation
Bigelow WG[2]	1950	Studied the application of hypothermia to cardiac surgery in canines
Swan H	1953	Showed that hypothermic arrest (26°C) in humans provided a bloodless field for operating
Melrose DG, Bentall HH[3]	1955	Introduced the concept of reversible chemical cardiac arrest in canines
Lillehei CW	1956	Detailed a method for delivering hypothermic crystalloid cardioplegia by cannulating coronary arteries
Lam CR	1957	One of the earliest known uses of the term "cardioplegia"
Gerbode F, Melrose DG	1958	Used potassium citrate to induce cardiac arrest in humans
McFarland JA	1960	Challenged the safety of the Melrose technique; changed from potassium arrest to intermittent aortic occlusion or coronary artery perfusion for myocardial protection
Bretschneider HJ[7]	1964	Developed a sodium-poor, calcium-free, procaine-containing solution to arrest the heart
Sondergaard KT	1964	Adopted Bretschneider's cardioplegic solution and was one of the first to routinely use it for myocardial protection in clincial practice
Gay WA, Ebert PA[10]	1973	Credited with revival of potassium-induced cardioplegia; demonstrated that potassium solution could arrest a canine heart for 60 minutes without cellular damage
Roe BB[11]	1973	Demonstrated that "the modalities of cardioplegia, hypothermia, and capillary washout" provided effective myocardial protection
Tyers WA[4]	1974	Demonstrated that an infusion of cold blood to keep the myocardial tissue below 4°C provided 90 minutes of ischemia in animals
Hearse DJ[8]	1975	Emphasized preischemic infusions to negate ischemic injuries in rats; this formula became known as St. Thomas solution no. 1
Braimbridge MV[9]	1975	One of the first to use St. Thomas solution no. 1 clinically
Effler DB	1976	Recommended simple aortic clamping at operating room tempreatures
Buckberg GD[13]	1979	Introduced the use of blood as the vehicle for infusing potassium into coronary arteries
Akins CW[84]	1984	Utilized technique of hypothermic fibrillatory arrest for coronary revascularization without cardioplegia
Murray CE[99]	1986	Noted that brief periods of ischemia and reperfusion enable the heart to withstand longer periods of ischemia
Lichtenstein SV, Salerno TA[90,91]	1991	Reported clincally beneficial results using continuous, warm blood cardioplegia

afforded by the Melrose solution without the associated myocardial necrosis reported earlier.[10] Shortly thereafter, Roe and colleagues reported an operative mortality of 5.4% for patients who underwent cardiac surgery with potassium-induced arrest as the primary form of myocardial protection.[11] In 1977, Tyers and colleagues reported that potassium cardioplegia provided satisfactory protection in over 100 consecutive cardiac patients.[12]

By the 1980s, normothermic aortic occlusion had been replaced for the most part by cardioplegia to protect the heart during cardiac surgery. The major controversy at the time (and one that persists today) was not whether cardioplegic solutions should be used, but what were the ideal components of those solutions. The chief variants consisted of (1) the Bretschneider solution, consisting primarily of sodium, magnesium, and procaine, (2) the St. Thomas solution, consisting of potassium, magnesium, and procaine added to Ringer's solution, and (3) potassium-enriched solutions containing no magnesium or procaine (Table 15-2). Coincident with this controversy, another variant of cardioplegia was introduced, that of using potassium-enriched blood cardioplegia.[13,14] The theory was that blood would be a superior delivery vehicle based on its oxygenating and buffering capacity. Ironically, Melrose and colleagues initially used blood as the vehicle to deliver high concentrations of potassium citrate more than 20 years earlier.

While hypothermia and potassium infusions remain the cornerstone of myocardial protection during on-pump heart surgery, many other cardioprotective techniques and methodologies are available.[3,15] Although many of these techniques have been reported to confer superior protection and improve patient outcomes, the ideal cardioprotective technique, solution, and method of administration have yet to be found. Fortunately, the majority of cardioprotective strategies now available do allow patients to undergo conventional and complex heart operations with an operative mortality rate ranging from less than 2 to 4%.

ISCHEMIA-REPERFUSION INJURY

While the etiology of postischemic myocardial dysfunction after cardiac surgery is multifactorial, three basic types of injury occur during heart surgery: myocardial stunning, apoptosis, and MI. Myocardial stunning is an injury that may last for only a few hours or persist for several days despite the restoration of normal blood flow. Cells that have been reversibly injured (stunned) exhibit no sign of ultrastructural damage. Apoptosis is "suicidal" programmed cell death, characterized by retention of an intact cell membrane, cell shrinkage, chromatin condensation, and phagocytosis without inflammation.[16–19]

There is increasing evidence that apoptotic death of cardiomyocytes caused by ischemia-reperfusion contributes significantly to the development of infarction as well as the loss of cells surrounding the infarct area. A large fraction of dying cells may exhibit features of both apoptosis and necrosis, i.e., both nuclear condensation and plasma membrane damage. Ultimately, however, after more prolonged ischemia, the heart begins to sustain irreversible injury in the form of infarction, necrosis, and a spectrum of reperfusion-associated pathologies manifested as membrane destruction, cell swelling, DNA degradation, cytolysis, and the induction of an inflammatory response collectively called *reperfusion injury.*[20]

While the consequences of inadequate myocardial protection usually are apparent in the immediate postoperative period, the full impact may not be fully appreciated for months. Klatte and colleagues reported that patients with increased peak creatine kinase–myocardial band (CK-MB) enzyme ratios after CABG exhibited a greater 6-month mortality.[21] Specifically, the 6-month mortality rates for patients with peak CK-MB ratios of less than 5, 5 to less than 10, 10 to less than 20, and 20 and greater upper limits of normal were 3.4, 5.8, 7.8, and 20.2%, respectively. Conversely, the cumulative 6-month survival was inversely related to the peak CK-MB ratio. These observations support the concept that myocardial injury occurring as a result of inadequate myocardial protection intraoperatively is associated with subsequent death.

In order to appreciate the strategies that have evolved to protect the myocardium during heart surgery, it is important to understand the mechanisms implicated in the etiology of the various types of myocardial ischemia-reperfusion injury. Significant evidence now exists that the primary mediators of reversible and irreversible myocardial ischemia-reperfusion injury include intracellular Ca^{2+} overload during ischemia and reperfusion and oxidative stress induced by reactive oxygen species (ROS) generated at the onset of reperfusion[22–24] (Fig. 15-1). The molecule nitric oxide (NO) also can interact with ROS to generate various reactive nitrogen species that appear capable of both contributing to and reducing injury.[25,26] In addition, metabolic alterations occurring during ischemia can contribute directly and indirectly to Ca^{2+} overload and ROS formation. For example, decreased cytosolic phosphorylation potential, i.e., $[ATP]/-([ADP] \times [P_i])$, results in less free energy from ATP hydrolysis than is necessary to drive the energy-dependent pumps (sarcoplasmic reticulum Ca^{2+}-ATPase, the sarcolemmal Ca^{2+}-ATPase) that maintain intracellular calcium homeostasis.[27]

Restoration of intracellular pH at the onset of reperfusion via Na^{+}-H^{+} exchange contributes to intracellular Ca^{2+} overload via reversed Na^{+}-Ca^{2+} exchange.[28,29]

The metabolic changes that occur during ischemia also reduce the endogenous antioxidant defense systems of cardiac myocytes. The first line of defense against mitochondrial ROS formation and its deleterious effects is the GSH (reduced glutathione)/GSSG (oxidized glutathione) system, which is directly linked to the NADPH:$NADP^{+}$ ratio via the enzyme glutathione reductase. The depletion of glutathione levels increases ROS formation, oxidative stress, and $[Ca^{2+}]_i$.[30–33] Since NADPH is not formed during ischemia, the normal metabolic mechanism for regenerating the reduced glutathione does

Table 15–2.

Components of Various Cardioplegic Solutions

Solution	Usual components*							Other components
	Sodium	Potassium	Magnesium	Calcium	Bicarbonate	pH	Osmolarity (mOsm/L)	
Bretschneider's no. 3	12.0	10.0	2.0	–	–	5.5–7.0	320	Procaine; mannitol
Lactated Ringer's	130.0	24.0	–	1.5	–	7.14	–	Lactate; chlorine
Tyer's	138.0	25.0	1.5	0.5	20.0	7.8	275	Acetate; gluconate; chloride
St. Thomas no. 2	110.0	16.0	16.0	1.2	10.0	7.8	324	Lidocaine
Roe's	27.0	20.0	1.5	–	–	7.6	347	Glucose; tris buffer
Gay/Ebert	38.5	40.0	–	–	10.0	7.8	365	Glucose
Birmingham	100.0	30.0	–	0.7	28.0	7.5	300–385	Glucose; chloride; albumin; mannitol
Craver's	154.0	25.0	–	–	11.0	–	391	Dextrose
Lolley's	–	20.0	–	–	4.4	7.78	350	Dextrose; mannitol; insulin

**Values are expressed in millimoles per liter unless otherwise noted.*

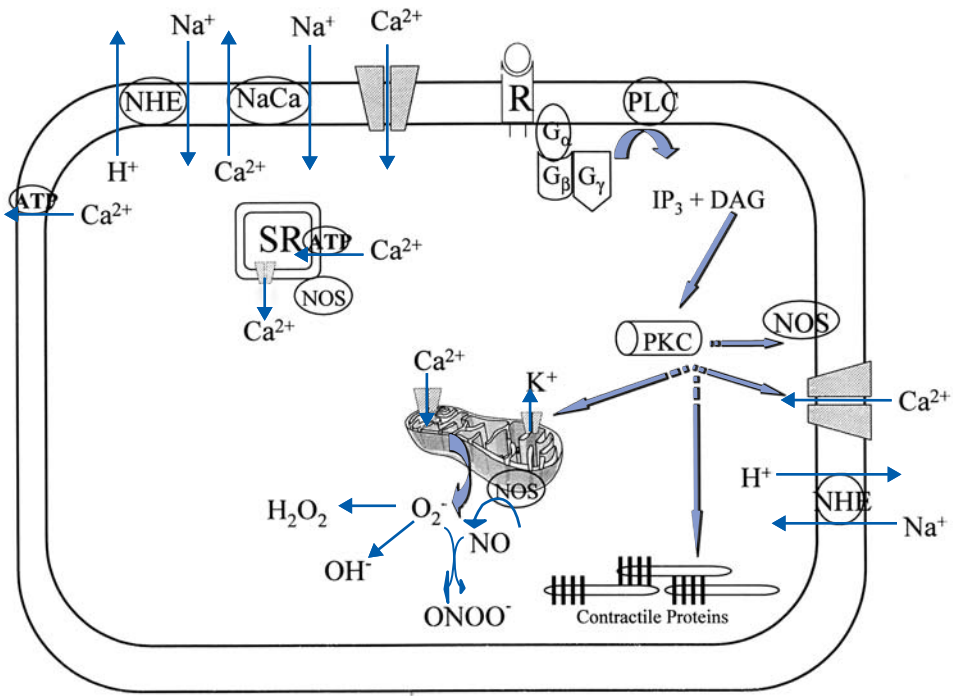

Figure 15-1. Intracellular mechanisms regulate cardiomyocyte Ca^{2+} homeostasis and reactive oxygen species formation, the two primary mediators of myocyte ischemia-reperfusion injury. During ischemia, intracellular Ca^{2+} increases via the inability of energy-dependent Ca^{2+} pumps in the sarcolemma and sarcoplasmic reticulum (SR) to maintain normal low resting cytosolic Ca^{2+} concentrations. Activation of various G protein–coupled receptors (R, alpha- and beta-adrenergic, angiotensin, endothelin, etc.) initiates signaling mechanisms [stimulatory G proteins (G_s) and phospholipase C (PLC)] and also increases Ca^{2+}. The generation of inositol triphosphate (IP_3) from this latter pathway increases Ca^{2+} release from intracellular stores, including SR. diacylglycerol (DAG) formation via the PLC pathway leads to the activation of Ca^{2+}-dependent and -independent isoforms of protein kinase C (PKC). PKC phosphorylation of various proteins and enzymes further modulates Ca^{2+} concentration, metabolism, and contractile protein Ca^{2+} sensitivity. The sodium-hydrogen exchanger (NHE) exchanges intracellular H^+ for extracellular Na^+, and the resulting increase in intracellular Na^+ may result in reverse Na^+ -Ca^{2+} exchange via the sodium-calcium exchanger (Na-Ca). During reperfusion, the generation of reactive oxygen species [superoxide anion (O_2^-), hydroxyl anion (OH^-), and hydrogen peroxide (H_2O_2)] oxidizes various proteins (Ca^{2+} pumps, SR Ca^{2+} release channels, contractile proteins, etc.) that contribute to both reversible and irreversible injury. Superoxide may combine with nitric oxide (NO) generated from sarcolemmal NOS and possibly mitochondrial NOS to form peroxynitrite ($ONOO^-$) and other reactive nitrogen species to modulate ischemia-reperfusion injury. Early reperfusion is also associated with increased NHE activity, further exacerbating Ca^{2+} overload via reverse Na^+ -Ca^{2+} exchange. Preischemic activation of some myocyte inhibitory G protein (G_i)–-coupled receptors, such as adenosine A_1 and opioid receptors, reduces these deleterious effects of ischemia-reperfusion. It also has been proposed that PKC may phosphorylate an ATP-dependent K^+ channel in the mitochondrial membrane and/or membrane-bound nitric oxide synthase (NOS) that protects the myocyte against ischemia-reperfusion injury.

not function. Thus, the formation of ROS during reperfusion occurs at a time when the myocyte's endogenous defense mechanisms are depressed. The NADPH:$NADP^+$ ratio is a primary determinant of the redox state of the cell, and there is evidence that redox state plays a key role in determining the bioactivity and redox state of NO.[26,34,35] In addition, there are several reports that in the absence of normal levels of its cofactors, nitric oxide synthase (NOS) itself can generate superoxide anion.[36,37] Although systolic calcium $[Ca^{2+}]_i$ may return to normal levels early in reperfused stunned myocardium, the transient increases in intracellular $[Ca^{2+}]_i$ can activate Ca^{2+} -dependent protein kinase (PKC), proteases such as calpain, and endonucleases.[38–40] Calpain activation and its subsequent action on contractile proteins have been implicated in the reduction of myofilament Ca^{2+} sensitivity observed in stunned myocardium.[41,42]

Similarly, there is significant evidence that ROS are involved in mediating myocardial stunning. Various spin-trap agents and chemical probes have demonstrated the rapid release of ROS into the vascular space during reperfusion after brief ischemia in vivo.[43–46] It is also now recognized that mitochondria are a primary source of intracellular ROS

in cardiac myocytes.[47,48] Scavengers of ROS and antioxidants attenuate myocardial stunning in vitro and in vivo, and these interventions are effective when administered prior to or at the onset of reperfusion.[22,49,50] It has been shown that ROS can attack thiol residues of numerous proteins such as the SR Ca^{2+}-ATPase, the ryanodine receptor, and contractile proteins.[51–53] This may explain why myofibrils isolated from in vivo reperfused stunned but not ischemic myocardium exhibit reduced Ca^{2+} sensitivity.[54]

More prolonged ischemia, which produces irreversible injury, is associated with more severe intracellular Ca^{2+} overload and further depletion of endogenous antioxidants, conditions that both contribute to and are exacerbated during reperfusion by the production of ROS. The production of ROS during reperfusion appears to contribute to Ca^{2+} overload because exposure of normal myocytes to exogenous ROS is associated with increased L-type Ca^{2+} channel current and increased $[Ca^{2+}]_i$.[33,55,56] Conversely, increases in $[Ca^{2+}]_i$ during ischemia-reperfusion may adversely affect mitochondrial function, leading to further ROS production.[57,58] Mitochondria can buffer small increases in intracellular Ca^{2+} via the Ca uniporter, a process that is energetically favorable owing to the $[Ca^{2+}]$ gradient and the mitochondrial membrane potential. During reperfusion, the increase in cytosolic Ca^{2+} enhances mitochondrial Ca^{2+} uptake. Since excess cytosolic Ca^{2+} has been associated with the loss of myocyte viability, mitochondrial Ca^{2+} buffering is initially cardioprotective.[59] However, continued mitochondrial Ca^{2+} buffering in the face of decreased antioxidant reserves and excess ROS formation sets up a cycle that ultimately may lead to the total collapse of mitochondrial membrane potential and cell death.[58] The synergistic interactions between Ca^{2+} overload and ROS formation during conditions of decreased antioxidant reserves also may provide an explanation of why ROS scavengers are not very effective at reducing irreversible injury when administered at reperfusion.[60,61]

Historically, myocardial ischemia-reperfusion injury has been characterized as either reversible or irreversible (based on staining techniques, enzyme release, and histology). There is now increasing evidence that this injury represents a transition from reversible to irreversible injury and that it occurs as a continuum and not as an all-or-none phenomenon. For example, apoptosis occurs prior to severe depletion in ATP and loss of membrane integrity but ultimately leads to cell death.[17,19] The phenomenon of apoptosis appears to commence during reperfusion with the formation of intracellular ROS and/or intracellular calcium overload[62–64] (Fig. 15-2). This process is initiated by translocation of the proapoptotic proteins Bad and Bax from the cytosol to the mitochondrial membrane. Heterodimerization of Bad or Bax with the antiapoptotic Bcl-2 or Bcl-xl can lead to the release of the mitochondrially localized cytochrome c into the cytosol.[65–67] Formation of a cytosolic complex consisting of cytochrome c, apoptosis-activating factor 1 (APAF-1), and caspase-9 leads to activation of caspase 3 and the cleavage of poly(ADP)-ribosylating (PARP) protein. Activation of PARP is the final step in apoptosis, leading to DNA fragmentation.[68]

As described earlier, the increased intracellular ROS and/or intracellular calcium overload collapse the mitochondrial membrane potential, leading to mitochondrial permeability transition pore (MPTP) opening, which, if not reversed, can result in the loss of mitochondrial proteins such as cytochrome c.[56]

The physiologic relevance of apoptosis during myocardial ischemia-reperfusion has yet to be determined. This is due to the fact that the majority of reports on apoptosis in this setting have been based on measurements of DNA fragmentation and laddering, the final steps in apoptotic cell death. Once DNA is fragmented, the cell's ability to synthesize new proteins to repair itself is severely compromised, and these cells, even if they survive a first ischemic episode, may die at an accelerated rate during subsequent stress or ischemia. However, studies conducted in other tissues and in isolated cells (including cardiomyocytes) indicate that the apoptotic program can be detected much earlier than these late stages. One of the earliest signs of apoptosis is the translocation of phosphatidylserine from the inner face of the plasma membrane to the cell surface, a process that can be detected by annexin V, which has a strong affinity for phosphatidylserine.[69,70] Apoptosis in cardiac myocytes can be demonstrated with fluoroscein isothiocyanate (FITC)-conjugated annexin V staining of the plasma membrane much earlier than DNA fragmentation (via the TUNEL assay and DNA laddering).[71–74.] There are also reports that this early stage of apoptosis does not irreversibly commit cells to programmed cell death in noncardiac tissue and that a significant proportion of myocytes, when submitted to simulated ischemia-reperfusion, exhibit signs of early apoptosis (positive annexin-FITC staining, intact membrane cell death, decreased cell width, and increased mitochondrial $[Ca^{2+}]$).[74–76]

Thus, it appears that ischemia-reperfusion injury (i.e., myocardial stunning, apoptosis, and infarction) manifests in a variety of interrelated ways. For example, apoptosis may proceed to necrosis when mitochondria are no longer able to withstand the intracellular Ca^{2+} overload and oxidative stress induced by ROS and when oxidative phosphorylation is unable to keep pace with energy demands. Due to the resulting decrease in the myocardial phosphorylation potential, energy-dependent ion pumps cannot maintain normal ion gradients. This results in cell swelling and, ultimately, loss of membrane integrity. These disturbances can be further exacerbated by the influx of macrophages and leukocytes, complement activation, and endothelial plugging by platelets and neutrophils. If cell death in ischemic-reperfused myocardium progresses from apoptosis to necrosis, and if early apoptosis is indeed reversible, then one therapeutic approach for the treatment or prevention of ischemia-reperfusion injury would be to target the early events in apoptosis. Regardless of which stage is being addressed, current cardioprotection strategies are designed to reduce cellular and subcellular ROS formation and oxidative stress, to enhance the heart's endogenous antioxidant defense mechanisms, and to prevent intracellular Ca^{2+} overload.

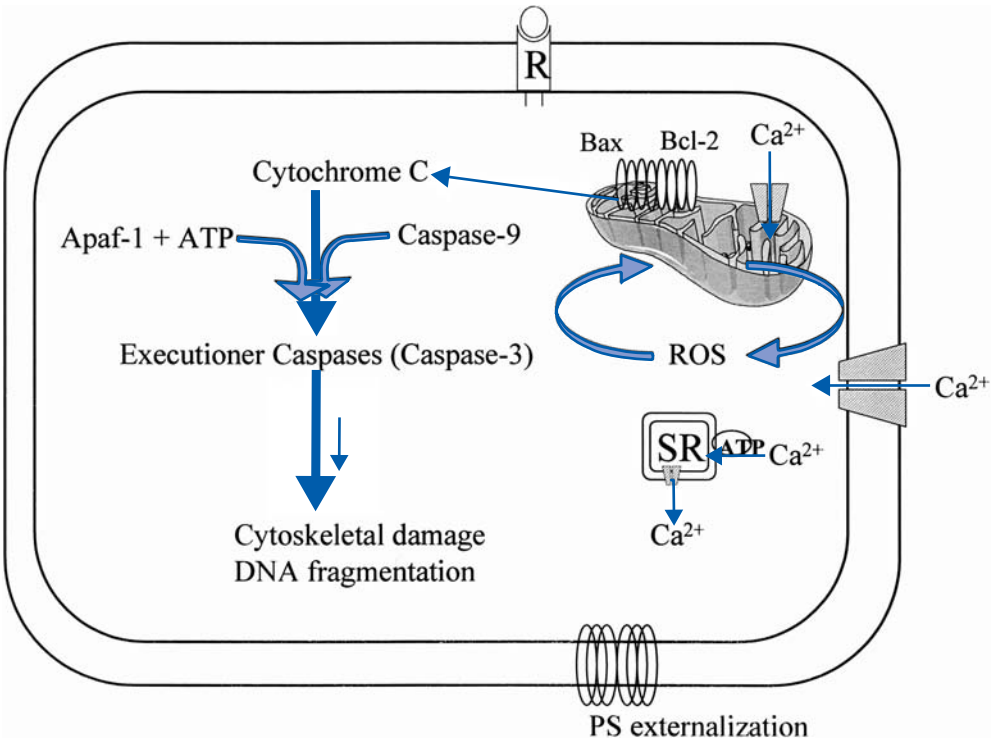

Figure 15-2. Proposed mechanisms of cardiomyocyte apoptosis following ischemia-reperfusion injury. Intracellular Ca^{2+} overload during ischemia and reperfusion and reactive oxygen species (ROS) formation during reperfusion are thought to be the primary mediators of the intrinsic pathway of apoptosis. The mechanisms of Ca^{2+} overload and ROS formation are described in detail in the text. Ischemia-reperfusion-associated effects on metabolism and decreased levels of the endogenous antioxidant glutathione lead to excess electron leak from the mitochondrial electron transport chain generating mitochondrial ROS. The mitochondrial Ca^{2+} uniporter can buffer increases in cytosolic Ca^{2+}, but increased mitochondrial Ca^{2+} can induce excess ROS formation. Likewise, ROS formation can induce intracellular Ca^{2+} overload. Through mechanisms that are not well defined, two families of closely related proteins (Bcl-2 and Bax) modulate the cell's response to apoptotic stimuli. Bcl-2 is an antiapoptotic protein that appears to be capable of inhibiting cytochrome c release either directly or by forming a complex with and inhibiting the proapoptotic family of proteins (Bax). Bax is thought to translocate from the cytosol to the mitochondrial membrane during the apoptotic process. Two early events in apoptosis are the externalization of phosphatidyl serine (PS) residues in the sarcolemma and the release of cytochrome c from the mitochondria. The significance of PS externalization is not clear; however, its occurrence can be detected with fluorescently tagged annexin-5, thus permitting the detection of the early stages of apoptosis. Cytochrome c released from the mitochondria complexes with an apoptotic protease-activating factor 1 (Apaf-1) and procaspase 9. In the presence of near-normal ATP levels, procaspase 9 is cleaved into the active caspase 9 with the resulting activation of the cytosolic protease caspase 3, often referred to as the *executioner caspase*. Caspase 3 protease activity leads to irreversible damage to cell morphology and DNA fragmentation and laddering.

NONCARDIOPLEGIC TECHNIQUES

Intermittent Cross-Clamping with Fibrillation

One of the earliest forms of cardioprotection, still used at some centers today, is known as *intermittent aortic cross-clamping with fibrillation and moderate hypothermic perfusion* (30 to 32°C). Using this approach, CABG can be performed on the unarrested heart with ascending aorta cannulation and generally a two-stage single venous cannula. This technique allows the surgeon to operate in a relatively quiet field (during ventricular fibrillation) and to avoid the consequences of profound metabolic changes that occur with more prolonged periods of ischemia. The duration of fibrillation is determined by how long it takes to perform the distal anastomoses. After completion of the last distal graft, the heart can be defibrillated and the proximal aortic-based graft anastomoses performed on the beating heart using an aortic partial occlusion clamp.

As a result of increasing pressures to reduce costs and yet maintain acceptable levels of myocardial protection, there has been a renewed interest in this approach. There are, in fact, a number of reports that indicate that satisfactory protection can be conferred using this technique. In 1992, Bonchek and colleagues reported a large clinical series in which the advantages and safety of using this technique were

meticulously analyzed.[77] In this study, the authors reviewed the outcomes of the first 3000 patients at their institution who underwent primary CABG using the intermittent aortic cross-clamping technique. Preoperative risk factors (e.g., age, gender, left ventricular dysfunction (LVD), preoperative intra-aortic balloon pumping (IABP), and urgency of operation) and operative deaths were analyzed as well. In this series, 29% of the patients were older than 70 years of age, 27% were females, 9.7% had an ejection fraction of less than 0.30, 13% had an MI less than 1 week preoperatively, and 31% had preinfarction angina in the hospital. Only 26% underwent purely elective operations. Using the noncardioplegic cardioprotective technique, the authors reported an elective operative mortality rate of 0.5%, an urgent mortality rate of 1.7%, and an emergency rate of 2.3%. Postoperatively, inotropic support was needed in only 6.6% of the patients, and only 1% required IABP. It is important to note, however, that this was a retrospective, single-center institutional experience. The findings would have been more enlightening if the analysis had included a similarly matched group of patients at the same institution in which cardioplegic arrest had been employed. Nevertheless, the findings do suggest that noncardioplegic strategies can provide satisfactory myocardial protection even in high-risk patients.

As a result, a minority of surgeons continues to use this technique.[78–80] In 2002, Raco and colleagues[81] reported the results of 800 consecutive CABG operations performed by a single surgeon using aortic cross-clamping in both elective and nonelective procedures. The patients were divided into three cohorts: (1) elective, (2) urgent, and (3) emergent. The mean age, number of distal grafts, and mortality in the elective group were 61.5 years, 3.2 grafts, and 0.6%, respectively. For the urgent group, they were 63.1 years, 3.2 grafts, and 3.1%. In the emergent group, they were 63.8 years, 2.9 grafts, and 5.6%. These findings support the contention that intermittent aortic cross-clamping is a safe technique in both elective and nonelective patients when performed by an experienced surgeon.[82,83]

Systemic Hypothermia and Elective Fibrillatory Arrest

Although used infrequently, this technique appears to be a safe approach to protecting the heart during CABG. In 1984, Akins and colleagues reported a low incidence of perioperative infarction and a low hospital mortality rate in 500 consecutive patients using this technique.[84] With this method, systemic hypothermia (28°C), elective fibrillatory arrest, and maintenance of systemic perfusion pressure at between 80 and 100 mm Hg are the key elements. On fibrillatory arrest, the local vessel can be isolated and myocardial revascularization performed. The limitations of this technique include (1) the surgical field may be obscured by blood during revascularization, (2) ventricular fibrillation is associated with increased muscular tone, which can limit the surgeon's ability to position the heart for optimal exposure, and (3) it is generally not applicable for intracardiac procedures.[85]

CARDIOPLEGIC TECHNIQUES

Cardioplegic solutions contain a variety of chemical agents that are designed to arrest the heart rapidly in diastole, create a quiescent operating field, and provide reliable protection against ischemia-reperfusion injury. In general, there are two types of cardioplegic solutions: crystalloid cardioplegia and blood cardioplegia. These solutions are administered most frequently under hypothermic conditions.

Cold Crystalloid Cardioplegia

There are basically two types of crystalloid cardioplegic solutions: the intracellular type and the extracellular type. The intracellular types are characterized by absent or low concentrations of sodium and calcium. The extracellular types contain relatively higher concentrations of sodium, calcium, and magnesium. Both types avoid concentrations of potassium >40 mmol/L, contain bicarbonate for buffering, and are osmotically balanced. In both types, the concentration of potassium used ranges between 10 and 40 mmol/L (for potassium 1 mmol/L = 1 mEq/L). Examples of some of the various crystalloid cardioplegic solutions used are shown in Table 15-2.

Operative procedure

While the degree of core cooling varies from center to center, patients undergoing cardiac surgery are placed on cardiopulmonary bypass (CPB) and often cooled to between 33 and 28°C. To initiate immediate chemical arrest, the solution is infused after cross-clamping the aorta through a cardioplegic catheter inserted into the aorta proximal to the cross-clamp. The catheter may or may not be accompanied by a separate vent cannula. The cold hyperkalemic crystalloid solution then is infused (antegrade) at a volume that generally does not exceed 1000 mL. One or more infusions of 300 to 500 mL of the cardioplegic solution may be administered if there is evidence of electrical heart activity resumption or if a prolonged ischemic time is anticipated. If myocardial revascularization (MR) is being performed, the aortic cross-clamp can be removed after completing the distal anastomoses, and the heart can be reperfused while the proximal anatomoses are completed using a partial occlusion clamp. Alternatively, the proximal grafts can be performed after the distal grafts have been completed with the cross-clamp still in place (the single-clamp technique). Another approach is to perform the proximal aortic grafts first and then to cross-clamp the aorta and infuse the cardioplegic solution. When valve repair or replacement is being performed, the crystalloid cardioplegia can be administered directly into the coronary arteries via cannulation of the coronary ostia. Crystalloid cardioplegia also can be administered retrograde via a coronary sinus catheter with or without a self-inflating silicone cuff.

Results

Numerous studies have been performed to determine the efficacy of using cold crystalloid cardioplegic solutions to protect the heart during cardiac surgery. While there is considerable controversy regarding the "ideal" solution and its components, there is evidence that in those centers in which crystalloid cardioplegia is used almost exclusively, excellent myocardial protection can be achieved. In many reports, the perioperative MI rate is less than 4%, and the operative mortality rate is less than 2%.

Cold Blood Cardioplegia

Cold blood cardioplegia, widely employed throughout the world, is the cardioplegic technique used most commonly in the United States today. Although there are a variety of formulations, it is usually prepared by combining autologous blood obtained from the extracorporeal circuit while the patient is on cardiopulmonary bypass with a crystalloid solution consisting of citrate-phosphate-dextrose (CPD), tris-hydroxymethyl-aminomethane (tham) or bicarbonate (buffers), and potassium chloride. The CPD is used to lower the ionic calcium, the buffer is used to maintain an alkaline pH of approximately 7.8, and the final concentration of potassium is used to arrest the heart (approximately 30 mmol/L).

Prior to administering blood cardioplegia, the temperature of the solution usually is lowered with a heat-exchanging coil to between 12 and 4°C. The ratio of blood to crystalloid varies among centers, with the most common ratios being 8:1, 4:1, and 2:1. This, in turn, affects the final hematocrit of the blood cardioplegia infused. For example, if the hematocrit of the autologous blood obtained from the extracorporeal circuit is 30, these ratios would result in a blood cardioplegia with a hematocrit of approximately 27, 24, and 20, respectively.

The use of undiluted blood cardioplegia, or "miniplegia" (using a minimum amount of crystalloid additives), also has been reported to be effective. In an acute ischemia-reperfusion canine preparation, Velez and colleagues tested the hypothesis that an all-blood cardioplegia (66:1 blood:crystalloid ratio) would provide superior protection compared with a 4:1 blood cardioplegia delivered in a continuous retrograde fashion.[86] They found very little difference between the animal groups with respect to infarct size or postischemic recovery of function. This is consistent with the findings by Rousou and colleagues years earlier that it is the level of hypothermia that is important in blood cardioplegia, not necessarily the hematocrit.[87]

The rationales for using blood as a vehicle for hypothermic potassium-induced cardiac arrest include:

1. It can provide an oxygenated environment.
2. It can provide a method for intermittent reoxygenation of the heart during arrest.
3. It can limit hemodilution when large volumes of cardioplegia are used.
4. It has an excellent buffering capacity.
5. It has excellent osmotic properties.
6. The electrolyte composition and pH are physiologic.
7. It contains a number of endogenous antioxidants and free-radical scavengers.
8. It can be less complex than other solutions to prepare.

With respect to efficacy, there are numerous preclinical studies as well as nonrandomized and randomized clinical trials that demonstrate that cold blood cardioplegia is an effective way to provide excellent myocardial protection. While many of these same studies also have suggested that cold blood cardioplegia is superior to cold crystalloid cardioplegia, it is important to note that other investigators have shown crystalloid cardioplegia to be just as cardioprotective and cost-effective, if not more so, and that crystalloid cardioplegia more reliably ensures a quiet, bloodless operative field. Unfortunately, many of the clinical trials that have compared the efficacy of blood and crystalloid cardioplegia have been single-center studies, involved a limited number of patients, focused on a specific subset of patients, and/or omitted details regarding the clinical management of the patients.

Warm Blood Cardioplegia

The concept of using warm (normothermic) blood cardioplegia as a cardioprotective strategy in humans dates back to the 1980s. In 1982, Rosenkranz and colleagues reported that warm induction with normothermic blood cardioplegia, with a multidose cold blood cardioplegia maintenance of arrest, resulted in better recovery of function in canines than a similar protocol using cold blood induction.[88] In 1986, Teoh and colleagues reported an experimental study demonstrating that a terminal infusion of warm blood cardioplegia before removing the cross-clamp (a "hot shot") accelerated myocardial metabolic recovery.[89] This was followed by a report in 1991 by Lichtenstein and colleagues that normothermic blood cardioplegia in humans is an effective cardioprotective approach.[90] They compared the results of 121 consecutive patients who received antegrade normothermic blood cardioplegia during MR operations with a historical group of 133 patients who received antegrade hypothermic blood cardioplegia. The operative mortality in the warm cardioplegic group was 0.9% compared with 2.2% for the historical controls. At about the same time, Salerno and colleagues reported a series of 113 consecutive patients in which continuous warm blood cardioplegia was administered via the coronary sinus.[91] In this series, 96% had spontaneous return of rhythm on reperfusion, 7% needed transient IABP circulatory support, 6% had evidence of a perioperative MI, and 3% did not recover. A control cohort was not provided for comparison.

Despite these encouraging reports, there are still concerns with this approach. For example, for any given patient, it is not known just how long the warm heart can tolerate an ischemic event, which may occur when the infusion is

interrupted, flow rates are reduced owing to an obscured surgical field, or a maldistribution of the cardioplegic solution occurs. Another concern is the report by Martin and colleagues that suggested that the use of warm cardioplegia is associated with increased incidence of neurologic deficits.[92] In their prospective, randomized study (conducted on more than 1000 patients), the efficacies of warm blood cardioplegia and cold oxygenated crystalloid cardioplegia were analyzed. While operative mortalities were similar between the warm blood group and the cold oxygenated crystalloid cardioplegia cohort (1.0 versus 1.6%, respectively), the incidence of permanent neurologic deficits was threefold greater in the warm blood group (3.1 versus 1.0%). Thus, it appears that warm blood cardioplegia offers no distinct advantage over cold blood or cold crystalloid cardioplegia, and it may be less than ideal if its delivery is interrupted for any reason.

Tepid Blood Cardioplegia

Both cold blood (4 to 10°C) and warm blood cardioplegic solutions (37°C) have temperature-related advantages and disadvantages. As a consequence, a number of studies were performed in the 1990s to determine the optimal temperature. Hayashida and colleagues were one of the first groups to study specifically the efficacy of tepid blood (29°C) cardioplegia.[93] In this study, 72 patients undergoing CABG were randomized to receive cold (8°C) antegrade or retrograde, tepid (29°C) antegrade or retrograde, or warm (37°C) antegrade or retrograde blood cardioplegia. While protection was adequate for all three, the tepid antegrade cardioplegia was the most effective in reducing anaerobic lactate acid release during the arrest period. These authors reported similar findings when the tepid solution was delivered continuously retrograde and intermittently antegrade.[94] Since then, other studies also have demonstrated that tepid blood cardioplegia is safe and effective. The majority of these studies, however, have been single-center studies and/or conducted in a relatively small cohort of patients. Whether tepid cardioplegia confers better protection over other current methodologies remains to be determined.

Methods of Delivery

In addition to a variety of solutions and temperatures, there are also many different ways of administering the solutions (Fig. 15-3). As one might expect with so many options, the optimal delivery method of a cardioplegic solution also remains controversial. The various methods include intermittent antegrade, antegrade via the graft, continuous antegrade, continuous retrograde, intermittent retrograde, antegrade followed by retrograde, and simultaneous antegrade and retrograde infusions. While all methods generally are good, comparisons are difficult because there are numerous confounding factors such as (1) the composition of the solution, (2) the temperature of the solution, (3) the duration of the infusion, (4) the infusion pressure, (5) the type and complexity of the operation, (6) the need for surgical exposure, and (7) the expected versus actual cross-clamp time. One method that is being used frequently is the retrograde technique. This approach originated with a concept developed by Pratt in 1898, who suggested that oxygenated blood could be supplied to the ischemic heart via the coronary venous system.[95] Sixty years later, Lillehei and colleagues used retrograde coronary sinus perfusion to protect the heart during aortic valve surgery.[96] Today, it is an accepted method for delivering a cardioplegic solution and is used frequently as an adjunct to antegrade cardioplegia.

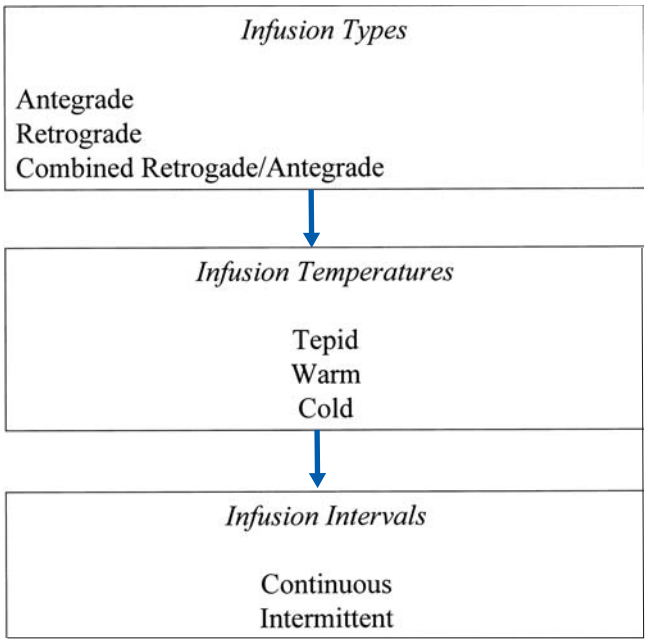

Figure 15-3. Methods and delivery of cardioplegic solutions.

In favor of the retrograde approach is the theoretical advantage of ensuring a more homogeneous distribution of the cardioplegic solution to regions of the heart that are poorly collateralized. It is also effective in (1) the setting of AR and valve surgery, (2) reducing the risk of embolization from saphenous vein grafts that could occur during antegrade perfusion during reoperative coronary artery surgery, and (3) delivering cardioplegia in a continuous manner.

Despite these advantages, retrograde cardioplegia is not without its limitations. Numerous experimental and clinical studies have shown that cardioplegia administered via the coronary sinus can result in a poor distribution of the solution to the right ventricle. This may be related to the variable venous anatomy of the heart. Because the anterior region of the right ventricle is not drained by the coronary sinus, and it is not uncommon for the heart to have a number of coronary sinus anomalies, these factors may result in the heterogeneous distribution of cardioplegic solutions and thus limit myocardial protection.

As a consequence, a technique for simultaneously delivering cardioplegia both antegrade and retrograde is

available. The feasibility and safety of this approach were reported in 1984 by Ihnken and colleagues.[97] In a more recent study, Cohen and colleagues used sonicated albumen and transesophageal echocardiography (TEE) intraoperatively to assess the effects of delivering a cardioplegic solution antegrade and retrograde simultaneously.[98] Compared with the antegrade or retrograde routes, the best and most consistent perfusion of the anterior left and right ventricles was achieved using the simultaneous technique. These investigators also reported that antegrade infusion resulted in superior perfusion of the left ventricle when compared with retrograde delivery alone and that right ventricular perfusion was inconsistent with both antegrade and retrograde delivery. Thus, it remains to be determined in which setting the simultaneous use of both methods is most appropriate.

With respect to intermittent cardioplegic infusions versus continuous infusions, the major advantage of the former is the ability to achieve and sustain a dry, quiescent operative field. While a continuous infusion, especially if it is oxygenated, has the theoretical advantage of minimizing ischemia, from a practical standpoint, it is unlikely that this can be achieved reliably. There is also the theoretical potential for an excessive infusion of cardioplegic solution.

PROTECTION STRATEGIES UNDER INVESTIGATION

Ischemic Preconditioning

Ischemic preconditioning is an adaptive biologic phenomenon in which the heart (and numerous other tissues) becomes more tolerant to a period of prolonged ischemia if first exposed to a prior episode of brief ischemia and reperfusion. This adaptation to ischemia was first described by Murray and colleagues and is referred to as *classic* or *early-phase preconditioning.*[99] This increased tolerance to ischemia is associated with a reduction in infarct size, apoptosis, and reperfusion-associated arrhythmias.[100–104] It has been demonstrated in every animal species studied and appears to persist as long as 1 to 2 hours after the ischemic preconditioning stimulus.[105,106] It becomes ineffective when the sustained ischemic insult exceeds 3 hours.[107] This suggests that the protection is conferred only when prolonged ischemia is followed by timely reperfusion.[108]

Subsequent studies have revealed that this endogenous defense mechanism can manifest itself in multiple ways. After the acute phase of preconditioning disappears, a second phase of protection appears 24 hours later and is sustained for up to 72 hours. This has been referred to as the *second window of protection, late-phase preconditioning,* or *delayed preconditioning.* Unlike classic preconditioning, which protects only against infarction, the late phase protects against both infarction and myocardial stunning.[101,109] Concurrent with these reports is an additional observation that ischemia induced in other organs could precondition the heart, a phenomenon referred to as *remote* or *interorgan preconditioning.*[110] Remote myocardial preconditioning, which has been reported by multiple investigators in various species, can be induced by brief occlusions of the renal and mesenteric arteries, as well as by skeletal muscle ischemia.[111–114] More recent studies indicate that multiple, brief coronary occlusions during the initial minutes of reperfusion following prolonged ischemia can reduce myocardial infarct size to a similar extent as ischemic preconditioning.[115,116] This adaptive response is referred to as *ischemic postconditioning.*

These observations have resulted in major investigative efforts to elucidate the intracellular mechanism(s) that underlie the heart's endogenous defenses against ischemia-reperfusion injury. The assumption is that a better understanding of these mechanism(s) could lead to the development of potent new therapeutic modalities that are more effective in treating or preventing the deleterious consequences of ischemia-reperfusion injury. One of the earliest hypotheses was that stimulation of cardiomyocyte adenosine A_1 and/or A_3 receptors was the primary mediator of acute ischemic preconditioning.[106,117,118] Subsequent studies have shown, however, that in addition to adenosine, there are multiple guanine nucleotide-binding (G) protein–coupled receptors that, once activated, can mimic the infarct-reducing effect of ischemic preconditioning (e.g., bradykinin, endothelin, α_1-adrenergic, muscarinic, angiotensin II, and delta-opioid receptors)[103,119] (Fig. 15-4). Transient infusion of exogenous agents that mimic ischemic preconditioning is referred to as *pharmacologic preconditioning.* Exactly which of these receptors is the most important in mediating endogenous preconditioning is unknown because there appear to be species differences and redundant pathways. Regardless, it is now thought that these triggers of ischemic preconditioning result in alterations in certain enzymes, such as tyrosine kinases, protein kinase C (PKC) isoforms, and mitogen-activated protein kinases [p38 and extracellular signal regulated kinase (ERK)] that, in turn, confer protection against irreversible injury prior to the onset of prolonged ischemia.[103,117–119] While the actual effector(s) of the protection has(have) yet to be determined, significant evidence has accumulated indicating that the cardiomyocyte mitochondria appear both to play a primary role in triggering this protection and to be a key target of preconditioning-induced protection.[103,117–121]

While early-phase preconditioning shares many of the same signaling mechanisms with late-phase preconditioning, the most obvious difference between the two is the apparent requirement for protein synthesis in the latter. Both late-phase ischemic and pharmacologic preconditioning have been shown to be associated with the upregulation of various proteins, including, but not limited to, heat-shock proteins, inducible NOS (iNOS), cyclooxygenase 2, and manganese superoxide dismutase.[110,124] There are, however, conflicting reports on what specific proteins are upregulated during late-phase preconditioning, which may be due to species differences, as well as stimulus-specific responses.[120–123]

The results of remote preconditioning studies indicate that this form of cardioprotection can be induced by

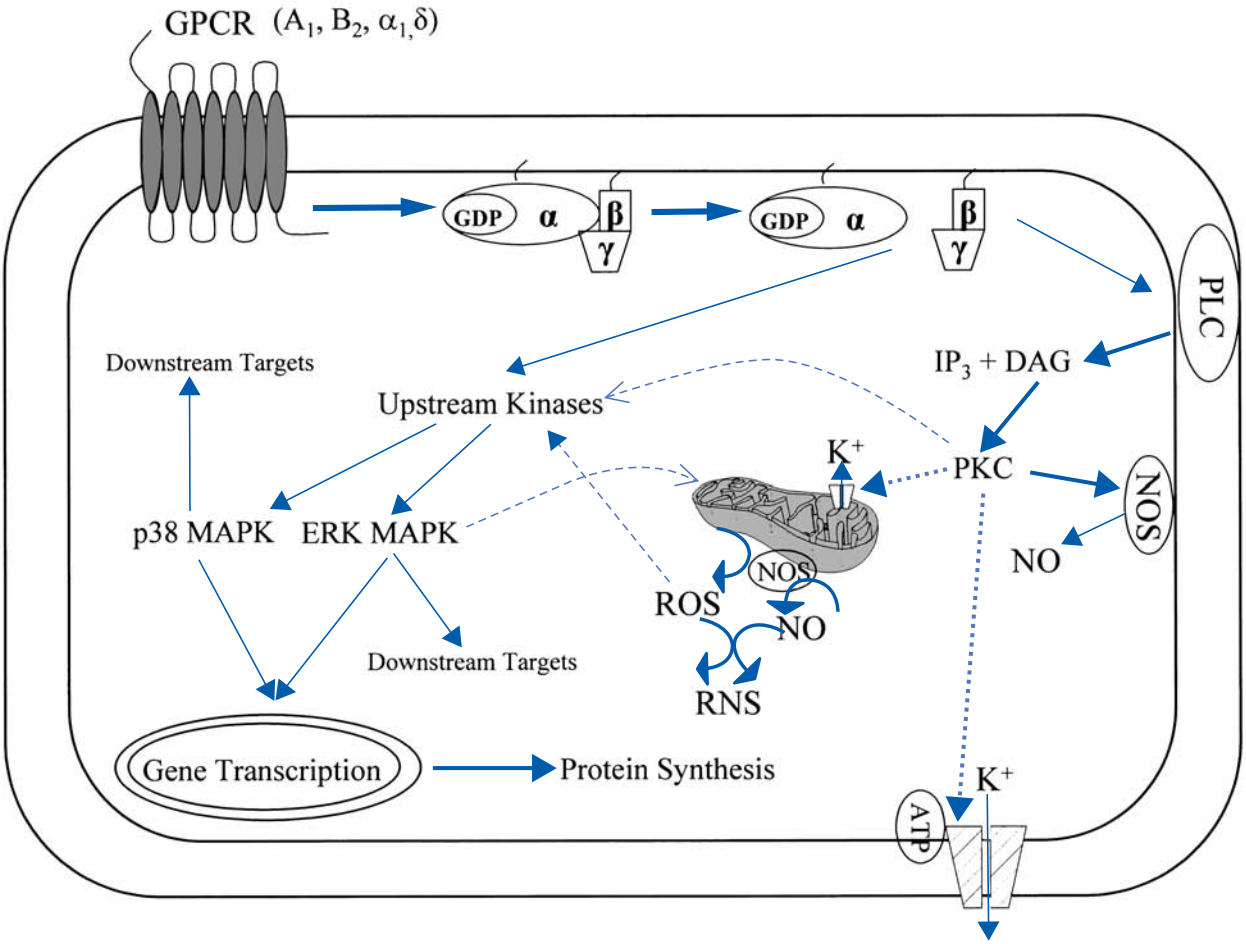

Figure 15-4. Proposed mechanisms of acute- and late-phase preconditioning. The stimulation of multiple G protein–coupled receptors (GPCRs), such adenosine A_1, bradykinin, α-adrenergic, and δ-opioid receptors, by endogenous ligands or by exogenous receptor agonists results in the activation of one or more G proteins. These initial events initiate the activation of several intracellular signaling pathways. Nitric oxide (NO) donors and reactive oxygen species (ROS) also can induce preconditioning. Significant evidence implicates the activation of one or more protein kinase C (PKC) isoforms and the mitogen-activated protein kinases (MAPKs) p38 and ERK in both acute and delayed preconditioning, although several other mechanisms may be involved. The complexities of these proposed signaling pathways are compounded by the subcellular compartmentation of these kinases and their downstream targets, as well as signaling crosstalk in either a stimulatory or an inhibitory manner or both. The identities of all the distal mediators and the effectors of protection have not been definitively established, but there is strong evidence that sarcolemmal and/or mitochondrial ATP-dependent potassium (K_{ATP}) channel opening may initiate both acute and delayed protection. Constitutive (or endothelial) nitric oxide synthase has been shown to be a downstream target of PKC and ERK, and there is significant evidence that NO plays a role in myocardial protection. There is also accumulating evidence that one or more nitric oxide synthase (NOS) isoforms are expressed in mitochondria. Although PKC, MAPKs, mitochondria, ROS, and NO appear to play primary roles in preconditioning, the definitive mechanisms have yet to be identified unambiguously. For example, it is well known that ROS are potent stimuli for MAPK activation, but it also has been hypothesized that MAPK activation induces mitochondrial ROS formation. The major difference between acute and delayed preconditioning is that de novo protein synthesis is required in the latter. The upregulation of multiple proteins has been implicated in delayed preconditioning, including, but not limited to, heat-shock proteins (HSPs), inducible iNOS, manganese-dependent superoxide dismutase (Mn-SOD), and cyclooxygenase 2 (COX-2). The upregulation of specific proteins may depend on the preconditioning stimulus and also may be species-dependent.

humoral factors and/or neurogenic mechanisms. Adenosine has been implicated as a mediator of remote myocardial preconditioning, an effect that was inhibited by the ganglionic blocker hexamethonium.[106] Given adenosine's rapid metabolism in the vascular endothelium and by erythrocytes, it is unlikely that this effect would be via a humoral mechanism. In fact, the results of a recent study indicate that preconditioning induced by intravenous adenosine was not associated with an increase in interstitial adenosine levels but was blocked by hexamethonium.[124] Alternatively, calcitonin

gene-related peptide (CGRP) has been implicated in remote preconditioning via a humoral, but not a neurogenic, mechanism.[125]

Ischemic postconditioning has been described only very recently, and thus there have been fewer studies examining potential mechanisms. Although there is evidence that adenosine A_{2a} receptors may play a role in mediating ischemic postconditioning,[126] it is unknown whether this is a direct effect on cardiomyocytes. Additional studies indicate that postconditioning may be mediated by some of the same protein kinase pathways that are involved in preconditioning.[127–130]

There is increasing evidence that ischemic preconditioning and postconditioning may occur in the human heart, although some of this evidence remains circumstantial. A number of investigators have reported that patients experiencing angina prior to an MI have better in-hospital prognoses and a reduced incidence of cardiogenic shock, fewer and less severe episodes of congestive heart failure, and smaller infarcts as assessed by cardiac enzyme release.[131–134] There are also follow-up studies that suggest patients who have had angina prior to an infarct have better long-term survival rates.[135–137] There are also a myriad of reports that patients who undergo percutaneous coronary interventions (PCIs) have an enhanced tolerance to ischemia after the first balloon inflation, provided that the first balloon inflation exceeds 60 to 90 seconds.[105] Chest pain severity, regional wall motion abnormalities, ST-segment elevation, QT dispersion, lactate production, and CK-MB release all have been reported to be attenuated in this setting as well.[138–143]

In patients undergoing PCIs, a preconditioning-like effect also has been mimicked by the administration of a variety of pharmacologic agents that are known to induce preconditioning in animal studies. For example, the administration of adenosine prior to PCI has been reported to attenuate myocardial ischemic indices during the first balloon inflation.[144,145] Administration of other agents, such as bradykinin and nicorandil (a K_{ATP} channel opener), also has been reported to produce similar effects.[146–148] Conversely, the administration of aminophylline (a nonselective adenosine receptor antagonist), glibenclamide (a K_{ATP} channel blocker), or naloxone reportedly abolishes the effects of ischemic preconditioning during PCI.[149–151]

Additional studies provide evidence of delayed pharmacologic preconditioning and postconditioning in the clinical setting. Leesar and colleagues reported that a 4-hour intravenous infusion of nitroglycerin (an NO donor) 24 hours prior to PCI decreased ST-segment changes and chest pain during the first balloon occlusion compared with patients treated with saline vehicle.[152] A subsequent report by this same group indicated that delayed preconditioning with nitroglycerin decreased exercise-induced ST-segment changes and improved exercise tolerance.[153] Two recent studies provided the first clinical evidence of ischemic postconditioning.[154,155] Patients receiving brief balloon inflations/deflations in the initial minutes of reperfusion during PCI exhibited reduced ST-segment changes and total creatine kinase release compared with control subjects.

Thus, there are many observational studies that support the hypothesis that myocardial protection conferred by ischemic preconditioning and its possible mediators in animal studies is translatable to humans. It is important to note, however, that classic or early ischemic preconditioning observed in animals is associated with a reduction in infarct size, not stunning, and that many of the clinical studies are either retrospective in nature or have used surrogate markers of injury as end points.

With respect to cardiac surgery, one of the first studies indicating that preconditioning may exist in humans was conducted by Yellon and colleagues in 1993.[156] In this study, patients undergoing cardiac surgery were subjected to a protocol that involved two cycles of 3 minutes of global ischemia. Cross-clamping the aorta intermittently and pacing the heart at 90 beats per minute were used to induce ischemia. This was followed by 2 minutes of reperfusion before a 10-minute period of global ischemia and ventricular fibrillation. Myocardial biopsies were obtained during a 10-minute period of global ischemia, and ATP tissue content was measured. The results showed that the ATP levels in the biopsies obtained from patients subjected to the preconditioning-like protocol were higher. However, since ATP content is not a marker of necrosis, a follow-up study was performed, and troponin T serum levels were used. In this study, the investigators reported that the release of this marker of necrosis also was less in patients subjected to the preconditioning protocol.[157]

It is unknown whether the phenomenon of ischemic preconditioning plays any role in conferring protection when using the intermittent cross-clamp technique. Teoh and colleagues, however, reported that ischemic preconditioning might confer additional myocardial protection beyond that provided by intermittent cross-clamp fibrillation in patients undergoing CABG.[158] The fact that other human studies have not shown additional protection when ischemic preconditioning was added to a myocardial protection protocol makes this less likely.[159,160] For the immediate future, the most promising strategy for developing new methods to protect the heart against ischemia-reperfusion injury lies with elucidation of the intracellular events underlying the phenomenon of late-phase ischemic preconditioning (see Fig. 15-4).

Adenosine

There is considerable experimental evidence that the preischemic administration of the nucleoside adenosine retards the rate of ischemia-induced ATP depletion, prolongs the time to onset of ischemic contracture, attenuates myocardial stunning, enhances postischemic myocardial energetics, and reduces infarct size.[161] As mentioned earlier, there is also evidence that adenosine may play a role in mediating the infarct size–limiting effects of ischemic preconditioning.[103,115,116] A transient infusion of adenosine or certain adenosine receptor

agonists prior to ischemia is associated with infarct size reduction similar to that of ischemic preconditioning.[103,161] There are, however, conflicting reports regarding the ability of adenosine receptor antagonists to block ischemic preconditioning.[115,162–165] When analyzing these studies, it is important to recognize a small but important difference between adenosine preconditioning and adenosine pretreatment. The former involves a brief infusion of adenosine that is terminated prior to the onset of ischemia, whereas the latter involves the continuous infusion of adenosine until the onset of ischemia. The significance of this difference lies with the observation that adenosine pretreatment, not adenosine preconditioning, attenuates myocardial stunning.[166,167] Myocardial stunning is the most common form of injury in patients after heart surgery. The beneficial effects of adenosine infusions prior to ischemia appear to be due to the direct effects of adenosine on the cardiac myocyte because (1) adenosine must be infused at a dose that reaches the interstitial fluid (ISF) space that surrounds the cardiac myocyte and (2) adenosine reduction of ischemic and hypoxic injury can be demonstrated in isolated myocyte preparations.[168–170]

Although the cardioprotective effects of adenosine have been recognized for some time, there are still many questions regarding its mechanism of action. Genetic, biochemical, and pharmacologic studies indicate that there are at least four distinct sarcolemmal adenosine receptor subtypes, designated A_1, A_{2a}, A_{2b}, and A_3, that couple to a variety of guanine nucleotide-binding (G) proteins (G_o, $G_{i\alpha 2}$, $G_{i\alpha 3}$, G_q, and G_s) depending on the receptor subtype and tissue studied. Currently, there is definitive evidence that two, and possibly three, of these receptors are expressed in the adult heart. Radioligand binding studies have verified the presence of A_1 and A_{2a} adenosine receptors in mammalian myocardium, and numerous studies since have reported the physiologic roles of these receptors.[171] More recent studies, using both pharmacologic approaches and receptor knockout mice, suggest that adenosine A_{2b} receptors may be expressed in the coronary vasculature.[172] Although there are some reports of A_3 receptor mRNA expression in cardiac tissue, presently there is no definitive evidence for the expression of this receptor in the normal mammalian heart.[173,174]

With respect to clinical studies, Lee and colleagues pretreated seven patients undergoing CABG with adenosine and compared their postoperative course with that of a similar group of untreated patients.[175] Adenosine was infused incrementally before the initiation of CPB at a rate of 50 μg/kg per minute every minute until a dose of 350 μg/kg per minute was reached. The total duration of the adenosine infusion lasted for 10 minutes, or until the patient developed systemic arterial pressures less than 70 mm Hg, at which time the infusion was discontinued. Five minutes after completion of the adenosine or the saline control infusion, patients were placed on CPB and underwent CABG. Cold blood cardioplegia was used to facilitate the arrest. The investigators reported that adenosine pretreatment was associated with improved postoperative myocardial function. Major limitations of this study were the small number of patients studied and the limited number of parameters used to assess ventricular function. In contrast, Fremes and colleagues reported the results of an open-label, nonrandomized adenosine study in which no effect was observed.[176] In this study, the patients also underwent CABG. Antegrade warm blood cardioplegia was used, with adenosine added to the initial 1-L dose and the final 500-mL dose of cardioplegia. The adenosine concentrations studied were 15, 20, and 25 μmol/L. These investigators found that adenosine could be added safely as a supplement to cardioplegic solutions, but the agent had no effect on myocardial function at the doses studied.

A similar lack of efficacy in humans was reported by Cohen and colleagues in a phase II double-blind, placebo-controlled trial performed in patients also undergoing CABG.[177] Patients were treated with placebo (saline) or warm blood cardioplegia supplemented with 15, 50, or 100 μM adenosine. These investigators also reported that the adenosine additive had no effect on survival, on the incidence of MI (as determined by CK-MB levels), or on the incidence of low cardiac output syndrome. A major limitation of this study was the use of low concentrations of adenosine in the setting of warm blood cardioplegia. The nucleoside is metabolized rapidly to inosine and hypoxanthine, and the half-life in blood is measured in seconds.

In contrast, Mentzer and colleagues reported a beneficial effect in an open-label, single-center study in which the safety, tolerance, and efficacy of high doses of adenosine were assessed.[178] As in the previous studies, adenosine was added to cold blood cardioplegia in patients undergoing CABG. In this study, 61 patients were randomized to receive standard cold blood cardioplegia or cold blood cardioplegia containing one of five adenosine doses (100 μM, 500 μM, 1 mM, 2 mM, or 2 mM with a preischemic infusion of 140 μg/kg per minute). Invasive and noninvasive studies of myocardial function were obtained at 1, 2, 4, 8, 16, and 24 hours postbypass. This included the recording of inotropic utilization rates for the postoperative treatment of low cardiac output. Blood samples were collected before and after the first, second, and last dose of cardioplegia, as well as at 1 and 24 hours after cessation of CPB, for the measurement of nucleoside levels. These investigators found that high-dose adenosine treatment was associated with a 249-fold increase in the plasma adenosine concentration and a 69-fold increase in the combined levels of adenosine and its degradation products inosine and hypoxanthine. The high-dose adenosine and associated high plasma levels of adenosine were associated with a reduction in postbypass inotropic drug utilization and improved regional wall motion and global function measured by transthoracic echocardiography (TTE).

Using a similar protocol, Mentzer and colleagues examined the effects of high-dose adenosine treatment in 253 patients randomized to one of three treatment arms.[179] This was a double-blind, placebo-controlled multicenter

trial. The three cohorts consisted of patients who were administered intraoperative cold blood cardioplegia, those administered cold blood cardioplegia containing 500 μM adenosine, and those receiving cold blood cardioplegia containing 2 mM adenosine. Patients receiving the adenosine cardioplegia also were given an infusion of adenosine (200 μg/kg per minute) 10 minutes before and 15 minutes after removal of the aortic cross-clamp. Invasive and noninvasive measurements of ventricular performance were obtained before, during, and after surgery. The results of this study revealed a trend toward a decrease in high-dose inotropic agent utilization rates and a lower incidence of MI. A composite outcome analysis showed that patients who received the high-dose adenosine were less likely to experience one of five adverse events: high-dose dopamine use, epinephrine use, insertion of an IABP, MI, or death. A major limitation of this study was the failure to demonstrate a reduction in dopamine use or overall inotropic use, the two primary end points of the study. Another factor was the relatively low adverse event rates of MI and death, namely, 5.1 and 3.6%.

In summary, there is preclinical and clinical evidence that adenosine is a cardioprotective agent. Its clinical use, however, is somewhat limited because large doses are associated with marked hypotension. Although this can be managed easily while the patient is on CPB, it would be preferable to use a more selective A_1 receptor agonist that would confer protection without peripheral vasodilation. The administration of such an agent prior to surgery (much in the same way that late-phase preconditioning has a salutary effect in limiting myocardial stunning, apoptosis, and infarction 24 hours later) could result in a reduction in the current rates of postoperative stunning and infarction and represent a significant advance in the field of myocardial protection.

Sodium-Hydrogen Exchange Inhibition

The sodium-hydrogen exchangers (NHEs) are a family of membrane proteins that are involved in the transport of hydrogen ions in exchange for sodium ions. The driving forces behind the exchange are the transmembrane Na^+ and Ca^{2+} gradients and the membrane potential.[224,225] The gradient is regulated by the intracellular pH through interaction of H^+ with a sensor site on the exchanger protein (Fig. 15-5). To date, nine NHE isoforms have been identified and are designated as NHE-1 through NHE-9.[180–183] While the exact role the exchanger plays in the normal excitation-contraction coupling process has yet to be determined, there is increasing evidence that these proteins perform an important role in many pathophysiologic conditions. They have been implicated in the etiology of arrhythmias, stunning, apoptosis, necrosis associated with acute myocardial ischemia-reperfusion injury, and postinfarction ventricular remodeling and heart failure.[184,185]

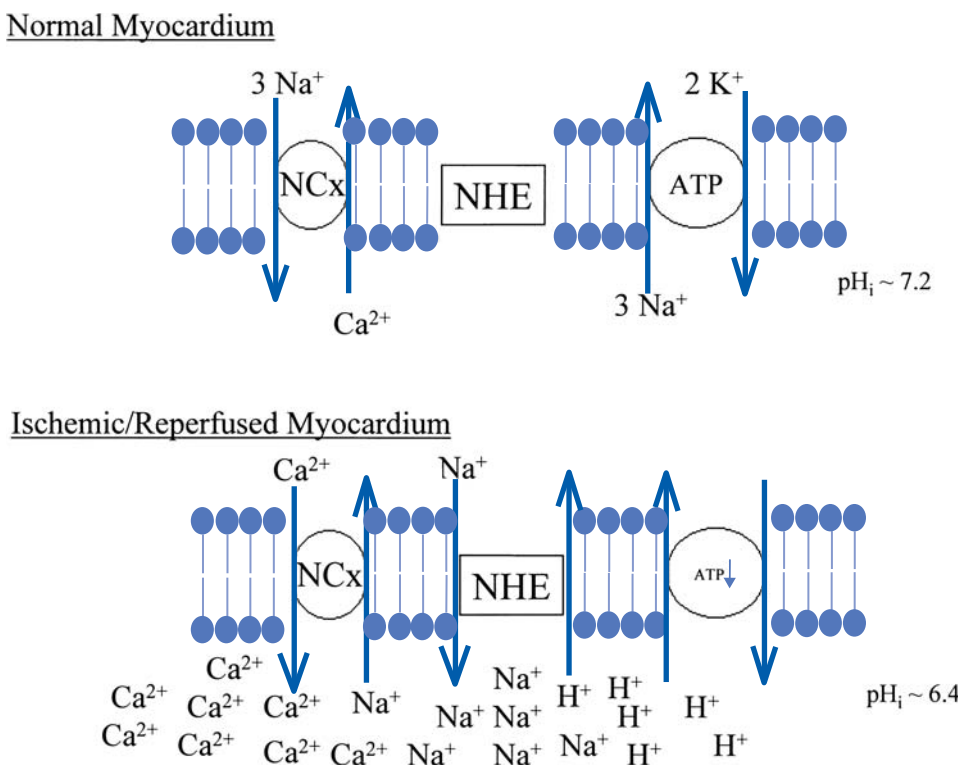

Figure 15-5. Sodium-hydrogen exchangers in the normal and ischemic myocardium.

One of the primary mechanisms of injury that all these conditions have in common is the deleterious effect of an excess accumulation of intracellular calcium.[184,185] Normally, sodium-hydrogen (Na^+ -H^+) exchange plays an important role in regulating cardiac myocyte physiology. The influx of extracellular Na^+ via its concentration gradient is coupled with the efflux of H^+, helping to maintain the intracellular pH (see Fig. 15-5). The Na^+ -Ca^{2+} exchanger uses the normal Na^+ gradient to extrude Ca^{2+} in order to maintain normal intracellular Ca^{2+} homeostasis. However, during ischemia, intracellular Na^+ accumulates owing to decreased activity of Na^+, K^+-ATPase and increased production of H^+ owing to anaerobic glycolysis. During the initial phase of reperfusion, the Na^+ -H^+ exchanger is accelerated in an attempt to restore intracellular pH. This results in even more Na^+ and ultimately more Ca^{2+} accumulating intracellularly. As a consequence of increased intracellular sodium, the Na^+ -Ca^{2+} exchanger operates in the reverse direction, resulting in a marked increase in the intracellular Ca^{2+} concentration (Ca^{2+} overload). This Ca^{2+} overload can result in the activation of various enzyme systems and signaling pathways that over time can lead to cell contracture, membrane rupture, gap junction dysfunction, and cell death.[186,187]

Accordingly, the EXPEDITION study was conducted to address the efficacy and safety of NHE inhibition by cariporide in the prevention of death or MI in patients undergoing CABG. High-risk CABG patients ($n = 5770$) were randomized to receive either intravenous cariporide (180 mg/h preoperative loading dose and then 40 mg/h over 24 hours and 20 mg/h over the subsequent 24 hours) or placebo. The primary composite end point of death or MI was assessed at 5 days, and patients were followed for up to 6 months. The results of this study indicated that there was an 18.3% relative risk reduction in the incidence of death or MI at 5 days ($p = .0002$). At day 30 and month 6, the relative risk reduction of death or MI was 16.1% ($p = .0009$) and 15.7% ($p = .0006$), respectively. When analyzed separately, the relative risk reduction in the incidence of MI alone at 5 days was 23.8% ($p = .000005$) and at month 6 was 25.6% ($p = .000001$). The mortality rate, however, increased at 5 days from 1.5% in the placebo group to 2.2% in the group with cariporide. This was associated with an overall increase in the incidence of cerebrovascular events, specifically 86 events (2.7%) in the placebo group versus 146 (5.2%) in the cariporide group. Thus, while cariporide treatment was effective in reducing the incidence of nonfatal MI, its efficacy was associated with toxicity, and the overall assessment of benefits and risks associated with cariporide indicated that the imbalances in the safety profile outweighed the reduction in the observed MI rate. Thus, it is unlikely that cariporide will be used clinically. The importance of the study should not be underestimated, however, because (1) EXPEDITION demonstrated that myocardial necrosis after CABG is higher than previously appreciated, and (2) these findings suggest that NHE-1 inhibition holds promise as a new class of drugs that could reduce myocardial injury associated with ischemia-reperfusion injury significantly.

Nitric Oxide

There is increasing evidence that the signaling molecule nitric oxide (NO) plays an important role in modulating the heart's tolerance to ischemia. However, the combination of the short half-life of NO, the multiple redox states in which it can exist, the subcellular compartmentalization of NOS isoforms, and the multiple targets of its actions has hindered determination of the specific role this molecule plays in modulating ischemia-reperfusion injury.[188–190] This explains, in part, why NO and related reactive nitrogen species have been reported to both exacerbate injury and exert a cardioprotective effect.[188, 191] For the most part, however, studies performed using in vivo preparations indicate that the administration of NO donors reduces infarct size.[191,192] There are also reports that the infusion of NOS inhibitors during reperfusion exacerbates ischemia-reperfusion injury.[191,192] These reports are consistent with evidence that NO modulates coronary blood flow and that the molecule can reduce neutrophil adherence to endothelium and inhibit platelet aggregation. There is also evidence that NO produced during reperfusion may scavenge the oxygen free-radical superoxide (O_2^-), an effect observed in oxidant-stressed cells exposed to constant low levels (1 to 2 μM) of NO.[193,194]

With respect to clinical studies, there is only a modest amount of evidence that the NO mechanism can be manipulated to confer myocardial protection in humans. Leesar and colleagues reported that the infusion of nitroglycerin (an NO donor) 24 hours prior to angioplasty mimicked the protection associated with the first balloon inflation in the control group in terms of ST-segment shifts, regional wall motion abnormalities, and chest pain scores.[155] Zhang and Galinanes studied the effects of arginine (a precursor to NO) on human myocardial specimens obtained from right atrial appendages of patients undergoing elective CABG.[195] The tissues were subjected to 120 minutes of simulated ischemia followed by 120 minutes of reoxygenation. Ischemic injury was assessed by measuring the leakage of lactate dehydrogenase (LDH) into the incubation medium and the capacity of the tissue to reduce MTT [3-(4-dimethylthiazol-yl)-2,5-diphenyltetrazolium bromide] to a formazan product. In this study, L-arginine (a precursor of NO) decreased LDH leakage but had no effect on MTT reduction or oxygen consumption. However, the effect of arginine was not reversed by L-NAME (an NO synthase inhibitor), nor was it mimicked by *S*-nitroso-*N*-acetylpenicillamine (an NO donor). These data suggested that L-arginine was effective but provided only a modest degree of protection against simulated ischemia-reperfusion injury in human myocardial atria tissue.

These studies are limited, however, because the demonstration of efficacy depended on the measurement of surrogate markers of injury and because sample sizes were small. Additional preclinical studies and clinical trials are needed to demonstrate whether NO plays an important role

in protecting the ischemic heart. As noted by Feng and colleagues, the potential cytoprotective role of iNOS-derived NO needs to be reconciled with the known detrimental actions associated with iNOS in the setting of septic shock, organ rejection, inflammation, autoimmune diseases, and ischemic brain injury.[196]

MYOCARDIAL PROTECTION DURING BEATING-HEART SURGERY

As many as 10 to 15% of the patients in the United States who undergo surgical MR have the operation performed on the beating heart, i.e., off-pump coronary artery bypass (OPCAB) surgery. The acceptance of this technique is due, in part, to the development and availability of better shunt appliances and mechanical stabilization devices, as well as the demonstration of satisfactory outcomes.[197,198] Overall, the incidence of death, perioperative MI, renal failure, and respiratory failure appears to be similar among patients undergoing either OPCAB or on-pump surgery.[1,199] If sensitive myocardial marker proteins are used to detect myocardial necrosis, it is possible that cell necrosis may be less in OPCAB patients. The fact that any necrosis occurs, however, suggests that OPCAB patients may be susceptible to ischemia-reperfusion injury. For the most part, the indications for OPCAB remain controversial, and long-term outcomes have yet to be determined. Likewise, there is a paucity of data regarding the extent to which the myocardium is reversibly or irreversibly damaged after OPCAB. This is due, in part, to the fact that the primary focus among beating-heart advocates has been the demonstration of feasibility, safety, and cost-effectiveness.

CONCLUSION

While considerable progress has been made in the field of myocardial protection, the ideal solution, technique, or delivery method has yet to be identified. This is due, in part, to our increasing awareness of the complexity of ischemia-reperfusion injury and recognition that the definition of ideal protection is no longer limited to the time that the patient is in the operating room. As long as the incidence of myocardial stunning ranges from 20 to 80%, postischemic ventricular dysfunction from 3 to 7%, severe dysfunction in high-risk patients from 15 to 20%, and non-Q-wave and Q-wave infarction nearly 20%, there is clearly a need to develop new therapeutic strategies to protect the heart during cardiac surgery. This need is even greater when one considers that long-term survival after heart operations is determined, in part, by adequate myocardial protection during the operation itself.

CHAPTER 16

Postoperative Care of Cardiac Surgery Patients

Zain I. Khalpey • Rose B. Ganim • James D. Rawn

THE EVOLUTION OF CARE

Mortality and morbidity in cardiac surgery have continued to decline despite increases in patient age, comorbid conditions, and procedure complexity. Much of this success can be attributed to advances in critical care. This chapter will outline strategies and principles of modern postoperative care.

CARDIOVASCULAR CARE

Hemodynamic Assessment

Assessment and optimization of hemodynamics generally are the principal focuses of care following cardiac surgery. Appropriate management requires knowledge of preoperative cardiac function and an appreciation of the impact of intraoperative events. The goal of postoperative hemodynamic management is the maintenance of adequate oxygen delivery to vital tissues in a way that avoids unnecessary demands on a heart recovering from the stress of cardiopulmonary bypass, ischemia, and surgery.

A basic initial hemodynamic assessment includes a review of current medications, heart rate and rhythm, mean arterial pressure, central venous pressure, and electrocardiogram (ECG) to exclude ischemia and conduction abnormalities. The presence of a pulmonary artery catheter enables the measurement of pulmonary artery pressures, left-sided filling pressures [e.g., pulmonary capillary wedge pressure (PCWP)], and mixed venous oxygen saturation ($M\dot{V}O_2$). Cardiac output, as well as pulmonary and systemic vascular resistances, also can be calculated when a pulmonary artery catheter is present. Cardiac output is determined using thermodilution or the Fick equation. Cardiac output (CO), blood pressure (BP), and systemic vascular resistance (SVR) are related to each other using Ohm's law (Table 16-1). Reasonable minimum goals for most patients include an $M\dot{V}O_2$ of about 60%, a mean arterial pressure (MAP) of more than 65 mm Hg, and a cardiac index (CI) of more than 2 L/m^2 per minute. Goals should be individualized. Patients with a history of hypertension or significant peripheral vascular disease probably will benefit from higher blood pressure; patients who are bleeding or who have suture lines in fragile tissue are best served with tighter control. Strategies designed to produce a supranormal cardiac index or $M\dot{V}O_2$ have failed to demostrate a survival advantage.[1]

Failure to achieve adequate cardiac output and end-organ oxygen delivery can be caused by many, often codependent factors. These include volume status (preload), peripheral vascular tone (afterload), cardiac pump function, heart rate and rhythm, and blood oxygen-carrying capacity.

Volume status is determined readily by invasive monitoring. Central venous pressure (CVP), unless it is very low, is an unreliable indicator of left ventricular end-diastolic volume (LVEDV). (An elevated CVP can be seen in volume overload, right-sided heart failure, tricuspid and mitral regurgitation, pulmonary hypertension, tamponade, tension pneumothorax, and pulmonary embolism.) Plumonary artery diastolic pressure correlates with left-sided filling pressures when pulmonary vascular resistance (PVR) is normal (low). PCWP (or left atrial pressure if this is being measured directly) provides the most accurate assessment of left-sided filling pressures, and its correlation with pulmonary artery diastolic pressure should be noted to enable a more continuous assessment of left-sided pressures. Determination of optimal filling pressures generally is empirical; a wedge pressure of 15 mm Hg generally is adequate, but many patients require significantly higher pressures. Most patients arrive from the operating room with a significant net fluid gain, but much of this excess volume is extravascular owing to third space and pleural cavity accumulation. Vasoplegia often is created by a systemic inflammatory response to cardiopulmonary bypass (CPB), and it is common to have a

Table 16–1.

Common Intensive Care Values and Formulas

Early postoperative hemodynamic parameters	Expected values
Mean arterial pressure (**MAP**)	60–90 mm/Hg
Systolic blood pressure (**sBP**)	90–140 mm/Hg
Right arterial pressure (**RAP**)	5–15 mm/Hg
Cardiac index (**CI**)	2.2–4.4 L/min/m^2
Pulmonary artery wedge pressure (**PAWP**)	10–15 mm/Hg
Systemic vascular resistance (**SVR**)	1400–2800 dyn-s/cm^5
Common hemodynamic formulas	**Normal values**
CO = SV × HR **CI** = CO ÷ BSA CO = cardiac output; HR = heart rate; SV = stroke volume; BSA = body surface area	4–8 L/min 2.2–4.0 L/min/m^2
$\textbf{SV} = \frac{\text{CO (L/min)} \times 1000 \text{ (mL/L)}}{\text{HR}}$	60–100 mL/beat (l mL/kg/beat)
SVI = SV ÷ BSA SVI = stroke volume index	33–47 mL/beat/m^2
$\textbf{MAP} = \text{DP} + \frac{(\text{SP} - \text{DP})}{3}$	70–100 mm/Hg
$\textbf{SVR} = \frac{\text{MAP} - \text{CVP}}{\text{CO}} \times 80$ CVP = central venous pressure; **Ohm's law**: voltage (***V***) = Current (***I***) × resistance (***R***); resistance is directly proportional to viscosity (hematocrit) and inersely proportional to the radius to the fourth power.	800–1200 dyn-s/cm^5
$\textbf{PVR} = \frac{\text{PAP} - \text{PCWP}}{\text{CO}} \times 80$ PVR = pulmonary vascular resistance; PAP = mean pulmonary arterial pressure; PCWP = pulmonary capillary wedge pressure	50–250 dyn-s/cm^5
LVSWI = SVI × (MAP − PCWP) × 0.0136 LVSWI = left ventricular stroke work index	45–75 mg-M/beat/m^2
O_2 delivery = CO (Hb × %sat)(1.39) + (Pa_{O_2})(0.0031) 1.39 is milliliters of oxygen transported per gram of serum hemoglobin (Hb); 0.0032 is solubility coefficient of oxygen dissolved in solution (mL/torr of Pa_{O_2})	60–80%
AV O_2 difference = (1.34)(Hb) × (Sa_{O_2} − Sv_{O_2}) $\textbf{Fick cardiac output} = \frac{\text{estimated } O_2 \text{ comsumption}}{\text{AV } O_2 \text{ difference}}$ AV = arteriovenous oxygen difference; oxygen consumption is measured from a nomogram based on age, sex, height, height; Hb = serum hemologlobin (g/dL); Sa_{O_2} = arterial oxygen saturation (%) in arterial blood; Sv_{O_2} = mixed venous oxygen saturation (%) from the pulmonary artery in the absence of a shunt or calculated $M\dot{V}_{O_2}$ = (3 × SVC saturation + IVC saturation) ÷ 4, if a left-right shunt is present); 1.34 = mL O_2 per gram of Hb; 10 dL/L)	Normal Pv_{O_2} = 40 torr and Sv_{O_2} = 75% Normal Pa_{O_2} = 100 torr and Sa_{O_2} = 99%

Table 16–1.

Common Intensive Care Values and Formulas (*continued*)

Shunt fraction $= \frac{Q_p}{Q_s} = \frac{(Sao_2 - M\dot{V}o_2)}{(Pvo_2 - Pao_2)}$ Q_s = systemic flow (L/min); Qp = pulmonary flow (L/min)	Normal, < 5%
EF (%) $= \frac{\text{end-diastolic volume} - \text{end-systolic volume}}{\text{end-diastolic volume}}$ EF = ejection fraction (an index of ventricular activity)	60–70%
Respiratory formulas	**Normal values**
D(A–a)O_2 $= (FIO_2) \times (713) - PaO_2 - (PaO_2 \div 0.8)$ D(A–a)O_2 = alveolar-arterial oxygen difference, taking FIO_2 (inspired oxygen into consideration); a sensitive index of efficiency of gas exchange	Suboptimal oxygenation > 350 on 100% oxygen Or PaO_2 < 500 torr on 100% oxygen
Renal and metabolic values and formulas	
$C_{Cr} = \frac{(140 - \text{age}) \times \text{wt (kg)}}{72 \times Cr} \times 0.8$ (for females) Cockroft & Gault equation for creatinine clearance (C_{Cr}) (an approximation to glomerular filtration rate, GFR) Or more precisely with 24- or 2-h urine specimen: $C_{Cr} = (U_{Cr} \div P_{Cr}) \times$ (volume/1440 min, or 120 min) U_{Cr} & P_{Cr} = urinary and plasma creatinine concentrations	C_{Cr} < 55 mL/min threshold below which surgical risk increases[159]

Evaluating oliguria (adapted from ref. 37)	**Prerenal**	**Renal**
BUN/Cr	> 20:1	< 10:1
U/*P* creatinine	> 40	< 20
U_{osm}	> 500	< 400
U/*P* osmolality	> 1.3	< 1.1
Urine specific gravity	> 1.020	1.010
U_{Na} (mEq/L)	< 20	> 40
FE_{Na}	< 1%	>2%
Urinary sediment	Hyaline casts	Tubular epithelial casts; granular casts
BUN = urea nitrogen, serum (7–18 mg/dL)		

$\mathbf{FE_{Na}} = \frac{U_{Na} \times P_{Cr}}{P_{Na} \times U_{Cr}} \times 100$ FE_{Na} = fractional excretion of sodium; *U* and *P* are urinary and plasma concentrations of sodium and creatinine, respectively	Normal, 1–3%
Anion gap $= (Na^+) - [(Cl^-) + HCO_3^-)]$ Elevated by ethanol, uremia (chronic renal failure), diabetic ketoacidosis, paraldehyde, phenformin, iron tablets, isoniazide, lactic acidosis (CN^-, CO, shock), ethanol, ethylene glycol, salicylates	Normal, 8–12

Table 16–1.

Common Intensive Care Values and Formulas (*continued*)

$$C_{H_2O} = V - C_{osm}$$
$$C_{osm} = U_{usm} \times V/P_{osm}$$

C_{H_2O} = free water clearance; V = urine flow rate; P_{osm} and U_{osm} = plasma and urine osmolarity, respectively

P_{osm} = 275–295 mOsmol/kg

Capillary fluid exchange (Starling forces)

Net filtration pressure = $P_{net} = [(P_c - P_i) - (\pi_c - \pi_i)]$

K_f = filtration constant (capillary permeability)

Net fluid flow = (P_{net}) (K_f)

P_c = capillary pressure—tends to move fluid out of capillary

P_i = interstitial fluid pressure—tends to move fluid into capillary

π_c = plasma colloid oncotic pressure—tends to cause osmosis of fluid into capillary

π_l = interstitial fluid colloid osmotic pressure—tends to cause osmosis of fluid out of capillary

Edema

1. High P_c, heart failure
2. Low π_c, nephritic syndrome
3. High K_f, toxins, sepsis
4. High π_l, lymphatic blockage

Prosthetic heart valves: current anticoagulation regimens (adapted from ref. 160)	**Coumadin target INR/aspirin 81 mg**
AVR mechanical	2.5–3.0/yes, if high risk
AVR bioprosthetic (tissue)	2.5–3.0 (3 months) or none if aspirin used/yes
MVR mechanical	2.5–3.5 (indefinitely)/yes, if high risk
MVR bioprosthetic or MV repair	2.5–3.0 (3 months; continue 1 yr if history of embolism; indefinitely if AF and LA thrombus at time of surgery)/yes, after 3 months
AVR & MVR mechnical	2.5–3.0 (indefinitely)/yes
AVR & MVT bioprosthetic (tissue)	2.5–3.0 (3 months)/yes, after 3 months
Atrial fibrillation (with any of the above)	2.5–3.0 (indefinitely)/yes

AF = atrial fibrillation; AVR = aortic valve replacement; MVR = mitral valve replacement; High risk = AF, myocardial infarction, enlarged left atrium (LA), endocardial damage, low EF, history of systemic emobolism despite adequate anticoagulation.

significant ongoing volume requirement in the immediate postoperative period. Urine output and bleeding are common sources of ongoing fluid loss. Hypothermia promotes vasoconstriction. As patients rewarm, changes in peripheral vascular tone contribute to labile hemodynamics, which often are best treated with volume.

Peripheral vascular tone needs to be sufficient to provide the patient with adequate blood pressure; excess vasoconstriction can create dangerous levels of hypertension and decrease cardiac output. Decreased afterload can be caused, in part, by medications (e.g., anesthetic agents and preoperative angiotensin-converting enzyme inhibitors), increased temperature, and a systemic inflammatory response to CPB. Increases in afterload can be caused by medications, hypothermia, and increased sympathetic output (including pain and anxiety) or may be secondary to hypovolemia or pump failure.

Pump function can be influenced by levels of exogenous or endogenous inotropes, postoperative stunning, ischemia or infarction, valve function, acidosis, electrolyte abnormalities, hypoxia, or tamponade. Bradycardia, arrhythmias, and conduction defects also can adversely affect cardiac output. The

oxygen-carrying capacity of blood is a function of hematocrit and oxygenation. A hematocrit of 21% and a oxygen saturation of greater than 92% usually are adequate for a stable postoperative patient.

It is important not to allow evaluation of the patient to become obscured by too many numbers or theories, and an overall assessment of the patient is always more important than any single parameter. Trends in hemodynamic parameters usually are more important than isolated values. Patients generally do well if they have warm, well-perfused extremities, normal mental status, and good urine output (>0.5 mL/kg per minute). Acute changes in hemodynamic status are common postoperatively, and vigilant monitoring enables care to be more preemptive than reactive.

Hemodynamic Management

Fluid management

As emphasized previously, the goal of postoperative hemodynamic management is the maintenance of adequate end-organ perfusion without unnecessarily taxing the heart. Assessment and optimization of intravascular volume status generally are the first steps in this process. Most patients have ongoing fluid requirements in the immediate postoperative period that can be caused by persistent third spacing, warming, diuresis, vasodilation, and bleeding. Careful monitoring of fluid balances and filling pressures should guide volume resuscitation. Starling curves are highly variable; it is helpful to correlate cardiac output and $M\dot{V}O_2$ with changes in volume status. Patients with ventricular hypertrophy (e.g., those with a history of hypertension or aortic stenosis) or diastolic dysfunction usually need higher filling pressures. Patients with persistently low filling pressures despite aggressive fluid administration usually are either bleeding or vasodilated. Calculation of CO and SVR often can help to sort this out. In the case of significant vasodilation, judicious use of a pressor agent can help to decrease fluid requirements. Inotropes should not be administered for the treatment of hypovolemia. Fluid requirements often can be reduced following extubation; decreased intrathoracic pressure improves venous return.

The choice of an optimal resuscitation fluid is unresolved. In the acute setting, colloid infusions achieve comparable hemodynamic effects with less volume than crystalloid solutions. After 1 hour, 80% of 1000 mL of 5% albumin solution is retained intravascularly. In situations characterized by loss of vascular endothelial integrity (e.g., following CPB), albumin may redistribute into the interstitial space and increase third-space fluid accumulation.[2,3] One study has shown that the accumulation of extravascular pulmonary water is unaffected by the prime type or the type of fluid administered postoperatively.[4] The largest prospective, randomized, controlled study comparing colloid with crystalloid has been unable to demonstrate a difference in outcomes.[5] Albumin and hetastarch provide comparable hemodynamic benefits, although hetastarch should be avoided in bleeding or coagulopathic patients and in those with renal impairment.[6,7]

Although unusual in the immediate postoperative period, volume overload is a common problem in the days following surgery. If patients have normal cardiac function, they often diurese appropriately without intervention. Conversely, volume overload is a common cause of postoperative heart failure. Diuretics and vasodilators are required frequently in patients with impaired pump function before or following surgery or in those who received large volumes of fluid perioperatively. Patients with impaired renal function may require renal replacement therapy (e.g., ultrafiltration, continuous venovenous hemofiltration, or hemodialysis) to become euvolemic. Rapid diuresis accompanied by inadequate electrolyte repletion frequently is arrhythmogenic.

Pharmacologic support

Medications are used perioperatively to provide vasoconstriction, venous and arterial vasodilation, and inotropic support as well as to treat arrhythmias. As summarized in Table 16-2, many of the commonly used medications have multiple actions. Selection of appropriate agents depends on accurate hemodynamic assessment.

Pressors are indicated for vasodilated patients who have normal pump function and are unresponsive to volume. These agents include *alpha agents* (e.g., neosynephrine) and *vasopressin. Methylene blue* has demonstrated efficacy in vasopressor-resistant hypotension.[8,9] Pressors can contribute to peripheral ischemia and vasospasm of coronary arteries and arterial conduits. Careful monitoring of extremity perfusion and electrocardiographic changes is required when using these agents.

Vasodilators are indicated for hypertensive patients and for patients who are normotensive with poor pump function. *Nitroglycerin* and *sodium nitroprusside* are used commonly in the immediate postoperative period. Both have the advantage of being short acting and easy to titrate. Both can cause hypoxia by inhibiting pulmonary arterial hypoxic vasoconstriction and increasing blood flow through poorly oxygenated lung. Nitroglycerin is a stronger venodilator than an arterial dilator and can increase intercoronary collateral blood flow,[10] but patients quickly can become tachyphylactic. Prolonged nitroprusside use can lead to cyanide toxicity, and methemoglobin levels must be monitored. *Nicardipine* is a calcium channel blocker with minimal effects on contractility or atrioventricular (AV) nodal conduction; it appears to have the efficacy of nipride without its toxicity. *Nesiritide,* or brain naturetic peptide, promotes diuresis in addition to vasodilation and may have beneficial lusitropic effects in patients with diastolic dysfunction.

Hypertension also can be treated with *beta blockers.* These agents work by decreasing heart rate and contractility. Esmolol is useful in the presence of labile blood pressure because of its short half-life. Labetalol combines beta- and alpha-adrenergic blockade. Patients whose pump function is inotrope-dependent should not receive beta blockers.

Table 16–2.

Common ICU Scenarios and Management Strategies

Cardiac output syndromes

MAP	CVP	CO	PCW	SVR	Strategy
Normotensive	High	Low	High	Normal/high	Venodilator/diuretic/inotrope
Hypertension	High	Normal	High	High	Vasodilator
Hypotension	Low	Low	Low	Normal	Volume
Hypotension	High	Low	High	High	Inotrope/IABP/Vasodilator
Hypotension	Normal/low	Normal/high	Normal/low	Low	α-agent

CVP = central venous pressure; CO = cardiac output; SVR = systemic vascular resistance; iNO = inhaled nitric oxide; $iPGI_2$ = inhaled prostacyclin

Common ICU Scenarios and Management Strategies (*continued*)

Postoperative mediastinal bleeding		
Bleeding Scenario	**Diagnosis**	**Strategy**
<50 mL/h Stable BP, coagulopathy	Post-CPB	Observation
>100 mL/h		
Hypothermic	Hypothermia (see above)	Rewarming strategies
Acute hypotension (MAP <50 mm Hg)		Fluid resuscitation (aim MAP 60–65 mm/Hg)
Diffuse bloody ooze	Borderline coagulopathy	
Coagulopathy:		PEEP trial (5–10 cm H_2O)
1. High PTT, PT	Rebound heparin effect	Coagulation screen
2. INR >1.4	Deficient clotting factors	Heparin level; protamine
3. Low fibrinogen	Deficient clotting factors	Fresh-frozen plasma
4. Platelets $<10^5/\mu L$	Thrombocytopenia	Fresh-frozen plasma
5. Platelets $>10^5/\mu L$	Platelet dysfunction	Platelet pool
6. Bleeding > 10 min	Fibrinolysis	DDAVP
7. Bleeding >30 min (High D-dimers, evidence of fibrinolysis)	Fibrinolysis	Tranexamic acid, ε-aminocaproic acid, aprothinin
> 200–300 mL/h (Adapted from ref 37) > 200 mL/h for 4 h > 300 mL/h for 2–3 h > 400 mL/h for 1 h	Surgical bleeding	Surgical reexploration

DDAVP = desmopressin (synthetic vasopressin); PTT = activated partial thromboplastin time; FDP = fibrin and fibrinogen degradation products; PEEP = positive end-expiratory pressure; PT = prothrombin time; BP = blood pressure; CPB = cardiopulmonary bypass

Inotropic agents are indicated when low cardiac output persists despite optimization of fluid status (preload) and vascular tone (afterload). These agents include beta-adrenergic agents (e.g., *dobutamine*) and cyclic nucleotide phosphodiesterase inhibitors (e.g., *milrinone*). Both these agents increase cardiac output by increasing myocardial contractility and reducing afterload through peripheral vasodilation. Dobutamine is shorter acting and easier to titrate; milrinone achieves increases in cardiac output with lower myocardial oxygen consumption.[11] Both are arrhythmogenic and can exacerbate coronary ischemia. Both *epinephrine* and *norepinephrine* combine beta- and alpha-adrenergic agonist effects; they are pressors in addition to positive inotropes. *Dopamine* in low doses causes splanchnic and renal vasodilation. Since perioperative beta blockade has been shown to improve mortality and morbidity following cardiac surgery, it seems reasonable to avoid the gratuitous use of inotropes, and efforts should be made to wean these agents rapidly when they are no longer required.

Heart Rate and Rhythm Management

Deviations from normal sinus rhythm can cause significant clinical deterioration, and optimization of heart rate and rhythm frequently is an effective way to improve hemodynamic status.

Pacing (see Table 16-2)

Within normal rate ranges, cardiac output increases linearly with heart rate, and pacing often is very helpful. It is important to monitor the response to pacing carefully, however. For example, sinus bradycardia often is more effective than ventricular pacing at a more normal rate. Ventricular pacing can cause ventricular dysfunction and dyssynchrony, and the loss of consistent filling from atrial contraction can lead to clinical deterioration. If possible, atrial pacing is preferred to AV pacing, which is preferred to ventricular pacing. Pacing too rapidly can have an adverse effect on cardiac performance by decreasing filling time or inducing ischemia. Internal pacemakers often can be reprogrammed to improve output.

Heart block can occur following aortic, mitral, and tricuspid valve surgery. It is also associated with inferior myocardial infarction and can be secondary to medications (e.g., digoxin, amiodarone, calcium channel blockers, and beta blockers). If a biatrial transseptal approach to the mitral valve is employed, the sinus rhythm can be lost owing to divi-

sion of the sinoatrial (SA) node.[12] Heart block frequently is transient. If the ventricular escape rate is absent or insufficient, pacing wire thresholds need to be monitored carefully and backup pacing methods employed (e.g., a transvenous wire or pacing pulmonary artery catheter or external pacing pads) if needed while waiting for placement of a permanent pacemaker.

Ventricular arrhythmias

Nonsustained ventricular tachycardia (VT) is common following cardiac surgery and typically a reflection of perioperative ischemia-reperfusion injury, electrolyte abnormalities (typically hypokalemia and hypomagnesemia), or an increase in exogenous or endogenous sympathetic stimulation. Generally, nonsustained VT is more important as a symptom of an underlying cause requiring diagnosis and correction than as a cause of hemodynamic instability.

Sustained VT (persisting for more than 30 seconds or associated with significant hemodynamic compromise) requires more aggressive treatment. Ongoing ischemia should be ruled out (with coronary angiography if necessary), electrolytes should be replaced, and inotrope should be minimized. Beta blockers, amiodarone, and lidocaine are useful therapies. Electrocardioversion should be employed if sustained VT causes significant compromise.

Atrial fibrillation and flutter

PROPHYLAXIS: Atrial fibrillation and flutter occur in 20 to 40% of patients undergoing coronary artery bypass grafting (CABG) and generally is more common in patients undergoing valve and combined procedures. Beta blockers are the most commonly used and effective prophylactic treatment and should be started or resumed as soon as they can be tolerated safely following surgery. Inotropic support, hemodynamic compromise, and AV block (e.g., PR interval $>$ 0.24 ms or, second- or third-degree block) are contraindications. Beta blockers appear to provide more effective prophylaxis when they are dosed with high frequency and titrated to produce an effect on heart rate and blood pressure. Sotalol and amiodarone are also effective for prophylaxis but not superior. Beta blockers confer benefits other than atrial fibrillation prophylaxis, are easy to titrate, and do not have the toxicities associated with amiodarone.

TREATMENT: There are many treatment strategies for the management of atrial fibrillation.[13] We have found that the use of a guideline reduces the incidence of atrial fibrillation and decreases the disruption and anxiety that it creates (Table 16-1). The principal premise of this strategy is recognition of the fact that for most patients with new-onset atrial

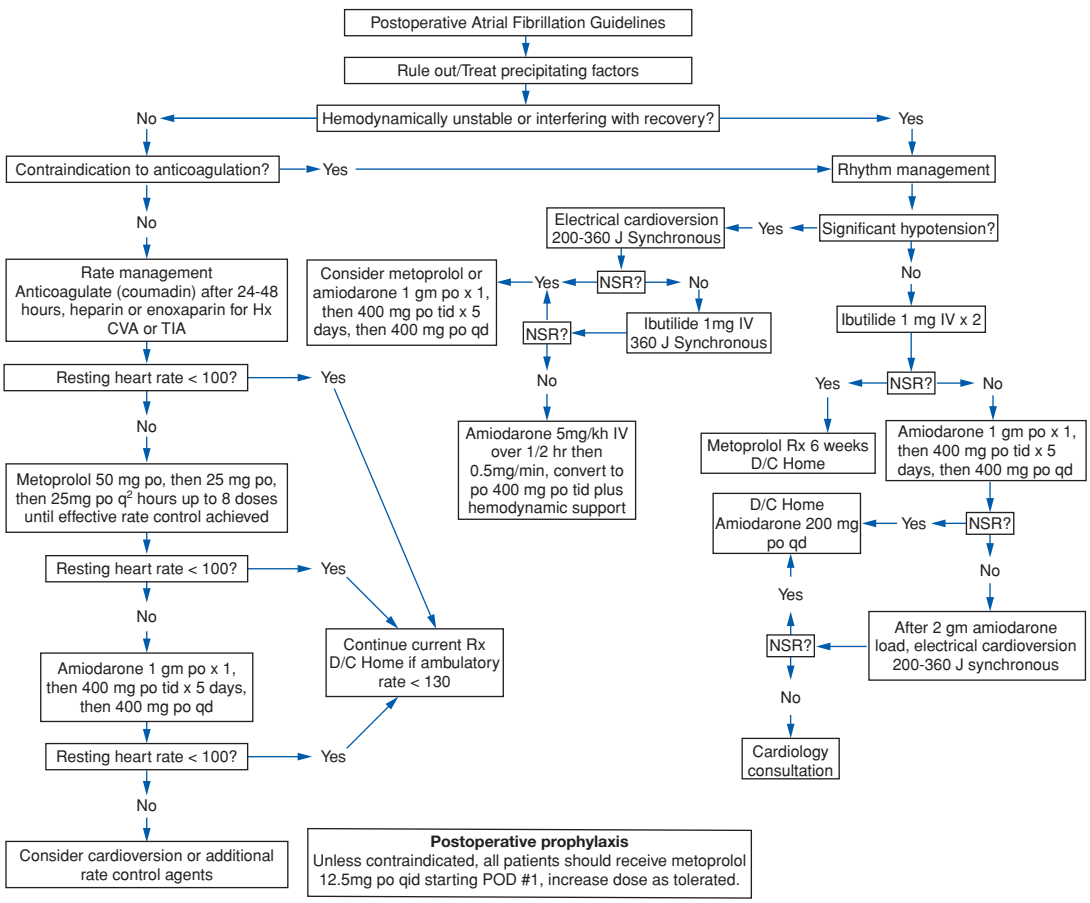

Figure 16-1. Postoperative atrial fibrillation guidelines. *(Adapted from Maisel WH, Rawn JD, Stevenson WG: Atrial fibrillation after cardiac surgery.* Ann Intern Med *2001; 135:1061.)*

fibrillation, the arrhythmia is self-limited (90% of patients are in sinus rhythm within 6 to 8 weeks independent of treatment approach). The pursuit of a rate control and anticoagulation strategy usually produces outcomes comparable with a rhythm-control strategy. Our prophylactic regimen begins with metoprolol 12.5 to 25 mg PO qid and is titrated upward as tolerated.

A. *Initial assessment.* The management of atrial fibrillation should be guided by the answers to the following three questions:
   1. *Is the patient symptomatic?* Atrial fibrillation generally is well tolerated, and overly aggressive management can cause significant morbidity. Nonetheless, the first step in the management of atrial fibrillation is an assessment of its hemodynamic significance. Significant symptoms may respond to rate control alone or may require chemical or electrical cardioversion. Evidence of compromise includes hypotension, changes in mental status, decreased urine output, impaired peripheral perfusion, anginal symptoms, and decreased cardiac output or increased filling pressures.
   2. *What are the precipitating factors?* Appropriate management of atrial fibrillation requires identification and treatment of potential risk factors. Atrial fibrillation can result from ischemia, atrial distension, increased sympathetic tone, electrolyte imbalances (particularly hypokalemia and hypomagnesemia precipitated by diuresis), acid-base disturbances, sympathomimetic medications (e.g., inotropes and bronchodilators), beta-blocker withdrawal, pneumonia, atelectasis, and pulmonary embolism.
   3. *What are the goals of therapy?* Hemodynamic stability is the primary goal. For most patients, rate control is sufficient because 90% of patients with new-onset atrial fibrillation following cardiac surgery will be in normal sinus rhythm in 6 weeks. Evidence of hemodynamic compromise or interference with recovery should prompt chemical or electrical cardioversion.

B. *Drug therapy.* Agents can be divided conveniently into rate-control and rhythm-control agents, although beta blockers are also effective in converting atrial fibrillation postoperatively. Monodrug therapy generally is better than polydrug therapy.
   1. *Rate-control agents:*
      a. *Beta blockers.* Metoprolol should be first-line therapy in most patients and can be given orally or intravenously. Metoprolol should be titrated to effect with a heart rate goal of less than 100 beats per minute at rest. The suggested treatment for new-onset atrial fibrillation is 50 mg PO, followed by 25 mg PO until normal sinus rhytum (NSR) or adequate rate control is achieved, up to eight doses. Some patients may require over 400 mg/d.
      b. *Calcium channel blockers.* Diltiazem is the agent of choice. It should be initiated as a bolus at 0.25 mg/kg IV, followed by 0.35 mg/kg IV, followed by a continuous infusion of 5 to 15 mg.
      c. *Digoxin* can be considered in patients with contraindications to beta blockers, in particular those with poor ejection fraction. There is some evidence that it increases atrial automaticity. It has a half-life of 38 to 48 hours in patients with normal renal function, significant potential toxicity, and a narrow therapeutic range. Levels must be monitored, particularly in patients with renal insufficiency. Many agents, including amiodarone, increase its serum level. Following chemical cardioversion, attempts should be made to minimize the number of rate-control agents used.
   2. *Antiarrythmics:*
      a. *Metoprolol* (diltiazem).
      b. *Ibutilide.* Ibutilide is given as a 1-mg intravenous bolus and repeated once if cardioversion fails to occur. Patients need to be monitored for a small but significant incidence of torsades de pointes that may be increased if given in conjunction with amiodarone.
      c. *Amiodarone* can cause myocardial depression and heart block; significant hypotension is associated most commonly with rapid bolus infusion. Significant toxicity can be associated with both short-term and prolonged use of amiodarone.
      d. *Adenosine* is helpful in the treatment of supraventricular tachycardia (SVT). (It should be avoided in transplant recipients, partially revascularized patients, and patients with atrial flutter.)

C. *Electrical cardioversion.* Electrical cardioversion should be used emergently for the treatment of hemodynamically unstable atrial fibrillation, starting at 200 J (synchronous). Sedation should be used. In patients with atrial wires who are in atrial flutter, overdrive pacing can be attempted.

D. *Anticoagulation.* Patients who remain in atrial fibrillation for more than 24 hours or have multiple sustained episodes over this period should be started on coumadin in the absence of contraindications. Heparin (intravenously, or low-molecular-weight heparin subcutaneously) should be considered after 48 hours in patients with a history of stroke or transient ischemic attacks (TIAs) or who have a low ejection fraction. Coumadin should not be initiated in patients who may require permanent pacer placement.

Postoperative Ischemia and Infarction

Postoperative ischemia and infarction can be caused by inadequate intraoperative myocardial protection; kinked, spasmed, or thrombosed conduits; thrombosed endarterectomized vessels; or embolization by air or atherosclerotic debris. It should be suspected in the presence of otherwise unexplained poor pump function, ST changes, new bundle-branch block or complete heart block, ventricular arrhythmias, or enzyme elevation. Electrocardiographic changes should be correlated with the anatomy of known atherosclerotic or revascularized territories. Air embolism preferentially involves the right coronary artery, and inferior ST-segment changes generally are

present in the operating room. It typically resolves within hours. It is worth noting that nonspecific ST-segment changes are common postoperatively and usually benign. Pericarditic changes generally are characterized by diffuse concave ST-segment elevations, accompanied by a pericardial rub and delayed in onset by at least 12 hours following surgery.

New wall motion abnormalities or mitral regurgitation diagnosed echocardiographically can help to determine the hemodynamic significance of suspected ischemia or infarction. Knowledge of the quality of conduits, anastomoses, and target vessels is critical in planning management strategy (e.g., there may be little to be gained and much to lose in attempting to improve flow to a small, highly diseased posterior descending artery with poor runoff). If there appears to be significant myocardium at risk, on the other hand, a timely trip to the operating room or the cardiac catheterization laboratory can improve outcomes dramatically. Ongoing ischemia should prompt consideration of standard strategies, including anticoagulation, beta blockade, and nitroglycerin as tolerated. Intra-aortic balloon placement should be considered to minimize inotrope requirements, decrease myocardial oxygen requirements, and/or minimize infarct size.

Right Ventricular Failure and Pulmonary Hypertension

Right ventricular failure can be a particularly difficult postoperative problem. It can be caused by perioperative ischemia or infarction or by acute increases in pulmonary vascular resistance (PVR). Preexisting pulmonary hypertension is caused commonly by left-sided heart failure, aortic stenosis, mitral valve disease, and pulmonary disease. Chronic pulmonary hypertension is characterized by abnormal increased vasoconstriction and vascular remodeling.[14] Acute increases in PVR are caused commonly by acute left ventricular dysfunction, mitral valve insufficiency or stenosis, volume overload, pulmonary edema, atelectasis, hypoxia, or acidosis. Pulmonary embolism also should be considered, but it is rare in the immediate postoperative period. As the right side of the heart fails, it becomes distended, central venous pressure increases, tricuspid regurgitation may develop, and pulmonary artery pressures and left-sided filling pressures become inadequate. Strategies for reversing this potentially fatal process begin with identifying potentially reversible etiologies. Volume status and left-sided function should be optimized. The right ventricle has its own Starling curve, and while the failing right ventricle often needs more volume to ensure adequate left-sided filling, overdistension will worsen function. Judicious use of positive end-expiratory pressure (PEEP) to recruit atelectatic lung and hyperventilation can decrease the impact of pulmonary vasoconstriction mediated by hypoxia and hypercarbia. Use of intravenous vasodilators [commonly, nitroprusside, nitroglycerin, tolazoline (PGI_2), hydralazine, prostacyclin, adenosine, and nicardipine] to reduce PVR frequently is limited by systemic hypotension. Inotropes (typically milrinone, which also provides vasodilatation) can be beneficial.[15] Since no intravenous vasodilator is selective for the pulmonary vasculature, topical administration can be significantly more effective in reducing PVR without causing systemic hypotension. Inhaled nitric oxide (NO) and PGI_2 have comparable efficacy. They also can improve oxygenation by shunting blood to ventilated lung.

Valvular Disease: Special Postoperative Considerations

Aortic valve replacement

The different pathophysiologies associated with aortic stenosis (primarily a pressure-overload phenomenon) versus aortic insufficiency (volume overload) can result in significantly different postoperative courses.

AORTIC STENOSIS: Aortic stenosis can lead to the development of a hypertrophied, noncompliant left ventricle. For some patients, replacement of a stenotic valve allows a ventricle conditioned to pumping against abnormally high afterload to easily achieve supranormal levels of cardiac output and blood pressure postoperatively. Meticulous blood pressure control frequently is required to avoid disrupting fresh suture lines. In some patients, the degree of ventricular hypertrophy can lead to dynamic outflow obstruction; the condition is treated most effectively with volume, beta blockers, and afterload augmentation. Even without dynamic outflow obstruction, reduced compliance (diastolic dysfunction) can create significant hemodynamic compromise if the patient becomes hypovolemic or loses normal sinus rhythm. (Up to 30% of stroke volume can be dependent on synchrony between atria and ventricle.) The placement of atrial wires in addition to ventricular wires can provide significant advantages in the event that the patient is bradycardic or experiences heart block postoperatively.

AORTIC REGURGITATION: The left ventricle in a patient with aortic regurgitation frequently is dilated without significant hypertrophy and often functions poorly postoperatively. Optimization of volume, afterload, inotropy, and rhythm in these patients often is challenging.

Mitral valve repair/replacement

MITRAL REGURGITATION: Following repair or replacement of an incompetent mitral valve, increased afterload and consequent greater wall stress unmask left ventricular dysfunction. Frequently, inotropic support and systemic vasodilatation are required to reduce the afterload mismatch seen following surgery.[16] Occasionally, left ventricular dysfunction can be the result of inadvertent suture placement over the circumflex coronary artery.

MITRAL STENOSIS: Unlike patients with mitral regurgitation, patients with mitral stenosis typically have preserved left ventricular function. Exacerbation of preexisting pulmonary

hypertension is common, however. Postoperative strategies focus on optimizing right ventricular function and decreasing pulmonary vascular resistance.

BLEEDING, THROMBOSIS, AND TRANSFUSION STRATEGIES

One of the principal challenges of cardiac surgery is to achieve sufficient anticoagulation while the patient is supported on CPB without experiencing excessive bleeding postoperatively. Not surprisingly, patients undergoing off-pump CABG experience a significant reduction in postoperative bleeding and blood product transfusion requirements.[17,18] Excessive bleeding and its complications, including blood product transfusions, cause significant morbidity and mortality.

Preoperative Evaluation

Preoperative evaluation includes documenting a history of abnormal bleeding or thrombosis and obtaining basic coagulation studies, a hematocrit, and a platelet count. A history of recent heparin exposure associated with thrombocytopenia should suggest a diagnosis of *heparin-induced thrombocytopenia* (HIT). Confirmation of the presence of IgG directed against platelet factor 4 (the prevalence of these antibodies in patients with previous heparin exposure can be up to 35%[19]) requires either a delay in surgery until the assay is negative (usually 3 months) or, if surgery is urgently required, an alternative anticoagulation strategy. Recent experience with the direct thrombin inhibitor *bivalirudin* appears promising in this scenario.

Preoperative medications that can increase bleeding risk are common. *Aspirin* inhibits cyclooxygenase, reduces the synthesis of thromboxane A_2 (TXA_2), and decreases platelet aggregation.[20] Preoperative aspirin use modestly increases postoperative bleeding,[21,22] but preoperative and early postoperative use (i.e., within 6 hours) is beneficial to outcome and ultimate survival.[23] Other antiplatelet agents have more profound impacts on platelet function. The *glycoprotein IIb/IIIa inhibitors* eptifibitatide (Integrillin) and tirofiban (Aggrastat) are sufficiently short acting that surgery can be conducted safely despite recent exposure. *Abciximab* (Reopro) usually requires a 24- to 48-hour delay of surgery, if feasible, to avoid catastrophic bleeding.[24] *Clopidogrel* (Plavix) is a thienopyridine derivative that blocks platelet ADP P_2Y_{12} receptors, inhibiting platelet activation by preventing ADP-mediated responses, decreasing alpha-granule release, and lowering TXA_2 and P-selectin expression with some anti-inflammatory effects.[25] Cessation of clopidogrel is preferred 5 days preoperatively but is not advisable in patients with drug-eluting coronary artery stents. Customarily, *coumadin* (which inhibits the vitamin K–dependent clotting factors II, VII, IX, and X) is discontinued 4 to 7 days preoperatively to allow gradual correction of the international normalization ratio (INR).

Intraoperative Strategies

Multiple *intraoperative strategies* have evolved to prevent unnecessary bleeding during blood product transfusion. Antithrombolytics *ε-aminocaproic acid* (Amicar) and *tranexamic acid* (Cyclokapron) inhibit plasminogen activation and limit fibrinolysis. Topical use of tranexamic acid intraoperatively prior to closure[26] may be a simple and effective way to reduce postoperative bleeding, particularly in patients with friable tissue who are having reoperations or have had previous exposure to chest irradiation. *Aprotinin* (Trasylol), a serine protease inhibitor, activates factor XII (Hageman factor), has antifibrinolytic properties (main hemostatic effect), and protects platelets. The drug is used primarily for patients who are at high risk for postoperative bleeding. A recent retrospective study has questioned aprotinin's safety.[27]

Retrograde autologous priming of the CPB circuit involves displacing circuit prime solution at the initiation of CPB with the patient's blood draining both antegrade through the venous cannula and retrograde through the arterial cannula.[28] This strategy has been shown to decrease the requirement for blood transfusion significantly following CABG. The use of heparin-bonded circuitry has enabled the safe use of lower anticoagulation targets while on bypass. Careful attention to hemostasis intraoperatively and avoidance of excessive use of a blood salvage device (e.g, cell saver®) (which depletes platelets and clotting factors) pays dividends postoperatively.

Postoperative Bleeding

Strategies for avoiding postoperative *hypothermia* are also very important. Hypothermia (≤35°C) on arrival to the ICU is associated with delayed extubation,[29] shivering and increased peripheral O_2 consumption,[30] hemodynamic instability, atrial and ventricular arrhythmias, and increased systemic vascular resistance and coagulopathy.[31,32]

Most patients are mildly *coagulopathic* postoperatively, but only a minority bleed excessively. Postoperative coagulopathy can be due to residual or rebound heparin effects following CPB, thrombocytopenia (qualitative and quantitative), clotting factor depletion, hypothermia, and hemodilution. Chest tube outputs persistently greater than 50 to 100 mL/h or other clinical evidence of bleeding demand attention.

The treatment of postoperative bleeding depends initially on making a judgment: Is bleeding surgical, coagulopathic, or both? Surgical bleeding is treated as soon as possible by reexploration; coagulopathies are corrected in the ICU. Coagulopathic patients rarely have significant clot formation in their chest tubes. Standard maneuvers include warming the patient, controlling blood pressure, extra PEEP, additional ε-aminocaproic acid, calcium gluconate, and blood products. In general, blood products should not be used to correct coagulation abnormalities unless the patient is bleeding significantly. All allogeneic blood products can contribute to transfusion-related lung injury and have other adverse effects. *Protamine* is indicated rarely and can increase bleeding. *Desmopressin* (DDAVP) is a synthetic vasopressin analogue that acts by increasing the concentration of von

Willebrand factor, an important mediator of platelet adhesion. It is of benefit in patients with von Willebrand's disease and in patients with severe platelet dysfunction secondary to uremia anitplatelet agents.[33]

Recombinant factor VIIa (rFVIIa) is a drug approved for use in hemophiliacs that has been used successfully in arresting bleeding in patients with life-threatening hemorrhage after cardiac surgery. On combination with tissue factor, it activates the extrinsic coagulation system via factor X, resulting in thrombin generation and prompt correction of the prothrombin time (PT) with no evidence of systemic thrombosis.[34–36]

Mediastinal Reexploration

Reexploration should be considered when CT outputs are greater than 400 mL/h for 1 hour, greater than 300 mL/h for 2 to 3 hours, and 200 mL/h for 4 hours[37] (see Table 16-2) or if signs of tamponade or hemodynamic instability develop. *Tamponade* should be considered in the presence of hypotension, tachycardia, elevated filling pressures, increasing inotrope requirements, pulsus paradoxus, and/or equalization of right and left atrial pressures.[38] An echocardiogram can be useful in this situation but cannot rule out tamponade. Chest x-rays are a necessary element of the evaluation for bleeding; look for a widening mediastinum or evidence of a hemothorax. Chest x-rays should be repeated on all patients with initial high chest tube output that later subsides to ensure that chest tubes have not clotted.

Autotransfusion

Autotransfusion of shed mediastinal blood remains controversial.[39] Red blood cell viability in unwashed shed mediastinal blood is comparable with that of autologous whole blood[40]; additionally, there is evidence indicating no apparent clinical coagulopathy (e.g., low fibrinogen levels but normal coagulation times at 1 and 24 hours) following reinfusion of shed blood.[41–43] This method of blood salvage is without allogeneic transfusion risks and possibly is immunostimulatory.

Blood Transfusions

Despite meticulous preoperative planning, correcting drug-induced coagulopathies, and employing intraoperative "cell saving" techniques with "bloodless" fields, bleeding is inevitable postoperatively. The adverse effects of blood transfusions are well defined. The benefits are not. There is considerable evidence to suggest that blood transfusion increases the risk of postoperative infection and mortality following cardiac surgery.[44] The Canadian Critical Care Trials group in a randomized trial restricted transfusion for hemoglobin to less than 7.0 g/dL versus 10.8 g/dL, with no change in mortality rate.[45] These findings are consistent which are NIH consensus recommendation. A National Institutes of Health (NIH) consensus conference concluded that patients with a hemoglobin level of greater than 10.9 g/dL do not require blood, whereas those with less than 7.0 g/dL hemoglobin benefited from blood.[46] Tissue perfusion depends on cardiac output and hemoglobin level. A marginal $M\dot{V}O_2$ or evidence of ischemia provides a rationale for increasing hematocrit.

Immunomodulation

It has become evident that blood transfusions have *immunomodulating effects* (by either alloimmunization or tolerance induction) that may increase the risk of nosocomial infections, transfusion-associated graft-versus-host disease (TAGVHD), transfusion-related lung injury (TRALI), cancer recurrence, and the possible development of autoimmune diseases later in life.[47] Furthermore, the risk of "newer" transfusion-transmitted diseases has become recognized. Proinflammatory mediators and cytokines have been associated with an increased risk of wound infection, sepsis, and pulmonary and renal insufficiency.[48]

RESPIRATORY CARE

Postoperative Pulmonary Pathophysiology

Following the introduction of CPB nearly 50 years ago, pulmonary complications were recognized and attributed to pulmonary vascular overload.[49] *Pump lung* is pulmonary dysfunction secondary to an inflammatory response provoked by the bypass circuit. Increases are seen in the alveolar-arterial (A-a) gradient, pulmonary shunt fraction, and pulmonary edema, with a resulting decrease in compliance. Many inflammatory mediators have been implicated. Complement is activated (e.g., C3a and C5b–C9) and can damage pulmonary endothelium directly, as well as sequester neutrophils. When activated, these neutrophils release oxygen free radicals and proteases, furthering injury. Macrophage cytokine production and platelet degranulation also have been demonstrated in models of bypass-induced lung injury.[50,51] Transfusion-related lung injury also may exacerbate lung dysfunction.

Despite increased knowledge of the mechanisms of injury, to date, there have been no interventions with clear clinical benefit. To the contrary, administration of methylprednisolone in a randomized, double-blind study significantly increased A-a gradient and shunt fraction, decreased both static and dynamic compliance, and delayed early extubation in a dose-dependent manner.

Assessment on Arrival

On arrival to the ICU, auscultation of the lungs should be performed to ensure equal breath sounds and the absence of bronchospasm. Ventilator settings usually are a mandatory mode such as synchronized intermittent mandatory ventilation (SIMV) or assist-control (AC) with an F_{IO_2} of 100%, a rate of 12 to 18 breaths per minute, a tidal volume (TV) of 6 to 10 mL/kg, PEEP of 5 cm H_2O, and pressure support (PS) of 8 to 10 cm H_2O if on intermittent mandatory ventilation (IMV). A review of the initial postoperative chest x-ray (CXR) confirms proper endotracheal tube position 2 to 3 cm

above the carina and proper nasogastric tube and intravenous line placement. Clinicians should be alert for pneumothoraces, hemothoraces, and a widened mediastinum. Arterial blood gas analysis should confirm adequate oxygenation and the absence of hypercapnea and metabolic acidosis. Arterial blood gas results should be correlated with pulse oximetry and minute ventilation.

Troubleshooting Hypoxia

As discussed earlier, oxygenation in all patients will be diminished compared with baseline. The inability to wean F_{IO_2} below 50% within the first few postoperative hours, however, should prompt a reevaluation because many causes can be treated. Sometimes simply replacing the pulse oximeter probe onto another finger or an earlobe will improve the reported oxygen saturation. This is particularly true in patients with peripheral vasoconstriction, and arterial blood gas analyses may be necessary for correlation. The use of vasodilators including nitroglycerin, milrinone, and particularly sodium nitroprusside can increase shunt fraction (by antagonizing hypoxic pulmonary vasoconstriction) enough to require a high F_{IO_2} to maintain adequate oxygenation. Increasing PEEP to improve alveolar recruitment may help,[52] or changing agents may be necessary. Nebulizer treatments may be necessary for bronchospasm, and repeat CXR may demonstrate pneumothorax, hemothorax, mediastinal hematoma, atelectasis, or a new infiltrate representing aspiration.

Atelectasis, particularly in the left lower lobe, is present to some degree in nearly all patients. Bibasilar atelectasis is believed to be the combined product of prolonged supine position and intraoperative muscle relaxation allowing upward displacement of abdominal contents and the diaphragm. This reduces functional reserve capacity (FRC) by up to 1 L.[53] On the left, this is compounded by pleurotomy for internal mammary artery (IMA) takedown, compression of the left lung, and decreased ventilatory tidal volumes to clear the field for IMA dissection. Left lower lobar atelectasis owing to phrenic nerve injury is not likely to resolve acutely with bronchoscopic aspiration. Lobar atelectasis in general, however, especially when associated with mucus plugging, is improved by bronchoscopic aspiration in approximately 80% of patients.[54] A prospective study comparing bronchoscopy with aggressive chest physiotherapy found the two techniques to be equally effective,[55] but only if the chest physiotherapy regimen is adhered to.[56]

Sedation

Sedation and pain relief in cardiac surgery "fast tracking" rely on short-acting agents, including propofol, fentanyl, and midazolam. Dexmedetomidine is a highly selective alpha$_2$-adrenoreceptor agonist that has anxiolytic, sympatholytic, and analgesic effects without contributing to respiratory depression, oversedation, or delirium. It may provide myocardial protection.[57] Hypotension and bradycardia can occur.

Early Extubation

Stable patients with a normal mental status often can be extubated either in the operating room or within a few hours following arrival in the ICU. Once an arterial blood gas analysis has confirmed adequate oxygenation and ventilation, pulse oximetry and monitoring of minute ventilation can guide extubation, often without the need for subsequent blood gas determinations.

Patients usually excluded from planning for early extubation include those with (1) preoperative pulmonary failure requiring intubation, (2) uncompensated congestive heart failure with pulmonary edema, (3) severe pulmonary hypertension or right-sided heart failure requiring hyperventilation or nitric oxide, (4) cardiogenic shock (including a requirement for intra-aortic balloon counterpulsion), (5) deep hypothermic circulatory arrest, (6) persistent hypothermia ($<$35.5(C), (7) persistent hypoxia (Pa_{O_2}:F_{IO_2} $<$ 200), (8) persistent acidosis (pH less than 7.30), (9) persistent mediastinal bleeding, or (10) a cerebrovascular accident or reduced mental status (inability to follow commands or protect airway).

Ventilator Weaning and Extubation

For patients unable to wean from the ventilator immediately following surgery, a spontaneous breathing trial (30 minutes of spontaneous breathing with 5 cm H_2O of pressure support or unassisted breathing through a T-tube) has been shown to be the most accurate predictor of successful extubation. Breathing trials typically are discontinued for such signs of distress as respiratory frequency more than 35 breaths per minute, O_2 saturation less than 90%, heart rate greater than 140 beats per minute, systolic blood pressure greater than 180 mm Hg or less than 90 mm Hg, agitation, diaphoresis, or anxiety.[58,59] Yang et al. introduced the concept of a rapid-shallow breathing index (RSBI, f/VT, breaths per minute per liter). In their study of medical patients, the RSBI was calculated over 1 minute of unassisted spontaneous breathing through a T-tube. An RSBI of greater than 105 indicated a 95% likelihood that a subsequent weaning trial would not lead to successful extubation, and an RSBI of less than 105 indicated an 80% likelihood of subsequent success. The minute ventilation $\dot{V}_E$ and Mean Inspiratory Pressure (MIP) were significantly less predictive.

The strategy of daily or intermittent spontaneous breathing trials (SBTs) also was compared directly with weaning strategies based on stepwise reduction of the frequency of intermittent mandatory ventilation (IMV) or stepwise reduction of the level of pressure-support ventilation (PSV). Daily or intermittent SBTs lead to successful extubation two to three times earlier than either IMV or PSV weaning.[58]

In a prospective series of ICU patients,[60] the 20% false-positive predictive value of an RSBI of less than 105 is overwhelmingly due to newly acquired problems, with only 7% of failures being referable to the process that initially required intubation. No direct study of the outcome of these strategies exists in the cardiac surgery population, but they are in broad clinical use, and we recommend at least daily SBTs, as quided by the SBI.

The decision to extubate must take into account the combined factors of mechanics, as described earlier, as well as an estimation of the patient's ability to manage secretions and protect his or her airway.[61]

Extubation Failure

Overall, approximately 5% of cardiothoracic patients require reintubation.[62,63] Patients with chronic obstructive pulmonary disease (COPD) have a 14% incidence,[64] whereas those with a past history of stroke have a 10% incidence.[65] Other risk factors include New York Heart Association (NYHA) class IV functional status, renal failure, need for intra-aortic balloon counterpulsion, reduced Pa_{O_2}:F_{IO_2}, reduced vital capacity, longer operating room time, a longer CPB run, and longer initial ventilatory requirement.[63] Unfortunately, in ICU patients overall, reintubation is an ominous predictor of increased length of stay and increased mortality.

Chronic Ventilation and Tracheotomy

In the early 1960s, translaryngeal intubation was associated with a prohibitively high rate of tracheal stenosis. As a result, a consensus existed that tracheotomy should be performed on patients requiring mechanical ventilation for longer than 3 days.[66] Low-pressure cuffs and soft tubes since have muddled this question of timing. A consensus subsequently evolved in that patients who continue to require mechanical ventilation at 2 weeks should undergo tracheotomy. Data surrounding this practice have been soft.[67] Several trials suggest earlier discontinuation of mechanical ventilation and reduced complications associated with earlier tracheotomy.[67,68] Causation is not clear, but compelling arguments for reduced dead space and airway resistance, as well as facilitated pulmonary toilet, are made in favor of early tracheotomy. Additionally, less sedation is required. It is also strongly suggested that clinician behavior is positively affected by the presence of a tracheostomy tube. That is, more aggressive attempts at weaning and discontinuation of mechanical support are made because reconnecting the ventilator is easy.[68]

Percutaneous dilatational tracheotomy (PDT) performed in the ICU is becoming recognized increasingly as a safe procedure.[68] A recent randomized, prospective study of medical patients projected to require more than 14 days of mechanical ventilation[69] compared two groups: PDT within 48 hours and PDT within 14 to 16 days. One hundred and twenty patients were enrolled. In the early PDT group, there was a strongly significant reduction in duration of mechanical ventilation (7.6 $\pm$ 4.0 versus 17.4 $\pm$ 5.3 days; $p < .001$), incidence of pneumonia (5% versus 25%; $p < .005$), and mortality (31.7% versus 61.7 %; $p < .005$). There was no difference in incidence or severity of tracheal stenosis identified in-hospital and at 10 weeks. With hope and with increasing evidence, early tracheotomy will come to be viewed more widely as beneficial to patient recovery rather than as an admission of defeat.

Pleural Effusion

Accumulation of fluid in the pleural space is common after cardiac surgery, particularly on the left side, and usually resolves with time and diuresis. The specific cause often is unknown, but a combination of factors can contribute, including fluid overload, hypoalbuminemia, pericardial and pleural inflammation (i.e., postpericardiotomy syndrome), atelectasis, pneumonia, and pulmonary embolism. Pleural effusion can cause chest pain or heaviness, shortness of breath, and hypoxia. Symptomatic effusions should be tapped, and usually thoracentesis does not have to be repeated. Nonsteroidal anti-inflammatory agents are used to treat postpericardotomy syndrome. Occasionally, tube thoracostomy drainage may be necessary until resolution of the inciting process. In contrast, retained hemothorax should be evacuated to avoid delayed development of fibrothorax requiring decortication.

Pneumonia

Nosocomial pneumonias have high associated mortality, and the incidence of ventilator-associated pneumonia increases approximately 1% per day.[70] Clinical diagnosis involves identification of a new or progressive infiltrate on CXR, change in character of sputum, leukocytosis, and fever.[71,72] Expectorated sputum cultures are considered to be very inaccurate, and directed bronchosopic sampling is preferred. Proper bronchoalveolar lavage requires large volumes of irrigant (>100 mL) and is performed infrequently. More commonly, tracheobronchial aspiration is performed using several milliliters of normal saline. Gram stain containing 25 or more squamous epithelial cells per low-power field indicates oral contamination. More than 25 neutrophils per low-power field suggests infection. Quantitative culture of 10^5 to 10^6 colony-forming units per milliliter (i.e., "moderate to numerous" or "3 to 4+") is indicative of infection, whereas 10^4 or fewer colony-forming units per milliliter (i.e., "rare to few" or "1 to 2+") is more suggestive of colonization. Gram-negative organisms are seen most commonly and should be the target of first-line empiric antibiotic coverage. Specific patient factors and culture results and sensitivities will further refine antibiotic therapy.[73]

The important role of pulmonary toilet in both the prevention and the treatment of nosocomial pneumonias cannot be overemphasized. All patients should be encouraged to get out of bed and ambulate (even if attached to the ventilator), turn, cough, and deep breathe with chest physiotherapy and bronchodilators. Sterile in-line suctioning should be performed in ventilated patients to aid in secretion clearance. Nasotracheal suctioning is extremely effective in unintubated patients in that the procedure stimulates very strong coughing and secretion clearance. Therapeutic fiberoptic bronchoscopy also can be performed.

Pulmonary Embolism

Deep venous thrombosis (DVT) and pulmonary thromboembolism (PE) are considered uncommon in the cardiac

surgery population.[74] Reported incidence of PE ranges from 0.5 to 3.5%, accounting for only 0.3 to 1.7% of perioperative deaths. This is believed to be due to large intraoperative doses of heparin, both a quantitative and qualitative thrombocytopenia after CPB, and increased use of antiplatelet agents and anticoagulants, as well as early ambulation. A recent autopsy study[75] demonstrated a 52% incidence of DVT, that 20% of deceased patients have minor PE, and that PE is identified as the cause of death in 7%. Unfortunately, risks of bleeding and heparin-induced thrombocytopenia make the choice of heparin DVT prophylaxis problematic. Intermittent pneumatic compression devices are effective if patients and staff are compliant with their use.

The diagnosis of PE requires a high index of suspicion and should be considered in any patient who postoperatively acquires a newly increased Pa_{O_2}:F_{IO_2} gradient, shortness of breath, or reduced exercise tolerance, particularly in the setting of a clear or unchanged CXR. Diagnosis is fairly reliably obtained by PE-protocol thin-cut high-speed helical computed tomography of the chest,[76] although accuracy is still influenced by pretest probability.[77]

RENAL AND METABOLIC SUPPORT

Perioperative Renal Dysfunction/Insufficiency

The new onset of renal dysfunction following cardiac surgery is correlated with significant morbidity and mortality. The incidence of acute renal failure (ARF) in CABG patients in the 1997 STS database was 3.14%, and 0.87% of these patients required dialysis.[78] Chertow[79] studied 43,642 Veterans Administration (VA) patients undergoing CABG or valve surgery. The overall risk of acute renal failure requiring dialysis was 1.1%. The mortality rate in this group was 63.7% versus 4.3% in patients without ARF. Decreased myocardial function and advanced atherosclerosis were independent risk factors for the development of dialysis-dependent renal failure.

Patients with preoperative renal dysfunction (serum creatine >1.5 mg/dL) have a higher incidence of stroke, bleeding complications, dialysis, prolonged mechanical ventilation, length of stay, and death.[80] Chertow found that preoperative renal function correlated with postoperative renal failure. The risk of ARF was 0.5, 0.8, 1.8, and 4.9% with baseline serum creatinine concentrations of less than 1, 1.0 to 1.4, 1.5 to 1.9, and 2.0 to 2.9 mg/dL, respectively. Chronic dialysis patients undergoing cardiac surgery have an 11.4% operative mortality rate, a 73% complication rate, and 32% 5-year actuarial survival rate.[81] Cardiac surgery following renal transplantation has an associated operative mortality rate of 8.8%.[82]

Patients with recent or long-standing hypertension should undergo renal angiography at the time of catheterization to assess renal artery stenosis, which, if significant, can be treated preoperatively in hope of improving postoperative renal function. To optimize preoperative renal function, contrast loads should be minimized, and patients should be well hydrated and receive renoprotective agents (e.g., *N*-acetylcysteine).[83]

Effects of CPB on Renal Function

Operative considerations include limiting the duration of CPB and maintaining mean arterial pressures at greater than 60 mm Hg.[84,85] Additional effects of CPB include trauma to the blood constituents, especially erythrocytes, with increased free hemoglobin levels and microparticle embolic insults to the kidneys. Hypothermia (during rewarming, vasodilatation and hyperemia of tissue beds result in third spacing of fluid), hemodilution (reduces viscosity of blood and plasma oncotic pressure), and ischemia-reperfusion injury can influence renal function; additionally, CPB leads to an increased release of catecholamines, hormones (e.g., rennin, aldosterone, angiotensin II, vasopressin, atrial natriuretic peptide, and urodilan[86]), and inflammatory cytokines (e.g., kallikrein and bradykinin) that also affect renal function adversely. These adverse stimuli cause decreased renal blood flow, a decreased glomerular filtration rate (GFR), and an increase in renal vascular resistance. Hypotension and pressor agents accentuate this response. Ultrafiltration is used in long pump runs to decrease volume overload in patients with renal dysfunction.

Independent of preoperative renal function, the primary postoperative goal is the maintenance of adequate renal perfusion pressure and a urine output greater than the 0.5 mL/kg per hour. Brisk diuresis (>200 to 300 mL/h) is common following CPB. Volume replacement and maintenance of adequate blood pressure and cardiac output are required for adequate renal perfusion. The best measure of kidney perfusion is adequate urine output independent of diuretics. Beyond optimizing hemodynamics and avoiding nephrotoxic medications, there is no convincing evidence that treatment with diuretics, mannitol, dopamine, fenoldapam, nesiritide, or any other agent is renoprotective. This is not to say, however, that these agents are of no benefit in promoting diuresis and avoiding renal replacement therapies in the event of renal dysfunction.

Electrolyte Disturbances

Calcium

Levels of ionized calcium (normal 1.1 to 1.3 mmol/L) are critical for myocardial performance and are involved in reperfusion injury. Hypocalcemia causes a prolonged QT interval. Hypocalcemia is common following CPB or an episode of hemodilution, sepsis, or citrated blood transfusions. The concentration of calcium ion is greatest in the intracellular space, with small amounts in the extracellular fluid (ECF). Calcium levels bound to albumin change with the levels of serum albumin, whereas ionized levels remain unchanged.[87]

Potassium

Potassium fluxes during cardiac surgery can be significant and may affect cardiac automaticity and conduction. Cardioplegia, decreased urine output, decreased insulin levels, and red blood cell (RBC) hemolysis all contribute to hyperkalemia.[88] Brisk diuresis, insulin, and alkalosis can cause hypokalemia.[89] Aggressive treatment of hypokalemia decreases the incidence

of perioperative arrhythmias. Serum potassium levels and replacement protocols are an integral part of the early postoperative management. Serum potassium rises logarithmically with replacement; larger quantities are required to treat significant hypokalemia.

Magnesium

Magnesium (normal 1.5 to 2 mEq/L) is the second most common intracellular cation after potassium. It is involved in endothelial cell homeostasis,[90] cardiac excitability, and muscle contraction through its role as an ATP cofactor and calcium antagonist; it is also closely involved in the regulation of intracellular potassium.[91] Following hemodilution and CPB, hypomagnesemia is common (>70% of patients) and is associated with an increased risk of atrial fibrillation and torsades de pointes.[92–94]

Endocrine Dysfunction

Diabetes mellitus

Up to 30% of patients have diabetes (type I or II) in the cardiac surgery population. Following CPB, the hormonal stress response (i.e., increased growth hormone, catecholamines, and cortisol) causes hyperglycemia (even in nondiabetics) with a decrease in insulin production; this may persist for up to 24 hours postoperatively and is exacerbated by exogenous catecholamine administration. Tight control of blood glucose levels with continuous insulin infusions has been shown to reduce the incidence of sternal wound infection by an order of magnitude.[95] Although a trial in critically ill ICU patients found a survival benefit in patients those blood sugars were kept below 110 mg/dL, only patients with an ICU length of stay greater than 3 days were shown to benefit, and hypoglycemia was shown to be an independent risk factor for mortality. It is not clear whether such aggressive control will benefit the majority of cardiac surgery patients. A recent study has shown an increase in stroke rate and mortality from intraoperative targets between 80 and 100 mg/dL.[96]

Adrenal dysfunction

The stress of cardiac surgery activates the hypothalamic-pituitary-adrenal (HPA) axis and increases plasma adrenocorticotropic hormone (ACTH) and cortisol levels. Subclinical adrenal insufficiency is present in up to 20% of the elderly population and can be unmasked by the stress of surgery. Any patient taking exogenous steroids within 6 months of surgery should receive stress-dose steroids perioperatively. Any patient exhibiting prolonged, unexplained vasodilatory shock should be suspected of having adrenal insufficiency. In a stressed patient, a low or normal cortisol plasma level can be assumed to be associated with adrenal insufficiency. In a stressed patient, a low or normal plasma cortisol leval can be assumed to be associated with adrenal insufficiency. A cosyntropin stimulation test can also be performed for diagnosis. In the interim, dexamethasone may be administered intravenously without interfering with the test.

RELEVANT POSTOPERATIVE COMPLICATIONS

Neurologic

Central nervous system

The incidence of *stroke* following cardiac surgery is procedure-specific and varies between 1 and 4%. Ricotta and colleagues[97] showed that associated carotid stenosis (>50%), redo heart surgery, valve surgery, and prior stroke are associated with an increased postoperative risk of stroke. John and colleagues[98] reviewed 19,224 patients in New York State. The stroke rate was 1.4% following CABG, with a 24.8% mortality rate in that group. Multivariable logistic regression identified the following predictors: calcified aorta, prior stroke, age, carotid artery disease, duration of CPB, renal failure, peripheral vascular disease, smoking, and diabetes. Intraoperative factors that may cause postoperative neurologic deficits include particulate macroembolization of air, debris, or thrombus[99]; microembolization of white blood cells, platelets, or fibrin[100]; duration of CPB[101]; cerebral hypoperfusion during nonpulsatile CPB; and hypothermic circulatory arrest.[102]

Up to 50% of cardiac surgery patients experience *delirium,* particularly those with preexisting organic mental disorders, significant prior alcohol consumption, advanced age, or intracranial cerebral artery disease.[107] Perioperative anesthetic and sedative administration are significant contributing factors. Causes of postoperative delirium in the cardiac intensive-care patient include sleep deprivation, renal failure, hepatic failure, and thyroid abnormalities. Electroencephalograms (EEGs) on these patients usually are abnormal, whereas in primary psychiatric diseases they are normal. Treatment involves correcting metabolic abnormalities, establishing a normal sleep-wake cycle, and minimizing medications likely to cause delirium.

Brachial plexus injury/peripheral nerve injury

Excessive *sternal retraction* during a median sternotomy may cause a brachial plexus injury because the first rib may impinge on the lower trunk and branches.[108,109] IMA harvesting also may cause damage to the brachial plexus.[110] *Malpositioning* of the upper limbs during surgery may result in a neurapraxia owing to compression of the ulnar nerve.[111] Palsy or plegia of dorsiflexion and eversion of the foot can be caused by common peroneal nerve stretch or compression at the level of the head of the fibula.[112] Saphenous neuropathy (i.e., sensory changes on the medial side of the calf to the great toe) following open vein graft harvesting (less so with endoscopic harvest) is also a potential complication secondary to the avulsion of pretibial or infrapatellar branches of the nerve.[113]

Gastrointestinal

Mesenteric ischemia following cardiac surgery is infrequent but usually catastrophic.[114,115] Risk factors include duration of bypass (i.e., hypoperfusion), use of pressor support (i.e.,

sympathetic vasoconstriction), use of the intra-aortic balloon pump (IABP) or other sources of atherosclerotic embolism, atrial fibrillation, peripheral vascular disease, and heparin-induced thrombocytopenia. Early surgical intervention (<6 hours) is associated with a 48% mortality rate, and this rises to 99% with delays (>6 hours) in surgical intervention. Gastrointestinal bleeding is common and can cause significant morbidity. The incidence of gastrointestinal bleeding can be reduced with the use of H_2 inhibitors, proton pump inhibitors, and sucralfate.[116] Other pertinent complications affecting the gastrointestinal system include pancreatitis (hyperamylasemia, 35 to 65% leads to 0.4 to 3% with overt pancreatitis)[117,118,119] acute acalculous cholecystitis (2 to 15% of all acute cholecystitis patients,[120] likely owing to hypoperfusion, narcotics, or parenteral nutrition that promote biliary stasis[121]), swallowing dysfunction or oropharyngeal dysphasia secondary to tracheal intubation or perioperative use of transesophageal echocardiography),[122] and small or large bowel ileus (i.e., Olgilvie's syndrome is associated with long-term ventilation).[123] Preoperative liver dysfunction (noncardiac cirrhosis) is associated with a high incidence of postoperative morbidity and mortality (Child class A cirrhosis: 20% morbidity, 0% mortality; Child class B cirrhosis: 80% morbidity, 100% mortality).[124] Although 20% of patients develop a transient hyperbilirubinemia, fewer than 1% have significant hepatocellular damage that progresses to chronic hepatitis or liver failure.[125]

Infections

Nosocomial infections

Between 10 and 20% of cardiac surgery patients develop a nosocomial infection. Infections may be related to the surgical wound, lung, urinary tract, invasive lines or devices, or the gastrointestinal tract. Prolonged mechanical ventilation is associated with nosocomial pneumonia. These are second only to urinary tract infection in frequency and carry the highest mortality rate.[126] Smokers and COPD patients are most likely to be colonized preoperatively and have a higher incidence of pneumonia (15.3% versus 3.6% in controls).[127]

Catheter-related infections (i.e., bladder and vascular-related) are common in the ICU. The most common pathogens are *Staphylococcus aureus* (12%), coagulase-negative staphylococci (11%), *Candida albicans* (11%), *Pseudomonas aeruginosa* (10%), and *Enterococcus* spp.[128,129]

Fever

Fevers are common in the ICU setting but are an insensitive indicator of postoperative bacteremia (3.2% incidence in 835 febrile CABG patients).[130] The yield of true-positive bacteremia ranges from 4 to 5%, with a contamination rate ranging from 32 to 47%.[131] Noninfectious causes of fever relative to cardiac surgery include myocardial infarction, postpericardiotomy syndrome, and drug fever. Infectious causes include wound infection, urinary tract infection, pneumonia, catheter sepsis, and loculated areas of contaminated blood accumulation (e.g., pericardial, pleural, retroperitoneal, and leg wound spaces).

Sepsis/septic shock

Septic shock following cardiac surgery can have devastating consequences. Pathophysiologic features of sepsis include systemic inflammation, coagulation changes, impaired fibrinolysis, and subsequent target-organ failure, with overall multiorgan failure, irreversible shock, and death (20 to 50%).[132,133] Mixed venous oxygen saturation can be abnormally high secondary to shunting and a failure to extract oxygen at the cellular level. In vasodilatory shock, the maintenance of end-organ tissue perfusion is critical; treatment includes aggressive fluid management and vasopressin.[134–137] Methylene blue (which inhibits NO synthesis)[138] has been used successfully in refractory hypotension. Bernard and colleagues[139] for the PROW/ESS study group showed a distinct survival advantage in the treatment of severe sepsis using drotrecogin alfa (activated) or recombinant human activated protein C (Zigris). The mechanism of action is a modulation of the systemic inflammatory, procoagulant, and fibrinolytic reaction to infection. In a randomized study of 1690 patients, the mortality rate was 30.8% in the placebo group versus 24.7% in the treatment group.

Wounds

DELAYED STERNAL CLOSURE/STERNAL INFECTION: Complicated operations with persistent bleeding and hemodynamic instability (owing to tissue edema) may preclude primary sternal closure. Delayed sternal closure allows hemodynamic stabilization and diuresis.[140] Anderson and colleagues[141] outlined the recent BWH experience; 1.7% (87 of 5177) open chests were managed with a hospital survival rate of 76%. Complications included deep sternal infection ($n = 4$), stroke ($n = 8$), and dialysis ($n = 13$). Multivariate analysis revealed mechanical ventricular assistance and reoperation for bleeding as independent predictors of in-hospital mortality.

SUPERFICIAL AND DEEP STERNAL WOUNDS: Superficial and deep sternal wound infections are significant complications of cardiac surgery. Deep sternal infection with associated mediastinitis occurs in 1 to 2% of cardiac operations, with a resulting mortality rate approaching 10%.[142] Common organisms are *Staphylococcus epidermidis*, *Staphylococcus* [including methicillin-resistant *S. aureus* (MRSA)], *Corynebacterium,* and enteric gram-negative bacilli.[143] Patients predisposed to sternal infections include those with significant comorbidities (e.g., obesity, diabetes, COPD, renal dysfunction, and low serum albumin), prolonged CPB, reoperations, diabetics with bilateral IMA harvests,[144,145] and patients with hyperglycemia.[146] Simple preoperative measures such as clipping of chest hair,[147] using Hibiclens washes,[148] administering adequate prophylactic antibiotics prior to skin incision, ensuring good intraoperative hemostasis without the use of bone wax,[149] and closure with subcuticular sutures and a topical adhesive (e.g., DERMABOND®) rather than

skin staples are helpful; additionally, tight glucose control during surgery and in the days following surgery results in a significantly lower sternal wound infection rate.[95]

Minor infections frequently respond to intravenous antibiotics, opening of the wound, and local wound care. Deeper infections require intravenous antibiotics (6 weeks); initial empirical therapy should consist of broad coverage against gram-positive cocci and gram-negative bacilli, with the regimen adjusted when cultures (i.e., blood or mediastinal or deep sternal wound drainage) have been speciated. The mainstay of treatment is surgical exploration and extensive débridement, which may require removal of the sternum with primary or secondary closure with muscle or an omental flap.[150] Postoperative vacuum-assisted closure (VAC)[151] of mediastinal wounds improves wound healing and reduces hospital length of stay.[152]

Nutrition

Preoperative debilitated or cachectic patients (i.e., more than 10% weight loss over 6 months) with albumin levels of less than 3.5 g/dL[153] are exceptionally prone to complications, such as infections, following surgery. There is no evidence to support a role for preoperative hyperalimentation.[154] Body mass index (a good nutritional index) of less than 15 kg/m^2 is associated with increased morbidity.[155] Postoperative patients have accelerated catabolic protein loss, usually requiring 25 to 40 kcal/kg per day. Advances in immunonutritional pharmacology (i.e., arginine, glutamine and *n*-3 fatty acids) in complex postoperative cardiac surgery patients may have a defined role in the future.[156–158]

CHAPTER 17

Cardiopulmonary Resuscitation

Mark P. Anstadt • James E. Lowe

Cardiovascular disease remains the leading cause of death in the United States.[1,2] In 2002, 696,947 people died of heart disease, the majority attributed to coronary artery disease (CAD).[1] It is estimated that over 500,000 ST-elevation acute myocardial infarctions occur annually in the United States.[3] and ischemic heart disease accounts for the majority of sudden cardiac deaths.

Sudden cardiac death is the unexpected, nontraumatic, abrupt cessation of effective cardiac function associated with absent or acute symptoms of less than 1 hour.[4,5] Prodromes such as chest pain, palpitations, or fatigue may occur within the preceding 24 hours.[4] The majority of deaths occur suddenly, usually within 2 hours of the onset of symptoms.[1,2,6–8] Most victims die before reaching a hospital.[1,2] Although most sudden deaths in the United States result from CAD, other etiologies may be responsible.

Cardiopulmonary resuscitation (CPR) describes the emergency measures used to restore cardiovascular and respiratory function. Clinical interventions for treating cardiopulmonary arrest have been formulated in advanced cardiac life support (ACLS) guidelines.[19] The recommendations are based on scientific data established by the American Heart Association (AHA) and International Liaison Committee on Resuscitation.[9]

CPR and/or ACLS are performed in 1 to 2% of patients admitted to teaching hospitals (including approximately 30% of patients who die).[10,11] The goal is to achieve restoration of spontaneous circulation (ROSC), and ultimately, survival. Early defibrillation is the single most effective means for ROSC. When initial attempts fail, ROSC depends on improving myocardial perfusion and treating underlying disorders. Novel CPR techniques, mechanical circulatory support devices, antiarrhythmic agents, and therapeutic hypothermia can all play a role in these life-saving efforts. Overall survival rates remain low (Table 17-1),[12–14] and successful resuscitation frequently results in neurologic impairment.[15–17] Appropriate integration of rapid response, defibrillation, adjunctive devices, hypothermia, and pharmacologic agents has promise for improving resuscitation results.

TECHNIQUES IN CARDIOPULMONARY RESUSCITATION

Basic life support (BLS) defines the methods used to sustain ventilation and blood flow. BLS measures are recommended until ACLS can restore spontaneous circulation. Airway, breathing, circulation, and defibrillation (ABCD) algorithms describe standardized approaches to cardiac arrest (Fig. 17-1).[3]

Airway Management

Initial management of unresponsive patients is directed toward ensuring a patent airway.[19] The airway is opened using the head-tilt–chin-lift maneuver. The jaw-thrust technique is an alternative for suspected neck trauma; however, it is more difficult to perform.[20] Both relieve posterior displacement of the tongue, which is the most common cause of airway obstruction.[20–22] If signs of respiration are absent, rescue breathing is initiated. Difficult ventilation should be addressed by repositioning and considering foreign body obstruction. The Heimlich maneuver, or *subdiaphragmatic abdominal thrust,* is recommended for relieving obstruction from foreign bodies.[23] Rapid thrusts to the subxiphoid region dislodges a foreign body by increasing expiratory pressure.[24] This is repeated until ventilation is established. Chest thrusts are an alternative for obese patients and women in late stages of pregnancy. Magill forceps can be used to retrieve foreign bodies when necessary. Back blows are only recommended for pediatric patients.[24]

Masks and oral and nasal airways may be used with mouth-to-mask ventilation or bag-valve devices. Mouth-to-mask breathing more reliably provides adequate tidal volumes

Table 17–1.

Published Clinical Series in Which Cardiopulmonary Bypass was Utilized for Resuscitation of Patients Suffering Refractory Cardiac Arrest

Author	Hospital setting	No. treated	No. (%) ROSC	No. (%) survival	CPR duration (min) median (range) or mean +/– SD
Chen[195]	In	57	38 (67)	18 (32)	47+/–13

Younger[194]	ED and In	21 (cannulated 25)	14 (57)	9 (36)	Survivors: 21+/–16 Deaths: 43+/–32

ED = emergency department; NR = not reported; ROSC = restoration of spontaneous circulation. Outcomes represented as percent of patients in which cannulation was attempted.

than bag-valve-mask respiration.[25–27] Bag-valve devices reduce exposure to potential infection, but require two rescuers.[9] Nasopharyngeal airways are considered for nonintubated patients. Oropharyngeal airways are only for unconscious patients; otherwise they add risk for laryngospasm and regurgitation.[9]

Endotracheal tube (ETT) intubation is the preferred method of airway management. Use of an ETT maintains an open airway, decreases risk of gastric distention and aspiration, and is an alternative drug administration route.[28] Orotracheal intubation is ideal unless a neck injury is suspected, in which case nasotracheal intubation is recommended. End-tidal CO_2 ($ETCO_2$) is an adjunct to confirm tube placement; esophageal intubation is likely with low $ETCO_2$.[29,30] ETT placement can be complicated by esophageal intubation, oral trauma, pharyngeal laceration, vocal cord injury, pharyngeal-esophageal perforation, main stem bronchus intubation, and aspiration.[31–33]

Transtracheal catheter (TTC) ventilation is instituted when routine methods fail. A catheter passed through the cricothyroid membrane attaches to a pressurized oxygen tank (30 to 60 lb/in^2), regulated by a triggered valve. Use of a TTC may provide suboptimal ventilation, leading to a respiratory acidosis.[34] Other problems include pneumothorax, hemorrhage, and esophageal perforation.[35] Cricothyroidotomy is considered when ETT ventilation is not possible.[36] Complications may include hemorrhage, esophageal perforation, and mediastinal and subcutaneous emphysema.[37] Tracheostomy is indicated when ventilation cannot otherwise be achieved.

Mouth-to-mouth ventilation is used in the absence of airway devices and generally results in alveolar partial oxygen pressure (P_{O_2}) of 80 mm Hg.[38] Respiratory rates of 10 to 12 per minute are recommended.[9] Cricoid pressure (Sellick maneuver), maintaining a patent airway, and slow breaths decrease risk for gastric distention, regurgitation, and aspiration.[27,37,39,40] Mouth-to-nose breathing is performed when the mouth-to-mouth is problematic.

Concern of transmissible diseases during resuscitation has reduced enthusiasm for CPR. Barrier devices (face shields and masks) have been developed to protect from exposure. Studies indicate minimal risk of hepatitis B virus, hepatitis C virus, or human immunodeficiency virus transmission during CPR.[41,42] Inadvertent exchange of blood with an

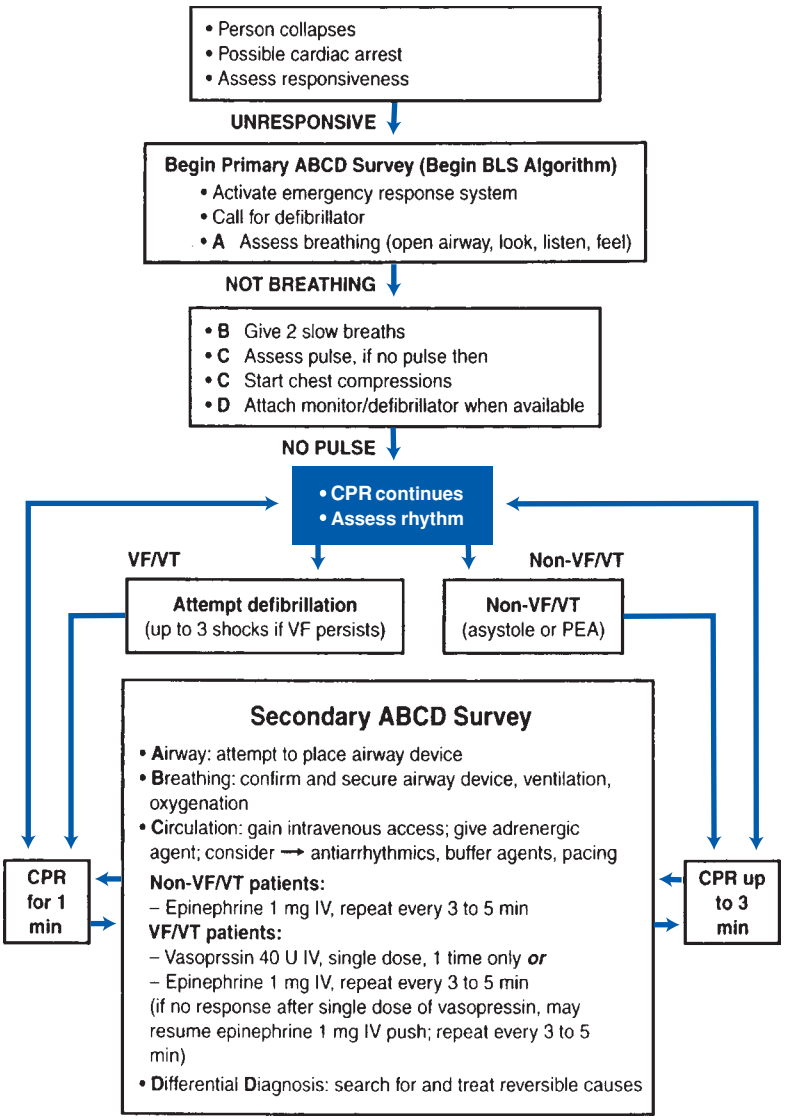

Figure 17-1. Universal treatment algorithm for adult emergency cardiac care. BLS = basic life support; CPR = cardiopulmonary resuscitation; VF/VT = ventricular fibrillation/ventricular tachycardia; PEA = pulseless electrical activity.

infected victim is always a risk.[43] Therefore, universal precautions should always be observed.[41] Rarely, herpes[44] and tuberculosis[19,45] have been transmitted. Chest compressions alone are better than no resuscitation attempt if one is reluctant to perform mouth ventilation. Chest compressions alone may result in survival rates comparable to CPR with ventilation.[46]

Closed Chest Cardiac Massage

Closed chest cardiac massage (CCM) is the principal means of restoring blood flow during CPR. CCM is performed with the victim supine on a firm surface (Fig. 17-2). Compressions are recommended over the lower sternum at 100/min. Compressions of 4 to 6 cm should occupy 50% of the cycle.[47] Complete release after compression allows ventricular filling, while light hand contact avoids repositioning between compressions.[9] In the best circumstances, CCM generates 25 to 30% of normal cardiac output.[48–51] Systolic blood pressure can range from 60 to 80 mm Hg; however, diastolic pressure is typically less than 20 mm Hg.[52] Organ perfusion is poor; cerebral flow is 10 to 15%[52] and coronary perfusion 1 to 5% of normal.[53–55] Clearly, CCM is a temporary means for providing flow to vital organs. In the absence of interventions (e.g., defibrillation), CCM is unable to sustain life and survival becomes unlikely. ROSC is exceedingly low with more than 30 minutes of CCM.

ROSC is dependent on proper CCM techniques. Recent studies examining CCM quality have demonstrated that CCM techniques are frequently suboptimal.[48,49] Inadequate compressions were observed in over $^1/_3$ of cases. Suboptimal compression rates have since been correlated with decreased ROSC.[50] Attention to detail deserves emphasis when performing life-sustaining methods.

Discontinuation of CPR remains controversial with no clearly defined criteria. Simply determining the adequacy of CCM can be quite subjective. Palpable pulses signify differences between systolic and diastolic pressures,[56] not forward flow. Venous pulse pressures may be similar.[57] Reactive pupils and/or spontaneous respirations indicate cerebral perfusion, but these are frequently absent and correlate

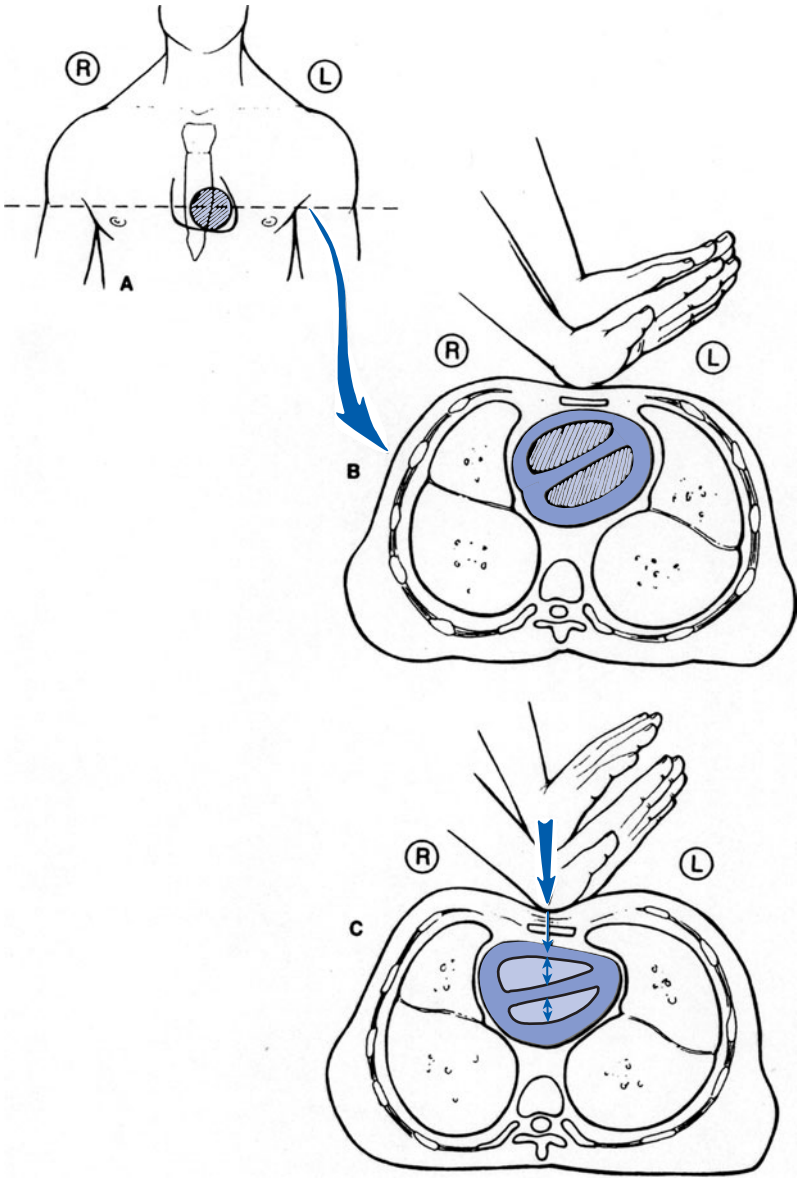

Figure 17-2. Cross-sectional view of closed cardiac massage. Compressions are delivered with high velocity and moderate force, resulting in cardiac compression.

poorly with outcome.[58] Aortic diastolic pressure is a measure of CPR's effectiveness[59] because it best correlates with coronary perfusion.[18] This measurement is usually not available.

Measuring $ETCO_2$ can provide useful information.[30,60,61] Low $ETCO_2$ suggests low blood flow, esophageal intubation, airway obstruction, massive pulmonary embolus, or hypothermia.[62] $ETCO_2$ can predict ROSC.[63,64]

Successful ROSC and survival are influenced by many factors. Ventricular fibrillation (VF), early defibrillation, rapid onset of CPR or ACLS, witnessed arrest, and younger age all have favorable implications.[82,230–232,234] These factors, proper CPR technique, and response are all considered before abandoning resuscitation.

Complications of CPR

Common complications associated with CPR are CCM rib and sternal fractures.[65] Others include aspiration, gastric dilatation, anterior mediastinal hemorrhage, epicardial hematoma, hemopericardium, myocardial contusion, pneumothorax, air embolus, hemothorax, lung contusion, and oral/dental injuries.[65–67] The liver and spleen are the most commonly injured intra-abdominal organs, reported in 1 to 2% of cases.[65] Rarely, significant injuries can involve the trachea, esophagus, stomach, cervical spine, vena cava, retroperitoneum, and myocardium.[65]

SUDDEN DEATH TREATMENT CONSIDERATIONS

Sudden death generally presents as ventricular fibrillation/tachycardia (VF/VT), asystole, or electromechanical dissociation (EMD), also called *pulseless electrical activity* (PEA). VF may continue after defibrillation attempts (*shock-resistant*) or persist despite other therapeutic interventions (*persistent*

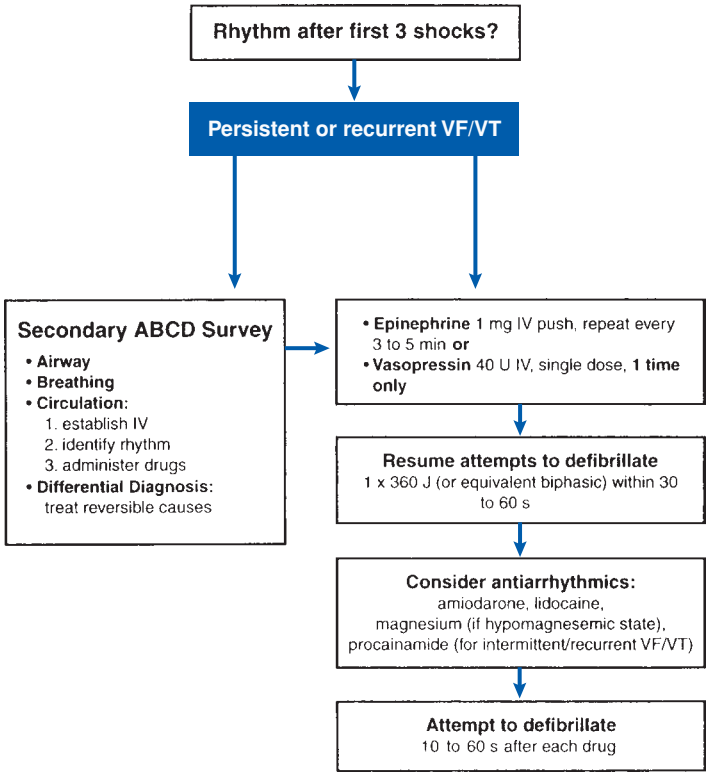

Figure 17-3. Treatment algorithm for persistent ventricular fibrillation and pulseless ventricular tachycardia (VF/VT).

or *refractory*). Also, successfully treated VF may recur (*recurrent*). These patterns are believed to have different etiologies, priorities of treatment, and prognoses. Early identification of the underlying rhythm is important for selecting the recommended treatment algorithm (see Fig. 17-1).

Ventricular Tachycardia

Ventricular tachycardia is an arrhythmia characterized by premature ventricular depolarizations (>100/min). Cardiac arrest occurs with rapid, sustained VT. VF is uncoordinated, continuous contraction of the ventricles. Over 80% of monitored cardiac arrests originate with VF/VT.[49,68] Most survivors have VF/VT as the initial rhythm.[69,70,82,232,233] Rapid defibrillation is the key determinant for survival[71–74,82] and should precede all other therapy if immediately available.[9,19] Delay negatively impacts successful defibrillation.[75,76] Mortality increases 4 to 10% for every minute preceding defibrillation attempts.[73,75,77] Survival rates approach zero when countershocks are attempted more than 10 to 12 minutes after arrest.[78] Current guidelines therefore emphasize early defibrillation and use of automated external defibrillation systems.[9]

Optimal treatment VF or pulseless VT begins with immediate defibrillation when possible. Energy for initial defibrillation is 200 J. Electrodes should remain in place between defibrillation attempts. If VF continues, a second shock (200 to 300 J) is given immediately. A third countershock (360 J) is given if the second fails. It is vital that three consecutive shocks are given without delay for other interventions. CPR is performed whenever defibrillation attempts fail. Figure 17-3 outlines treatment algorithms for persistent VF/VT. Epinephrine or vasopressin is given IV or via the endotracheal tube. Vasopressin should only be given once. Subsequent defibrillation attempts (360 J) may be stacked at this point. Epinephrine is given every 3 to 5 minutes. Refractory VF is treated with antiarrhythmics (see Fig. 17-3). Amiodarone may be the most efficacious in this setting.[12,79–81] Lidocaine is also acceptable for recurrent VF or pulseless VT; however, it is not recommended over amiodarone.[82] Magnesium and procainamide are recommended for recurrent VF/VT. Defibrillation should be attempted 30 to 60 seconds after administration of each drug.[9]

Prognosis for VF or pulseless VT is better than for asystole or PEA. Up to 30% of patients with witnessed VF/VT arrest are successfully resuscitated.[83,84,172,232,233] Early defibrillation conclusively improves survival in out-of-hospital arrests and increases when defibrillation is provided in the field.[71,72] Failure of initial defibrillation attempts is a poor prognostic sign. Underlying disorders, effective CPR, antiarrhythmic therapy, and further defibrillation attempts are considered before discontinuing CPR.[9]

Asystole is absence of electrical and mechanical cardiac activity and frequently indicates a terminal event. ACLS is indicated while other treatable causes are considered. Priorities (Fig. 17-4) include effective CPR and rhythm confirmation.[85] Low-amplitude VF may masquerade as asystole.[86] This scenario is rare in clinical practice.[87] Incorrect lead placement or equipment malfunction should be considered.[87] Confirming asystole is important, as countershocks do not benefit *true* asystole;[88,89] they induce parasympathetic

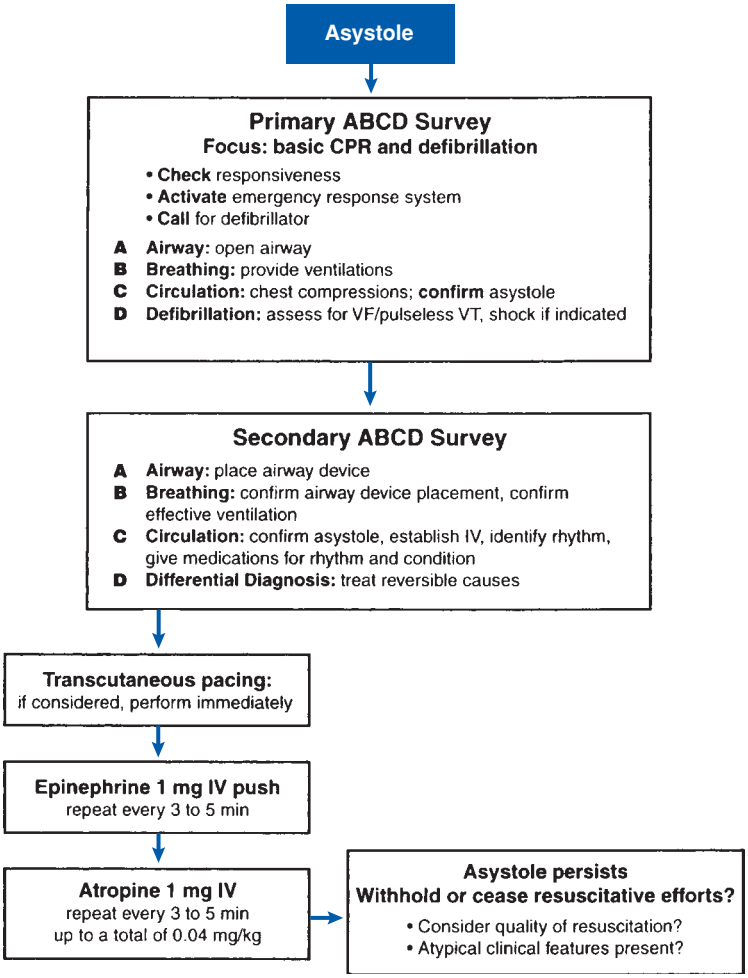

Figure 17-4. Treatment algorithm for asystole.

discharge and diminish chances of ROSC.[90,91] When VF is suspected, defibrillation should be attempted.

Once verified, asystole is managed by ABCD guidelines (see Fig. 17-4). Epinephrine raises perfusion pressures[9,92] and is repeated every 3 to 5 minutes. Atropine treats the high parasympathetic tone underlying severe brady-asystolic arrests.[90,91,93] Transcutaneous or transvenous pacing may be effective if applied early.[94] Timely pacing can result in successful capture and effective cardiac contraction.[95] Unfortunately, the prognosis of asystole remains grim. Less than 2% of patients survive.[96] Asystole following VF has a better prognosis than asystole after prolonged CPR.[97]

Pulseless electrical activity generally carries a very poor prognosis. Characterized by organized electrical activity without effective cardiac contractions, PEA is synonymous with EMD and includes pulseless idioventricular bradycardia, and ventricular escape rhythms.[9] These dysrhythmias have an extremely poor prognosis,[98,99] and are common proximate causes of death in delayed or difficult resuscitations.[85] As with asystole, PEA mandates assessment for reversible causes (Fig. 17-5). Rapid, narrow-complex activity increases the probability of treatable conditions.[85,100] Effective CPR and vasopressors are important for treatment.[99,101–103] Atropine is indicated for bradycardia.[9] Trauma is an indication for emergency left anterolateral thoracotomy[104] to address cardiac tamponade of cardiovascular injury. Thoracotomy allows cardiac massage and aortic occlusion, which may be life-saving. PEA following open heart surgery has a more favorable prognosis and chest reopening is recommended.[188]

Cardioversion is the *only* effective treatment for VF. Defibrillation depolarizes and results in temporary asystole;[91,105] pacemaker cells then restore myocardial activation. Myocardial contraction resumes if high-energy phosphates depleted by CPR[106] are sufficient.[107,108] The probability of successful defibrillation approaches 90% immediately following witnessed arrests.[106,109,110] Success rates decline rapidly, as ROSC decreases 7 to 10% every minute.[78] At best, CPR only slows the deteriorating state. Once available, a defibrillator should be positioned with quick-look paddles for rhythm evaluation. VF or pulseless VT is treated immediately. Blind defibrillation is rarely indicated. Asynchronous shocks are given for VF or pulseless VT. Synchronous shocks are given for stable rhythms (e.g., atrial fibrillation/flutter or monomorphic VT)[9] to avoid impinging on the relative refractory period.[111]

Energy levels for cardioversion impact success. Low currents may be ineffective and excessive energy levels cause

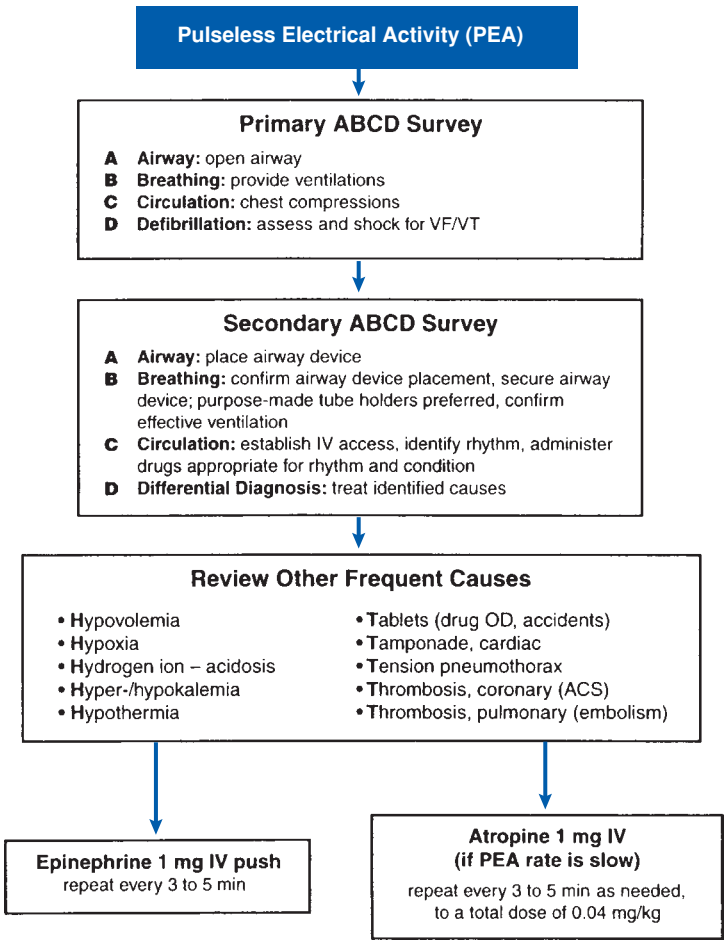

Figure 17-5. Treatment algorithm for pulseless electrical activity (PEA). ACS = acute coronary syndrome; OD = overdose.

myocardial injury.[112,113] The lowest energy that accomplishes defibrillation is desired. A prospective study demonstrated that 175 J and 320 J were equally effective for initial defibrillation attempts.[114] Therefore, 200 J is recommended for initial defibrillation attempts.[9] Most adults can be defibrillated with a 200-J shock delivered promptly.[115,116] The range for second countershocks is 200 to 300 J. Transthoracic impedance decreases with repetitive shocks, explaining why serial countershocks deliver greater energy to the heart.[117,118]

Body size impacts defibrillation energy requirements.[9] The optimal *current* for defibrillation is 30 to 40 A.[119–121] Adult transthoracic impedance is 70 to 80 gV, requiring a 200-J countershock for a 30-A current.[122] However, impedance varies significantly depending on energy delivery, chest size, electrode size, inter-electrode distance, paddle-skin coupling, respiration, and antecedent countershocks.[117-121,123,124] Therefore, the defibrillation techniques are critical. Electrodes are positioned to maximize current flow. Usually, one electrode is placed on the right parasternal border below the clavicle and the other in the left midaxillary line, level with the nipple.[9] Electrodes must not touch so current passes through the heart. During open chest resuscitation, one paddle is placed over the right ventricle, and the other behind the apex. Larger paddles are preferred for lower resistance;[117,124] small paddles should only be used if required to fit in the chest.[125] It is also noteworthy that compression of the heart reduces the defibrillation threshold.[133]

Defibrillation threshold (DFT) describes the amount of current required to defibrillate the heart. DFT increases during CPR and is primarily affected by coronary perfusion pressure. Catecholamines decrease the DFT.[126–128] It was thought that epinephrine decreased the DFT through beta-adrenergic effects; instead, this is due to alpha-adrenergic increases in systemic pressure.[129] Time-dependent increases in DFT observed during CPR are not completely understood. The etiology is not secondary to metabolic or respiratory acidosis.[130,131] Adenosine may act through A_1 receptors to increase DFT over time.[132] Aminophylline, an adenosine receptor antagonist, decreases DFTs.[134–136]

The presence of pacemakers and automatic internal cardiodefibrillators (AICDs) impact defibrillation management. Paddles should not be placed directly over pacemaker generators,[137] and these devices should be interrogated to reassess pacing thresholds after defibrillation. AICDs are not a contraindication to external defibrillation for VF/VT[138] and are shielded to withstand countershocks. AICD patches may increase transthoracic resistance.[139] Therefore, paddle orientation should be changed if initial countershocks fail. After defibrillation, the AICD unit should be tested.

Automated external defibrillators (AEDs) are increasingly common. AEDs analyze electrocardiographic patterns and sound an alarm and discharge when VF is detected. They require less training and are more rapid at administering countershocks.[78,140,141] AEDs have equivalent survival compared with manual defibrillators[142–144] and are endorsed by the AHA for out-of-hospital arrest.[145]

Current-controlled defibrillators may improve the success of defibrillation.[119,120,146] These devices enhance delivery of *appropriate* energy and reduce the risk of excessive energy delivery. Other developmental areas include delivery of biphasic (bidirectional) or multipulse, multipathway shocks.[122] These methods are in use for internal defibrillators, but their efficacy for external defibrillation has not been established.[147,148]

A precordial thump may achieve defibrillation and be used when a defibrillator is not immediately available. It may be successful in 11 to 25% during VT.[149,150] Unfortunately, precordial thumps may result in VF, asystole, or EMD,[150,151] and are less likely to convert VF.

Chest compressions must be temporarily discontinued to avoid electrical shock of those performing CPR. This "hands-off" interval is also used for rhythm analysis before defibrillation. Prolonging the hands-off period can significantly reduce the probability of successful cardioversion, and should be kept as short as possible.[151]

PHYSIOLOGY OF CARDIOPULMONARY RESUSCITATION

Mechanisms generating forward blood flow during CPR have been a subject of significant controversy. Kouwenhoven postulated that chest compressions translate directly to the heart.[152,153] This became known as the *cardiac pump*. Multiple laboratory and clinical investigations have verified this during closed-chest compression.[154–157] However, other mechanisms have been demonstrated.

At least two other mechanisms appear responsible for blood flow during CPR. The thoracic pump was discovered by observing that coughing during cardiac arrest generated forward flow. Chest compressions also cause a rise in thoracic pressures capable of forcing blood into the systemic circulation.[51] The heart in this circumstance merely functions as a conduit. Many studies have validated the thoracic pump mechanism during CPR.[48,158–160]

Another mechanism for blood flow generated during CPR is the abdominal pump. This emphasizes effects of abdominal compressions, which are now advocated for CPR.[161–164] The abdominal pump operates through arterial and venous components. The arterial component reflects compression of the abdominal aorta, forcing blood into the peripheral circulation. The aortic valve remains closed during abdominal compression and resists retrograde arterial flow. Simultaneously, the venous component fills the heart from venous pressure. Both contribute hemodynamic benefits during abdominal compressions in CPR.

Clearly, the cardiac, thoracic, and abdominal pump mechanisms are important concepts of CPR physiology. The technique(s) employed during CPR dictates which mechanism predominates. Other factors that can influence effectiveness of these pump mechanisms include: cycle rates, compression duration, body habitus, cardiac size, chest wall stiffness, and the presence of pulmonary disease, as well as the duration of the resuscitation effort. Understanding these mechanisms has led to improved CPR techniques and adjunctive devices.

CPR TECHNIQUES AND MECHANICAL ADJUNCTS

High mortality rates associated with cardiac arrest have led to investigators exploring several new techniques for performing CPR. Adjunctive devices to better facilitate performance of such new techniques have also been developed.

Active compression-decompression (ACD) is a promising means for improving CPR. Originating from successful resuscitation with a plunger, a device consisting of a handheld suction cup with a central piston and handle has been developed (Fig. 17-6). ACD-CPR can increase aortic pressures resulting in improved cerebral, coronary, and renal blood flow.[176] Ventricular filling and venous return are augmented by negative intrathoracic pressure during the active decompression phase.[177] Two initial studies reported increased ROSC and 24-hour survival with the ACD device. Survival to discharge was higher with ACD in both studies but did not reach statistical significance.[178,179] Data from 2866 patients using the ACD device were subsequently combined.[180] ACD improved 1-hour survival but long-term outcome was not significantly different from standard CPR. A randomized clinical trial demonstrated significantly improved 1-year survival following ACD compared to standard CPR.[181] Most recently, a prospective trial found that the ACD combined with controlled ventilation using an inspiratory impedance threshold device improved short-term survival when compared to standard CPR.[173]

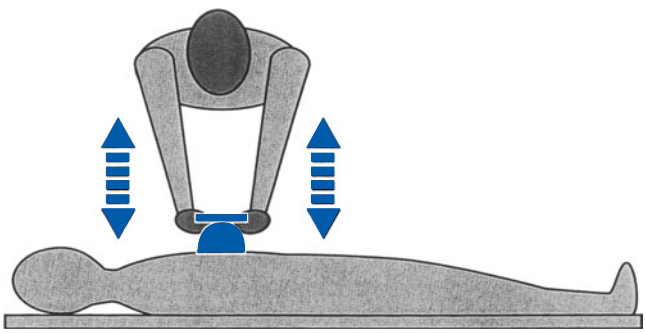

Figure 17-6. Active compression-decompression cardiopulmonary resuscitation (ACD-CPR) using a suction cup device attached to chest wall.

Combining chest and abdominal pumping techniques within the same compression cycle is another means for improving the effectiveness of CPR. The method has been termed *interposed abdominal compression* CPR (IAC-CPR). The technique employs chest compressions with abdominal compression during the relaxation phase of chest compression. The simplest application involves compressing the chest and abdomen at equal durations and is not associated with intra-abdominal injuries or aspiration. Initial clinical studies using IAC-CPR yielded encouraging results with significant improvement in outcome measures.[168] Return of spontaneous circulation and survival to discharge were both improved using IAC-CPR when examining inpatient cardiac arrests.[166,168,169] A hand-held device that allows IAC-CPR combined with compression-decompression mechanics has been developed for single-rescuer use (Fig. 17-7). The "Lifestick" was deemed safe and effective by the investigators.[172] Further studies will determine if this adjunct for manual CPR can favorably impact survival rates.

Noninvasive mechanical devices have been developed to enhance the effectiveness of CPR. These devices not only improve noninvasive CPR performance but also eliminate operator fatigue associated with the physical demands of performing CPR.

Fatigue becomes a particularly significant problem when attempting to perform ACD-CPR for extended periods of time. This has led to the development of an automatic chest compression device termed "LUCAS." Clinical applications using LUCAS have found it feasible for out-of-hospital CPR.[174] Preliminary trials indicate that the device may improve the 30-day survival of patients suffering witnessed cardiac arrest.[175]

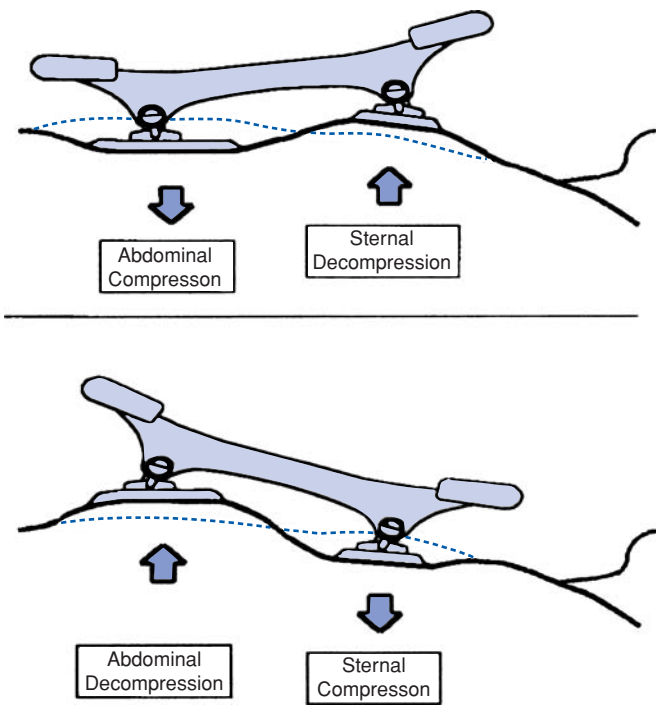

Figure 17-7. The Lifestick is designed to performed abdominal and sternal compression-decompression in a seesaw-like fashion. (*Reproduced with permission from Arntz HR et al: Phased chest and abdominal compression-decompression versus conventional cardiopulmonary resuscitation in out-of-hospital cardiac arrest. Circulation 2001; 104:768.*)

The pneumatic vest is another noninvasive mechanical device that alternates pressures around the thoracic cage (Vest-CPR). Vest-CPR utilizes a pneumatic bladder tailored to fit the chest wall. Air is forced into and out of the vest by a pneumatic drive. Clinical trials demonstrated improved outcomes with an increased rate of ROSC.[170] However, energy consumption and portability of the inflation system have made further clinical use impractical. An improved circumferential chest compression device has been developed that uses a pneumatically actuated constricting band.[171] Further trials are required to determine the feasibility of compression devices for clinical use.

Open chest cardiac massage (OCM) is an invasive resuscitative method which is more effective at returning blood flow during cardiac arrest. OCM was relatively common prior to 1960.[182] OCM is now only advocated for specific circumstances such as cardiac arrest from penetrating thoracic trauma. OCM should also be considered for cardiac arrest due to hypothermia, massive pulmonary embolism, pericardial tamponade, intrathoracic hemorrhage, and chest deformity precluding effective CPR. OCM is usually performed via a left lateral thoracotomy except following recent cardiac surgery, for which the prior sternotomy is re-entered. Thoracotomy is performed through the fifth intercostal space and the pericardium opened anterior to the phrenic nerve. The heart is compressed between both hands, or alternatively, with one hand while the other is used to occlude the thoracic aorta (Fig. 17-8).

Numerous studies have demonstrated superior hemodynamics during OCM compared to CCM.[56,183–187] Most notable are increased diastolic pressures and reduced central venous pressures,[56,185,188] which illustrate the favorable impact on coronary perfusion during OCM versus CCM. Cardiac output and cerebral blood flow are higher during OCM,[186,187] explaining successful ROSC when OCM follows failed resuscitative efforts with CCM. However, clinical outcomes are generally not improved when OCM follows prolonged CPR efforts.[189] Animal studies have suggested that OCM may improve results if applied early after a short period of ineffective CCM. A recent prospective, nonrandomized clinical trial illustrated the importance of instituting OCM earlier to improve outcome.[190] Patients receiving OCM had improved outcome which declined as the period of CCM prior to instituting OCM increased.

Early application of OCM may improve survival if downtimes prior to thoracotomy are minimized to reduce neurologic impairment. One setting in which OCM has been used routinely is in the postcardiotomy ICU. A recent review strongly confirmed the benefit of open chest massage in patients suffering cardiac arrest following open-heart surgery.[188] The study suggests that reopening the chest in this

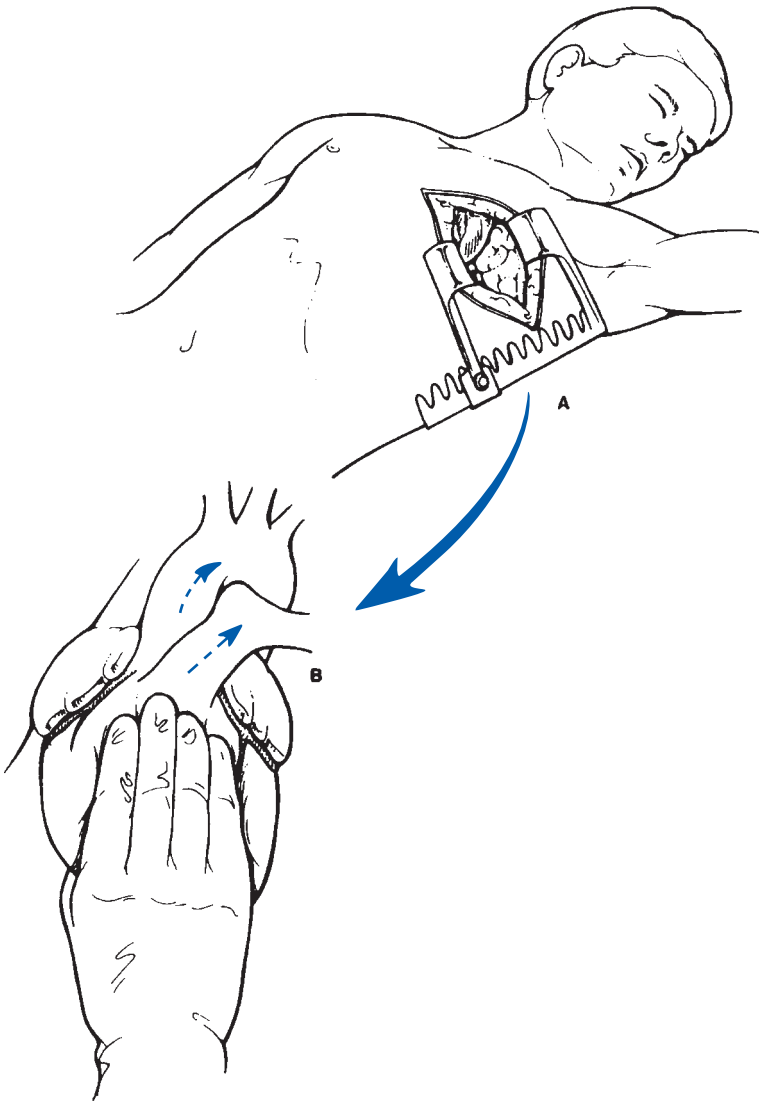

Figure 17-8. Technique of open chest cardiac massage. (*A*) The heart is exposed via an anterolateral thoracotomy through the fifth intercostal space. The pericardium is opened if there is evidence of pericardial tamponade; otherwise it is left intact. (*B*) The heart is massaged at a rate of 60 to 80 beats per minute.

setting has the greatest potential benefit in patients arresting within 24 hours of surgery and when performed within 10 minutes of cardiac arrest.

Potential complications of OCM include right ventricular perforation, hemorrhage, lung laceration, phrenic nerve injury, esophageal and aortic injury, cardiac lacerations, and empyema. Infection is surprisingly low (5%) given the nature of the procedure and related limitations on sterile technique.

The intra-aortic balloon pump improves hemodynamics during CPR; however, its value in this setting appears limited.

Cardiopulmonary bypass (CPB) can be used for treating cardiac arrest refractory to CPR. Hemodynamics, survival, and neurologic function improved in experimental models of cardiac arrest treated with CPB versus standard CCM. However, availability of emergency CPB is generally limited to tertiary care centers. A number of institutions have utilized CPB to bridge patients to transplantation following cardiac arrest.[192,193,196] Development of newer portable CPB systems has made the technology more attractive; CPB has been reported in a number of centers for treating cardiac arrest.[191–205] Cardiac arrest is a category for CPB in the registry for extracorporeal membrane oxygenation.[200] Multiple clinical series have demonstrated improved outcomes when CPB was utilized to treat refractory cardiac arrest (see Table 17-1). Survival was over 20% in most reported series. Identified prognostic factors include age, treatable conditions, and timely intervention. Generally, CPB should be instituted within 30 to 45 minutes of witnessed arrests, but survival after more extended periods of CCM has been documented.[193,195] Clearly, CPB can result in successful resuscitation following prolonged periods of CPR in pediatric cases[191,199] and hypothermic cardiac arrests.

Hypothermic cardiac arrest is a unique category in which survival can follow prolonged cardiac arrest. Here CPB is the method of choice because of its unique ability to rewarm the patient while providing resuscitative circulatory

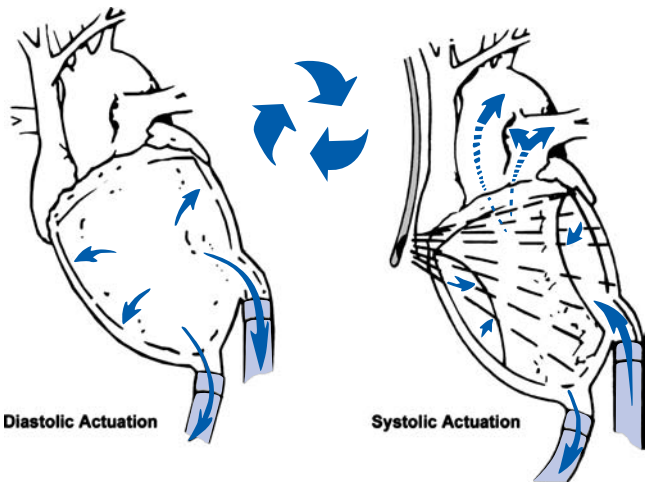

Figure 17-9. Direct mechanical ventricular actuation (DMVA). The ventricles are encompassed by a pneumatically driven device that is vacuum-attached to the arrested heart. Echocardiography allows assessment of device performance.

support.[165,167] The largest experience in adults treated for hypothermia was in Finland.[198] Findings demonstrated that age and arterial pH at the time of presentation had significant prognostic implications. The duration of CPR did not impact the likelihood of survival.

Direct mechanical ventricular actuation (DMVA) is a unique device that provides systolic and diastolic actuation of the ventricular myocardium without contact with the blood (Fig. 17-9). DMVA is pneumatically regulated with an atraumatic vacuum attachment. Rapid application is performed within minutes through a thoracotomy or sternotomy which results in physiologic, pulsatile blood flow.[206–210] Pulsatile reperfusion probably best explains the improved neurologic outcome following resuscitative circulatory support using DMVA versus CPB in animals.[222–224] Lack of blood contact also circumvents the need for anticoagulants and reduces thromboembolic complications. DMVA has been used successfully in humans for bridge to transplantation, postcardiotomy support, and recovery from severe myocarditis.[209,210] Further evaluations are currently aimed at supporting the acutely failing heart.[208] Recent improvements in drive control integrated with performance feedback from echo interrogation are anticipated to provide a more user-friendly device for resuscitative circulatory support.

PHARMACOLOGIC THERAPY DURING CPR

Peripheral venous access is preferred for speed, safety, and avoiding CPR interruption. Drugs take 1 to 2 minutes to reach the central circulation during CPR. Administration should be by bolus followed by flushes and extremity elevation. Peak drug concentrations are lower with peripheral versus central injection. Central access should be considered if responses to peripheral administration are absent. Internal jugular and supraclavicular sites are preferred to the femoral because return to the inferior vena cava is impaired during CPR. Long femoral lines overcome this problem. Routine fluid administration is not indicated without evidence of hypovolemia, as this may adversely affect coronary perfusion pressure by raising right atrial pressure.

When venous access is not possible, drugs may be administered via an endotracheal tube. Medications are given via a catheter passed beyond the tube's tip using twice the IV dose diluted in saline or water. Water provides better absorption but more adversely affects Pa_{O_2}. Rapid insufflations are given after each bolus for drug dispersion. Intracardiac injection is not recommended routinely during CPR. It may be used for epinephrine during OCM or if no other access is obtainable. Intracardiac injection results in high complication rates including cardiac injury, tamponade, and pneumothorax.

The principal agents recommended for ACLS are adrenergic agonists and antiarrhythmics. Alpha-adrenergic agonists have been the only drugs that definitively improved outcome in CPR. Their primary benefit is vasoconstriction. Increased peripheral resistance results in elevated aortic pressure, improving coronary perfusion. Epinephrine is given for this purpose.[129] Epinephrine's beta-adrenergic effect has not shown clear benefit in treating cardiac arrest. One milligram is recommended every 3 to 5 minutes during resuscitation attempts.[9] Epinephrine improves ROSC and survival in animal models of cardiac arrest. The minimum coronary perfusion pressure and blood flow needed for successful defibrillation are 15 mm Hg and 15 to 20 mL/min/100 g, respectively.[52,85] CPR rarely achieves these minimums without pressors. Reports using higher epinephrine doses generated enthusiasm. Subsequent clinical trials reported higher rates of ROSC, but no survival benefit.[211–212] One trial found that high-dose epinephrine had more adverse effects, which may be partly explained by increased oxygen demands.

Other nonadrenergic vasoconstrictive agents have been studied as alternatives to epinephrine. Vasopressin acts on unique receptors and may be beneficial for treating cardiac arrest refractory to epinephrine. Laboratory and clinical data indicate that vasopressin may be preferable to epinephrine.[213,214] A recent meta-analysis of five randomized clinical trials comparing vasopressin to epinephrine during cardiac arrest[216] found no evidence to support the use of one drug over the other. Though epinephrine is less expensive, vasopressin continues to be an acceptable alternative for treating cardiac arrest.

Vasopressin also mediates adrenocorticotropin release during CPR.[219] The hypothalamic-pituitary-adrenal axis is suppressed in cardiac arrest victims,[217–219] and low serum cortisol levels have been identified as a poor prognostic factor for ROSC.[217,218] Adrenal function in patients who have ROSC may also be insufficient for survival.[220] Further clinical trials are needed to determine if administration of

corticosteroids during CPR and/or following ROSC may benefit outcome.

The effectiveness of antiarrhythmics in sudden death has not been well substantiated. Recent randomized clinical trials have demonstrated amiodarone's effectiveness in treating cardiac arrest.[12,80,81,215] Amiodarone significantly improved survival to hospital admission compared to placebo for VF/VT.[215] In a more recent randomized clinical trial, amiodarone significantly increased survival to hospital admission compared to lidocaine when used to treat sudden death.[12] Improved survival to discharge with amiodarone did not reach statistical significance. Amiodarone is recommended for the treatment of persistent VT and/or VF. Lidocaine is an acceptable alternative.

Procainamide is recommended for recurrent VF/VT. Rapid infusion can cause hypotension. Procainamide is of little benefit *during* cardiac arrest and may worsen ventricular arrhythmias in the setting of hypokalemia and/or hypomagnesemia.

Magnesium sulfate should be administered for suspected hypomagnesemia or torsades de pointes. It is recommended for refractory VF/VT. Hypomagnesemia is associated with ventricular arrhythmias and sudden cardiac death and may hinder potassium replenishment in hypokalemic patients. Hypermagnesemia can cause flaccid paralysis and cardiorespiratory arrest.

Atropine enhances atrioventricular node conduction and sinus node automaticity. It is indicated for symptomatic bradycardia and asystolic arrest.[90,91,93] Asystole from prolonged ischemia is usually fatal. Atropine is unlikely to benefit, but is not harmful in such circumstances.[97] Adverse effects include tachycardia and anticholinergic effects.

Sodium bicarbonate is recommended for acidosis during cardiac arrest. Administration increases CO_2 which is eliminated by respiration. During CPR, CO_2 may accumulate rapidly, leading to a hypercarbic venous acidemia. Since CO_2 is diffusible across membranes, paradoxical intracellular acidosis may result and decrease the likelihood of successful resuscitation. Hypocarbic arterial alkalemia or the so-called venoarterial paradox may develop. Therefore, sodium bicarbonate may increase CO_2 levels, worsen the venoarterial paradox, and exacerbate intracellular acidosis. Other potential adverse effects include alkalemia with leftward shifts in the oxyhemoglobin desaturation curve, hyperosmolality, hypernatremia, and hypotension. Sodium bicarbonate has not been shown to improve results in cardiac arrest and is only recommended for acidosis, hyperkalemia, tricyclic antidepressant overdose, or prolonged CPR.[19]

CEREBRAL PROTECTION AND RESUSCITATION

The principal goal of CPR is to provide sufficient blood flow to prevent irreversible organ damage while awaiting definitive intervention. Unfortunately, *less than 10% of CPR* victims survive without neurologic damage.[221]

During cardiac arrest, consciousness is lost within seconds. High-energy phosphates and glycogen stores are depleted in minutes. Lactic acid accumulates which has direct cytotoxic effects. Limited cerebral flow may exacerbate intracellular acidosis by allowing anaerobic metabolism. Survival with normal neurologic function declines in minutes and ROSC after 5 minutes is associated with variable degrees of neurologic damage. Laboratory investigations using mechanical support have demonstrated that pulsatile flow is beneficial compared to nonpulsatile flow in the initial reperfusion period. Pulsatile reperfusion resulted in favorable flow to the gray matter[222] which correlated with increased postresuscitation cerebral high-energy phosphate content.[223] Cerebral function and histopathology significantly improved following pulsatile versus nonpulsatile reperfusion in a canine model of cardiac arrest.[224,225]

Mechanical circulatory support is advocated for resuscitation because CCM generates limited blood flow. During CPR, only venous valves can prevent transmission of high intrathoracic pressures to the jugular venous system. Cerebral blood flow is kept at 50 mL/min/100 g by autoregulation when cerebral perfusion pressures are in the normal physiologic range.[221] CPR results in low cerebral perfusion pressures, seldom exceeding 40 mm Hg.[18,52] Cerebral flow is only 10 to 15% of normal,[185] which may be more harmful than no flow at all.

Effects of cerebral reperfusion may be as important as ischemia itself because neurons function up to 60 minutes during ischemia. Reperfusion injury appears to be multifactorial. Calcium overload in mitochondria, free-radical injury, and the no-reflow phenomenon may all contribute to reperfusion injury.[221] The no-reflow phenomenon describes continued hypoperfusion that may last up to 3 hours. Platelet aggregation, altered calcium flux, vasoconstriction, and pericapillary edema are all presumed causative factors. Intracranial pressure may not be as important because it usually returns to normal soon after cardiac arrest. Cerebral blood flow remains depressed for 18 to 24 hours following a severe ischemic insult. Subsequent periods of hypoperfusion are believed to be secondary to calcium-induced precapillary vasoconstriction.

Abnormal cerebral blood flow following ischemic injury is more dependent on perfusion pressure. Moderate hypotension can lead to further cerebral ischemia and injury. Blood pressure should be normal to mildly elevated in the postresuscitation period. Moderate hyperoxia (P_{O_2} of 100 mm Hg) and mild hyperventilation (partial arterial pressure of carbon dioxide of 30 to 35 mm Hg) are desirable. Arterial pH is kept in the normal range. Anticonvulsants should be given as needed, as seizures occur in up to 30% of patients.

Mild hypothermia is proven effective for cerebral resuscitation. Animal experiments demonstrated improved neurologic function with active cooling following arrest. Clinical trials have subsequently shown cooling following ROSC improves neurologic outcome. More recent randomized

clinical trials found that mild therapeutic hypothermia improves neurologic outcome and survival in patients with ROSC.[226] And, patients who suffer coma following ROSC appear to benefit from therapeutic hypothermia.[227] These findings have led to new AHA recommendations for therapeutic hypothermia.[235]

Other considerations after ROSC include continuous hemodynamic monitoring, and use of supplemental oxygen. Antiarrhythmics are continued, as arrhythmias commonly occur due to increased circulating catecholamines. Beta-adrenergic blockade should be instituted unless bradycardia is a problem. Bradycardia requires that the airway and ventilation be carefully assessed. Atropine, epinephrine, and/or pacing are indicated if hypotension accompanies bradyarrhythmias.

Antiarrhythmics, pacemakers, and automatic internal cardiodefibrillators are also important considerations for patients surviving sudden death. Clinical studies have shown survival can be significantly improved with these interventions.[146,228,229] Amiodarone has also been shown to be effective in this regard.

Predicting which patients survive resuscitation efforts remains elusive. Patients presenting in VF/VT have a better prognosis compared with asystole or PEA.[10,232,233] Advanced age may not be a prognostic indicator when considering other comorbidities.[10,11,233,234] Location of the arrest (ICU versus non-ICU) also impacts outcome.[10,11] Comorbid conditions are associated with more than 95% of mortalities after cardiac arrest including renal failure, metastatic cancer, pneumonia, sepsis, hypotension, stroke, and home-bound lifestyle.[10] Survival is more likely for witnessed arrests, CPR initiated within 5 minutes, and CPR durations of 15 minutes or less. Mortality increases from 44% for CPR less than 15 minutes to 95% for CPR that is longer in duration.[10,234]

In contrast to inpatients, in whom comorbidities play a major role, delayed therapy outweighs all other prognostic factors for out-of-hospital arrests. Other key determinants for survival include the initial rhythm, witnessed arrest, downtime prior to CPR, and any delay in treatment. Survival rates are highly variable, ranging from 20 to 25% following relatively short down times. Early definitive care is also associated with improved outcome. As with in-hospital arrest, VF/VT has the best prognosis and bystander CPR has repeatedly been associated with improved survival rates.[235] In addition, several studies found less neurologic morbidity in cardiac arrest victims who received bystander CPR. The decrease in mortality from bystander CPR is primarily due to reduced postresuscitation anoxic encephalopathy. Return of consciousness within 24 to 48 hours of arrest is a favorable prognostic sign.[10]

Long-term survival in patients discharged after out-of-hospital arrest is reasonably good. The reported 1-year survival rate ranges from 75 to 85%, and approximately 50% are still alive at 4 years (Table 17-2). The majority of these patients ultimately die of cardiac causes.[16,236] Positive predictors for long-term survival are cardiac arrest associated with acute myocardial infarction; no prior history of myocardial infarction; and short time intervals between arrest, CPR, and definitive care.[237] Primary antiarrhythmic events, congestive heart failure, impaired left ventricular function, extensive CAD, and complex premature ventricular depolarizations are less likely to result in long-term survival after discharge.

Unfortunately, not all patients who survive sudden death have a subsequent good quality of life.[242] Depression is a common problem following discharge but usually resolves within a few months.[10] The rate of significant mental impairment in those who survive is variable. Significant neurologic impairment usually results in death prior to hospital discharge. While neurologic deficits are a significant problem,[238] many survivors of sudden death enjoy normal neurologic function (see Table 17-2).

ETHICAL CONSIDERATIONS

Resuscitation efforts should be discontinued when ACLS efforts do not result in ROSC. Discontinuation is based on clinical judgment. Although several studies show that CPR for longer than 30 minutes is unlikely to result in long-term survival, there are many anecdotal reports of neurologically intact survival following prolonged resuscitations.[10] Determination of medical futility is relevant when the patient has a significant underlying medical condition; metastatic cancer and sepsis are examples of such conditions.

CONCLUSION

Early defibrillation, effective BLS, and timely ACLS measures remain the mainstay for ROSC and survival following cardiac arrest. Unfortunately, survival rates remain dismally low. Use of adjunctive methods may improve reperfusion in select patients when initial ACLS efforts fail. Application of CPB for hypothermic cardiac arrest is an example of how devices can favorably impact select patients. Recommended use of CPB and other adjunctive devices for refractory cardiac arrest should be considered.

Combining rapid response, automatic defibrillators, optimal pharmacologic support, therapeutic hypothermia, and selected use of circulatory support devices can further strengthen the "chain of survival" promoted by the AHA.[19] Improvements in survival and neurologic outcome demonstrated by therapeutic hypothermia have led to new additions in AHA guidelines.[235] Integrating such therapy in appropriately selected patients deserves careful attention.

Timely implementation of any indicated therapy will be critical for improving outcomes in cardiopulmonary resuscitation. Identifying patients at risk for sudden death will provide additional opportunity for preventive measures (AICDs and antiarrhythmics). Well-designed clinical trials remain the best means to direct these treatment strategies.

[a]*ALL= cardiac arrest, PEA, VT/VF, respiratory arrest.*

CPC = Cerebral Performance Categories (1–5); NR= not reported; PEA, pulseless electrical activity; VT/VF = ventricular tachycardia/ventricular fibrillation.

Neurologic outcome expressed as percent patients with designated cerebral perfusion categories as defined in Cohn et al.[233]

CHAPTER 18

Temporary Mechanical Circulatory Support

Edwin C. McGee, Jr. • Patrick M. McCarthy • Nader Moazami

A number of devices have been developed and approved for acute circulatory support. As opposed to the more long-term devices that are for prolonged use as a bridge to transplantation, this group of support devices is more applicable to the acute resuscitative phase. Patients in cardiogenic shock require early aggressive therapy. Despite inotropic drugs, intubation, and control of cardiac rhythm, some patients remain hemodynamically unstable, are refractory to medical therapy, and require some type of mechanical circulatory support.[1,2] The need for circulatory support in the postcardiotomy period is relatively low and has been estimated to be in the range of 0.2 to 0.6%.[3] In addition, cardiogenic shock occurs in 2.4 to 12% of patients with acute myocardial infarction (AMI)[4] with a mortality as high as 75%.[5]

The expansion of indications for circulatory support, development of better support devices, and improved results mandate that all surgeons acquire an understanding of the devices currently available and be familiar with one or two of these support systems. Studies show that even smaller facilities that do not have advanced heart failure programs or cardiac transplantation can have improved patient survival if a device can be implemented rapidly and the patient transferred to a tertiary-care facility with expanded capabilities.[6] In this chapter, we describe the devices currently available, indications for support, patient management, and the overall morbidity and mortality associated with temporary mechanical support. In addition, we describe some of the more promising devices that have just received approval or that are currently undergoing trial. The goal of all temporary assist devices is to achieve improved function of the native heart, allowing for removal of the device. If recovery is unlikely, then transition to heart transplantation (see Chap. 65) or a long-term device (see Chaps. 67 and 68) are the only solutions for achieving long-term survival.

COUNTERPULSATION

Historical Notes

The concept of increasing coronary blood flow by retarding the systolic pulse pressure was demonstrated by Kantrowitz and Kantrowitz in 1953 in a canine preparation and again by Kantrowitz and McKinnon in 1958 using an electrically stimulated muscle wrap around the descending thoracic aorta to increase diastolic aortic pressure.[7–9] In 1961, Clauss and colleagues used an external counterpulsation system synchronized to the heartbeat to withdraw blood from the femoral artery during systole and reinject it during diastole.[10] One year later, Moulopoulos, Topaz, and Kolff produced an inflatable latex balloon that was inserted into the descending thoracic aorta through the femoral artery and inflated with carbon dioxide.[11] Inflation and deflation were synchronized to the electrocardiogram to produce counterpulsation that reduced end-systolic arterial pressure and increased diastolic pressure. In 1968, Kantrowitz reported survival of one of three patients with postinfarction cardiogenic shock refractory to medical therapy using an intra-aortic balloon pump.[12] These pioneering studies introduced the concept of supporting the failing circulation by mechanical means. Currently, intra-aortic balloon counterpulsation is used in an estimated 70,000 patients annually.[8]

Physiology

The major physiologic effects of the intra-aortic balloon pump (IABP) are a concomitant reduction in left ventricular afterload along with an increase in coronary perfusion pressure secondary to an increase in aortic diastolic pressure.[13–15] Important related effects include reduction of left ventricular systolic wall tension and oxygen consumption, reduction of left ventricular end-systolic and end-diastolic volumes,

reduced preload, and an increase in coronary artery and collateral vessel blood flow.[16–19] Cardiac output increases because of improved myocardial contractility owing to increased coronary blood flow and the reduced afterload and preload, but the IABP does not directly move or significantly redistribute blood flow.[20,21] IABP counterpulsation reduces peak systolic wall stress (afterload) by 14 to 19% and left ventricular systolic pressure by approximately 15%.[16,20,22,23] Since peak systolic wall stress is related directly to myocardial oxygen consumption, myocardial oxygen requirements are reduced proportionately.[24–26] Coronary blood flow is subject to autoregulation, and in experimental animals, the IABP does not increase flow until hypotension reduces flow to less than 50 mL/100 g of ventricle per minute.[14] However, as measured by echocardiography and color-flow Doppler mapping, peak diastolic flow velocity increases by 117% and the coronary flow velocity integral increases by 87% with counterpulsation.[27] Experimentally, collateral blood flow to ischemic areas increases up to 21% at mean arterial pressures greater than 190 mm Hg.[28]

Several variables affect the physiologic performance of the IABP. The position of the balloon should be just downstream of the left subclavian artery (Fig. 18-1). Diastolic augmentation of coronary blood flow increases with proximity to the aortic valve.[29,30] The balloon should fit the aorta so that inflation nearly occludes the vessel. Experimental work indicates that for adults, balloon volumes of 30 or 40 mL significantly improve both left ventricular unloading and diastolic coronary perfusion pressure when compared with smaller volumes. Inflation should be timed to coincide with closure of the aortic valve, which for clinical purposes is the dicrotic notch of the aortic blood pressure trace (Fig. 18-2). Early inflation reduces stroke volume, increases ventricular end-systolic and end-diastolic volumes, and increases both afterload and preload. Diastolic counterpulsation is visualized easily as a pressure curve in the arterial waveform and indicates increased diastolic perfusion of the coronary vessels (and/or bypass grafts).[31,32] Deflation should occur as late as possible to maintain the duration of the augmented diastolic blood pressure but before the aortic valve opens and the ventricle ejects. For practical purposes, deflation is timed to occur with the onset of the electrocardiographic R wave. Active deflation of the balloon creates a suction effect that acts to decrease left ventricular afterload (and therefore myocardial oxygen consumption).

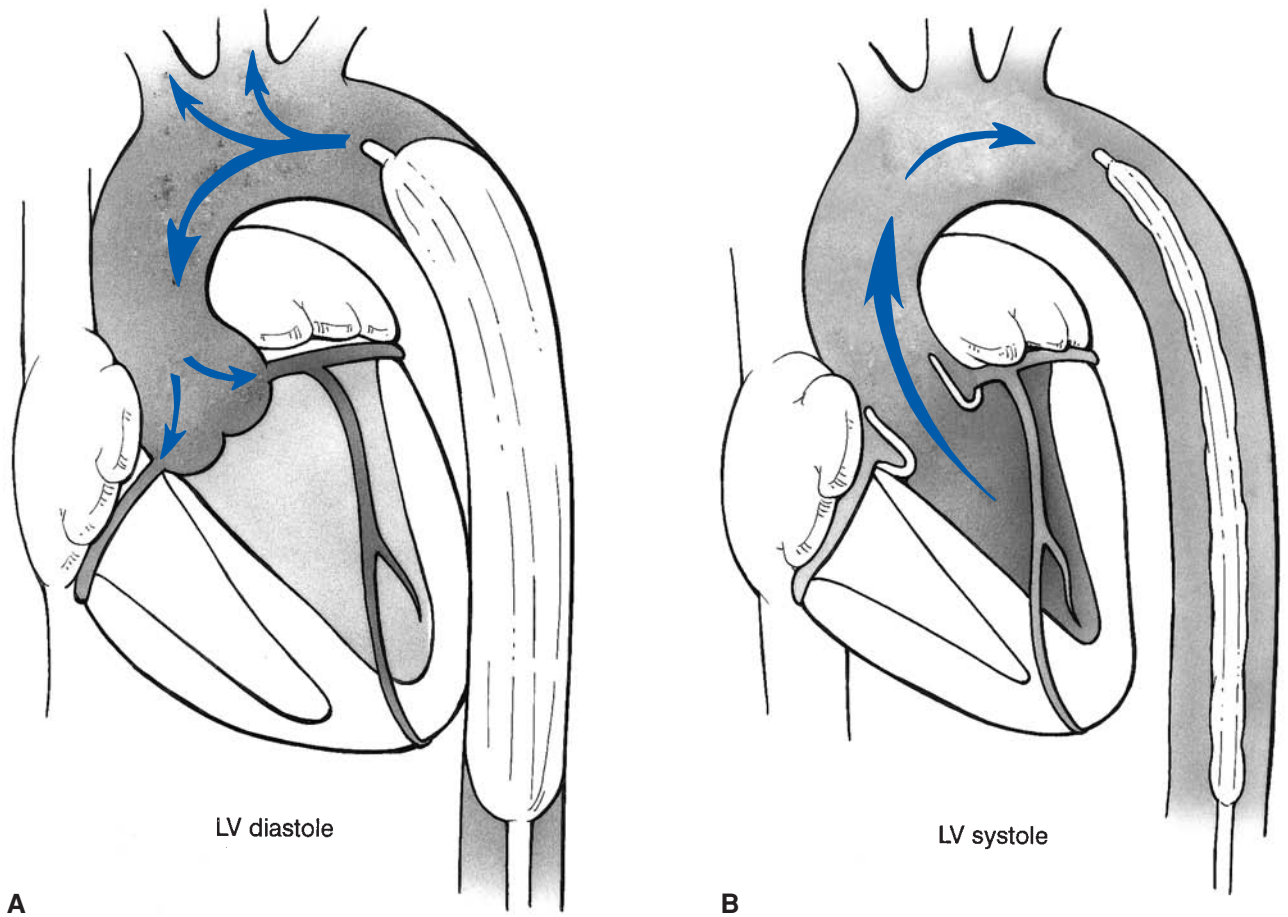

Figure 18-1. (**A**) Balloon inflation during left ventricular (LV) diastole occludes the descending thoracic aorta, closes the aortic valve, and increases proximal coronary and cerebral perfusion. (**B**) Balloon deflation during LV systole decreases LV afterload and myocardial oxygen demand.

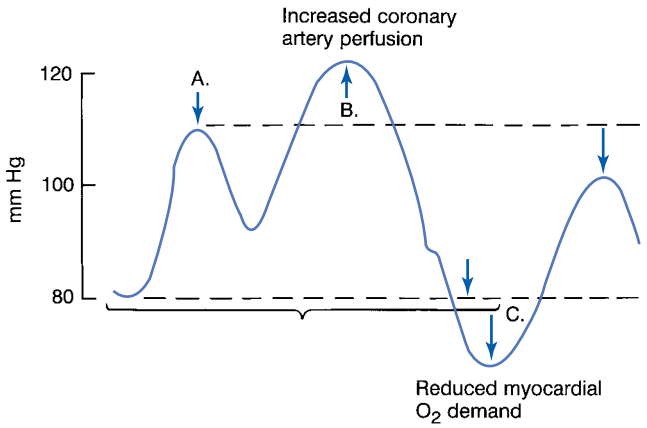

Figure 18-2. Illustration showing the effect of the intra-aortic balloon on aortic pressure. After ejection produces the pulse (*A*), inflation of the balloon increases aortic diastolic pressure (*B*). At end diastole, sudden deflation reduces aortic end-diastolic pressure (*C*) below that of an unassisted beat and reduces afterload and myocardial oxygen demand.

Biologic factors that influence the in situ hemodynamic performance of the IABP include heart rate and rhythm, mean arterial diastolic pressure, competence of the aortic valve, and compliance of the aortic wall. Severe aortic regurgitation is a contraindication to use of the IABP; very low mean aortic diastolic pressures reduce aortic root pressure augmentation and coronary blood flow. A calcified, noncompliant aorta increases diastolic pressure augmentation but risks injury to the aortic wall. On the other hand, young patients with a highly elastic, compliant aorta may manifest decreased diastolic pressure augmentation.

By far the most important biologic variables are heart rate and rhythm. Optimal performance requires a regular heart rate with an easily identified R wave or a good arterial pulse tracing with a discrete aortic dicrotic notch. Current balloon pumps trigger off the electrocardiographic R wave or the arterial pressure tracing. Both inflation and deflation are adjustable, and operators attempt to time inflation to coincide with closure of the aortic valve and descent of the R wave. During tachycardia, the IABP usually is timed to inflate every other beat; during chaotic rhythms, the device is timed to inflate in an asynchronous fixed mode that may or may not produce a mean decrease in afterload and an increase in preload. In unstable patients, every effort is made to establish a regular rhythm, including a paced rhythm, so that the IABP can be timed properly. The newer-generation IABP consoles come with algorithms that select the most appropriate trigger mode and time inflation and deflation automatically.

Indications

The traditional indications for insertion of the IABP are cardiogenic shock, uncontrolled myocardial ischemic pain, and postcardiotomy low cardiac output.[33–36] In recent years, indications for IABP have broadened to include patients with high-grade left main coronary artery stenosis, high-risk or failed percutaneous transluminal coronary angioplasty, atherectomy, or stents; patients with poorly controlled ventricular arrhythmias before or after operation; and patients with postinfarction ventricular septal defect (VSD) or acute mitral insufficiency after myocardial infarction (MI).[37–40] In addition, the IABP occasionally is used prophylactically in high-risk patients with poor left ventricular function (LVF) with either mitral regurgitation or preoperative low cardiac output owing to hibernating or stunned myocardium. These patients may benefit from temporary afterload reduction during weaning from cardiopulmonary bypass, particularly if myocardial contractility is not improved immediately by revascularization. In some institutions, a femoral artery catheter is inserted in anticipation of IABP use in patients undergoing complex procedures who have myocardial dysfunction.[41] In exceptional patients, IABP is used with extracorporeal membrane oxygenation (ECMO) to unload the left ventricle and generate pulsatility while providing circulatory assistance for postcardiotomy patients.[42–44] Some groups routinely insert an IABP prior to insertion of more long-term left ventricular assist sytems in order to optimize right ventricular function.

Nearly 90% of patients who receive IABP counterpulsation have various manifestations of ischemic heart disease with or without associated valvular heart disease.[45–47] A few patients have insertion of the balloon pump for end-stage cardiomyopathy, acute endocarditis, or before or after heart transplantation.[48]

The vast majority of patients who receive the IABP on the medical service have ischemic heart disease primarily manifested by cardiogenic shock or unstable, refractory angina. Of 231 patients who had IABP insertions at the Cleveland Clinic, Eltchaninoff reports that 83 (34.6%) were for complications of AMI. Forty-four (18.3%) were owing to failed angioplasty, 48 (20%) were for high-risk angioplasty, and 31 (12.9%) were for stabilization before cardiac surgery.[35] Only 13 (5.4%) were for end-stage cardiomyopathy.

The timing of IABP insertion varies widely between reports. The percentage of IABPs inserted before cardiac surgery varies between 18% at St. Louis University Medical Center and 57% in a group of community hospitals that do cardiac catheterization.[49,50] The overwhelming reason for intraoperative use of the IABP is failure to wean from cardiopulmonary bypass. Approximately 75% of intraoperative balloon insertions are for this reason. Preoperative low cardiac output and postinfarction angina are additional indications for intraoperative insertion of the IABP. Approximately one-half of patients who require intraoperative IABP have urgent or emergency operations.

Techniques of Insertion

The IABP usually is inserted into the common femoral artery either by the percutaneous technique or by surgical cutdown.[51] A cutdown is used most often during cardiopulmonary

bypass when the pulse is absent. The superficial femoral artery is avoided because of its smaller size and increased possibility of leg ischemia. For patients with small vessels, a 7.5F catheter without a sheath is recommended to lessen the possibility of leg ischemia. The iliac and axillary arteries and, very rarely, the abdominal aorta are infrequently used alternate sites.[52,53] Direct insertion into the ascending aorta is used intraoperatively in patients with severe aortoiliac or femoral occlusive disease that prevents passage of the balloon catheter.[54–56]

The percutaneous method uses a guidewire and is faster than a cutdown.[57] Approximately two-thirds to three-quarters of all femoral arterial insertions use the percutaneous method.[58] Although percutaneous insertion was associated with a higher incidence of leg ischemia in the past, this is no longer true.[57,59] In the catheterization laboratory, both the guidewire and balloon are monitored by fluoroscopy, but this is not essential if not readily available. The cutdown technique may be done with local anesthesia outside the operating room but preferably is done in the operating room with local or general anesthesia because the risk of contamination is less. After the femoral artery is exposed, a guidewire is introduced, followed by dilating catheters and the balloon. The catheter can be inserted without the sheath in some instances.[60] The balloon catheter usually fits snugly in the arterial wound, so a purse-string suture is not needed. If bleeding is present around the entrance site, sutures are used for control. The wound is closed completely. Whenever possible, the tip of the balloon is visualized by fluoroscopy or transesophageal echocardiography in order to ensure optimal position just distal to the left subclavian artery.[61]

The timing of inflation and deflation of the balloon must be monitored closely during counterpulsation. This usually is done easily by observing the continuously displayed arterial pressure tracing; a second systolic pulse should appear with every heartbeat and begin just after the smaller first pulse begins to decay. Timing the balloon for irregular rhythms is difficult, and the circulatory support provided by the balloon is compromised; in these patients, attempts are made to convert the patient to a sinus or paced rhythm or to slow (80 to 90 beats per minute) atrial fibrillation using appropriate drugs or cardioversion. For tachycardias over 110 to 120 beats per minute, the balloon is timed to provide inflation on alternate beats if the machine is not able to follow each beat reliably. Generally, patients are not given heparin for the IABP. The exit site of the catheter must be kept clean with antiseptics and covered in an effort to prevent local infection or septicemia.

A percutaneous IABP can be removed without exposing the femoral puncture site. The exit site is prepped, and securing sutures are cut. The balloon catheter is disconnected from the pump and completely deflated using a 50-mL syringe. Pressure is first maintained over the iliac artery. The balloon is removed, and backbleeding is allowed from the femoral artery, which theoretically flushes any distal clot into the wound. The femoral artery then is compressed, and prograde flushing then is allowed. Finally, steady nonocclusive pressure is held over the femoral puncture site. Pressure is maintained over the puncture site for 30 minutes to ensure that thrombus closes the hole. If the balloon is inserted via a cutdown, the balloon preferably is removed in the operating room. The puncture site is closed with sutures. If blood flow to the lower limb is impaired after removal, a local thromboembolectomy using Fogarty catheters and an angioplasty procedure with a vein patch are done to restore full flow to the limb.

If the percutaneous needle punctures the iliac artery above the inguinal ligament intentionally or inadvertently in obese individuals, removal should be done through a surgical incision in the operating room because the backward slope of the pelvis makes pressure difficult to maintain after withdrawal, and substantial occult retroperitoneal bleeding may occur.

If the common femoral or iliac arteries cannot be used because of occlusive disease or inability to advance the guidewire, the axillary artery usually is exposed below the middle third of the clavicle for insertion.[52,53] This vessel is smaller than the femoral artery but generally more compliant. Fluoroscopy or transesophageal (not transthoracic) echocardiography is recommended to ensure that the guidewire does not go down the ascending thoracic aorta into the heart.

Transaortic insertion is done only for postcardiotomy patients who have severe peripheral vascular or aortoiliac disease that precludes femoral insertion. The catheter may be inserted through an 8- or 10-mm woven Dacron or polyfluorotetraethylene graft that is beveled and sutured end to side to the ascending aorta using a side-biting clamp on the aorta.[56] The opposite end of the graft is passed through a stab incision in the chest wall below but near the xiphoid. The incision in the fascia and soft tissues must be large enough to accommodate the balloon catheter. The balloon is passed through this sleeve into the aorta and guided into the proximal descending thoracic aorta so that the balloon does not occlude the left subclavian orifice when inflated. The suture cuff of the balloon catheter is trimmed so that it can be inserted into the graft and tied tightly to achieve secure hemostasis. This connection is placed just beneath the skin so that none of the graft protrudes. The catheter is secured in place and managed in the same way as IABPs placed through other insertion sites.

A simpler method uses two aortic purse-string sutures to secure the aorta around the balloon catheter. No graft is used, yet bleeding complications are minimal.[54,55] Regardless of the technique of insertion, balloon catheters inserted through the ascending aorta are removed in the operating room to secure closure of the aorta.

Pulmonary arterial counterpulsation for right-sided heart failure has not achieved wide use.[62,63] Because of the short length of the pulmonary artery, a prosthetic graft (20 to 25 mm) is sewn end to side to the main pulmonary artery and tied around the balloon catheter placed inside. There are

little data regarding the amount of afterload reduction of the right ventricle.

Complications

Reported complication rates of the IABP vary between 12.9 and 29% and average approximately 20%.[36,58,64] Life-threatening complications are rare.[65] Leg ischemia is by far the most common complication (incidence 9 to 25%); other complications include balloon rupture, thrombosis within the balloon, septicemia, infection at the insertion site, bleeding, false aneurysm formation, lymph fistula, lymphocele, and femoral neuropathy.[66,67] There is no significant difference in limb ischemia in the five different types of IABPs clinically available.[64,68]

Balloon rupture occurs in approximately 1.7% of patients and usually is manifested by the appearance of blood within the balloon catheter and only occasionally by the pump alarm. Rupture may be slightly more common with transaortic insertion. Although helium usually is used to inflate the balloon, gas embolism has not been a problem. If rupture occurs, the balloon should be deflated forcibly to minimize thrombus formation within the balloon and should be promptly removed. If the patient is IABP-dependent, a guidewire is introduced through the ruptured balloon, the original balloon is removed, and a second balloon catheter is inserted over the wire. If the ruptured balloon is not removed easily, a second balloon is inserted via the opposite femoral or iliac artery or through the axillary artery to maintain circulatory support.[69]

Removal of a kinked or thrombosed ruptured balloon that cannot be withdrawn by firm traction requires operation. A thrombosed balloon can severely lacerate the femoral artery. The catheter should be withdrawn as far as possible with firm traction. The location of the tip should be determined by x-ray or ultrasound, and an incision should be planned to expose that segment of the vascular system. In the operating room, thrombolytic drugs may be considered if these drugs are not contraindicated by recent surgery.[70] The trapped balloon is removed through an arteriotomy after control of the vascular segment is obtained.

Although the incidence of clinically significant lower leg ischemia varies from 9 to 25% of patients, up to 47% have evidence of ischemia during the time the IABP is used.[66,67] Thus, the preinsertion status of the pedal pulses should be determined and recorded before the IABP is inserted in every patient. After insertion, the circulation of the foot is followed hourly by palpating pulses or by Doppler ultrasound. Foot color, mottling, temperature, and capillary refill are observed; the appearance of pain, decreased sensation, and compromised circulation indicates severe ischemia that requires restoration of the circulation to the extremity as soon as possible. There are three alternatives. If the patient is not balloon-dependent, the balloon removed immediately. In the majority of patients, this relieves the distal ischemia; a few patients require surgical exploration of the puncture site, removal of thrombus and/or emboli, and reconstruction of the femoral artery. If the patient is balloon-dependent, a second balloon catheter can be introduced into the opposite femoral or iliac artery and the first removed. If this alternative is not available or attractive, circulation to the ischemic extremity is restored using a cross-leg vascular graft or, less commonly, an axillofemoral graft.[70,71] Prompt revascularization preempts development of the compartment syndrome (incidence 1 to 3%) and the need for fasciotomy. Prompt and aggressive treatment of leg ischemia has reduced the incidence of amputation to 0.5 to 1.5%, but if amputation is necessary, the level often is above the knee. Several risk factors for development of leg ischemia have emerged. Female gender, peripheral vascular disease, diabetes, cigarette smoking, advanced age, obesity, and cardiogenic shock are reported to increase the risk of ischemic complications after IABP. Since the IABP is inserted for compelling indications, identification of risk factors does not influence management, except to encourage removal of the device as soon as the cardiac status of the patient allows. In some series, longer duration of IABP counterpulsation is associated with an increased risk of complications.[66]

Although most ischemic complications are the result of impairment of arterial inflow, severe atherosclerotic diseases of the descending thoracic aorta may produce trash embolization of atherosclerotic material that can cause the blue toe syndrome and eventually require amputation. Emboli also may reach the renal and visceral arteries to produce ischemia of these organs. The presence of aortic atherosclerosis can be determined by echocardiography, and if present, insertion through the axillary artery may be considered.[72] The ischemic rate of axillary insertions is not known because of the low number of cases reported.

Approximately 1% of patients develop false aneurysms at the femoral puncture site either in the hospital or shortly after discharge, and rare patients develop an arteriovenous fistula. Both conditions are confirmed readily by duplex scanning and require repair; neglected false aneurysms can rupture. The rare complication of lymphocele or lymph fistula preferably is treated surgically by local exploration and suture control.

Bleeding produces a local hematoma that is not evacuated unless skin necrosis is likely. If bleeding occurs in the wound, the wound is explored, bleeding is stopped, part of the hematoma is evacuated without extending the dissection, and the wound is reclosed. Bleeding from transaortic insertion is uncommon (3 to 4%). Retroperitoneal bleeding from an iliac artery puncture may not be obvious but may cause death.

Septicemia occurs in up to 1% of patients, but the risk increases with the duration of IABP residence. Most catheters are removed within 48 to 72 hours. Septicemia is an indication for IABP removal, but if the patient is balloon-dependent, a replacement balloon catheter is inserted in a new site. Suspected septicemia is treated aggressively, after blood cultures are obtained, with broad-spectrum

antibiotics that are switched to one or more specific antibiotics when the organism is known. Local infections occur in 2 to 3% of patients and usually are treated by drainage, packing, antibiotics, and secondary closure.

Acute aortic dissection from the catheter tip piercing the intima has been reported.[36] This problem is prevented preferably by not advancing the catheter against resistance and monitoring with fluoroscopy or transesophageal echocardiography. Occasional femoral neuropathies resolve over time but can be disabling. Transaortic IABP is associated with a 2 to 3% incidence of cerebral vascular accidents.[55]

Results

Very few complications of IABP cause death. Rare instances of bleeding (retroperitoneal or aortic), septicemia, central nervous system injury, or aortic dissection may cause or contribute to a patient's death. Mortality is higher in patients with ischemic leg complications than in those without.

Counterpulsation increases coronary arterial flow, reduces afterload and myocardial oxygen consumption, and experimentally reduces infarct size early after infarction.[73] Without revascularization, IABP produces a marginal increase in survival, but with revascularization, both short- and long-term survival and quality of life are improved substantially.[74–76]

However, mortality is high in patients who receive an IABP because of the cardiac problems that led to the need for the device. Overall hospital mortality ranges from 26 to 50%[77–79] (Fig. 18-3). Risk factors for hospital mortality include advanced age, female gender, high New York Heart Association (NYHA) class, preoperative nitroglycerin, operative or postoperative insertion, and transaortic insertion in one study and age and diabetes mellitus in another. A third study correlates hospital death with AMI, ejection fraction of less than 30%, NYHA class IV, and prolonged aortic cross-clamp and bypass times.[78] Time of insertion affects hospital mortality. Preoperative insertion is associated with a mortality of 18.8 to 19.6%.[48] Mortality for intraoperative insertion is 27.6 to 32.3%.[48] Postoperative insertion produces a mortality of 39 to 40.5%. Mortality is highest at 68% for patients with pump failure, is lowest at 34% for patients with coronary ischemia, and is 48% for patients who had a cardiac operation.[33] Risk factors available at the time of weaning from cardiopulmonary bypass associated with the likelihood of hospital death are heart block, advanced age, female gender, and elevated preoperative blood urea concentration.[72]

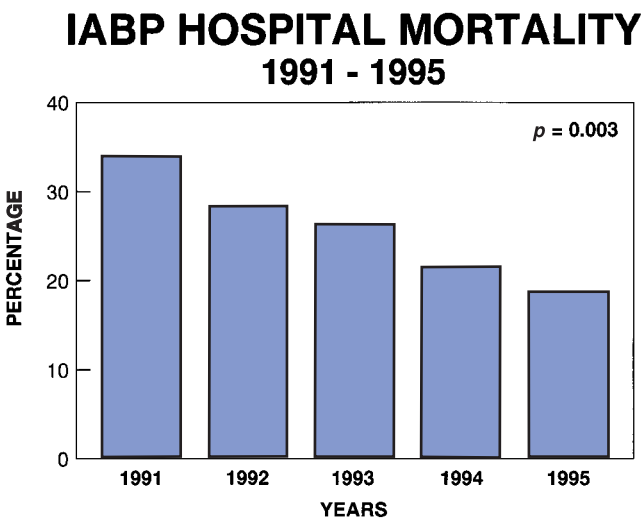

Figure 18-3. Hospital mortality for this 5-year period was 26%.

Long-term survival varies with the type of operation and is highest in patients who had cardiac transplantation or myocardial revascularization.[48] Patients who received an IABP and who required valve surgery with or without revascularization have a poorer prognosis. Creswell and colleagues found 58.8% of all patients alive at 1 year and 47.2% alive at 5 years. Naunheim and associates found that nearly all survivors were in NYHA class I or II.[45] Approximately 18% of hospital survivors have some symptoms of lower extremity ischemia.[79] Although the literature supports a significant complication rate and mortality with IABP use, the more recent data suggest a trend toward continued improvement of results. The report from the IABP registry from 1996 to 2000 reports the same trends in terms of IABP use: hemodynamic support during cardiac catheterization (20.6%), cardiogenic shock (18.8%), weaning from cardiopulmonary bypass (16.1%), preoperative use in high-risk patients (13%), and refractory unstable angina (12.3%).[80] Major complications (including major limb ischemia, severe bleeding, balloon leak, and death directly due to IABP insertion or failure) occurred in only 2.6% of patients, with an in-hospital mortality of 21.2%.[80]

Given the overall ease of IABP insertion, excellent physiologic augmentation of coronary blood flow and left ventricular unloading, this form of therapy should be considered as the first line of mechanical support in patients who do not have significant peripheral vascular disease. There is some suggestion that preoperative prophylactic IABP insertion in high-risk patients [e.g., left ventricular ejection fraction (LVEF) of less than 40%, unstable angina, left main stenosis of greater than 70%, or redo coronary artery bypass grafting (CABG)] can improve cardiac index, length of intensive-care unit (ICU) stay, and reduce mortality.[81,82] However, with meticulous myocardial protection and the judicious use of inotropes, such as epinephrine and milrinone, most groups experienced in dealing with such high-risk patients do not find routine IABP insertion helpful.

DIRECT CIRCULATORY SUPPORT

Background

The need for acute cardiac support beyond cardiopulmonary bypass was clear from the early days of cardiac surgery. Spencer and colleagues reported the first successful clinical use of a temporary device in 1965 after four patients were placed on

femoral-femoral cardiopulmonary bypass. Only one patient survived to discharge. Subsequently, in 1966, the first successful use of a left ventricular assist device was reported after a double-valve operation.[83] Debakey used an assist device that was implanted in an extracorporeal location between the left atrium and the axillary artery, marking the first use of an extracorporeal temporary device support system. The patient survived for 10 days on the pump and eventually was discharged home.

The excitement surrounding these events prompted the formation of the Artificial Heart Program in 1964 and propelled the National Heart Institute to support and encourage the development of mechanical circulatory support systems.[84] One of the objectives of this program was to promote the development of a support system that would be used in cases of acute hemodynamic collapse.

Ideal Device

Despite recent advances in biotechnology, recognition of many of the problems and complications associated with extracorporeal circulation has delineated the limitations of these devices. The components of an ideal device must overcome some of the existing problems.

An ideal device should be capable of supporting adequate flow, maximizing hemodynamics, and unloading the ventricle for patients of all sizes. Although the use of different cannulation approaches can address some of these issues (see below), even under ideal conditions, the currently available pumps are only able to support flows up to a maximum of 6 L/min. This limitation may be detrimental in large or obese patients.

At the other extreme is the need to support patients with small body surface areas. Current devices have addressed the problem associated with variations in patient size by being designed as extracorporeal systems. Therefore, by virtue of having small-diameter cannulas transversing the chest, the pumps can support patients with varying body surface area. The disadvantage of such a system is the potential for driveline and mediastinal infections. In addition, the length of the cannula between the heart and the device, particularly the inflow cannula, predisposes to areas of stasis and potential thrombus generation. Thromboembolic complications, despite adequate anticoagulation, are one of the leading causes of death in patients supported on devices.

All current pumps require anticoagulation, which increases the ever-present threat of early postoperative bleeding. In addition, requirements for transfusion of large amounts of coagulation factors and platelets enhance the inflammatory response that is induced by surgery and is further perpetuated by the circuit. Activation of the contact and complement systems and the release of cytokines by leukocytes, endothelial cells, and macrophages further increase the potential negative and detrimental effects of use of temporary assist devices.[85,86] The ensuing inflammatory cascade and volume overload can have detrimental effects on the pulmonary vascular resistance and lead to right ventricular overload, often necessitating the addition of a right ventricular assist device.

Current temporary assist devices all have the capability of biventricular support as needed, provided that the lungs can support oxygenation and ventilation. In cases of acute lung injury superimposed on circulatory failure, extracorporeal life support (ECLS, i.e., with ECMO) is the only device currently approved that can support an in-line oxygenator.

The multitude of clinical scenarios that often lead to the need for mechanical support all require that support be instituted in an expeditious manner. All current devices therefore must be easily implantable. In the postcardiotomy setting with access to the great vessels, the cannulas should allow the versatility of choosing any inflow or outflow site that is clinically indicated (see below). In an active resuscitative setting, such as cardiac arrest in the catheterization laboratory, in which time is critical and transport to the operating room often impractical, percutaneous cannulation must be an option.

Table 18-1 summarizes some of the components of an ideal temporary support device. At present, no single device is inclusive of all the components. Until the rapid innovations in this field lead to the development of an ideal device, the currently available technology must be tailored to the specific requirements of each patient, taking into consideration the duration of support needed.

Table 18–1.

Characteristics of an Ideal Temporary Support Device

1. Accommodates patients of all sizes, regardless of body surface area
2. Easy to insert
3. Maximizes hemodynamics while unloading the heart to allow for myocardial recovery
4. Is adaptable for patients who require biventricular support
5. Supports the use of an oxygenator as needed, particularly in the group of patients with acute lung injury
6. Requires minimal anticoagulation
7. Has a biocompatible surface that does not promote thrombus generation
8. Causes minimal destruction of blood or plasma components
9. Allows for ambulation and physical rehabilitation
10. Converts easily to a long-term implantable device

Indications for Support and Patient Selection

A wide range of indications exist for acute mechanical support, the primary goal of all being rapid restoration of the circulation and stabilization of hemodynamics. The routine use of transesophageal echocardiography (TEE) has helped greatly in assessing the etiology of cardiogenic shock by allowing evaluation of ventricular function, regional wall motion abnormalities, and valvular mechanics. In a patient with mechanical complications secondary to MI such as acute rupture with tamponade, acute papillary muscle rupture, or postinfarction VSD, emergent surgical correction may obviate the need for device support. Similarly, in the postcardiotomy setting with failure to separate from cardiopulmonary bypass, TEE may direct the surgeon to the need for additional revascularization and reparative valve surgery and successful weaning from bypass.

If echocardiography fails to reveal a surgically correctable cause for cardiogenic shock, most surgeons use hemodynamic data to consider the need for mechanical assistance. These criteria include a cardiac index of less than 2.2 L/min/m^2, systolic blood pressure of less than 90 mm Hg, mean pulmonary capillary wedge pressure or central venous pressure of greater than 20 mm Hg, and concomitant use of high doses of at least two inotropic agents.[87] These situations may be associated clinically with arrhythmias, pulmonary edema, and oliguria. In such circumstances, use of an IABP may be considered as the first step. In the postcardiotomy setting, the preceding hemodynamic criteria, in absence of mechanical support, are associated with a greater than 50% chance of mortality.[88] In this setting, some believe that earlier implantation of an assist device capable of supporting higher flows and allowing the heart to rest may improve results and allow for recovery of stunned myocardium.[89] Furthermore, new pharmacologic agents such as the phosphodiesterase inhibitor milrinone, nitric oxide, and vasopressin have helped to optimize hemodynamics during this critical initial period, reducing the need for concomitant right ventricular support.[90,91]

Once mechanical assistance has been instituted, the stabilized patient can undergo periodic evaluation to assess native heart recovery, end-organ function, and neurologic status. If appropriate, evaluation for cardiac transplantation ensues. Patients without malignancy, severe untreated infection, or neurologic deficit or who are at an advanced age are selected for cardiac transplantation if all other criteria are met, and there is no sign of cardiac recovery. In this subgroup, we generally transition to a chronic ventricular assist device until an organ becomes available. In patients with gradual improvement in myocardial pump function, the devices may be weaned and removed (see below).

DEVICES

Devices currently approved by the Food and Drug Administration (FDA) for temporary support include centrifugal pumps, roller pumps, venoarterial extracorporeal membrane oxygenation (ECMO), the ABIOMED devices, the Thoratec device, and the TandemHeart device. A number of other devices are undergoing investigation for short-term support.

Continuous-Flow Pumps

Two types of pumps are available commercially for extracorporeal circulation: roller pumps and centrifugal pumps. In adults, roller pumps are used rarely, if ever, for temporary circulatory support beyond routine cardiopulmonary bypass applications because of important disadvantages. Although inexpensive, roller pumps are insensitive to line pressure and require unobstructed inflow. Additionally, roller pumps may cause spallation of tubing particles and are subject to tubing failure at unpredictable times. These systems require constant vigilance and are difficult to operate for extended periods. Use of roller pumps beyond 4 to 5 hours is associated with hemolysis and, for this reason, is inappropriate for mechanical assistance that may involve several days to weeks of support.[92]

Centrifugal pumps

Centrifugal pumps are familiar assist systems because of their routine use in cardiopulmonary bypass. Although many different pump-head designs are available, they all work on the principle of generating a rotatory motion by virtue of moving blades, impellers, or concentric cones. These pumps generally can provide high flow rates with relatively modest increases in pressure. They require priming and deairing prior to use in the circuit, and the amount of flow generated is sensitive to outflow resistance and filling pressures. The differences in design of the various commercially available pump heads are in the numbers of impellers, the shape and angle of the blades, and the priming volume. The only exception is the Medtronic BioPump (Medtronic Bio-Medeicus, Inc., Eden Prairie, MN), which is based on two concentric cones generating the rotatory motion. The pump heads are disposable, relatively cheap to manufacture, and mounted on a magnetic motorized unit that generates the power. Despite design differences, in vitro and in vivo testing has shown no clear superiority of one pump over the other.[93–95] Although earlier designs caused mechanical trauma to the blood elements leading to excessive hemolysis, the newly engineered pumps are less traumatic and can be used for longer periods. Studies have documented that centrifugal pumps have a superior performance with regard to mechanical injury to red blood cells when compared with roller pumps.[96]

COMPLICATIONS: Complications with temporary mechanical assistance are high and very similar for patients on centrifugal pump support or ECLS (see below). The major complications reported by a voluntary registry for temporary circulatory assistance using primarily left ventricular, right ventricular, and biventricular assist devices (LVADs, RVADs, and BVADs) are bleeding, low cardiac output with BVADs, renal failure, infection, neurologic deficits, thrombosis and emboli, hemolysis, and technical problems (Table 18-2). The incidence of these complications in 1279 reported patients

Table 18–2.

Significance of Differences Between Prevalence of Complications among Circulatory Assist Devices

Complication	Centrifugal devices (%)	Pneumatic devices (%)	*p* Value
Bleeding/DIC	48.3	38.2	.002
BV failure/low CO	33.1	29.1	NS
Renal failure	30.7	37.2	.030
Infection	11.3	24.3	<.001
Neurologic	11.9	11.7	NS
Thrombus/emboli	9.6	12.9	NS
Hemolysis	5.1	10.4	< .001
Technical problems	3.6	7.4	.003

DIC = disseminated intravascular coagulopathy; BV = biventricular; CO = cardiac output; NS = no significance demonstrated.

differed significantly between continuous perfusion systems and pneumatically driven systems (see below) with respect to bleeding, renal failure, infection, and hemolysis. Neurologic deficits occurred in approximately 12% of patients, and in Golding's experience, noncerebral emboli occurred equally often.[97] Golding also found that 13% of patients also developed hepatic failure. An autopsy study found anatomic evidence of embolization in 63% of patients even though none had emboli detected clinically.[98]

Complications reported from the University of Missouri[99] in 91 patients who had undergone centrifugal mechanical support for postcardiotomy failure are also very similar, with 45% incidence of bleeding, 35% renal failure, 21% infection, and 4.4% thromboembolism. In addition, seal disruption between the pump head and the magnet is a common problem with prolonged support and will cause fluid accumulation in the magnet chamber. Therefore, inspection of the pumps every 12 hours is mandatory.

RESULTS: Although a meaningful comparison of results of centrifugal support from different institutions is not possible, in general, overall survival has been in the range of 21 to 41% (Table 18-3). The voluntary registry reported the experience with 604 LVADs, 168 RVADs, and 507 BVADs;

Table 18–3.

Review of Large Series in the Literature Reporting Outcomes of Centrifugal Mechanical Assistance in the Setting of Postcardiotomy Cardiac Failure

Reference	Patients (no.)	Biventricular (%)	Mean duration of support days (range)	Weaned (%)	Survived (%)
Noon[159]	141	16.3	3.8 (1–22)	54	22
Magovern[94]	77	46.8	2.2 (<1–7.7)	56	35
Joyce[101]	34	NR	NR	62	41
Curtis[99]	91	54.0	2.2 (<1–18)	46	21
Combined registry*	559	NR	NR	45	26

NR = not reported.

approximately 70% were with continuous-flow pumps and the remainder with pulsatile pumps.[1] There were no significant differences in the percentage of patients weaned from circulatory assistance or the percentage discharged from the hospital according to the type of perfusion circuitry. Overall, 45.7% of patients were weaned, and 25.3% were discharged from the hospital.[1] The registry also reports that long-term survival of patients weaned from circulatory support is 46% at 5 years.[1] Most of the mortality occurs in the hospital before discharge or within 5 months of discharge.

Golding reported an identical hospital survival rate for 91 patients in 1992 using only centrifugal pumps, and Noon reported that 21% of 129 patients were discharged.[97–100] Patients who received pulsatile circulatory assistance were supported significantly longer than those supported by centrifugal pumps, but there were no differences in the percentage of patients weaned or discharged.[1] Survivors were supported an average of 3.1 days using continuous-flow pumps. Patients supported for AMI did poorly; only 11.5% survived to be discharged.

Data from the University of Missouri Hospital are also very similar.[99] From the 91 patients with postcardiotomy heart failure, 46% were weaned from the device, and 21% survived to hospital discharge. Although weaning was more successful with RVAD support alone compared with LVAD or BVAD support (100% for RVAD versus 48.5% for LVAD versus 44.9% for BVAD), survivals were not significantly different (RVAD 22%, LVAD 24.3%, and BVAD 18.4%). Some reports have suggested improved results. Joyce reports that 42% of patients supported by Sarn impeller pumps eventually were discharged.[101] This is the highest reported survival and probably reflects the fact that some of these patients were transplanted.

Extracorporeal life support (ECLS/ECMO)

By the 1960s, it was clear that cardiopulmonary bypass was not suitable for patients requiring circulatory support for several days to weeks. The development of ECLS as a temporary assist device [also referred to as *extracorporeal membrane oxygenation* (ECMO)] is a direct extension of the principles of cardiopulmonary bypass and follows the pioneering efforts of Bartlett and colleagues in demonstrating the efficacy of this technology in neonatal respiratory distress syndrome.[102]

There are a number of key differences between cardiopulmonary bypass and ECLS. The most obvious difference is the duration of required support. Whereas cardiopulmonary bypass typically is employed for several hours during cardiac surgery, ECLS is designed for longer duration of support. With ECLS, lower doses of heparin are used, and reversal of heparin is not an issue. Moreover, because a continuous circuit is used, areas of stasis have been minimized (such as cardiotomy suction or venous reservoir). In addition, the membrane oxygenator used allows for longer duration of support. These differences are thought to reduce the inflammatory response and the more pronounced coagulopathy that can be seen with cardiopulmonary bypass.[86]

A typical ECLS circuit is demonstrated in Fig. 18-4. The system consists of the following:

1. *Hollow-fiber membrane oxygenator with an integrated heat-exchange system.* The microporous membrane provides the necessary gas-transfer capability via the micropores where there is direct blood-gas interface with minimal resistance to diffusion. By virtue of the membranes being close to each other, the diffusion distance has been reduced

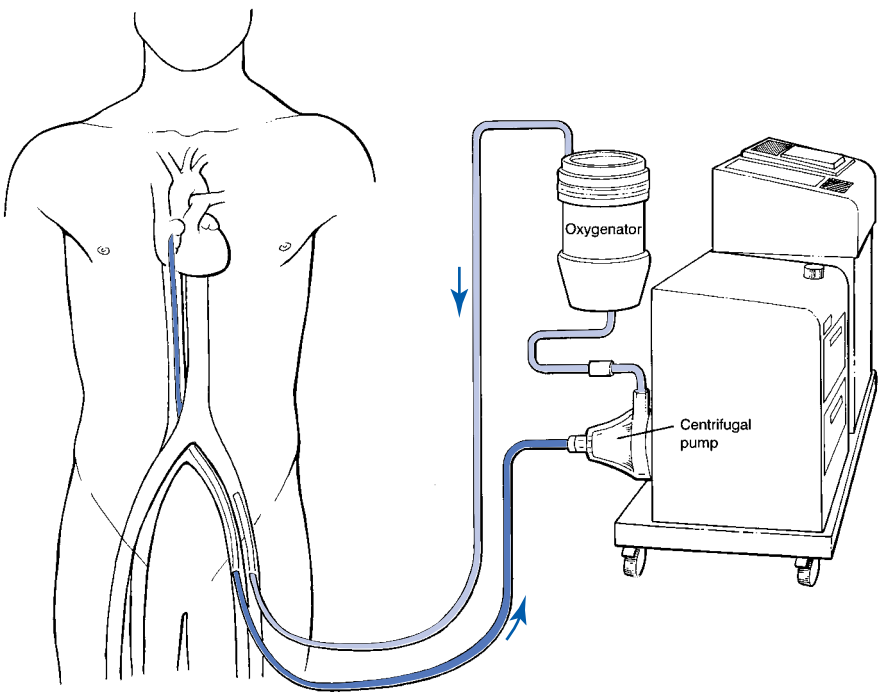

Figure 18-4. Percutaneous ECMO support is attained via femoral vessel access. Right atrial blood is drained via a catheter inserted into the femoral vein and advanced into the right atrium. Oxygenated blood is perfused retrograde via the femoral artery. Distal femoral artery perfusion is not illustrated.

without a significant pressure drop across the system.[104] Control of oxygenation and ventilation is relatively easy. Increasing the total gas flow rate increases CO_2 removal (increasing the "sweep") by reducing the gas-phase CO_2 partial pressure and promoting diffusion. Blood oxygenation is controlled simply by changing the fraction of O_2 in the gas supplied to the oxygenator.[103]

2. *Centrifugal pump.* These pumps are totally nonocclusive and afterload-dependent. An increase in downstream resistance, such as significant hypertension, will decrease forward flow to the body. Therefore, flow is not determined by rotational flow alone, and a flowmeter needs to be incorporated in the arterial outflow to quantitate the actual pump output. If the pump outflow should become occluded, the pump will not generate excessive pressure and will not rupture the arterial line. Similarly, the pump will not generate significant negative pressure if the inflow becomes occluded. This protects against cavitation and microembolus formation.
3. *Heat exchanger.* This allows for control of blood temperature as it passes through the extracorporeal circuit. Generally, the transfer of energy occurs by circulating nonsterile water in a countercurrent fashion against the circulating blood. Use of water as the heat-exchange medium provides an even temperature across the surface of the heat exchanger without localized hot spots.[103]
4. *Circuitry interfaced between the patient and the system.* The need for systemic anticoagulation on ECLS and the complications associated with massive coagulopathy and persistent bleeding during the postcardiotomy period lead to the development of biocompatible heparin-bonded bypass circuits. In 1991, the Carmeda Corporation in Stockholm, Sweden, released a heparin-coating process that could be used to produce an antithrombotic surface.[104] This process was applied to extracorporeal tubing and the hollow-fiber microporous oxygenator surface.[105] Initial experience suggested that the need for systemic anticoagulation had been eliminated. In addition, heparin coating has been associated with a decrease in the inflammatory response with reduced granulocyte[106] and complement activation.[107] Bindsler[108] and Mottaghy[109] reported excellent hemodynamic support with minimal postoperative blood loss in experimental animals for up to 5 days. Magovern and Aranki reported similar excellent results with clinical application.[110,111] Although these heparin-bonded circuits were thought initially to completely eliminate the need for heparinization, thrombus formation without anticoagulation remains a persistent problem. In a study of 30 adult patients with cardiogenic shock who underwent ECLS using the heparin-bonded circuits and no systemic anticoagulation, 20% of patients developed left ventricular thrombus by transesophageal echocardiography, and an additional 6% had visible clot in the pump head.[112] Protamine administration after starting ECLS can precipitate intracardiac clot. If the left ventricle does not eject and blood remains static within the ventricle, clot formation is more likely. Intracavity clot is more likely in patients with MI owing to expression of tissue factor by the injured cells. Protamine may bind to the heparinized coating of the new circuit and negate an anticoagulant effect.[113]

CANNULATION: A key difference between the centrifugal pump and ECLS is the presence of an in-line oxygenator. As a result, ECLS can be used for biventricular support by using central or peripheral cannulation. Intraoperatively, the most common application of ECLS has been for patients who cannot be weaned from cardiopulmonary bypass after heart surgery. In these cases, the existing right atrial and aortic cannulas can be used. An alternative strategy is to convert the system to peripheral cannulas, which potentially permits later decannulation without opening the chest.

The cannulation is done by surgical cutdown in the groin for exposure of the common femoral artery and vein. The entire vessel does not need to be mobilized, and exposure of the anterior surface of the vessels would suffice. A purse-string suture is placed over the anterior surface of the vessel. The largest cannula that the vessel can accommodate is selected. Typically, arterial cannulas are 16F to 20F and venous cannulas are 18F to 28F in size. The cannulation is performed under direct vision using Seldinger's technique. A stab incision is made in the skin with a no. 11 blade knife, a needle is inserted through the stab incision into the vessel, and a guidewire is advanced gently. Dilators then are passed sequentially to gently dilate the tract and the insertion point in the vessel. The cannulas then are inserted, the guidewire is removed, and a clamp is applied. For venous drainage, a long two-stage cannula (Fem-Flex II, Research Medical, Inc., Midvale, UT) is directed into the femoral vein to the level of the right atrium under transesophageal echocardiographic guidance.

To minimize limb complications from ischemia, one strategy is to place a 10F perfusion cannula in the superficial femoral artery distal to the primary arterial inflow cannula to perfuse the leg (Fig. 18-5). This cannula is connected to a tubing circuit that is spliced into the arterial circuit with a Y-connector.[114] The distal cannula directs continuous flow into the leg and significantly reduces problems with leg ischemia. An alternative strategy is to completely mobilize the common femoral artery and sew a 6 or 8 mm short Dacron graft to its anterior surface as a "chimney." The graft serves as the conduit for the arterial cannula, and no obstruction to distal flow exists. This strategy also allows for a more secure connection and avoids problems with inadvertent dislodgment of the cannulas because of loosening of the purse strings. In general,

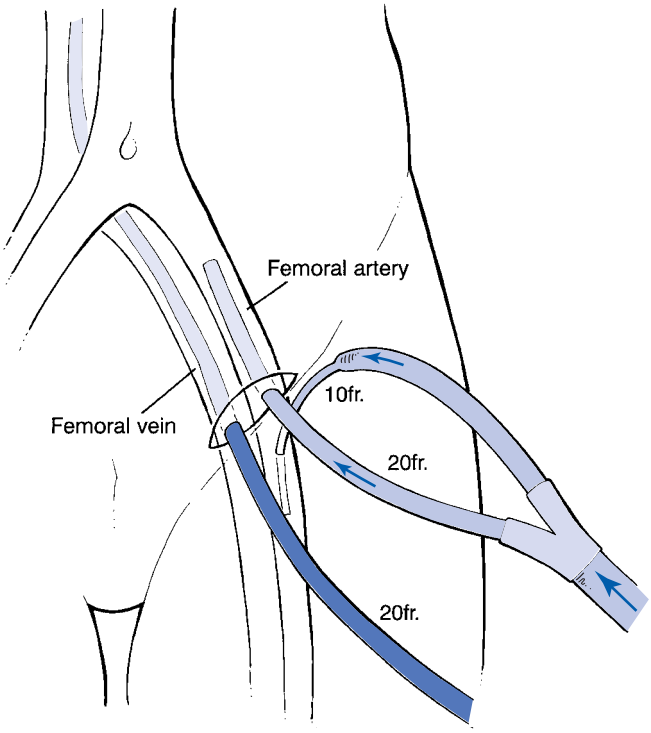

Figure 18-5. Surgical exposure of the femoral vessels facilitates cannulation for ECMO. A small 10F cannula is used to perfuse the distal femoral artery.

complete percutaneous placement of arterial cannulas is avoided to prevent iatrogenic injury during insertion and ensure proper positioning of the cannula. However, when venovenous bypass is the only mode of support needed, percutaneous cannulation is performed. Surgical exposure is not necessary, and bleeding is less with this technique. Although traditionally the perfusion circuit involves atrial drainage and femoral reinfusion (atriofemoral flow), a recent prospective study has shown the reverse circuit (femoroatrial flow) to provide higher maximal extracorporeal flow and higher pulmonary arterial mixed venous oxygenation.[115]

Central cannulation sometimes is indicated because of either severe peripheral vascular disease or the desire to deliver the highly oxygenated blood directly to the coronary arteries and the cerebral circulation. In patients with an open chest, aortic and right atrial cannulas are used. Reinforcing purse-string sutures are placed and tied over rubber chokers and buttons for later tying at decannulation. The catheters are brought through the chest wall through separate stab wounds, and after bleeding is secured, the chest is covered, but not closed, over mediastinal drainage tubes.[92]

An alternative central cannulation site is the axillary artery. Direct cannulation of this artery has been associated with progressive edema of the arm.[116] Therefore, the best strategy to maintain arm perfusion is to expose the axillary artery and sew a 6 or 8 mm graft to the vessel as a "chimney." The cannula then is place in the graft and tied securely with several circumferential umbilical tapes.

Once instituted, the system is simple enough to be monitored by trained ICU nurses and maintained by a perfusionist on a daily basis. Evidence of clots in the pump head requires a change. Leakage of plasma across the membrane from the blood phase to the gas phase continues to be a problem, gradually decreasing the efficiency of the oxygenator and increasing resistance to flow and necessitating oxygenator exchanges. Using this system, ECLS flows of 4 to 6 L/min are possible at pump speeds of 3000 to 3200 rpm. Higher pump speeds are avoided to minimize mechanical trauma to blood cells. Other means of improving flow include transfusion of blood, crystalloid, or other colloid solutions to increase the overall circulating volume. Physiologically, ECLS will unload the right ventricle but will not unload the ejecting left ventricle, even though left ventricular preload is reduced.[117] In normal hearts, the marked reduction in preload and small increase in afterload produced by the arterial inflow from the ECLS system reduces wall stress and produces smaller end-diastolic left ventricular volumes because the heart is able to eject the blood it receives. However, if the heart is dilated and poorly contracting, the marked increase in afterload provided by the ECLS system offsets any change in end-diastolic left ventricular volume produced by bypassing the heart. The heart remains dilated because the left ventricle cannot eject sufficient volume against the increased afterload to reduce either end-diastolic or end-systolic volume. ECLS, therefore, theoretically may increase left ventricular wall stress and myocardial oxygen consumption unless an IABP or other means is used to unload the left ventricle mechanically and reduce left ventricular wall stress.[119] We routinely use IABP in the majority of patients to decrease the increased afterload imposed by ECLS and add pulsatility to the continuous flow generated by the centrifugal pump. Kolobow has devised a spring-loaded catheter introduced through the femoral vein to render the pulmonary valve incompetent to decompress the left ventricle during ECLS, but this has not been used clinically.[118] Others use atrial septostomy to decompress the left ventricle if the pulmonary artery pressures remain elevated.[119]

As mentioned previously, the versatility of ECLS is that it allows rapid restoration of circulation by peripheral cannulation during active resuscitation in the setting of acute cardiac arrest, acute pulmonary embolism, or patients in cardiogenic shock who cannot be moved safely to the operating room. It is also used occasionally in the catheterization laboratory to support high-risk procedures. More recently, ECLS has been used to support some minimally invasive cardiac operations.

An isolated RVAD is rarely indicated in the postcardiotomy setting because, in general, these patients have global biventricular dysfunction. ECLS as an RVAD (with outflow to the pulmonary artery via the right ventricular outflow tract) may be used only in patients with good function of the left ventricle. Exclusive right ventricular dysfunction is rare but may occur if retrograde cardioplegia is used and fails to protect the right ventricle, in cases of pulmonary

thromboendarterectomy, or in patients with right ventricular infarction. Note that if significant pulmonary hypertension is present, this configuration may not load the left ventricle adequately.

COMPLICATIONS: The experience in adults with ECMO for postoperative cardiogenic shock is more limited because of nearly universal bleeding problems associated with the chest wound in combination with heparin anticoagulation with the ECMO circuit.[120] Pennington reported massive bleeding in six of six adults supported by ECMO following cardiac surgery. Even without the chest wound, bleeding was the major complication in a large study of long-term ECMO for acute respiratory insufficiency.[121] Muehrcke reported experience with ECMO using heparin-coated circuitry with no or minimal heparin.[122] The incidence of reexploration was 52% in the Cleveland Clinic experience; transfusions averaged 43 units of packed cells, 59 units of platelets, 51 units of cryoprecipitate, and 10 units of fresh-frozen plasma. Magovern reported somewhat less use of blood products but treated persistent bleeding by replacement therapy and did not observe evidence of intravascular clots; two patients developed stroke after perfusion stopped. Other important complications associated with ECMO using heparin-coated circuits included renal failure requiring dialysis (47%), bacteremia or mediastinitis (23%), stroke (10%), leg ischemia (70%), oxygenator failure requiring change (43%), and pump change (13%).[118] Nine of 21 patients with leg ischemia required thrombectomy and one amputation. Half the patients developed marked left ventricular dilatation, and six patients developed intracardiac clot detected by TEE.[90] Intracardiac thrombus may form within a poorly contracting, nonejecting left ventricle or atrium because little blood reaches the left atrium with good right atrial drainage.[40,82,89,108] We have observed intracardiac thrombus in heparinized patients and those perfused with pulsatile devices and a left atrial drainage cannula. The problem, therefore, is not unique to ECMO or the location of the left-sided drainage catheter but is related to LVF. In patients on ECMO with a left ventricular thrombus, we have removed the thrombus at the time a HeartMate LVAD was implanted for a bridge to transplantation.[122]

More recent reports demonstrate that the high incidence of complications using ECLS has continued to plague temporary support mechanisms based on continuous flow. Kasirajan reported an 18.9% incidence of intracranial hemorrhage, with female gender, heparin use, elevated creatinine, need for dialysis, and thrombocytopenia being important associated risk factors.[123] Smedira recently reported on 107 postcardiotomy patients supported on ECLS, with a 48% infection, 39% need for dialysis, 29% neurologic events, 5% pump thrombus formation, and 27% limb complications.[124]

RESULTS: Table 18-4 summarizes some of the reported results with ECLS for postcardiotomy circulatory support. Magovern reported improved results in 14 patients supported by a heparin-coated ECMO circuit after operations for myocardial revascularization.[117] Eleven of 14 patients (79%) with revascularization survived, but none of three patients with mitral valve surgery and none of four patients who underwent elective circulatory arrest survived. Overall, 52% of the whole group survived, but two patients developed post-perfusion strokes that probably were the result of thrombi produced during perfusion. Although the Cleveland Clinic experience with heparin-coated ECLS circuits produced a survival rate of 30%, the patient population was more diversified and represented only 0.38% of cardiac operations done during the same time period.[112] In a recent report on 82 adult patients supported with ECMO for a variety of indications, survival for postcardiotomy was 36%, whereas none of the patients who had acute cardiac resuscitation survived, and survival for cardiac allograft failure was 50%.[125]

More recently, the Cleveland Clinic reported their results looking at 202 adults with cardiac failure.[85] With an extended follow-up up to 7.5 years (mean 3.8 years), survival was reported to be 76% at 3 days, 38% at 30 days, and 24% at 5 years. Patients surviving 30 days had a 63% chance of being

Table 18–4.

Representative Clinical Trials Evaluating Extracorporeal Membrane Oxygenation for the Treatment of Postcardiotomy Cardiogenic Shock

Reference	Patients (no.)	Duration of support (range)	Weaned from device, no. (%)	Survived to hospital discharge, no. (%)
Magovern[117]	21	9–92 h	16 (76)	1 (52)
Wang[160]	18	7–456 h	10 (55)	6 (33)
Muehrcke[122]	23	0.5–144 h	9 (39)	7 (30)
Magovern[161]	55	8–137 h	36 (65)	20 (36)

alive at 5 years, demonstrating that the high early mortality remains the Achilles heal of this technology. Interestingly, patients who were weaned or bridged to transplantation had a higher overall survival (40 and 45%, respectively). Failure to wean or bridge was secondary to end-organ dysfunction and included renal and hepatic failure and occurrence of a neurologic event while on support.[85] Another report from the Cleveland Clinic looking at 19,985 patients undergoing cardiac operations found that 107 (0.5%) required ECLS for postcardiotomy failure. Younger age, number of reoperations, emergency operations, higher creatinine concentration, greater left ventricular dysfunction (LVD), and history of MI were significant predictors of the need for mechanical support.[124] Although overall survival was 35%, in the subgroup bridged to a chronic implantable device, system survival was 72% (see below for bridge-to-bridge experience).

Pulsatile Pumps

Abiomed BVS 5000/AB5000

The ABIOMED BVS 5000 blood pump is an extracorporeal device designed to provide pulsatile univentricular or biventricular support. In 1992, it became the first such device to receive FDA approval. It has been used in Europe and the United States for the purpose of postcardiotomy pump failure, with more than 2400 patients currently reported to the registry. The system is a simple, user-friendly extracorporeal pulsatile pump that is available in over 450 centers in the United States. The pump is configured as a dual-chamber device containing both an atrial chamber and a ventricular chamber that pumps the blood pneumatically to the outflow cannula (Fig. 18-6). The two chambers and the outflow tract are divided by trileaflet polyurethane valves that allow for unidirectional blood flow.

The pump chamber itself consists of a collapsible polyurethane bladder with a capacity of 100 mL. With the BVS 5000 and BVS 5000i consoles, filling of the atrial chamber depends on gravity (the height of the chamber relative to the patient's atrium), the central venous pressure (preload), and the central venous capacitance. The atrial bladder operates in a fill-to-empty mode and therefore can be affected by changes in the height of the pump relative to the patient or the volume status of the patient. The pump usually is set approximately 25 cm below the bed. The adequacy of filling can be assessed visually because the pump is transparent. The passive filling (absence of negative-pressure generation)

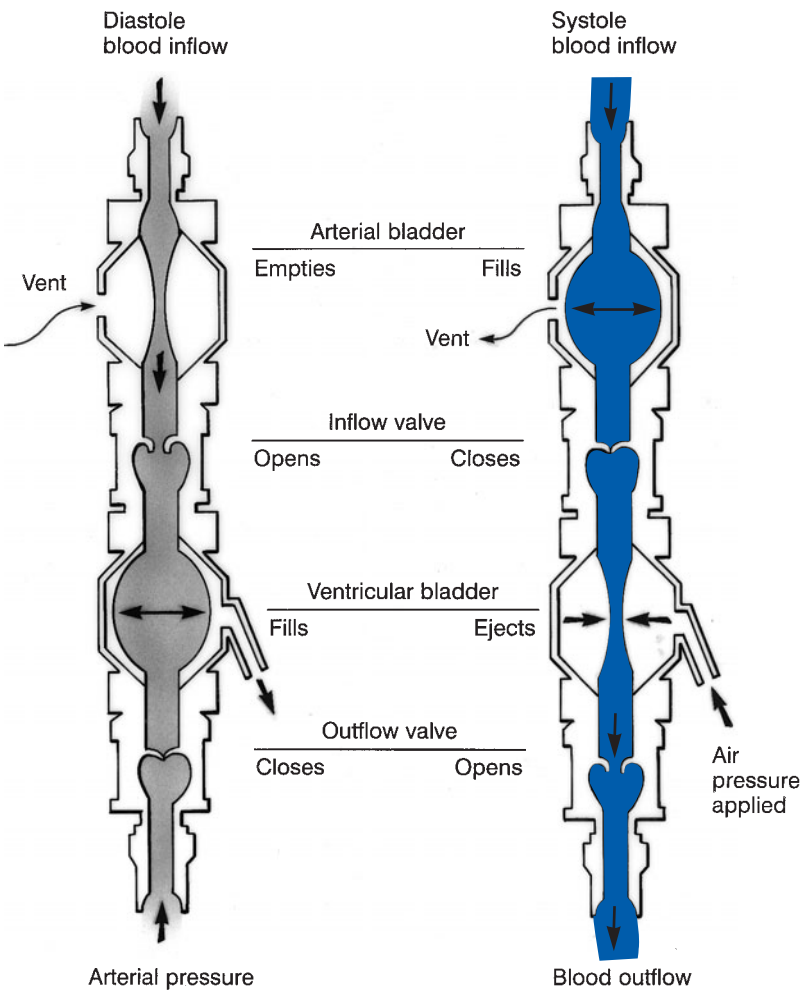

Figure 18-6. The ABIOMED BVS 5000. (*Left*) The atrial chamber empties through a one-way valve into the ventricular chamber (diastole). (*Right*) The pneumatically driven pump compresses the ventricular chamber, and blood flows through a one-way valve into the patient (systole). During pump systole, the atrial chamber fills by gravity.

is designed to prevent atrial collapse with each pump cycle as well as to prevent suctioning of air into the circuitry.

The ventricular chamber requires active pulsatile pumping by a pneumatic driveline. Compressed air is delivered to the chamber, causing bladder collapse and forcing blood out of the pump to the patient. During diastole, the air is vented to the atmosphere, allowing refilling of the chamber during the next cycle. The rate of pumping and the duration of pump systole and diastole are adjusted by the pump microprocessor that operates asynchronous to the native heart rate. The pump makes adjustments automatically to account for preload and afterload changes and delivers a constant stroke volume of approximately 80 mL. The maximum output is approximately 5 to 6 L/min with the BVS 5000i console. This design requires minimal input by personnel except during periods of weaning. Medical management should include optimizing the patient's hydration status and outflow resistance because the pump's performance depends on these parameters.

The main advantage of this device is the ability to provide independent univentricular or biventricular support as needed. The device has not demonstrated any significant hemolysis, and the pulsatile flow may have some degree of physiologic benefit. As opposed to the centrifugal pump and ECLS, patients can be extubated and can have limited mobility, such as transfer from bed to chair or dangling of the legs from the bed.

The AB5000 circulatory support system, introduced in 2004, consists of the pneumatically driven ABIOMED ventricle and an updated smaller console. The AB5000 console is easily portable and uses vacuum-assisted drainage and can drive both the standard blood pump, or "heart on a stick," and the newer ABIOMED ventricle. The ventricle is designed for short to intermediate (<3 months) support and incorporates many of the features of the ABIOCOR total artificial heart. It is driven pneumatically with valves that are constructed of Angioflex, ABIOMED's proprietary polyether-based polyurethane plastic. The AB5000 system uses the same cannulas as the BVS 5000 system. Inflow cannulas can be configured for atrial or ventricular placement. Perhaps the most attractive aspect of the upgraded system is that bedside conversion from the "heart on the stick" to the ventricle is made possible by quick-connect attachments. As such, patients implanted with a BVS 5000 system at an outlying hospital can be converted to the more long-term ventricle at the receiving institution without reopening the patient's chest or going on bypass. This makes for a very versatile and flexible system.

Another attractive option of the ABIOMED mechanical support system is the ease with which it can be placed without cardiopulmonary bypass. While off-pump placement of other ventricular assist systems has been described, they are cumbersome and are not used routinely. Off-pump insertion of the ABIOMED is facilitated by its small, flexible cannulas. The ability to avoid cardiopulmonary bypass is a distinct advantage in patients suffering cardiogenic shock. However, the combination of the high vacuum setting and smaller cannula size can lead to hemolysis.[125] Optimal cannula placement without chamber collapse or a high-velocity jet at the inflow cannula tip must be confirmed by transesophageal echocardiography prior to leaving the operating room. Anticoagulation to an activated clotting time (ACT) of 200 s should be started as soon as chest tube drainage is less than 50 mL/h for 4 hours.

CANNULATION: ABIOMED cannulas are constructed from polyvinyl chloride and have a velour body sleeve that is tunneled subcutaneously. Three sizes of wire-reinforced inflow cannulas are available commercially. These include malleable 32F, 36F, and 42F cannulas. Arterial cannulas have a precoated Dacron graft attached. They are available in two sizes and are sewn in an end-to-side fashion: a 10 mm graft for anastomosis to the smaller and lower-resistance pulmonary artery and a 12 mm graft for anastomosis to the ascending aorta.

Careful cannula insertion is important for optimal performance. Venous inflow must be unimpeded, and outflow grafts must not be kinked. In addition, careful consideration must be given to cannula position when bypass grafts cross the epicardial surface of the heart. Depending on the location of these grafts, these cannulas must be placed such that graft compression cannot occur. The three-dimensional layout of this geometry needs to be visualized and thought out in advance, particularly if chest closure is planned. Any graft compression will make recovery unlikely.

It is technically much easier to use cardiopulmonary bypass for placement of these cannulas, although off-pump insertion is possible and may be preferable in certain clinical situations, particularly for isolated right-sided support.[126] A side-biting clamp typically is used on the aorta to perform the outflow anastomosis. If the patient is on cardiopulmonary bypass, the pulmonary artery anastomosis can be done without the need of a partial cross-clamp. The length of the graft is measured from the anticipated skin exit site to the site of anastomosis, and the Dacron graft is cut to an appropriate length such that there is no excessive tension or any kinking. The cutaneous exit site is planned so that approximately 2 cm of the velour cuff extends from the skin and the remainder is in the subcutaneous tunnel. The cannula is not tunneled subcutaneously until after completion of the anastomosis. For the aortic anastomosis, incorporation of a Teflon or pericardial strip helps to control suture-line bleeding. (In addition, RVAD placement can be performed without the need for cardiopulmonary bypass. If this technique is used, the cannula must be externalized from the skin prior to insertion into the pulmonary artery.

For inflow cannulation, a double-pledgeted purse-string suture using 3-0 polypropylene is placed concentrically for cannula placement. Tourniquets must be secured firmly to prevent inadvertent loosening of the purse-string suture and bleeding from the insertion sites. In addition, the heart generally is volume loaded to prevent air embolism during insertion.

For right-sided support, the 42F cannula is used for drainage from the midatrial wall with the cannula directed to the inferior vena cava. For left-sided drainage, several options are available. The 36F malleable cannula is used because it provides the versatility to accommodate variations in anatomy and clinical conditions. Left atrial cannulation can be achieved via the interatrial groove, the dome of the left atrium, or the left atrial appendage. Alternatively, the body of the right ventricle or the left ventricular apex may be cannulated.[127] There is no need to excise a core of the ventricular apical muscle, as is common with other ventricular assist devices.[128] Ventricular cannulation offers the advantages of excellent ventricular decompression, which may improve ventricular recovery,[129] but bleeding from around the cannula also may become a problem, particularly in the setting of recent MI.

One of the advantages of the ABIOMED is that the perfusionist can prepare and de-air the circuit while the cannulas are being placed. Connecting the cannulas to the externalized circuit is easy and can be done expeditiously.

The consoles for both the BVS 5000i and AB5000 are simple to operate. The control system automatically adjusts the duration of pump diastole and systole primarily in response to changes in preload. Pump rate and flow are visible on the display monitor. With the AB5000, console vacuum is adjusted to the lowest possible setting that provides adequate flow. As further testament to the versatility of this system, the addition of an oxygenator to the RVAD has been described,[130] and this can be invaluable in the management of patients with concomitant lung failure after bypass.

COMPLICATIONS: As with all patients who require postcardiotomy mechanical support, complications are frequent. Guyton[131] reported 75% bleeding complications, 54% respiratory failure, 52% renal failure, and 26% permanent neurologic deficit. Infection occurred in 13 patients (28%) while on the device, but only three cases were considered device-related. Other complications included embolism in 13% and hemolysis in 17% and mechanical problems related to the atrial cannula site in 13% of patients.[124] No major changes in platelet count or blood chemistries occur during the period of circulatory support.

Jett and colleagues[127] reported on 55 patients supported on the ABIOMED for a variety of indications, including postcardiotomy failure (28), failed transplant allograft (8), AMI (2), and myocarditis (1). They reported a 40% incidence of bleeding, 50% respiratory complications, and 25% neurologic complications. Marelli[126] also reported a similar incidence of complications in 19 status I patients, with three developing renal failure, nine re-explored for bleeding, and three dying of sepsis and multisystem organ failure. As with all acute mechanical support systems, these relatively high complication rates are a reflection of the significant pre-existing hemodynamic insult that occurs necessitating implementation of mechanical support. Early device insertion should be considered and may improve overall outcome.[87]

RESULTS: The ABIOMED system is available in over 500 U.S centers, with over 6000 patients supported to date. Results from several reports have been summarized in Table 18-5. In a multicenter study, Guyton[131] reported that 55% of postcardiotomy patients were weaned from support and 29% were discharged from the hospital. However, 47% of patients who had not experienced cardiac arrest before being placed on circulatory support were discharged. Of 14 patients who had presupport cardiac arrest, only one (7%) was discharged. In another report of 500 patients treated with the BVS 5000 system that included 265 (53%) who could not be weaned from cardiopulmonary bypass, 27% of patients were discharged from the hospital.[132] Recent data using this device in a wide range of clinical situations, including postcardiotomy failure, have indicated successful wean of 83% and discharge to home of 45% of patients.[133] These excellent results are also reported by Marelli[126] in 14 of 19 patients who were weaned

Table 18–5.

Clinical Experience with ABIOMED Support for Postcardiotomy Cardiogenic Shock

Reference	Patients (no.)	Biventricular support (%)	Mean duration of support (days)	Weaned, no. (%)	Discharged, no. (%)

or transplanted with a 1-year survival of 79%. Korfer[133] also recently reported 50% hospital discharge in 50 postcardiotomy patients supported with the ABIOMED and 7 of 14 patients transplanted with a 1-year survival of 86%. The ABIOMED worldwide registry experience suggests that better results can be expected from experienced centers with heart transplant programs.[134] In fact, early transfer of patients from smaller facilities (the "spokes") to transplant centers (the "hub") has been shown to result in improved overall survival.[6]

Thoratec ventricular assist device

The Thoratec VAD (Thoratec Laboratories Corp., Berkeley, CA) was introduced clinically in 1976 under an investigational device exemption (IDE) and was approved as a bridge to heart transplantation in 1996. Although it was first used clinically for postcardiotomy support in 1982, it has been approved only recently for use as a temporary cardiac assist device. As such, it is the only device currently available that bridges the gap between short- and long-term devices. The advantage of this concept is that it allows the device to be implanted initially with the intent of myocardial recovery, particularly in the postcardiotomy heart failure setting. If myocardial recovery does not occur, then the device can be used long-term until a suitable heart becomes available for transplantation. Although this concept is desirable and offers the advantage of avoiding a second operation for transitioning from a temporary support device (bridge to bridge) to a more chronic device (see below), it comes at increased expense (because of the higher price of the pumps) and also can create ethical dilemmas if the patient recovers but ends up not being a transplant candidate.

The device is a pneumatically driven pulsatile pump that contains two seamless polyurethane bladders within a rigid housing.[135] The inlet and outlet ports contain monostrut tilting-disk valves to provide unidirectional flow. The effective stroke volume of each prosthetic ventricle is 65 mL. The pneumatic drive console applies alternating negative and positive pressures to fill and empty each prosthetic bladder. Driveline vacuum and positive pressures can be adjusted to improve filling and systemic arterial pressure. The pump eject time (equivalent of ventricular systole) also can be adjusted depending on preload and afterload conditions. One or both pumps may be used to provide univentricular (LVAD or RVAD) or biventricular support (BVAD).

The prosthetic ventricles are placed on the upper abdomen and are connected to the heart and great vessels by large-bore, wire-wrapped polyurethane cannulas that traverse the chest wall.[136,137] The cannulas are connected to a large console via pneumatic drivelines. The pumps can be operated in three control modes. The fixed-rate mode operates independently of the patient's heart, and the rate is set by the operator. In the external synchronous mode, the pump empties when triggered by the patient's R wave on the electrocardiogram. The usual mode for most patients is the fill-to-empty mode, in which ejection occurs when the device senses that the prosthetic ventricle is filled. In this volume mode, heart rate is determined by the rate of prosthetic ventricular filling.

Thoratec pumps reside on the upper abdominal wall and are connected to a large, wheeled console containing compressed-air tanks. A smaller, more portable TLCII driver is also available.

CANNULATION: Device implantation typically is performed on cardiopulmonary bypass. Recently, a method has been described for off-pump insertion as an RAVD.[138] As with the ABIOMED, it is important to select the cannula position and cutaneous exit sites carefully. The pump should be planned to rest on the anterior abdominal wall. Lateral placement may lead to excessive tension at the skin exit sites and prevent formation of a seal. Approximately 1.5 to 2 cm of the felt covering of the cannulas must extend beyond the skin exit site, with the remainder in the subcutaneous tunnel to promote ingrowth of tissue and create a seal. The length of the cannulas extending out must be adjusted based on the length of the atrial cannula (if one is used). The end of the atrial cannula widens out to connect to the inflow port of the device and therefore cannot be trimmed. On the other hand, ventricular or outflow cannulas can be trimmed to adjust the length. For optimal connection to the pump, the inflow and outflow cannula exit sites should be 4 cm apart.

The outflow cannula generally is attached first. The arterial cannulas are available with a 14 mm Dacron graft (for the pulmonary artery) or an 18 mm Dacron graft (for the aorta) and must be cut to length after the appropriate exit site has been selected. They come in two lengths, 15 and 18 cm, which again are selected based on the patient's anatomy and the planned exit site. The graft is generally sewn on the aorta or pulmonary artery after applying a partial-occluding clamp and sewn with 4-0 polypropylene suture with or without a strip of pericardium or Teflon felt for reinforcement. Inflow can be accomplished by cannulation of the atria or the ventricles.[139] All cannulations generally are reinforced with a double layer of pledgeted concentric purse-string sutures. For atrial cannulation, a 51F right-angled cannula is available in two lengths, 25 and 30 cm. For the left atrium, the cannula is inserted through the atrial appendage, the interatrial groove, or the superior dome of the left atrium. For right atrial cannulation, the cannula is inserted into the midright atrial wall and directed toward the inferior vena cava. If this cannula is inserted toward the tricuspid valve, the leaflets may interfere with proper inflow because they get sucked into the cannula during negative pressure. In addition, if the tip is not advanced to reside properly in the right atrium, negative pressure intermittently can cause the compliant right atrial wall to collapse around the cannula and interfere with proper filling of the pump.

An alternative approach can use the ventricles for inflow cannulation.[139] This provides better drainage,

higher flows, and perhaps improves the chance of myocardial recovery. This is achieved by placing a concentric layer of pledgeted horizontal mattress sutures at the apex of the left ventricle or the acute margin of the right ventricle (superior to the posterior descending artery). The cannulas used for this purpose can be either the blunt-tip 27 cm straight ventricular tube or the smooth-tipped, beveled 20 cm ventricular tube. The previously placed sutures are passed sequentially through the cuff, the apex of the heart is elevated, and the mean arterial pressure at the aorta is maintained at over 70 mm Hg to prevent air embolization during cannula insertion. Either a core of tissue is removed or a cruciate incision is made with care not to cut any of the mattress sutures. The cannula then is inserted and secured by tying the sutures. The free end can then be directed out through the previously planned cutaneous exit site, and a tubing clamp is placed on it.

INITIATION OF SUPPORT: Connecting the cannulas to the pump is difficult and must be done with care. The connections to the pump have a sharp, beveled edge that should be directed carefully under gentle pressure to fit the cannulas without damaging the inner surface of the tube. In addition, if this tip bends, it may provide a nidus for thrombus formation. The inflow cannula typically is connected first. Prior to connecting the outflow cannula, a purse-string suture is placed on the outflow Dacron graft, and a 5F to 7F vascular catheter with an aspiration port is introduced through it and directed into the pump chamber through the outflow valve. This maneuver is critical because de-airing can be difficult as a result of the way the pump sits on the abdomen. The outflow cannula then is connected. Prior to releasing the tubing clamps and flooding the chamber with blood, the air in the chamber is aspirated. Once all the air is evacuated, the de-airing catheter and the inflow tubing clamp are removed, allowing the chamber to fill with blood. Then gentle hand pumping can be performed to ensure complete air evacuation through the opening in the Dacron graft prior to removing the outflow tubing clamp.

Bypass flow is reduced before starting the pump. This ensures complete filling of the chambers to minimize the possibility of air being introduced into the circuit by the negative pressure of the pump. If a BVAD is in place, we start the LVAD first and then the RVAD. The pump is begun in the fixed-rate mode, and negative pressure is set low at –5 to –10 mm Hg. The inflow sites also should be covered with saline. Driveline pressure and systolic duration can be adjusted to optimize pump flows. Additional refinements can be made once the chest is closed.

COMPLICATIONS: The complications reported for patients bridged to transplantation are similar to those reported for postcardiotomy patients. In a multicenter trial, the most common complications were bleeding in 42%, renal failure in 36%, infection in 36%, neurologic events in 22%, and multisystem organ failure in 16% of patients.[135] Similar complications have been reported from other centers.[135,140,141]

RESULTS: Most temporary use of the Thoratec VAD is for postcardiotomy patients, but the device also has been used for patients after MI and during cardiac transplant rejection.[135,140,141] The Thoratec pump also has been used to support a patient with myocarditis who eventually recovered adequate native heart function.[142] After cardiotomy, results are similar to those obtained with continuous-flow devices and the ABIOMED BVS 5000. In a review of 145 patients with nonbridge use of the Thoratec device, 37% were weaned, and 21% were discharged.[71] More experienced centers have achieved hospital survival rates of over 40%.[140,141] Renal failure and MI are poor prognostic events for survival.[131]

The Thoratec premarket approval experience (Table 18-6) for the treatment of 53 patients with postcardiotomy heart failure had an in-hospital survival of 28%. The majority of these patients were supported with a BVAD. The Bad Oeynhausen group, however, has reported a 60% survival for postcardiotomy patients supported with the Thoratec device.[140] Clearly, the greatest advantage that the Thoratec device offers is that it can be applied for longer duration of support than any other temporary device mentioned previously. This feature may be uniquely advantageous, particularly because the duration of support necessary is usually unclear in advance. All other devices mentioned have an increasing complication rate with longer duration of support. Furthermore, the Thoratec device allows for physical rehabilitation and ambulation of the patients during the recovery period.

Newer devices

TANDEMHEART: The TandemHeart PTVA (percutaneous ventricular assist) System (CardiacAssist, Inc. Pittsburgh, PA) is a percutaneously deployed ventricular assist device that recently has received 510k FDA approval for short-term (<6 hours) support. The device is powered by a small hydrodynamic centrifugal pump that resides in a paracorporeal location. The rotor of the pump is suspended and lubricated by a fluid interface of heparinized saline. Cannulas are introduced from the femoral vessels by either percutaneous or direct insertion techniques. The inflow cannula is designed to be directed across the atrial septum to allow for left atrial decompression. The device can be introduced either in the catheterization laboratory using fluoroscopy or directly in the operating room using TEE guideance. Most of the experience with the device has been in the catheterization laboratory, where it has been used extensively to facilitate high-risk percutaneous interventions.[143] Flows of up to 4 L are reported. Patients with this device are bed-bound, given that the device is inserted through the femoral vessels. Patients also receive a moderate amount of heparin because the pump is hydrodynamic in design. It is

a very versatile system that can be deployed and discontinued rapidly. One beneficial aspect for postcardiotomy support is that the entire device can be removed in the ICU without reopening the patient's chest.[144] RVAD configurations with the outflow cannulas directed into the main pulmonary artery also have been described.

LEVITRONIX CENTRIMAG: The Levitronix CentriMag pump is a magnetically levitated paracorporeal ventricular assist device that is designed for postcardiotomy support.[145] It is capable of providing over 9 L of support. It is available commercially in Europe, but at the time of this writing, its use in the United States is investigational only. Very little friction is generated by its impeller, which is suspended magnetically, and it requires only a very small priming volume. It can be configured for both right- and left-sided heart support with pre-existing cannulas inserted directly through the chest. Careful ambulation is possible.

CANCION: The Cancion pump (Orqis Medical) is another magnetically levitated rotary pump currently undergoing testing in the MOMENTUM trial for patients with decompensated heart failure. It is not intended as full support but rather to augment renal blood flow. Designed to be used on an intermittent basis, the goal of therapy is to break the neurohormonal cycle of heart failure. Inflow consists of a percutaneously placed cannula that is directed into the iliac artery. Pump outflow is directed into the descending aorta by another catheter inserted from the contralateral femoral artery. Studies have shown improvements both in hemodynamic parameters and in the neurohormonal axis of heart failure patients.[146]

IMPELLA: The Impella pump has been acquired recently by ABIOMED and is being marketed as the Impella Recover system.[146] The device is a microaxial pump, with both peripheral or central cannulation configurations available. In either case, the pump is directed across the aortic valve into the left ventricle. Flows of up to 6 L are reported. A right ventricular support device also has been developed. An FDA-approved clinical trial has been approved recently for the percutaneous pump capable of flows of 2.5 L.

BRIDGE-TO-BRIDGE/HEART TRANSPLANTATION

The *bridge-to-bridge strategy* refers to the use of one of the short-term support systems to potentially stabilize a moribund patient to allow for the institution of a more long-term support device should short-term stabilization occur and more meaningful recovery be anticipated.

ECMO has many advantages in the bridge-to-bridge arena. The system is simple, relatively cheap, easy to assemble rapidly, and very portable. Full cardiopulmonary support can be established rapidly by peripheral cannulation. As a result, ECLS can be used as a lifesaving option in patients with hemodynamic collapse who initially are not known to be candidates for cardiac transplantation and therefore are candidates for more chronic ventricular assist device support.[119,148] The clinical settings in which ECLS is used include patients who present with massive MI who remain in cardiogenic shock despite inotropic support and IABP counterpulsation, chronic heart failure patients with acute decompensation, and patients with cardiac arrest. Improved results with implantable ventricular assist devices have prompted implementation of strategies using ECLS as a means to rapidly establish circulatory support to maintain hemodynamics as transplant evaluation is initiated and neurologic status is determined. This strategy is aimed at maximizing patient survival and limiting the duration of support with temporary assist devices by early transition to a chronic ventricular assist device (bridge to bridge) that would allow patient rehabilitation and eventual transplantation. Furthermore, operative and perioperative costs of implanting the more permanent LVADs are avoided in patients who already may have suffered irreversible sequelae of multisystem organ failure.[149] Pagani recently reported the results of 33 patients with primary cardiac failure who were placed on ECLS.[148] The etiology was ischemic in 58%, nonischemic in 30%, and postcardiotomy in 12%. Overall, 73% of these patients were in cardiac arrest or had experienced a cardiac arrest within 15 to 30 minutes of initiation of ECLS. Ten patients who were transplant candidates and could not be weaned from ECLS were bridged to an LVAD. Six patients were transplanted and discharged, two were alive on the LVAD awaiting transplantation, and two died. Overall, ECLS was discontinued in 27% of patients because of absolute contraindications to transplantation, primarily because of neurologic injury. However, 80% of patients transitioned to an LVAD survived. This aggressive strategy and remarkable survival are secondary to selection of patients who are most likely to survive at the expense of more initial deaths on ECLS. If the entire group of patients in this study are considered, only 36% survived to discharge. Interestingly, the need for RVAD support in the group of patients with ECLS as a bridge strategy was 40%, significantly higher than the 10% reported for patients who receive an LVAD as the initial device. This may be secondary to the inflammatory response to ECLS and associated increase in pulmonary vascular resistance.[150,151] On the other hand, an increased frequency of multisystem organ failure may lead to a greater need for perioperative BVAD support.[152–154]

Similar improved results have been reported from the Cleveland Clinic in which 18 of 107 postcardiotomy patients who were appropriate transplant candidates were converted to an LVAD.[125] Of these, 72% survived to trasplantation and 92% were alive at 1 year. The successful use of LVADs for postcardiotomy support also has been reported by DeRose in a group of 12 patients.[155] LVAD support was converted to a HeartMate device at a mean of 3.5 days. Of these, eight were transplanted, and one was explanted with an overall survival of 75%.

Korfer and associates also reported on 68 patients supported with the ABIOMED BVS 5000 system.[137] The majority of these patients were postcardiotomy, with 32 being weaned and 13 transplanted. Overall survival was 47%. More recently, Korfer reported on 17 patients with postcardiotomy shock who received the Thoratec device. In this group, seven were transplanted and one was weaned successfully, for an overall survival of 47%.[145] With its availability in the catheterization laboratory and the ease with which it can be implanted, it is likely that TandemHeart will have an important role in this evolving field.

Device Selection

To date, insufficient data exist to recommend one device over another for patients who require temporary mechanical support. Use of a particular device often is based on availability rather than science. Currently, the majority of heart centers use the ABIOMED BVS 5000 as their primary means of short-term cardiac support.

For centers with multiple devices, patient presentation and cardiopulmonary status will determine the device selected. Patients undergoing cardiopulmonary resuscitation are best serviced by urgent femoral cannulation. This avoids the time delay of transportation and sternotomy. Patients with severe hypoxia and lung injury either from aspiration or pulmonary edema benefit from the oxygenation and lung rest provided with ECMO.

For postcardiotomy support, all devices have been used with similar success. Typically, patients are supported for 48 to 72 hours while transplant evaluation is completed. Then they are transitioned to a more long-term device if myocardial recovery has failed. This approach avoids a high-risk emergency heart transplantation and provides the time necessary for improved organ function.

The best device for AMIs or myocarditis remains uncertain. However, a recent multicenter report of outcomes of patients in cardiogenic shock after AMI demonstrated a 67% rate of recovery when patients were supported with the

AB5000 system.[156] For fulminant myocarditis, the device that is least traumatic to the heart is advisable because recovery is likely. For more indolent myocarditis or giant cell myocarditis, transplantation is more likely, and a long-term implantable system may be the best choice.

For patients sustaining arrest in the catheterization laboratory, the TandemHeart with percutaneous transseptal left atrial drainage is a very attractive option.

Patient Management

The ultimate goal is to maintain optimal perfusion of all end organs, to allow time for recovery from an acute hemodynamic insult, and to prevent further deterioration of organ function. Ideally, pump flow would achieve a mixed venous saturation of greater than 70%. Low-flow states can often be corrected by intravascular volume expansion. With centrifugal pumps and ECMO, pump speed can be adjusted to control flow and allow some degree of cardiac ejection to decrease the likelihood of stasis and intracardiac thrombus formation. Increasing flow rates by using excessive pump speeds also cause significant hemolysis. Fluid administration to expand intravascular volume is the best way to increase flow. However, right-sided heart failure also may manifest as a low-flow state in the presence of low pulmonary artery pressures. This condition usually requires the institution of right-sided circulatory support and is associated with a lower overall survival.

Ventilatory support

Peak inspiratory pressures are maintained below 35 cm H_2O. Inspired oxygen is set initially at 100% with a positive end-expiratory pressure of 5 cm H_2O. Fractional inspired oxygen then is decreased gradually to less than 50%, with partial pressure of oxygen maintained at between 85 and 100 mm Hg. These measures are instituted to diminish the deleterious effect of barotrauma and oxygen toxicity in the setting of lung injury.

Anticoagulation

Anticoagulation should be done judiciously to weigh the balance of excessive risk of bleeding against clot formation in the pump. Platelet counts decrease within the first 24 hours of support; therefore, counts are monitored every 8 hours, and we routinely transfuse platelets to maintain counts above 50,000/mm^3 during routine support and above 100,000/mm^3 if bleeding is present. Fresh-frozen plasma and cryoprecipitate are given to control coagulopathy and maintain the fibrinogen concentration at greater than 250 mg/dL and also replace other coagulation factors consumed by the circuit. Although other institutions have reported on the use of plasminogen inhibitors such as aminocaproic acid and aprotinin to decrease fibrinolysis,[157] we have not used these drugs routinely because of concern for thrombus formation. In most cases, heparin infusion is started soon after adequate hemostasis is present. Anticoagulation is achieved by systemic heparinization with a continuous infusion starting at 8 to 10 μg/kg per hour and titrated to maintain the partial thromboplastin time (PTT) at between 45 and 55 seconds. For ECMO, in most cases, heparin infusion is started within 24 hours if used in the postcardiotomy setting but sooner in patients without a sternotomy. With heparin-bonded circuits, we target an ACT of 200 s.

Fluid management

Patients are diuresed aggressively while on support to minimize third-space fluid accumulations. If response to diuretic therapy is suboptimal because of renal insufficiency, we use a hemofilter/dialyzer spliced into the arterial or venous limb of the circuit, if feasible. Otherwise, we use continuous venovenous hemodialysis (CVVHD). This system permits control over fluid balance by continuous ultrafiltration that can be adjusted for volume removal and also allows for dialysis as needed.

Neurologic monitoring

Patients are sedated with fentanyl or propofol infusion to maintain comfort. Muscle paralysis is used as needed to decrease the energy expenditure and to decrease chest wall stiffness to allow for optimal adjustment of the ventilation parameters. All patients are assessed periodically off sedation to establish neurologic function. Response to simple commands, ability to move all extremities, and spontaneous eye movements are used as gross indications of intact sensorium. A low threshold of obtaining computed tomographic (CT) scans of the head is exercised if any change is noted or index of suspicion is high.

Weaning

A weaning trial is usually attempted after 48 to 72 hours of support. It is critical not to rush weaning and to allow time for myocardial as well as end-organ recovery. The principle of weaning is common to all devices, and all have various controls available that allow reduction of flow, thereby enabling more work to be performed by the heart. Flow is reduced gradually at increments of 0.5 to 1 L/min. Adequate anticoagulation is critical during this low-flow phase to prevent pump thrombosis, and in general, it is not recommended to reduce flow to $<$2.0 L/min for a prolonged period. We add additional heparin during this period to maintain an ACT of more than 300 s. With optimal pharmacologic support and continuous TEE evaluation of ventricular function, flows are reduced while monitoring systemic blood pressure, cardiac index, pulmonary pressures, and ventricular size. Maintenance of cardiac index and low pulmonary pressures with preserved LVF by echocardiography suggests that weaning is likely. A failed attempt at weaning results in resumption of full flow. Absence of ventricular recovery after several weaning attempts is a poor prognostic

sign. Patients who are transplant candidates undergo a full evaluation and subsequently are staged to a long-term ventricular assist device as a bridge to cardiac transplantation. We and others have found that early conversion to chronic ventricular support is beneficial and improves the low survival that is associated with cardiogenic shock, particularly in the postcardiotomy setting.[120,125,137,155]

SUMMARY OF COMPLICATIONS AND RESULTS

Duration of Support

Complications tend to increase with increasing length of support. Therefore, in general, these devices are used for less than 2 weeks, but longer durations have been reported (Table 18-7). An exception to this general rule is the Thoratec device, which can be extended for a longer period until cardiac transplantation. The longest reported duration of support with this device is 365 days. Table 18-8 summarizes the indications for which temporary support has been implemented.

Table 18–8.

Indications that Temporary Device Support has been Used for Acute Cardiogenic Shock

Postcardiotomy pump failure
Acute myocardial infarction
Decompensated heart failure
Postcardiac transplantation allograft dysfunction
Acute myocarditis
Deterioration during cardiac cathetrization procedures
Right ventricular failure after LVAD placement
Cardiac arrest
Massive pulmonary embolism

Complications

All current devices are thrombogenic and require anticoagulation. The delicate balance between overanticoagulation resulting in bleeding versus inadequate anticoagulation and thromboembolism is a major determinant of morbidity.

Bleeding

During the acute phase, bleeding remains a significant problem, occurring at suture lines and cannulation sites and often a diffuse coagulopathy that becomes difficult to localize. The high incidence is partly because of the hemostatic disarray associated with the operation, the low-flow physiologic state that necessitates pump placement, and the need for anticoagulation early in the course of support. In general, this translates into a large transfusion requirement that can be detrimental in terms of problems with transfusion reactions, increases in pulmonary vascular resistance, and importantly, increased sensitization of patients who later may require transplantation. The need for rapid transfusion often prohibits the use of filters that generally slow the rate of infusion. Golding had reported severe bleeding in 87% of patients supported with centrifugal pumps, with a mean transfusion requirement of 53 units of blood.[95] More recently, the Cleveland Clinic reported a median transfusion requirement of 14 units (range 1 to 99 units) using ECMO.[85]

The use of heparin-coated circuits has failed to reduce the coagulopathy and bleeding associated with ECMO effectively. However, peripheral cannulation with ECMO for acute support often is associated with much less bleeding than transthoracic approaches in the postcardiotomy setting. Similarly, with the ABIOMED and Thoratec devices, the incidence of bleeding has been as high as 27%.[89,135]

Table 18–7.

Duration of Support with Temporary Assist Devices

Device	Median support (days)	Range (days)
Centrifugal pump	2.3	1–14
ECMO	2.5	1–9
ABIOMED	5.6	1–81
Thoratec	42.0	6–365

Thromboembolism

Despite the development of heparin-coated systems, the incidence of thromboembolism remains a constant threat. Thrombin deposition in centrifugal pumps with increasing duration of support is a well-known phenomenon. Golding reported thromboembolism in 12.7% of 91 patients supported with a centrifugal pump for postcardiotomy pump failure.[95] In 202 adult patients supported with ECMO, pump-head thrombus was noted in 5%, and neurologic complications occurred in 29%.[85] Both factors were found to have a profound negative impact on survival or the ability to be weaned from support. Similarly, thromboembolic incidences of 8 and 13% have been reported for the Thoratec and ABIOMED devices, respectively. These numbers may underestimate the actual number of thromboembolic episodes. Curtis and colleagues reported autopsy results in

eight patients who had no clinical evidence of thromboembolism. In this group, five patients (63%) were found to have evidence of acute thromboembolic infarction in the cerebral, pulmonary, and system territories.[158]

Weaning and Survival

There are currently no data to indicate that one device is superior over another in terms of weaning and survival. Published reports suggest that weaning can be accomplished in approximately 45 to 60% of patients; however, survival overall is less than 30%, with only 50% of weaned patients discharged alive from the hospital. Reports on long-term follow-up in this group are unavailable. The Cleveland Clinic recently demonstrated in a cohort of patients supported on ECMO that the high early attrition rate diminishes rapidly within 6 months of ECMO removal, and 65% of patients discharged are alive at 5 years.[85] Risk factors associated with increased mortality have included age greater than 60 years, emergency operations, reoperations, renal insufficiency, and pre-existing LVD. In all series, sepsis, multisystem organ failure, and neurologic complications stand out as the causes of death.

The overall survival rate in reported series over the last decade has undergone a significant improvement at transplant centers where appropriate candidates are bridged to transplantation after a period of support. In the Cleveland Clinic experience, ECMO support was converted to an implantable LVAD in 18 patients.[85] Of these, 72% survived to transplantation with 92% 1-year survival. DeRose and colleagues have described the successful use of an implantable LVAD for postcardiotomy support in a group of 12 patients after elective or emergency coronary artery grafting requiring IABP, centrifugal, or ABIOMED LVAD support.[155] All were converted to the HeartMate device at a mean of 3.5 days. Of these patients, eight were transplanted, one was explanted, and all were discharged for an overall survival of 75%. Similar results have been described by Korfer and colleagues.[133] In their experience with 68 patients supported with the ABIOMED BVS 5000, the majority with postcardiotomy failure, 32 patients were weaned and 13 were transplanted with an overall survival of 47%. The Thoratec device was used in another 17 patients at their institution for postcardiotomy support, with eight survivors (47%), seven patients transplanted, and one weaned successfully.

CONCLUSION

Currently, a number of options exist for temporary circulatory support, and with advances in technology, the number of devices will expand. Each device has advantages and disadvantages, and to date, none satisfies all the requirements of an ideal device. We have clearly learned many lessons that should direct the development of systems and strategies that maximize survival and reduce complications. In this arena, better understanding of the host inflammatory response, appreciation of the induced derangement in the coagulation cascade, and development of systems that do not require anticoagulation should improve overall outcomes. In addition, development of therapies that alter reperfusion injury and preserve organ function is important. Agents and approaches that affect the inflammatory response in general, such as steroids, aprotinin, and plasmapheresis, or more specific blockades, such as leukocyte depletion or direct cytokine inhibition, will need evaluation.

Risk analysis also has taught us that patients requiring postcardiotomy support generally fit into a particular profile. Specifically, these are patients who require emergency operations, have poor ventricular reserve, are older, and have extensive atherosclerotic coronary disease and pre-existing renal dysfunction. Preoperative awareness should prompt maximization of medical pharmacologic support and a readiness to implement mechanical devices early in the face of cardiac pump failure.

Mechanical support also necessitates that adequate left ventricular decompression be achieved. In the postcardiotomy setting, current systems that allow these options are the ABIOMED, TandemHeart, and Thoratec assist devices. Levitronix and Impella devices are currently under investigation. Use of the centrifugal pump gradually has fallen out of favor. ECMO support should be reserved for cases of acute hemodynamic collapse in the immediate postmyocardial infarction period, disasters in cardiac catheterization laboratories, sudden witnessed cardiac arrest, or any other condition that requires rapid restoration of circulatory support. The primary advantage of ECMO in these settings is the ability to cannulate peripherally.

Finally, with the knowledge that myocardial ischemia can lead to irreversible damage in the postcardiotomy setting, recent data suggest an early transition of temporary support to more chronic vetricular access device support and transplantation. This strategy has improved survival rates from the 25 to 30% range to 50 to 75%.

CHAPTER 19

Late Complications of Cardiac Surgery

Samuel Jerome Durham • Jeffrey Philip Gold

The most significant progress in cardiothoracic surgery over the past 5 years has been the maturing of multiple large clinical databases and their subsequent analysis. This has begun to clarify the relationship between preoperative health, surgical procedure, and postoperative complications (Table 19-1). Conclusions from these studies have more substance than earlier studies because large numbers of patients are entered into these databases.

Because the largest numbers of patients have coronary artery bypass surgery (CABS), much of the discussion stems from these specific complications. For the first time, significant data are available on beating-heart surgery as compared with traditional CABS using cardiopulmonary bypass. The difference between these two techniques is discussed where relevant and where quality data exist.

The Society of Thoracic Surgeons has been collecting clinical cardiac surgery data since 1989. From this extensive database we have been able to identify many of the major perioperative complications, their association with patient characteristics, and attempts at modification by therapies. In a 2003 analysis of the data, the 30-day operative mortality was 3.05%, and the major complication rate was 13.04%. The major complications reported were renal failure, stroke, prolonged ventilation, reoperation, and sternal infection. Preoperative patient characteristics are important contributors to postoperative complications in all these areas. Postoperative complications may be due to preoperative patient illnesses, to unavoidable consequences of operative decisions, or to technical complications. By carefully recording these morbid events, we are able to provide a better-quality service for our patients.

CARDIAC COMPLICATIONS

Postoperative Myocardial Ischemia

Although coronary bypass surgery is performed to improve myocardial blood flow, multiple complications occur that can impair perfusion and cause postoperative myocardial ischemia (PMI), low cardiac output, and sudden death. Of 3982 patients having cardiac surgery, 29 patients (0.7%) had a sudden cardiac arrest.[1] Six of 29 patients (21%) died during the hospitalization, whereas 23 of the patients (79%) were discharged after both closed and open resuscitation. Fourteen patients (48%) had PMI as the underlying cause, eight patients (28%) had either tamponade or graft malfunction, and seven patients (24%) had no identifiable etiology.

The Society of Thoracic Surgeons has defined PMI as the occurrence of any one of the following three postoperative findings: electrocardiographic (ECG) changes, serum markers, and decreased ejection fraction (EF). The incidence of PMI in this database is 1% (see Table 19-1). However, the diagnosis of PMI is still debated because of trauma, reperfusion, and cardiac arrest elevating biochemical serum markers without ongoing ischemia. In the literature, the incidence of elevated markers varies from 8 to 35%.[2]

The current laboratory standard for measuring myocardial necrosis is either cardiac troponin I or cardiac troponin T.[3,4] However, the degree to which troponin must be elevated is uncertain.[5] In 100 cardiac surgical patients, 17 patients had either new wall motion abnormalities or new Q waves on ECG.[6] These patients had a cardiac troponin I level of greater than 40 ng/mL. If patients were divided into two groups of less than 40 ng/mL and greater than 60 ng/mL, the patients with greater than 60 ng/mL were in the intensive-care unit (ICU) longer and ventilated longer. (Cardiac troponins are measured in nanograms per milliliter or micrograms per liter; the number remains the same as the unit changes.)

Prior to the measurement of troponins, the diagnosis of a heart attack was based on any two of three criteria: ECG changes, angina, and elevation of the MB fraction of creatine kinase (CK-MB). Angina is not a good indicator in postoperative patients. Patients were identified as having PMI by ECG and CK-MB standards, and troponin I levels were measured at four postoperative intervals.[2] The criteria for PMI were

Table 19–1.

STS Complication Rates, Jan–June 2005 (69,880 cases)

Atrial fibrillation	20.1%
Prolonged vent.	8.3%
Renal failure	3.8%
Pneumonia	3.0%
Reop. for bleeding	2.2%
Reop. for noncardiac problem	2.1%
GI complication	2.1%
Cardiac arrest	1.6%
Permanent stroke	1.4%
Reop. for other cardiac problem	1.1%
Anticoagulant complication	1.1%
Preoperative MI	1.0%
Septicemia	1.0%
Heart block	0.9%
Multisystem failure	0.8%
Transient stroke	0.7%
Leg infection	0.6%
Deep sternal wound infection	0.4%
Coma	0.3%
Acute limb ischemia	0.3%
Reop. for graft occlusion	0.2%
Pulmonary embolism	0.2%
Tamponade	0.2%
UTI	0.0%

new Q waves with CK-MB myocardial band elevation of greater than 50 μg/L or CK-MB myocardial band greater than 100 μg/L. Six of 50 patients had PMI by these criteria. Forty-four patients did not meet these criteria, and their troponin I levels peaked in 7 hours at a mean of 20.97 μg/L (17.11 to 24.83 μg/L). Patients who met the criteria for PMI had a mean cardiac troponin I level of 46.85 μg/L (36.4 to 57.3 μg/L). The only preoperative risk factor for an elevated postoperative troponin was preoperative elevation of the cardiac troponin level. The level at which troponins become diagnostic of PMI is still debatable, with levels as low as 3.1 μg/L being considered significant.[7]

Because troponins and CK-MB may be elevated just from surgical trauma, and because chest pain is an inaccurate indicator of postoperative myocardial ischemia, graft occlusion is often hard to diagnose. ECG, biochemical markers, and predischarge angiography were performed in 103 patients having CABS. Twelve patients had at least one graft occluded. Peak CK-MB levels in these patients averaged 52.2 μg/L as compared with 24.7 μg/L. Peak troponin T levels were 3.7 μg/L as compared with 1 μg/L.[8] In a second study, 2078 patients were followed for cardiac troponin I levels greater than 20 ng/mL and acute changes in their ECG.[9] Fifty-five patients fulfilled these criteria and underwent repeat angiography, in addition to having myoglobin, creatine kinase (CK), and CK-MB isoenzyme determinations. Early graft failure was found in 35 patients, whereas 20 patients showed no failure. CK/CK-MB and ECG changes could not distinguish between those with and without graft failure. Cardiac troponin I levels of 21.5 ng/mL at 12 hours and 33.4 ng/dL at 24 hours were the best discriminator. A third study reviewed 3308 coronary artery bypass grafting (CABG) patients for PMI either caused by graft occlusion or with patent grafts.[10] Ninety-four patients had repeat emergency angiography, which was performed because of a troponin I level of greater than 20 ng/mL or significant ECG changes. Fifty-six of 94 patients had a PMI caused by graft occlusion and 38 did not.

Three groups of patients then were studied with cardiac troponin I, CK, and CK-MB determinations and ECGs: PMI and graft occlusion, PMI and patent grafts, and 95 patients with no PMI and patent grafts. The best discriminator between PMI and no PMI was a troponin I level of greater than 10 ng/mL. The best discriminator for graft occlusion was a troponin I level of greater than 35.5 ng/mL. CK-MB determinations were not useful, and troponin I levels peaked at 12 hours after removal of the cross-clamp.

Biochemical markers are also predictors of postoperative left ventricular (LV) dysfunction and increased mortality.[11] In one study, 800 patients were followed for 30 days for severe LV dysfunction or death. The median peak CK-MB level was 29 ng/mL, with more than one-half of the patients having levels five times greater than the upper limit of 5 ng/mL. The strongest predictor of LV dysfunction or death was a level greater than 100 ng/mL. In a second study, a level of 40 ng/mL was associated with increased risk of mortality.[12] However, this risk was gone at 1 year. Thirty-day mortality is increased by perioperative infarctions, and long-term quality of life is reduced.[13]

Serial troponin I determinations were followed in 60 patients randomly assigned to on-pump or off-pump coronary bypass procedures.[14] Off-pump patients had significantly less release of troponin I. Troponin levels often stay within the reference ranges after off-pump bypass surgery.[3]

Postoperative Atrial Fibrillation

From June to January 2005, the incidence of postoperative atrial fibrillation in the Society of Thoracic Surgeons'

National Adult Cardiac Surgery Database was 20% (see Table 19-1). The New York State Registry had 163 of 2111 (7.7%) readmissions owing to arrhythmias, which are the fourth most common reason for readmission with a median time from surgery of 8 days. Three-hundred and two patients were monitored continuously during hospitalization and for 2 weeks after discharge.[15] One-hundred and twenty-seven of 302 patients had atrial fibrillation, with 41 having it after discharge and 10 of these for the first time. The mean occurrence was 2.9 days from surgery, but the range was day 0 to 21 days. Sixty-nine percent of patients had no symptoms. Predictors of atrial fibrillation while hospitalized were greater than 65 years of age, history of intermittent atrial fibrillation, and atrial pacing. Predictors of atrial fibrillation after discharge were atrial fibrillation during hospitalization, valve surgery, and pulmonary hypertension. Four important issues are controlling the ventricular response to atrial fibrillation, preventing thromboembolism and anticoagulation management, chemical and electrical cardioversion, and preoperative prophylaxis.[16]

The Department of Veterans Affairs entered 3855 patients from 14 centers into a study and examined the incidence, risk factors, morbidity, and mortality from postoperative atrial fibrillation.[17] A total of 29.6% of patients had postoperative atrial fibrillation. Length of stay in the ICU and hospital stay were higher in the atrial fibrillation patients. ICU readmission, perioperative myocardial infarction (MI), congestive heart failure (CHF), reintubation, and stroke were increased. Hospital mortality was 5.95% for the atrial fibrillation patients and 2.95% for those without atrial fibrillation; six-month mortality was 9.36% as compared with 4.17%. In addition, postoperative atrial fibrillation was associated with a long-term decrease in survival, which also may be related to the treatment of atrial fibrillation with anticoagulants and antiarrhythmics.[18]

Risk factors for atrial fibrillation were studied in a multicenter trial that entered 4657 patients.[19] Of these patients, 32.3% had postoperative atrial fibrillation. Risk factors were advanced age, history of atrial fibrillation, chronic obstructive pulmonary disease (COPD), valve surgery, and postoperative withdrawal of a beta blocker or angiotensin-converting enzyme (ACE) inhibitor. Reduced risk was related to postoperative use of a beta blocker, ACE inhibitor, supplemental potassium, or nonsteroidal anti-inflammatory drug (NSAID). Recurrent atrial fibrillation occurred in 43% with risk factors of advanced age, history of CHF and LV hypertrophy, and withdrawal of beta blockers and ACE inhibitors. Patients with recurrent atrial fibrillation had more complications than those with a single episode.

The incidence of stroke is increased in patients with postoperative atrial fibrillation.[20] Fifty-two patients had a postoperative stroke in a study population of 2630 patients, and 36.5% of the stroke patients had atrial fibrillation prior to the stroke. The stroke occurred a mean of 21.3 hours after atrial fibrillation and a mean of 6 days after surgery. Postoperative atrial fibrillation also may be associated with a decrease in neurocognitive function.[21]

One-hundred and sixty patients were followed prospectively after off-pump coronary bypass surgery.[22] Atrial fibrillation occurred in 33 patients (20.6%). Older age, grafting of the ramus intermedius, and repeat bypass were the risk factors identified. A review of the literature documents postoperative atrial fibrillation at 19% for the off-pump patients and 24% for the on-pump patients.[23] The conclusion of these authors is that neither method now can claim to result in less postoperative atrial fibrillation.

Chest Re-exploration

In the Society of Thoracic Surgeons' database, reoperation for bleeding was 2.2%, reoperation for tamponade was 0.2%, and reoperation for graft occlusion was 0.2%. Three-hundred and five patients (3.6%) of a cohort of 8586 patients were re-explored for bleeding in this study from Dartmouth.[24] In-hospital mortality for patients re-explored was 9.5% compared with the control group of 3.3%. Average length of stay after surgery was 14.5 days versus 8.6 days. Risk factors for re-exploration were long cardiopulmonary bypass times, the need for an intra-aortic balloon pump (IABP), older age, smaller body surface area, and more distal anastomoses. In a second study, 2898 patients were reviewed.[25] Eighty-nine patients (3.1%) were re-explored, and they had risk factors of smaller size, emergency surgery, increased age, and greater than five distal anastomoses. Aspirin and heparin, when used preoperatively, did cause higher bleeding in patients placed on cardiopulmonary bypass. Mortality rates were similar in propensity-matched groups, but patients requiring re-exploration had more use of inotropic drugs and longer admissions to the ICU and hospital. Patients who waited longer than 12 hours for re-exploration after admission to the ICU had more complications.

Chest re-exploration for tamponade is only 0.2%, and the echocardiographic diagnosis may be difficult.[26] One-hundred and forty-eight patients were diagnosed with tamponade, and this was divided into two groups: less than 72 hours after surgery and longer than 72 hours. In the early patients, transthoracic echocardiography had difficulty documenting the effusion, and, thus, diagnosis required transesophageal echocardiography (TEE). In general, the effusions were small and localized and often had no echocardiographic evidence of classic tamponade. Effusions present after 72 hours, which also were hemodynamically significant, were larger, global, and had classic echocardiographic findings.

Re-exploration may occur for sudden cardiac arrest. Seventy-nine patients were studied after cardiac arrest after open-heart surgery, and 20 of 79 (25%) survived to discharge.[27] Determinants of success were arrest within 24 hours of surgery, arrest in the ICU, and opening the chest within 10 minutes. After reopening the chest, cardiopulmonary bypass may need to be restarted.[28] Fifty-five patients were in the study group, having an incidence of 0.8%. The three major causes were cardiac arrest, bleeding, and hypotension. Twenty died in the operating room, 12 died before discharge, and the overall survival to discharge was

42%. Patients with an identifiable etiology for the problem were more likely to survive.

The incidence of uncomplicated pericardial effusion after open-heart surgery is high.[29] One-thousand two-hundred and seventy-seven patients had postoperative transthoracic echocardiograms at 20 and 30 days. At day 20, 22% of patients had effusions, and at day 30, 4% had evidence of late tamponade. Late tamponade was higher in valve patients and in those on anticoagulants.

PULMONARY COMPLICATIONS

Early extubation has been the most significant advance in the ventilatory care of post–open-heart surgery patients. This has allowed us to identify the preoperative, intraoperative, and postoperative risk factors of prolonged intubation. Preoperative routine spirometry does not predict length of postoperative intubation.[30] In this study, patients with 20% of predicted forced expiratory volume in 1 second (FEV_1) were extubated as quickly as those with better pulmonary function. Smoking does increase postoperative pulmonary complications.[31] Smokers had longer ICU stays but not necessarily longer intubation times. Full benefit from cessation of smoking takes about 6 weeks, with some benefit seen after 10 to 14 days. Both surgery- and patient-specific factors are related to pulmonary complications.

Early extubation may result in shorter ICU stays and earlier discharge.[32] Early extubation is not associated with higher complications but may be beneficial only in low-risk patients. Extubation for less than 6 hours as compared with between 6 and 24 hours showed no difference in ICU or hospital stay.[33] Early extubation is possible by modification of sedation and anesthesia, early reversal of paralysis, and established protocols with experienced nurses.

Prolonged mechanical ventilation can occur in almost 50% of open-heart surgical patients.[34] In this study, 167 of 400 patients were not extubated at 8 hours. The mean and median duration of ventilation were 21.6 and 8 hours. Failure to extubate at 8 hours occurred in 42.1%, and prolonged ventilation at 24 and 48 hours was seen in 6.8 and 5.3%. The most common cause of mechanical ventilation at 8 hours was a depressed level of consciousness (34.7%), followed by hypoxemia (25.1%). Most patients with hypoxemia have it for unknown reasons, although many were on nitroprusside. An additional 10.2% of patients were not extubated at 8 hours owing to concern about excessive bleeding. Hemodynamic instability was not a common reason for failure to extubate early. At 24 hours, 93% of all patients were extubated, and the primary reason for continuing intubation thereafter was hypoxemia. The causes were acute respiratory distress syndrome (ARDS), cardiogenic pulmonary edema, and unknown.

Respiratory failure is the most common reason for readmission to the ICU in patients undergoing CABS.[35] Seventy-five of 2117 patients (3.6%) were readmitted to the ICU. Respiratory failure caused 47% of the ICU readmissions. The readmitted patients had a mortality rate of 17% versus an overall mortality rate of 2.8%. These ICU readmitted patients had a median length of stay of 23 days; patients not readmitted to the ICU had a median stay of 6 days. Two independent risk factors were identified: preoperative renal failure and initial postoperative mechanical ventilation greater than 24 hours.

Prolonged (>72 hours) postoperative respiratory failure was studied by a review of 8802 patients having CABS.[36] In this cohort, 5.6% required postoperative ventilation for more than 72 hours. The duration of ventilation was calculated by the summation of all episodes of mechanical ventilation during the postoperative time. On multivariate analysis, the most significant risk factors were preoperative insertion of an IABP, documented COPD, and advanced age. The noted intraoperative risk factor was the duration of cardiopulmonary bypass, which may be associated with the presence of concomitant defects. Postoperative risks of prolonged ventilation were sepsis, endocarditis, gastrointestinal bleeding, new stroke, renal failure, deep sternal wound infection, and reoperation for bleeding. The 30-day survival for patients with respiratory failure was 75.7 versus 90% in patients with one or more complications other than respiratory failure.

Improvements in respiratory function may be achieved by maintaining an intact pleura, particularly during harvesting of the internal mammary arteries (IMA), and by off-pump coronary surgery. In one series, patients were divided into three groups, with one group having the IMA skeletonized with intact pleura, the second with open pleura and pedicled IMAs, and the third with skeletonized IMAs and open pleura.[37] The incidences of prolonged mechanical ventilation, pleural effusion, the need for thoracentesis, and clinically important atelectasis were highest in the pedicled group with open pleura. Off-pump coronary artery surgery may improve postoperative pulmonary function, as demonstrated in a review of 200 patients who were randomized to either on-pump or off-pump coronary revascularization.[38] This comparison reveals that 73 of 100 off-pump patients versus 50 of 97 on-pump patients were extubated at 4 hours after surgery. There was no difference in mortality or hospital readmissions.

Two groups of 19 patients were divided between on- and off-pump surgery.[39] No differences were found in postoperative pulmonary course in either of the two groups.

NEUROLOGIC COMPLICATIONS

Stroke

Neurologic complications are divided into three categories: stroke, cognitive dysfunction, and delirium. However, these divisions may be arbitrary. Concerns about neurologic injury from cardiopulmonary bypass have encouraged the development and possible acceptance of strategies of less complete revascularization techniques as well as the popularization of beating-heart surgery.

A paper was published in 1996 that focused on neurologic complications of CABS using cardiopulmonary bypass; and 6.1% of patients had a neurologic complication, with 3.1% having a stroke and 3% having deterioration of "intellectual function."[40] Mortality was highest in stroke patients at 21%, followed by the second group at 10%, and the unaffected patients at 2%. Patients with stroke had longer hospitalizations at 25 days, deterioration of function at 21 days, and the normal group was discharged at 10 days. The more significant the neurologic impairment, the higher was the probability of admission to rehabilitation or long-term care facilities. Risk factors for stroke were ascending aortic disease, a history of stroke, and age greater than 70 years. Risk factors for deterioration of cognitive function were age, systolic hypertension on admission, pulmonary disease, and excessive alcohol use.

Strokes are caused by several mechanisms. One study attempted to identify these etiologies in coronary bypass patients, and 388 patients with strokes from five medical centers were studied for an 8-year period.[41] Embolic events caused 62.1% of the strokes, and multiple etiologies were responsible for 10.1%, cerebral hypoperfusion for 8.8%, lacunar infarcts for 3.1%, thrombotic events for 1%, and hemorrhagic events for 1%. The remaining 13.9% had no etiology identified. Most strokes were noted on the first postoperative day. Cerebral emboli are thought to be related to manipulation of the aorta.

Risk factors for strokes may depend more on preoperative conditions than on intraoperative occurrences.[42] A series of patients having CABS were studied for stroke risk factors. When these factors were identified, a validation group of 1298 patients was studied to confirm the results. The authors noted that 5.7% had strokes. Five factors were associated with perioperative strokes: previous stroke, presence of carotid bruit, history of hypertension, increasing age, history of diabetes, and prolonged cardiopulmonary bypass time.

Perioperative strokes increase morbidity, mortality, and cost.[43] In 10,860 patients who had CABS, 244 patients had strokes at a frequency of 2.2%. Univariate analysis showed age, female gender, hypertension, diabetes, prior stroke, prior transient ischemic attack (TIA), and carotid bruits as preoperative risk factors. Multivariate analysis identified age, previous TIA, and carotid bruit as risk factors. One-year survival in stroke patients was 64 versus 94% in nonstroke patients. Five-year survivals were 44 and 81%, respectively. The patients with perioperative strokes had a 23% mortality before hospital discharge.

Other evidence exists that places the most emphasis on the intraoperative and postoperative course.[44] A large series of 11,825 patients undergoing CABS were followed prospectively from 1996 to 2001. Strokes occurred in 1.5% of the study group, with 75% of the strokes occurring in what were designated as preoperative low- and medium-risk groups. The intraoperative and postoperative risk factors were intra- or postoperative IABP, prolonged length of cardiopulmonary bypass, the need for reinitiation of cardiopulmonary bypass, low-cardiac-output syndrome, prolonged inotrope use, and preoperative atrial fibrillation.

The complexity of surgical procedure also was noted to increase the incidence of stroke in 783 patients who were divided into four groups: coronary artery bypass surgery, isolated valve surgery, combined CABS, and valve surgery, and multivalve surgery.[45] The stroke rate was 1.7% for patients undergoing coronary artery bypass grafting (CABG) only, 3.6% for those with isolated valve procedures, 3.3% for those with combined CABG and valve operations, and 6.7% for those with multivalve procedures.

The etiology of perioperative stroke is multifactorial. Reduction in its incidence will occur as a result of research on multiple fronts. This research includes identification and mitigation of preoperative risk factors, understanding of the significance of carotid artery disease, decreased manipulation of the aorta and intraoperative use of epiaortic ultrasound, improvement in cardiopulmonary bypass filters, air emboli control, and postoperative treatment of hemodynamic alleviation and arrhythmias, particularly atrial fibrillation.

Neurocognitive Dysfunction

Neurocognitive dysfunction relates to the decrease in performance of patients on standardized tests of mental function after open-heart surgery. The severity of the problem depends on the extent and completeness of testing. In a review of published studies, 22.5% of patients had neurocognitive deficits after open-heart surgery at 2 months.[46] This effect may be apparent even at 5 years, although the brain has significant ability to recover.[47] In a third study, 104 patients undergoing CABG with cardiopulmonary bypass were matched with nonsurgical controls.[48] Repeat measurements were made at 7 days, 4 months, and 3 years. Cognitive measures in surgical patients were worse at all postoperative intervals compared with controls.

The causes of cognitive dysfunction are multifactorial. Cardiopulmonary bypass is thought to be the most significant of these. Three-hundred and eight consecutive coronary artery bypass patients were tested for cognitive dysfunction by cognitive P300 auditory evoked potentials.[49] Standard psychometric testing did not document this subclinical cognitive impairment. Cardiopulmonary bypass was the only predictor of impairment. Valve operations cause greater impairment than just CABG.[50] Off-pump CABG may cause fewer declines than on-pump CABG.[51]

However, control populations have not been studied adequately to justify suggesting that all cognitive dysfunction is related to cardiopulmonary bypass.[52] One-hundred and twelve healthy volunteers were repeatedly administered neuropsychological tests to study result variability, which documented a range of results as each volunteer repeated the test.[53] Neurophyschological tests of CABG patients then were reanalyzed, adjusting for this variability. The result was that 7.7% of patients had evidence of neurocognitive decline at 3 months as opposed to 14 to 28%. In a second

study, four groups of patients were followed simultaneously.[54] The groups were CABG patients, off-pump patients, patients with coronary artery disease (CAD) but not having surgery, and heart-healthy patients. At baseline, all patients with CAD performed worse than the heart-healthy patients, and at 1 year, all patients with CAD performed the same. A third study compared cognitive dysfunction in CABG patients and patients with CAD but not having surgery.[55] At 1 year, there were no differences between the two groups.

Twenty-five patients having off-pump bypass surgery were matched with 50 on-pump patients.[56] Both groups had early decline of cognitive function with recovery, and cardiopulmonary bypass by itself is not the etiology. However, cerebral microemboli are reduced in patients who are not placed on cardiopulmonary bypass.[57]

Peripheral Nerve Injuries

Significant peripheral nerve injuries in open-heart surgery are brachial plexus injuries, ulnar nerve injury, and phrenic nerve injury. Of 421 patients having CABG, 55 patients (13%) had the following injuries: brachial radiculopathy, 23 patients; saphenous mononeuropathy, 13 patients; common peroneal mononeuropathy, 8 patients; and ulnar mononeuropathy, 5 patients.[58] In addition, unilateral vocal cord paralysis was found in 5 patients. In the patients with brachial injuries, 21 of 23 injuries affected the lower or medial cord fibers. In a second study, 13 of 201 patients (6.5%) who had a median sternotomy had a brachial plexus injury.[59] These injuries were not thought to be associated with arm placement, jugular vein cannulation, duration of operation, bypass time, sex, or type of operation. Instead, the authors felt that the width of opening of the sternal wound and height of elevation of the left IMA exposure contributed to the injuries. The rate of injury is higher in patients having the IMA harvested.[60] In this study, patients not having the IMA harvested had a 1% incidence of injury, whereas those with harvesting had a 10.6% incidence. Lesions were seen most frequently in the roots of C8–T1, with symptoms being continuous pain and motor and sensory deficits. Symptoms in eight patients lasted over 3 months. Somatosensory evoked potential (SSEP) monitoring documents subclinical transient losses during surgery in many patients.[61,62]

Subclinical ulnar neuropathies also may be frequent.[63] Fifty-three patients having CABG were studied prospectively.[64] Twenty patients (37.7%) had findings of ulnar neuropathy, with five being related to the brachial plexus. The average duration of symptoms was 2.3 months, but some patients had prolonged findings.

Phrenic nerve injury after open-heart surgery may cause significant morbidity.[65] The diagnosis depends on clinical evidence of shortness of breath, chest radiographs, and nerve conduction studies. In one study, 78 of 92 patients had abnormal postoperative chest radiographs, but only 42 of 78 had abnormal diaphragmatic motion and 24 of the 42 had phrenic neuropathy.[66] The etiology of phrenic nerve injury has been related to cold injury owing to topical ice and to harvesting of the IMA.[67,68] Skeletonization of the IMA may reduce the incidence.[69] The right IMA is closer to the right phrenic nerve than it is to the left. Phrenic nerve injury has been reported to be as high as 4% in this location.[70]

RENAL COMPLICATIONS

Patients who develop acute renal failure after CABS surgery have a higher mortality than those who do not.[71–73] The Veterans Administration reviewed 42,773 patients who had open-heart surgery at 43 locations.[71] Acute renal failure developed in 1.1% of patients, with a mortality of 63.7%. Those who did not require dialysis had a mortality of 4.3%. This study defined acute renal failure as the new need for the institution of dialysis within 30 days of surgery. This increase in mortality is independent of other preoperative and postoperative comorbidities. The etiology of preoperative dialysis-dependent renal failure is divided into two groups based on preoperative renal function.[74] Patients with normal preoperative renal function may require postoperative dialysis if the surgical procedure is performed emergently or if technical complications of the surgical procedure occur. Patients with decreased preoperative renal function may require dialysis with an otherwise nonemergent and uncomplicated course.

The development of renal insufficiency after open-heart surgery is associated with higher mortality than in patients with a normal serum creatinine concentration.[73] Of 2843 patients studied over a 2-year span, renal failure was divided into two groups: those with a serum creatinine rise of 1 mg/dL over baseline (group A) and those with acute renal failure requiring dialysis (group B). In the coronary artery bypass patients, 7.9% developed renal failure without dialysis, and 0.7% required dialysis. The baseline mortality was 1%, with group A having a 14% mortality and group B having a 28% mortality. Preoperative and intraoperative characteristics related to group A were increased age, elevated preoperative serum creatinine concentration, longer duration of cardiopulmonary bypass, diabetes, decreased EF, and increased body weight; in group B, the risk factors included increased preoperative serum creatinine concentration, duration of cardiopulmonary bypass, and presence of diabetes.

Patients with preoperative renal insufficiency have higher short- and long-term complications.[75,76] Overall length of stay and ICU days were increased. Thirty-day and 1-year mortalities are increased.[76] In patients with a preoperative creatinine concentration of 1.5 mg/dL, the in-hospital mortality rate was 14%, with 5% requiring dialysis. Additional preoperative risk factors for preoperative dialysis-dependent renal failure at discharge were female gender and emergency procedures.[77]

The duration of cardiopulmonary bypass has been identified as a risk factor for the development of acute renal failure. Postoperative renal function was compared in two groups in which cardiopulmonary bypass time was less than 70 minutes or greater than 90 minutes. Creatinine clearance, fractional excretion of sodium, and urine concentrations of *N*-acetyl-β-D-glucosaminidase, alpha$_1$-microglobulin, glutathione transferase-π, and glutathione transferase-α were measured.[78] Kidney-specific proteins were elevated postoperatively in both groups, but they were higher and occurred for a longer postoperative time in patients with cardiopulmonary bypass exceeding 90 minutes in duration. Multiple factors contribute to the renal damage, including nonpulsatile flow, embolization, and activation of known inflammatory pathways. Manipulation of bypass parameters may ameliorate this damage. On bypass, hematocrits of 21 to 25% may offer the greatest protection.[79]

Off-pump (beating-heart) surgery provides an additional insight into the renal effects of cardiopulmonary bypass.[80,81] A prospective study of 9631 patients from 1996 to 2001 found a combined dialysis-dependent renal failure of 4.1%, with off-pump surgery at 1.8% and cardiopulmonary bypass at 4.3%. However, off-pump surgery may not add any further renoprotective effects in patients with normal kidney function.[82]

In low-risk patients, little difference has been found in both postoperative renal dysfunction and postoperative markers of renal injury in comparisons of on-pump versus off-pump procedures.[82] A study of unselected patients who had creatinine clearances of less than 60 mL/min showed no difference in postoperative renal dysfunction than in those having either on-pump or off-pump procedures.[83]

GASTROINTESTINAL COMPLICATIONS

In the Society of Thoracic Surgeons' data, the incidence of gastrointestinal (GI) complications was 2.1%. The significance of this complication is its high mortality rate. GI complications can be divided into two groups: mesenteric ischemia and all other. Forty-six patients required surgical consultation of 8709 patients undergoing open-heart surgery, for an incidence of 0.53%.[84] Thirty-one of 46 patients (67%) had mesenteric ischemia, with 22 of 31 patients being explored and 14 of those explored died within 2 days of surgery. Seven of nine patients with mesenteric ischemia not explored died within 3 days of open-heart surgery. The remaining GI complications in decreasing order were diverticulitis, pancreatitis, peptic ulcer disease, and cholecystitis. The mortality in this group was 40%, with death occurring at a much later date after surgery. Preoperative risk factors were prior cerebrovascular accident (CVA), COPD, type II heparin-induced thrombocytopenia, atrial fibrillation, previous heart attack, renal insufficiency, and use of an IABP. In patients with mesenteric ischemia, the diagnosis is difficult.[85] Twenty-six laparotomies were performed for suspected mesenteric ischemia in 3024 open-heart patients. Seventeen of 26 had mesenteric ischemia, and 13 of 17 died. The four survivors had the ischemia limited to one segment of bowel.

WOUND COMPLICATIONS

Mediastinitis

Mediastinal wound complications are a significant source of postoperative mortality and increased cost.[86] Wound infections may be classified as superficial or deep (i.e., bone and retrosternal space). The sternum may dehisce with an infection or without. The incidence of deep sternal wound infection varies from 0.4 to 5%. *Staphylococcus aureus* and *Streptococcus epidermidis* are cultured from 70 to 80% of the wounds. Deep and organ-related surgical infections result in increased length of stay, costs of care, and mortality.[87] Long-term survival is decreased in these patients.[88] In one series, sternal infections developed in 40 of 3760 patients (1.1%). Early mortality was the same in the control group, but at 5 years, patients without sternal infections had a survival rate of 73% compared with 51% in patients with infections.[88]

Clinical predictors of sternal infections are diabetes, obesity, preoperative hemodynamic instability, preoperative renal failure on dialysis, use of bilateral internal mammary arteries, sepsis, and transfusions of more than four units of packed red blood cells after surgery.[88,89] Preoperative patient management may lessen the impact of these risk factors. Both accurate timing of preoperative antibiotics and tight control of perioperative blood sugar concentration in diabetic patients have been suggested as means to decrease these infections.[90]

The Society of Thoracic Surgeons studied a temporal chart with 331,429 patients in its database for major surgical-site infections (i.e., mediastinitis, saphenous vein harvest sites, and septicemia) and for the risk factors.[91] Major infections occurred in 3.51%, with one-quarter of these due to mediastinitis. The risk factors most strongly associated with major infections were a body mass index of 30 to 40 kg/m^2, diabetes mellitus, previous MI, urgent operative status, and hypertension. Risk factors that were present in a smaller number of patients but that also were predictors of infections were cardiogenic shock, dialysis-dependent renal failure, cardiopulmonary bypass time greater than 200 minutes, and perioperative immunosuppressive therapy. High-risk patients for major infections may be identifiable prior to surgery, and the risk factors may be modifiable.

Technical modification of IMA harvesting may decrease the incidence of sternal dehiscence.[92] Of 1146 patients who had bilateral IMA harvests, 304 were pedicled grafts and 842 were skeletonized in one series.[93] Sternal complications were more frequent in the pedicled group (4.5% versus 1.7%). The overall sternal wound-healing complications in the diabetic patients were higher in the pedicled group (10%) than in the skeletonized group (2.2%). Surgical mortality and graft patency were similar in both groups.

Prevention of infection begins prior to surgery with identification of patient-related risk factors, careful antibiotic prophylaxis, and preoperative hair removal. Intraoperative considerations include surgical technique, with judicious use of electrocautery, and foreign bodies, including bone wax.

Once mediastinitis is diagnosed, treatment options vary from débridement and closure to sternectomy and muscle flaps. In one study, débridement, rewiring, and delayed skin closure resulted in shorter healing time.[94] In a series of 5337 patients, 62 patients developed deep sternal infections (1.1%). Thirty-two were treated with débridement, rewiring, and delayed primary closure. This treatment failed in six initially and ultimately in two, with a median length of stay of 32 days and a median time to healing of 85 days. Twenty-five patients had muscle flap closure without sternal reapproximation, with a median length of stay of 31 days and a median time to healing of 161 days. Vacuum-assisted closure devices may be an important adjunct in many cases of sternal wound treatment.[95]

Radial Artery Harvest-Site Complications

The radial artery is currently harvested more frequently, with a patency rate of between 87.5 and 96.5% at 4 years.[96] The radial artery was harvested in 3977 patients, with a total of 4172 anastomoses.[97] There were no acute ischemic events of the hand. Late infection was 0.4%, and numbness and paresthesias occurred in 6.5 and 3% at 3 months. The Allen test has been used to judge the safety of harvesting the radial artery, and 11.6% of patients had a unilateral positive Allen test.[98] Additional testing may be warranted because the Allen test may lack sensitivity and specificity.[99] Doppler ultrasound and digital plethysmography were used on 187 patients.[100] Three-hundred and forty-six arms were studied, and 94 (27.1%) were excluded. Perfusion abnormalities such as nonreversal of flow, abnormal digital pressure, and inappropriate increase in ulnar velocity eliminated 54% of the arms, and anatomic abnormalities such as size less than 2 mm, congenital anomalies, and radial artery occlusion eliminated 46% of the arms. Many of the patients with complaints of hand pain or numbness improve over 12 months.[101] Two-hundred and eighty-eight patients having radial artery conduits were compared with a control group of 174 patients undergoing only CABG.[102] The only difference in the groups was an incidence of radial sensory neuropathy of 9.9% versus 5.2% in the control group.

HEMATOLOGIC COMPLICATIONS

Deep Venous Thrombosis and Pulmonary Emobilization

In a New York State Registry study, deep vein thrombosis (DVT) and pulmonary embolus (PE) were the fifth most common reason for readmission, accounting for 6.3% of readmissions.[103] This is in contrast to data published 15 years ago, when DVT and PE were thought to be infrequent complications with no indication for postoperative prophylaxis.[104]

Predischarge venous ultrasonography was performed in 330 patients after CABG.[105] Sixty-seven of 330 patients (20%) had DVT documented. The clots were found equally in the vein harvest leg and the nonoperative leg; 84% were in the calf and 16% in a proximal thigh vein. One patient had a massive PE, and one patient a symptomatic proximal DVT. In a second study, 66,180 patients were reviewed for symptomatic venous thromboembolism within 90 days of CABG.[106] Seven-hundred thirty-six of 66,180 patients developed either a symptomatic DVT or a PE. Two-thirds of the patients had been discharged at the time of diagnosis.

The most common postoperative treatments to prevent DVT are pneumatic compression stockings and anticoagulation with heparin or low-molecular-weight heparin (LMWH). Two-thousand five-hundred and fifty-one patients were assigned randomly to either receive subcutaneous heparin alone or subcutaneous heparin and pneumatic compression devices.[107] Sixty-nine of 2551 patients had a PE diagnosed, with 48 of the 69 patients being inpatients receiving only subcutaneous heparin. The heparin-only group had twice the number of PEs. The incidence of DVT diagnosed at discharge and on admission to an extended-care unit is decreased by using subcutaneous heparin or LMWH until hospital discharge.[108] DVT was found in 17.4% of patients on admission to the facility, with two PEs and one death from PE. Unilateral compression devices were not as protective as bilateral devices because either leg can be involved. Risk factors for DVT and PE were age, female gender, and postoperative complications.

Heparin-Induced Thrombocytopenia

Unfractionated heparin used during cardiopulmonary bypass can cause heparin-dependent platelet antibodies in 25 to 50% of open-heart patients in the immediate postoperative period.[109,110] This antibody-mediated thrombocytopenia is important because of its relationship to hypercoagulability in the form of venous and arterial thrombosis.[111] Heparin-induced thrombocytopenia (HIT) is diagnosed when two criteria are met: antibody seroconversion with either thrombocytopenia or clinical findings such as fevers and skin lesions. The risk of developing this clinical syndrome may be as high as 1 to 2% of cardiac surgical patients.[109]

The incidence of heparin-platelet factor 4 (PF4) antibody formation to either bovine or porcine heparin was studied in 207 patients.[112] Forty-four of 99 patients who received bovine heparin converted (44.4%), as did 33 of 108 patients who had received porcine heparin (30.6%). Ninety percent of the patients converted by the second postoperative day.

Patients who have had an episode of HIT preoperatively still can undergo cardiac surgery. In 4850 patients reviewed over 2 years, 10 had HIT prior to surgery.[113] Four

patients were anticoagulated with danaparoid sodium and six with heparin sodium after pretreatment with epoprostenol sodium. Platelet counts were not affected, and bleeding was not an issue.

Patients who have a history of HIT but are antibody-negative may have cardiac surgery using heparin.[111] Patients with HIT but no thrombosis should have an alternative regimen using lepirudin, argatroban, bivalirudin, or danaparoid.

HOSPITAL READMISSIONS

Hospital readmissions were 12.9% at 30 days after surgery in a study by the New York State Cardiac Surgery Reporting System.[103] In 1999, 16,325 patients had CABS, with 2111 being readmitted within 30 days. Postoperative infection and heart failure were the two most common reasons for readmission. The patient characteristics that were related to readmission were older age, female sex, African-American race, greater body surface area, and MI within 1 week. In a second study, patients older than 75 years of age had a readmission rate twice as high as younger patients (<64 years of age).[114] The three most common reasons were atrial fibrillation, chest pain, and CHF. However, in this study, 75% of patients older than 75 years of age recovered uneventfully. Readmission rates for women when matched carefully for disease severity may be the same as for men.[115]

Predicting readmissions is difficult because many are related to inadequate home care.[116] In one study, 44% of patients who were readmitted after CABG entered a community hospital.[117] Early discharge is not related to readmissions.[118,119] The reasons for readmission 2 years after CABG are recurrent angina pectoris and CHF.[120] Forty-four percent of the patients discharged after bypass surgery were readmitted at 2 years.

QUALITY OF LIFE

Indications for CABS include treatment of symptoms, prevention of heart attacks, and prolongation of life. However, these are related to the basic end point of returning our patients to an activity level that makes life enjoyable and worth living. Revascularization trials, including angioplasty and surgery, have documented improvement in quality of life as compared with medical therapy.[121,122] Cardiovascular mortality has decreased over the past three decades, and this may be due to the availability of revascularization interventions as compared with medical therapy.[122]

Two-hundred and fifteen consecutive open-heart patients were followed preoperatively and postoperatively with questionnaires to assess changes in quality of life.[123] Eighty percent of patients documented improvement. Patients had less improvement in energy if they were older than 70 years of age and in New York Heart Association (NYHA) functional class III or IV; patients had less improvement in sleep if they were older than 70 years of age; patients had less improvement in physical mobility if they were in NYHA functional class of III or IV. Other areas studied were social isolation and postoperative pain. Postoperative complications versus an uncomplicated recovery and valve versus bypass surgery had the same improvement.

Patients were studied 10 years after CABG for identification of factors that decreased quality of life.[124] Two thousand patients were entered, with 663 patients dying in the 10 years. Diabetes and COPD predicted decreased quality of life in all three tests that were used. Older age, female gender, and hypertension were predictors in two of the three tests. Predictors in a single test were preoperative duration of angina, preoperative functional class, cerebrovascular disease, obesity, duration of respiratory treatment, and postoperative use of inotropic drugs.

Preoperative patient characteristics play an important role in postoperative improvement.[125] Five-hundred and twenty-nine patients were followed at 6 months after elective bypass surgery for physical and mental health improvement. Of these, 73.2% had improvement in physical health and 41.6% in mental health. Patients with a body mass index over 35 kg/m^2, diabetes, COPD, peripheral vascular disease, and poor baseline physical function did not improve as much.

Gender and age have been shown to have an impact on quality of life after bypass surgery. Five-hundred and eight bypass patients were divided into three age groups: younger than 64 years of age, 65 to 74 years of age, and older than 75 years of age. The groups were studied at 1 year for physical, mental, and general health. Patients over age 75 did not have significant improvement in scores postoperatively.[126] However, other papers show that elderly patients can benefit. One-hundred and twenty-seven patients older than 80 years of age were followed after open-heart surgery,[127] with a mortality of 7.9% at 30 days and actuarial survival at 1 year of 83% and 2 years of 80%. Of those living, 83.7% were living at home, and 74.8% felt that they were in good health. Female gender has been reported to be a risk factor for decreased quality of life.[128] When women are matched to men, female gender is not associated with increased mortality or morbidity.[129]

In patients who undergo emergency bypass surgery or who are extremely ill after surgery, functional results appear good in the survivors.[130] Patients who survived to discharge had as good a functional recovery as historical controls that were not in cardiogenic shock. In addition, patients who suffer a cardiac arrest after surgery, if they survive, have a good functional recovery.[131] However, functional recovery in patients who have prolonged ICU stays (>5 days) is poor.[132]

CONCLUSION

As databases mature, expected outcomes are established. These expected outcomes will be used to measure existing clinical programs against a national standard. As an example of how this information may be applied, the Society of Thoracic Surgeons has released data about process measures and outcome

measures on participating programs to insurance companies.[133] The federal government through Medicare is trying to institute "pay for performance " initiatives whose intentions are to link reimbursement with expected results. Thus, the data collected on postoperative complications will become increasingly scrutinized and addressed with national standards.

At no time in the history of modern medicine have physicians and the health care system been more able to define and accurately report data related to procedural complications. The best strategies for prevention of complications derives from a full understanding of the periprocedure risk factors. The practice of quality surgery no longer can be limited to perioperative judgment and technical skill but should embrace the broadest aspects of medical care. This must include ongoing analysis of personal and cohort research and selected refinement to improve judgment and skill.

CHAPTER 20

Indications for Revascularization

Morgan L. Brown • Thoralf M. Sundt, III • Bernard J. Gersh

Coronary artery disease (CAD) remains the most common pathology with which cardiologists and cardiac surgeons are faced. Accordingly, the practicing cardiac surgeon is confronted with no clinical question more often than "Is coronary bypass indicated in this patient?" It is our aim here to provide a practical overview of the current indications for myocardial revascularization with sufficient reference to the relevant studies on which they are based to afford the reader an appreciation of the strengths and limitations of their conclusions.

CLINICAL AND LABORATORY ASSESSMENT OF CORONARY ARTERY DISEASE

A surgeon's first introduction to a patient with CAD is frequently an angiogram. In addition to the coronary anatomy, the clinical presentation and results of noninvasive studies of myocardial perfusion and function are necessary to characterize the pathophysiologic implications of the angiographic disease and its impact on prognosis. Nonetheless, in the technological era in which we practice, the pivotal importance of the clinical history bears emphasis—particularly in an aging population. Since one of the objectives of surgery is to improve symptoms and quality of life, a thorough appreciation of the patient's functional status is a prerequisite to selecting the optimal therapeutic strategy.

The system proposed by the Canadian Cardiovascular Society (CCS) for grading the clinical severity of angina pectoris is accepted widely[1] (Table 20-1). Unfortunately, angina is a highly subjective phenomenon for both patient and physician, and prospective evaluation of the assessment of functional classification by the CCS criteria has demonstrated a reproducibility of only 73%.[2] Furthermore, there may be a strikingly poor correlation between the severity of symptoms and the magnitude of ischemia, as is notoriously the case among diabetic patients with asymptomatic "silent ischemia."

Electrocardiography, if abnormal, is helpful in assessing ischemic burden. Unfortunately, it demonstrates no pathognomonic signs in half of patients with chronic stable angina.[3] Conversely, a normal electrocardiogram (ECG) is a strong indicator of normal left ventricular (LV) function.[4] The monitoring of an ECG under stress conditions is simple and inexpensive and therefore is useful as a screening examination. Among patients with anatomically defined disease, stress ECG provides additional information about the severity of ischemia and the prognosis of the disease.[5–7] The sensitivity of the test increases with patient age, with the severity of the patient's disease, and with the magnitude of observed ST-segment shift.[5] If ST-segment depression is greater than 1 mm, stress ECG has a predictive value of 90%, whereas a 2-mm shift with accompanying angina is virtually diagnostic.[8] Early onset of ST-segment depression and prolonged depression after discontinuation of exercise are strongly associated with significant multivessel disease. Unfortunately, many patients cannot achieve their target heart rates owing to beta blockade or a limitation to their exercise tolerance as a result of coexisting disease, decreasing the usefulness of this test in these often high-risk patients. Resting abnormalities in the ECG also may limit the predictive accuracy of the test.

Perfusion imaging with thallium-201- or a technetium-99m-based tracer may be particularly useful in patients with abnormalities on their baseline ECG. Reversible defects demonstrated by comparison of images obtained after injection of the tracer at peak stress with rest images is indicative of ischemia and hence viability. An irreversible defect indicates nonviable scarring.[9,10] The results obtained with both tracers are similar, with the average sensitivity around 90% and specificity of approximately 75%.[5] For patients unable to exercise, pharmacologic vasodilators such as adenosine or dipyridamole may be used with similar sensitivity.[11–15]

Echocardiographic imaging during exercise or pharmacologic stress has gained increasing popularity among

Table 20–1.

Canadian Cardiovascular Society Angina Classification

0 = no angina
1 = angina only with strenuous or prolonged exertion
2 = angina with walking at a rapid pace on the level, on a grade, or up stairs (slight limitation of normal activities)
3 = angina with walking at a normal pace less than two blocks or one flight of stairs (marked limitation)
4 = angina with even mild activity

cardiologists. Comparative studies have demonstrated accuracy similar to that of nuclear studies,[4,16,17] with sensitivity and specificity both around 85%.[5] Patients unable to exercise may be stressed with high-dose dipyridamole[18,19] or, more commonly, dobutamine at doses from 5 to 40 μg/kg per minute.[5,18,19] An initial augmentation of contractility followed by loss or "dropout" is diagnostic of ischemia (and, accordingly, viability), whereas failure to augment contractility at low dose suggests scar.[10,20,21] Additionally, information regarding concomitant valvular disease may be obtained during the examination.

GUIDELINES FOR REVASCULARIZATION

The guidelines for surgical revascularization established by the American College of Cardiology (ACC) and American Heart Association (AHA) are shown in Table 20-2.[22] The basis for these guidelines reside in the large body of literature comparing medical therapy with surgical revascularization and, more recently, percutaneous coronary interventions (PCIs).

Before reviewing the results of the seminal trials of coronary artery bypass grafting (CABG) versus medical therapy performed in the 1970s and those of newer prospective, randomized trials comparing the results of surgery with PCI and medical therapy, some limitations of these trials must be recognized. First, in retrospective or registry studies, it is difficult to ensure comparable patient populations by virtue of the extraordinary anatomic and physiologic complexity of CAD, as well as the heterogeneity of the patient substrate. Differences in ventricular function and comorbidities such as age, diabetes, peripheral vascular disease, and pulmonary disease may have a profound impact on outcomes such as survival and quality of life. This becomes particularly relevant among the elderly "sick" patient population, which in many centers may comprise the majority referred for CABG. For example, caution must be exercised in interpreting the results of nonrandomized and registry reports of PCI versus surgery because the patients subjected to the former more often have single- or double-vessel disease,[23–25] whereas the latter commonly have triple-vessel or left-main disease.[23,25] Attempts to correct for selection bias with statistical techniques such as propensity matching, are only as valid as the parameters entered into the model. Data less tangible than gender or chronologic age, such as socioeconomic status or "physiologic age," are not accounted for easily in such analyses and yet may be a critical determinant of outcomes. Despite this limitation, retrospective and registry data provide a better glimpse of the real world of CAD. Most prospective, randomized trials include only a fraction of the total population undergoing revascularization by virtue of strict entry criteria. For example, the Bypass Angioplasty Revascularization Investigators (BARI) trial[26] entered only 5% of total patients screened. Therefore, although the prospective, randomized studies do provide objective data directly applicable to the specific patient subset represented in the study, extrapolation of the results to the more heterogeneous populations seen clinically can only be made if the implicit caveats are clearly understood. We must be mindful of the inescapable tradeoff between selection bias in registry studies and entry bias in randomized studies.

A second limitation of these studies is a consequence of the over-representation of patients at lowest risk of death in randomized trials; most are statistically underpowered with respect to survival analysis. For example, given current survival statistics, we would need approximately 2000 patients in each arm of a study to detect a 30% difference in mortality. The problem is compounded by the exclusion of the very patients for whom one would anticipate a survival advantage with adequate revascularization, such as those with depressed ventricular function. Randomized studies frequently employ softer endpoints such as angina or quality of life or create composites of qualitatively different endpoints, such as death, stroke, and myocardial infarction (MI). Meaningful analysis is further complicated by relatively short-term follow-up in most studies. Events, such as the need for subsequent revascularization and recurrence of angina, characteristically occur at different time intervals after these therapies (restenosis after PCI versus graft occlusion after CABG), and an 8- to 10-year follow-up period is needed to compare long-term results adequately. Patients themselves also generally are interested in outcomes measured in years, not months.

A third limitation is that significant improvements in each of these treatment strategies are occurring constantly. Examples include the use of antiplatelet agents,[27] angiotensin-converting enzyme (ACE) inhibitors,[28] lipid-lowering therapy,[29] internal thoracic aortic (ITA) grafts, and intravascular stents[30] and the development of drug-eluting stents.[31] These advances, along with aggressive secondary prevention after revascularization, have reduced the morbidity and mortality of CAD steadily in all patients, making

Table 20–2.

AHA/ACC Guidelines for CABG*

Asymptomatic/mild angina

Class I

1. Left main stenosis
2. Left main equivalent (proximal LAD and proximal circumflex)
3. Triple-vessel disease

Class lla

1. Proximal LAD stenosis and one- or two-vessel disease

Class IIb

1. One- or two-vessel disease not involving proximal LAD

If a large territory at risk on noninvasive studies or LVEF < 50%, IIa and IIb become class I indications

Stable angina

Class I

1. Left main stenosis
2. Left main equivalent (proximal LAD and proximal circumflex)
3. Triple-vessel disease
4. Two-vessel disease with proximal LAD stenosis and EF < 50% or demonstrable ischemia
5. One- or two-vessel disease without proximal LAD stenosis but with a large territory at risk and high risk criteria on noninvasive testing
6. Disabling angina refractory to medical therapy

Class IIa

1. proximal LAD stenosis with one vessel disease
2. One- or two-vessel disease without proximal LAD stenosis, but with a moderate territory at risk and demonstrable ischemia

If a large territory at risk on noninvasive studies and meets high risk criteria on noninvasive testing becomes a class I indication

Unstable angina/non-ST-segment elevation MI (NSTEMI)

Class I

1. Left main
2. Left main equivalent
3. Ongoing ischemia not responsive to maximal nonsurgical therapy

Class IIa

1. proximal LAD stenosis with one- or two-vessel disease

Class IIb

1. One- or two-vessel disease without proximal LAD stenosis when PCI not possible (becomes class I if high risk criteria on noninvasive testing)

ST-segment Elevation (Q-wave) MI

Class I

1. Failed PCI with persistent pain or hemodynamic instability and anatomically feasible
2. Persistent or recurrent ischemia refractory to medical treatment with acceptable anatomy who have a significant territory at risk and not a candidate for PCI
3. Requires surgical repair of postinfarction ventricular septal rupture or mitral valve insufficiency
4. Cardiogenic shock in patients less than 75 years of age who have ST-segment elevation, LBBB, or a posterior MI within 18 hours of onset
5. Life-threatening ventricular arrhythmias in the presence of ≥ 50% left main stenosis or triple-vessel disease

Class IIa

1. Primary reperfusion in patients who have failed fibrinolytics or PCI and are in the early stages (6–12 hours) of an evolving STEMI
2. Mortality with CABG is elevated the first 3–7 days after STEMI/NSTEMI. After 7 days, criteria for revascularization in previous sections apply

(continued)

Table 20–2.

AHA/ACC Guidelines for CABG* *(continued)*

Poor LV function
Class I
1. Left main stenosis
2. Left main equivalent
3. Proximal LAD stenosis and two- to three-vessel disease
Class IIa
1. Significant viable territory and noncontractile myocardium
Life-threatening ventricular arrhythmias
Class I
1. Left main disease
2. Three-vessel disease
Class IIa
1. Bypassable one- or two-vessel disease
2. Proximal LAD disease and one- or two-vessel disease
These become class I indications if arrhythmia is resuscitated cardiac death or sustained ventricular tachycardia
Failed PCI
Class I
1. Ongoing ischemia with significant territory at risk
2. Hemodynamic instability
Class IIa
1. Foreign body in critical position
2. Hemodynamic instability with coagulopathy and no previous sternotomy
Class IIb
1. Hemodynamic instability with coagulopathy and previous sternotomy
Previous CABG
Class I
1. Disabling angina refractory to medical therapy
2. Nonpatent previous bypass grafts, but with class I indications for native CAD
Class IIa
1. Large territory at risk
2. Vein grafts supplying LAD or large territory are greater than 50% stenosed

**Class I: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective. Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of a procedure. Class IIa: Weight of evidence/opinion is in favor of usefulness/efficacy. Class IIb: Usefulness/efficacy is less well established by evidence/opinion. Class III: Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful.*

ACC = American College of Cardiology; AHA = American Heart Association; CABG = coronary artery bypass grafting; EF = ejection fraction; LAD = left anterior descending; LITA = left internal thoracic artery; LVEF = left ventricular ejection fraction; PCI = percutaneous transluminal coronary angioplasty.

differences in the hard endpoint of survival difficult to demonstrate for any therapy.[32] This trend likely will increase as the beneficial impact of the "quiet revolution" of secondary prevention becomes more widely appreciated.

COMPARATIVE TRIALS OF REVASCULARIZATION VS. MEDICAL THERAPY IN STABLE ANGINA

Medical Therapy

In the decades since CABG was popularized[33] and coronary angioplasty was introduced,[34] an enormous volume of data on the results of invasive revascularization has been collected. Remarkably, almost from the outset, many of these studies have been prospectively randomized. Yet, in the current era, there is a dearth of data concerning pharmacologic therapies for chronic CAD despite remarkable progress in recent years. For example, although nitrates are unquestionably effective in relieving symptoms, the impact of long-acting nitrates on clinical outcomes has never been tested rigorously. Furthermore, there has been only one trial of beta-blocker therapy in the treatment of angina, the Atenolol Silent Ischemia Trial (ASIST), which demonstrated benefit for patients with mild effort-induced angina or silent ischemia.[35] A handful of studies of combination therapy with beta blockers and calcium channel blockers also has demonstrated antianginal benefit.[36–38] Most recently, randomized trials of

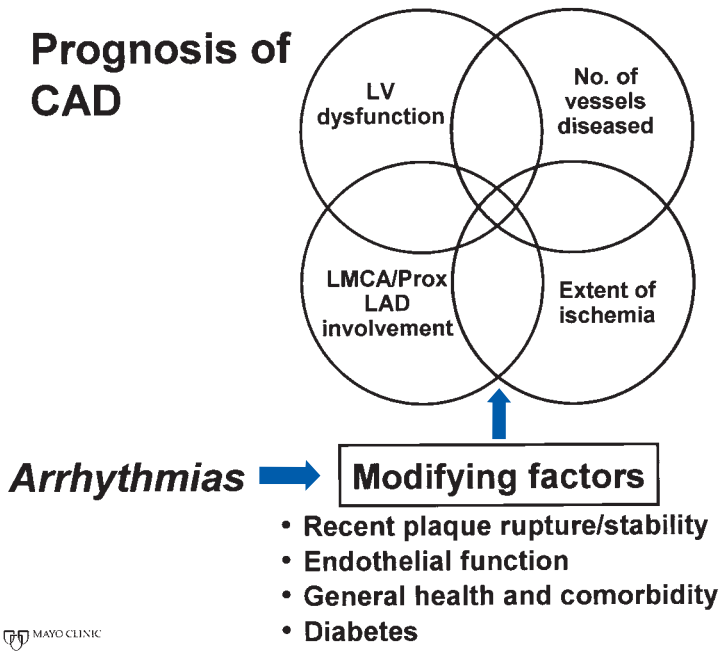

Figure 20-1. The decision regarding mode of therapy for coronary artery disease depends on the individual patient's prognosis as determined by both cardiac and noncardiac conditions.

two new drugs, nicorandil and ranolazine, have been reported.[39,40] However, beyond these few studies, there is little published on the impact of medical therapy alone on survival.

Surgical versus Medical Therapy

Three major randomized studies, the Coronary Artery Surgery Study (CASS),[41] the Veterans Administration Cooperative Study Group (VA),[42,43] and the European Coronary Surgery Study (ECSS),[44,45] as well as several other smaller randomized trials[46–48] conducted between 1972 and 1984, provide the foundation for comparing the outcomes of medical and surgical therapy. Despite the limitations noted earlier, these studies are remarkably consistent in their major findings, and the qualitative conclusions drawn from them continue to be generalizable to current practice.

The central message from all these studies is that the relative benefits of bypass surgery over medical therapy on survival are greatest in the patients at highest risk, as defined by the severity of angina and/or ischemia, the number of diseased vessels, and the presence of left ventricular (LV) dysfunction[42,49] (Fig. 20-1). For example, thus far, no study has shown survival benefit for CABG over medical therapy for patients with single-vessel disease.[50–52] It should be emphasized, however, that these trials involved primarily patients with moderate chronic stable angina. These conclusions therefore may not necessarily apply to patients with unstable angina or to patients with more severe degrees of chronic stable angina.

A meta-analysis[49] of the seven randomized trials cited earlier demonstrated a statistically enhanced survival at 5, 7, and 10 years for surgically treated patients at highest risk (4.8% annual mortality) and moderate risk (2.5% annual mortality) but no evidence of a survival benefit for the patients at lowest risk.[49] The overall survival benefit at 12 years for the three large and four smaller randomized studies is shown in Fig. 20-2. Nonrandomized studies also have demonstrated a beneficial effect of surgery on survival of patients with multivessel disease and severe ischemia regardless of LV function.[53–56]

There have been three recent randomized, controlled trials of invasive revascularization by PCI or CABG versus medical therapy. Their results make an even stronger case for revascularization. In the Asymptomatic Cardiac Ischemia Pilot (ACIP) trial, patients with anatomy amenable to CABG were randomized to angina-directed anti-ischemic therapy, drug therapy guided by noninvasive measures of ischemia, or revascularization by CABG or PCI.[57] At 2 years, mortality

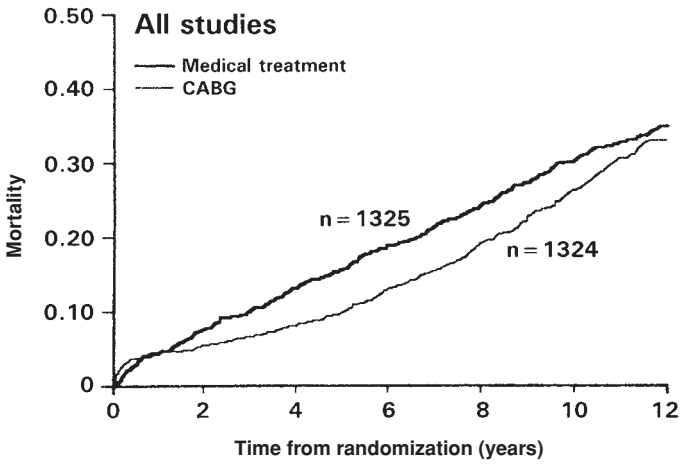

Figure 20-2. Survival (mortality) curves for all medically and surgically treated patients with chronic stable angina enrolled in seven prospective, randomized, controlled trials. *(Reproduced with permission from Yusuf S, Zucker D, Peduzzi P, et al: Effect of coronary artery bypass graft surgery on survival: Overview of 10-year results from randomized trials by the Coronary Artery Bypass Graft Surgery Trialist Collaboration. Lancet 1994; 344:563.)*

was 6.6% in the angina-guided group, 4.4% in the ischemia-guided group, and 1.1% in the revascularization group. The rates of death or MI were 12.1, 8.8, and 4.7%, respectively. By pairwise testing, the differences between revascularization and angina-guided therapy were statistically significant. The Medicine, Angioplasty, or Surgery Study (MASS-II) randomized patients with multivessel disease among medical therapy, PCI, and CABG. While survival at 1 year was equivalent, freedom from additional intervention was 99.5% for surgical patients and 93.7% for medically treated patients. Reintervention, incidentally, was even higher in the PCI group than in the medical group, with 86.7% free of additional intervention. Angina relief was superior in the CABG group (88%) than in the PCI group (79%) or the medical therapy group (46%).[58]

In the Trial of Invasive versus Medical Therapy in Elderly Patients with Chronic Symptomatic Coronary Artery Disease (TIME), elderly patients with chronic angina were studied. This trial failed to demonstrate a difference between optimized medical therapy and an invasive revascularization strategy (PCI or CABG) in terms of symptoms, quality of life, and death or nonfatal MI (20 versus 17%; $p = .71$). However, medically treated patients were at higher risk owing to major clinical events (64 versus 26% for invasive; $p < .001$), which mainly were attributable to rehospitalization and revascularization.[59] In this trial of severely symptomatic elderly patients, it was encouraging that the price of an initially conservative strategy, followed by crossover to revascularization in approximately 50% of patients, was not paid for in terms of death or MI.[59]

Early concern over a prohibitive operative mortality among patients with impaired ventricular function has been superseded by recognition that the survival of these patients on medical therapy was much worse than their survival with revascularization. This, coupled with ever-improving surgical techniques, such as advances in myocardial preservation and perioperative support, has made this specific subgroup the one in which the relative survival benefit of surgical therapy is the greatest. Accordingly, LV dysfunction in patients with documented ischemia is now considered an important indication—rather than a contraindication—for surgical revascularization.[41,49,53,60,61] Recent evidence that ischemic, viable, hypokinetic myocardium (hibernating or stunned) regains stronger contractile function following effective revascularization has prompted expansion of the indications for surgical revascularization among patients with severe LV dysfunction to include patients who otherwise would be considered candidates for cardiac transplantation. This subject is discussed in more detail below.

In summary, with regard to chronic stable angina, a survival advantage is demonstrable for surgical revascularization over medical therapy in patients with left main disease,[62] triple-vessel disease and LV dysfunction,[63,64] two-vessel disease and proximal left anterior descending (LAD) disease,[65] and severe ischemia and multivessel disease[66,67] (Fig. 20-3). These survival advantages have not been demonstrable among patients with single-vessel disease.[68–70]

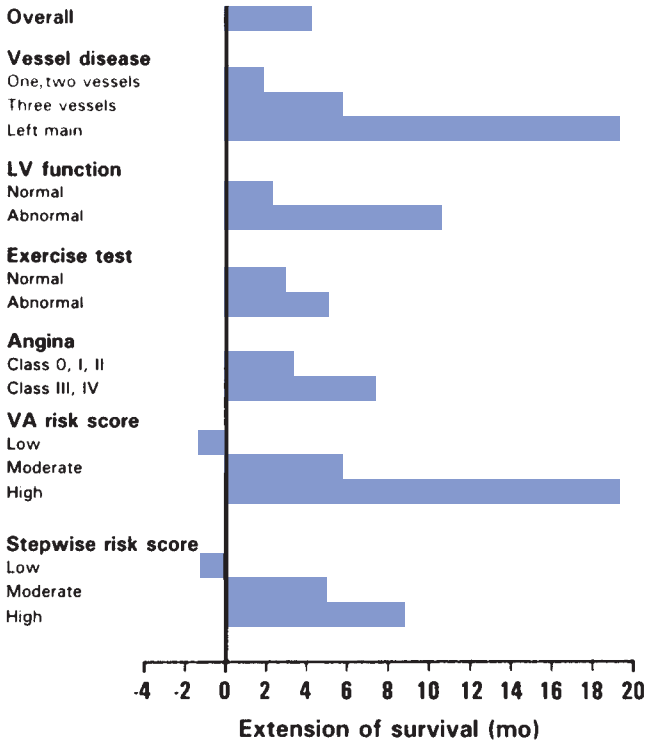

Figure 20-3. Extension of survival in months for various subgroups of patients with chronic stable angina treated by surgery as compared with those treated by medicine in seven prospective, randomized, controlled trials. *(Reproduced with permission from Yusuf S, Zucker D, Peduzzi P, et al: Effect of coronary artery bypass graft surgery on survival: Overview of 10-year results from randomized trials by the Coronary Artery Bypass Graft Surgery Trialist Collaboration. Lancet 1994; 344:563.)*

Apart from affording a survival benefit, CABG is indicated for the relief of angina pectoris and improvement in the quality of life. Between 80 and 90% of patients who are symptomatic on medical therapy become symptom-free following CABG. This benefit extends to low-risk patients for whom survival benefit from surgery is not likely.[49] Relief of symptoms appears to relate to both the completeness of revascularization and the maintenance of graft patency, with the benefit of CABG diminishing with time. Recurrence of angina following CABG occurs at rates of 3 to 20% per year. Although enhanced survival is reported when an ITA graft is used to the LAD artery, there is no significant difference in postoperative freedom from angina.[70] This may be due to vein graft occlusion or progression of native disease in grafted or ungrafted vessels.[42]

Unfortunately, few patients experience an advantage in work rehabilitation with surgery compared with medical management. Generally, employment declines in both groups and is determined nearly as much by socioeconomic factors such as age, preoperative unemployment, and type of job as by type of therapy or clinical factors such as postoperative angina. Notably, surgical revascularization has not been shown to reduce the incidence of nonfatal events such

as MI, although this may be due to perioperative infarctions that offset the lower incidence of infarction in each study follow-up.[54,71]

PCI versus Medical Therapy

Despite the increasing application of catheter-based technology to multivessel disease, most interventions historically have been in single-vessel disease.[25] Accordingly, most of the data comparing angioplasty with medical therapy are derived from studies consisting principally or exclusively of patients with a limited extent of obstructive disease, although most people with angiographically detectable stenosis in one vessel have more extensive atherosclerotic changes throughout other coronary vessels. Many of these trials also antedate the use of glycoprotein IIb/IIIa inhibitors, clopidogrel, and stents. Although angiographic success rates of 85 to 90% are commonplace, no study to date has ever shown a benefit in survival or subsequent MI for PCI over medical therapy in patients with stable angina pectoris. The results of several recent studies, however, have demonstrated improvement in symptoms and exercise tolerance.

In the ACME-I (A Comparison of Angioplasty with Medical Therapy) study, 212 patients with documented ischemia and a single coronary artery stenosis greater than 70% were assigned randomly to medical therapy or angioplasty.[72] After 6 months, there was no mortality difference in either treatment group, but PCI provided more complete angina relief with fewer medications and better quality-of-life scores, as well as longer exercise duration on stress testing, than medical therapy.[72] This benefit came at some cost, however; among the 100 angioplasty patients, 19 underwent repeat PCI, and 7 underwent CABG during the first 6 months, compared with 11 angioplasty procedures and no CABG in the patients randomized to medical therapy.[72] Moreover, nearly half of all patients assigned to initial medical therapy were asymptomatic at 6 months. Because this modest symptomatic benefit was achieved at such a large procedural and financial cost, patients who are either asymptomatic or have mild symptoms should have objective evidence of ischemia prior to PCI.[73] In a follow-up study by the same investigators, 101 patients with stable angina and two-vessel disease were randomized to PCI or medical therapy.[74] At 6 months, both groups had similar improvement in exercise duration, freedom from angina, and overall quality of life. These studies together suggest that in many patients an initial trial of medical therapy is appropriate.

Several recent studies have included patients with multivessel disease. In the Randomized Intervention Treatment of Angina-2 (RITA-2) study of 1018 patients with stable angina randomized to medicine or PCI, one-third had two-vessel disease, and 7% had three-vessel disease.[75] Perhaps surprisingly, at a median follow-up of 2.7 years, the primary endpoints of death or MI had occurred twice as often in the PCI group (6.3 versus 3.3%; $p < .02$). Surgical revascularization was required during the follow-up interval in 7.9% of the PCI group, and repeat angioplasty was required in 11%. In the medical group, 23% of patients required revascularization. Angina relief and exercise tolerance were improved to a greater degree in the angioplasty group early, but this difference disappeared by 3 years.[75] These results are echoed in the MASS-II trial, in which angina relief was superior with PCI, but rates of intervention/reintervention were higher in the PCI group.[58] Again, this supports an initial strategy of medical therapy.

A comparison of PCI versus medicine as initial strategy among patients with hyperlipidemia was done in the Atorvastatin versus Revascularization Trial (AVERT).[76] Among 341 patients with single- or double-vessel disease, ischemic events were less common in the medical therapy group than in the PCI group (13 versus 21%; $p < .05$). Although criticized for employing outdated angioplasty technology and other issues, the results of this study are consonant with the recent demonstration that lipid-lowering agents may have a powerful impact on ischemic events.[77–79] In some respects, the lower use of aggressive lipid-lowering agents in the PCI arm biased the results in favor of medical therapy.

A meta-analysis of percutaneous interventions versus medical management was published in 2005.[80] In patients with stable CAD, no benefit was found for invasive therapy in terms of death, MI, or need for subsequent revascularization. This provides compelling evidence that, thanks to substantial improvements in medical management, all patients should have a trial of optimized medical therapy prior to invasive intervention.[80]

PCI versus CABG

Randomized studies

A number of studies comparing an initial strategy of angioplasty versus early surgery have been carried out, all with similar results. It is important to recognize that these studies are comparisons of treatment strategies and not head-to-head comparisons of revascularization techniques. Accordingly, crossover is permitted, and endpoints are selected to determine adverse consequences of the algorithm.

A single-center Swiss study of 134 patients with isolated LAD artery disease was reported in 1994.[52] At 2.5 years of follow-up, there was no significant difference in combined outcomes of MI and cardiac death between treatment groups. There was, however, a greater need for surgical revascularization in the initial PCI treatment group, with 25% requiring a second revascularization procedure compared with only 4.4% in the initial CABG group. Although the PCI patients were taking significantly more antianginal medication, clinical impairment level, stress-test performance, and quality-of-life indices did not differ at 2 years. These findings held up at 5 years,[81] with no difference between groups with respect to mortality or functional outcome despite repeat procedures in the PCI group.

The Medicine, Angioplasty, or Surgery Study (MASS) from Brazil compared medical therapy, PCI, and CABG using an ITA bypass graft at a single center in 214 patients with stable angina, normal LV function, and proximal stenosis of the

LAD coronary artery.[51] In this relatively small but nonetheless important randomized trial, the combined endpoint of cardiac death, MI, or refractory angina requiring revascularization was statistically significantly less in surgically treated patients. Moreover, there was no significant difference between patients treated medically or with PCI. In comparison with medical therapy, however, both PCI and CABG surgery were shown to provide improved relief of severe symptoms of angina pectoris and a lower frequency of inducible ischemia on treadmill exercise testing. There was no difference among the three strategies with respect to mortality or late MI at 1 year. Similar findings were obtained at 5-year follow-up.[82]

The results of the MASS-II trial, which enrolled 611 patients with multivessel disease, have reported 1-year outcomes as noted earlier.[58] Although technology is a moving target, this trial has the advantage that approximately 70% of PCI patients had stents placed. Despite this, the results were remarkably similar to those of the first MASS trial, with a lower incidence of adverse events in the medical group than in the PCI group. Surgical therapy provided the best angina relief and lowest incidence of adverse events. All therapies had similar survival rates.

A number of larger prospective, randomized studies comparing PCI with CABG have been reported in recent years. All share the limitation that, in general, only a very small minority of patients undergoing revascularization at any center were entered into these trials.[83,84] Accordingly, the populations included in the trials may not be reflective generally of clinical practice. For instance, few patients in these studies had significant LV dysfunction, and most randomized patients had only one- or two-vessel disease. In the RITA trial, approximately one-third of patients had single-vessel disease.[85] Among clinically eligible patients in the BARI[68] trial and the Emory Angioplasty versus Surgery Trial (EAST),[69] approximately two-thirds of patients were excluded on angiographic grounds that included chronic total occlusion, left main coronary artery stenosis, diffuse disease, or other anatomic factors making PCI potentially dangerous.[68,69] Consequently, these randomized trials contain only a portion of the spectrum of patients with CAD encountered clinically.

Entry bias has a significant impact on the likelihood of observing an outcome difference between therapies. Since a high proportion of the randomized patients are in the low-risk group, in whom no survival advantage could be demonstrated when CABG was compared with medical therapy in the earlier CAST, ECSS, and VA randomized trials,[41–43] it is possible that any potential survival benefit of CABG over PCI in high- and moderate-risk groups may be masked.[84]

A second consideration in evaluating these studies is that the success of revascularization procedures depends not only on the criteria employed to define success but also on the interpretation of those criteria by both patient and physician. In the 1985–1986 National Heart, Lung, and Blood Institute PCI Registry, 99% of patients were discharged alive from hospital, and 92% did not sustain a MI or require CABG.[34] In the most recent BARI trial, 99% of patients survived hospitalization, and 88.6% of PCI-treated patients did not have an MI or require repeat revascularization by angioplasty or surgery during the initial hospitalization.[68] Employing event-free criteria (i.e., death, MI, or CABG) for the initial hospitalization, PCI can be judged successful. However, if a repeat revascularization procedure within 5 years is regarded as a negative outcome, then only 45.5% of PCI-treated patients are treated successfully.[68] Regardless, the lack of differences in mortality or MI rates permits individuals to select one or the other procedure as initial therapy without the likelihood that they will pay a serious price.

In the BARI, EAST, CABRI, GABI, and RITA multivessel PCI versus CABG trials,[68,69,85,86,177] mortality was similar between 1 and 5 years of follow-up in both the PCI and CABG treatment groups. Mortality ranged from 3% in the CABRI trial at 1-year follow-up[177] and 3.4% in the RITA trial at 2.5 years[85] to 13% in the BARI trial at 5 years.[68] A slightly higher incidence of MI was noted in some of these trials.

The incidence of repeat revascularization is higher among patients treated with angioplasty than in those treated with surgery in all trials carried out to date. The incidence of repeat revascularization in the PCI-treated patients ranged from 36.5% in the CABRI trial at 1-year follow-up to 62% in the EAST trial at 3 years. The repeat revascularization rate in the EAST trial for angioplasty-treated patients was much higher than that noted in the BARI, CABRI, and RITA trials. There was a concentration of repeat revascularization procedures in trials that required stress thallium and angiography studies at 1 year; thus, some of these procedures may have occurred in the EAST trial as a consequence of protocol-mandated tests rather than clinical indications.[17] In contrast to PCI, repeat revascularization is less common after CABG in these same studies. The incidence of repeat revascularization procedures in multivessel patients randomized to CABG ranged from 3.5% in the CABRI trial to 13.5% in the EAST trial.[69,177] Generally, repeat revascularization procedures were required five to eight times more often in patients with multivessel disease treated initially with angioplasty than in those randomized to initial CABG. The incidence of angina at follow-up also generally was greater in the PCI-treated patients than in those randomized to CABG.

In the BARI trial at 5 years, 54.5% of patients assigned initially to PCI had undergone a repeat revascularization procedure.[68] Of these, 23.2% had repeat PCI, 20.5% underwent CABG, and 10.8% had both PCI and CABG.[68] Sixty-nine percent of PCI-treated patients who were angina-free at 5 years had not required CABG. Among angina-free patients at 5 years, only 48% of the angioplasty-treated patients compared with 94% of the CABG patients had not had an additional revascularization procedure after the initial procedure.[68] An important subgroup analysis of the BARI trial demonstrated a marked survival benefit with surgery for patients with insulin-dependent diabetes receiving an ITA graft.[87]

Several more recent studies of PCI versus surgery have confirmed these findings. The Argentine Randomized Trial of Coronary Angioplasty versus Bypass Surgery in Multivessel Disease (ERACI) trial conducted between 1998 and 1990

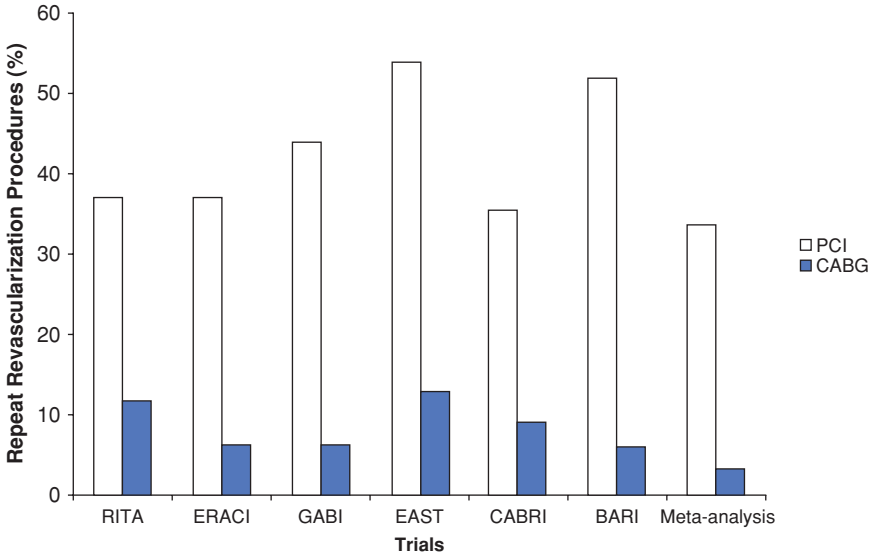

Figure 20-4. Risk of repeat revascularization in six randomized trials of PCI versus CABG and a meta-analysis.[83] See refs. 68, 69, 85, 86, 88, 177 for explanation of acronyms.

demonstrated no difference in death or MI but superior event-free survival in the CABG group at 1 and 3 years.[88,89] In the French Monocentric Study, 152 patients with multivessel disease underwent PCI or CABG.[90] Again, superior event-free survival was seen in the surgical group, driven predominantly by a lesser need for subsequent revascularization.

The impact of stent technology on the comparative results of PCI and CABG has been investigated recently. In the Arterial Revascularization Therapy Study (ARTS), 1205 patients with multivessel disease underwent CABG or PCI with bare-metal stents.[91] No significant differences in the primary endpoint of freedom from death, stroke, or MI at 1 year were observed, although the need for revascularization remained higher in the angioplasty group than in the surgery group. A similar study was performed by the second Argentine Randomized Trial of Coronary Angioplasty versus Bypass Surgery in Multivessel Disease (ERACI-2) study group.[92] Again, even with the use of stents, repeat revascularization was more common in the PCI group, particularly among diabetics, in whom repeat revascularization was reported as 22.3 versus 3.1% in the CABG group.[93] Of note, in this study, the 30-day mortality was higher in the CABG group than in the PCI group, as was the incidence of Q-wave MI. The relatively high operative mortality rate (5.7%) in the surgery group as compared with the angioplasty group has raised many questions. Despite this, at 5 years, there was no difference in survival, and again, CABG patients had a lower incidence of revascularization. The findings of the Surgery or Stent (SOS) study, which compared outcomes in almost 1000 patients with multivessel disease, demonstrated similar all-cause mortality among surgical compared with angioplasty patients and confirmed higher rates of repeat revascularization after angioplasty and lower freedom from angina pectoris in both patients with and without a recent acute coronary syndrome.[94] Of interest in this study, the reintervention rate, while still higher than after surgery, was far below that reported previously for angioplasty at only 17%.

A meta-analysis by Mercado and colleagues combined results from the ARTS, ERATS-II, MASS-II, and SOS trials. One-year outcomes demonstrated similar rates of death, MI, and stroke. Revascularization rates, however, remain higher with PCI.[95]

Recent progress in stent technology, particularly the introduction of drug-eluting devices, promises to further reduce the incidence of restenosis, likely narrowing the gap in late outcome between PCI and CABG. The use of stents certainly has reduced adverse remodeling,[96] and stent eluting medications such as sirolimus and paclitaxel are having a profound effect on the patterns of interventions for CAD. When compared with bare-metal stents, drug-eluting stents (DESs) have not been shown to convey any advantage in terms of MI or mortality but do demonstrate decreased rates of angiographic restenosis and major cardiac events in a meta-analysis of 11 randomized trials.[31] Despite a lack of long-term data, DESs are being implanted with increasing frequency. Interestingly, with the reduction in restenosis rates, evidence suggests that clinical outcomes after stenting may be limited by disease progression in native coronary arteries.[97] Therefore, it is not yet clear what the final impact will be of these burgeoning technologies.

In conclusion, the randomized trials of PCI versus CABG are useful, but only if results are interpreted in a context of patients entering or eligible to enter these trials.[83,84] PCI is a reasonable alternative to CABG, and for many patients, it is the preferred initial approach, provided that the patient understands that there may be a higher incidence of recurrent angina and need for repeat revascularization procedures. This applies to patients with multivessel disease and preserved LV function in the main. For most patients similar to those included in these published trials, it is reassuring that a nonsurgical revascularization procedure does not place them at increased risk of MI or death in comparison with the outcomes of surgical therapy. To extrapolate these results to patients who are not eligible for entry, however, it is intellectually flawed and potentially misleading.

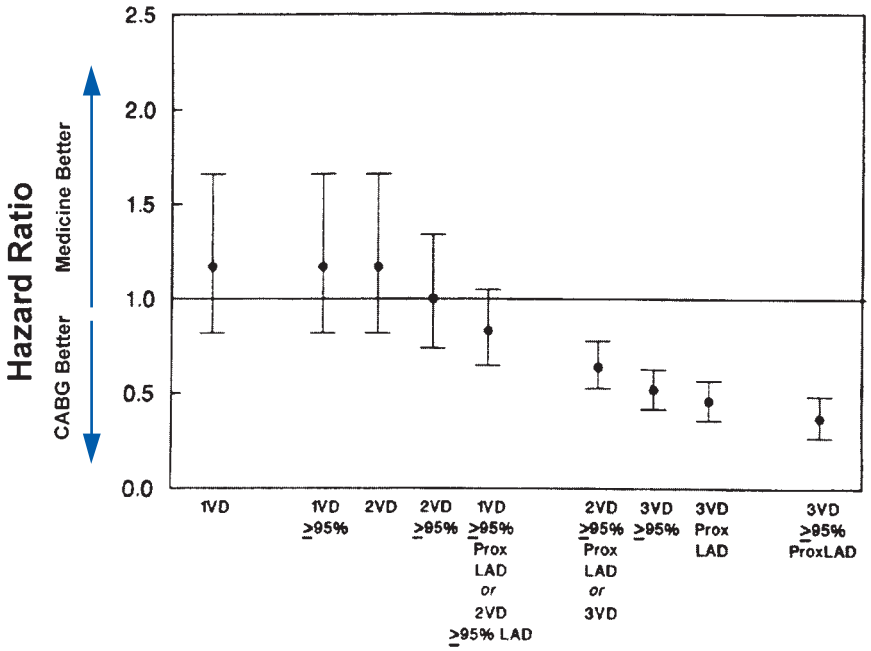

Figure 20-5. Hazard (mortality) ratios for CABG versus medicine calculated from the Cox regression model to evaluate relative survival differences. Points indicate hazard ratios for each level of a weighted (0 to 100), hierarchical, prognostic coronary artery disease index. Bars indicate 99% confidence intervals. Horizontal line at 1.0 indicates point of prognostic equivalence between treatments. Hazard ratios below this line favor CABG; those above the line favor medicine. VD, vessel disease; Prox LAD, proximal left anterior descending coronary artery. *(Reproduced with permission from Mark DB, Nelson CL, Califf RM, et al: Continuing evolution of therapy for coronary artery disease: Initial results from the era of coronary angioplasty. Circulation 1994; 89:2015.)*

Nonrandomized database comparisons

The information provided by randomized studies is completed by information gleaned from large, prospectively managed, nonrandomized database studies. In the Duke Cardiovascular Disease Databank, 9263 patients undergoing clinically indicated coronary angiography between 1984 and 1990 were followed for a mean of 5 years after nonrandomized treatment by CABG, PCI, or medical therapy.[25] Patients with valvular disease, prior revascularization, significant (>75%) left main disease, and congenital and nonischemic cardiomyopathy were excluded. Overall, 39% of the patients had single-vessel disease, 31% had two-vessel disease, and 30% had three-vessel disease. Initial therapy was medical in 3053 patients, PCI in 2788 patients, and CABG in 3422 patients. To correct for baseline differences among treatment groups, a standard covariate adjustment was performed that included all identified prognostic factors in a multivariate survival model. Complete follow-up was obtained in 97% of patients. The 5-year survival was 91%, remarkably similar to that reported from Emory, which showed an overall adjusted 5-year survival rate of 93% in both groups.[61] The mortality hazard ratios derived from the Cox regression model to evaluate relative survival differences in this database study are shown for medicine versus CABG in Fig. 20-5, PCI versus medicine in Fig. 20-6, and PCI versus CABG in Fig. 20-7.[25]

From a practical standpoint, in this database study and in the randomized trials, the effect of revascularization on survival depended largely on the extent of the CAD and is an example of the concept of benefit in relationship to a "gradient of risk." For the least severe (one-vessel) disease, there were no survival advantages of revascularization over medical therapy in up to 5 years of follow-up.[25] For intermediate levels of CAD severity (i.e., two-vessel disease), there was a higher 5-year survival rate for patients undergoing revascularization than for those treated medically. For patients with the most severe CAD (i.e., three-vessel disease), CABG provided a significant and consistent survival advantage over medical therapy. PCI appeared prognostically equivalent to medical therapy in these patients, but only a small number of patients in this subgroup underwent angioplasty. In comparing PCI with CABG, PCI demonstrated a small survival advantage over CABG for patients with less severe two-vessel disease, whereas CABG was superior for more severe two-vessel disease (i.e., proximal LAD artery involvement).[25]

These important findings have been confirmed in the current era of PCI with stent implantation using the New York State Database. Hannan and colleagues published results in 1999 using cases from 1993 to 1995.[98] In this study, a survival benefit was observed with angioplasty at 3 years for patients with single-vessel disease not involving the LAD, whereas those with LAD or three-vessel disease had superior outcomes with surgery. In the more recent study of patients with multivessel disease who received PCI, survival was higher among the 37,212 patients who underwent CABG than among the 22,102 patients who underwent stent placement after adjustment for known risk factors. The adjusted hazard ratio for the long-term risk of death after CABG relative to stents was 0.64 (95% CI 0.56 to 0.74) for triple-vessel disease and proximal LAD disease. This hazard ratio increased to 0.76 (95% CI 0.60 to 0.96) for patients with two-vessel disease and LAD involvement[99] (Fig. 20-8). This study has limitations of being a nonrandomized study and subject to bias; however, the surprising finding of a survival advantage apparent as early as 3 years postprocedure suggests that improvements in cardiac surgical anesthetic care, myocardial protection, and intensive-care management at least have matched, if not surpassed, advances in percutaneous technology. It is important to note that PCI targets the culprit lesion. In contrast, CABG targets both the culprit lesion and potential future culprit lesions by bypassing the diseased vessel. This may explain in part the apparent mortality benefit derived with CABG[100] (Fig. 20-9).

SPECIAL CIRCUMSTANCES

Acute Coronary Syndromes

The acute coronary syndromes (ACSs) cover a wide spectrum from ST-segment elevation MI with underlying coronary obstruction to Prinzmetal or variant angina in patients with coronary vasospasm in the absence of significant underlying obstruction. The term *non-ST-segment-elevation ACS* encompasses the entities of unstable angina, non-Q-wave MI, and postinfarction angina. They denote acute, symptomatic imbalances of the myocardial oxygen supply: demand ratio over a short time span. Prinzmetal angina, or coronary vasospasm, is diagnosed definitively by ECGs obtained during the episode of pain and is treated medically. Unstable angina is not a uniform clinical entity but consists of the spectrum of myocardial ischemia between chronic stable angina and MI. Unstable angina is defined as a recent change in the severity, character, or trigger threshold of

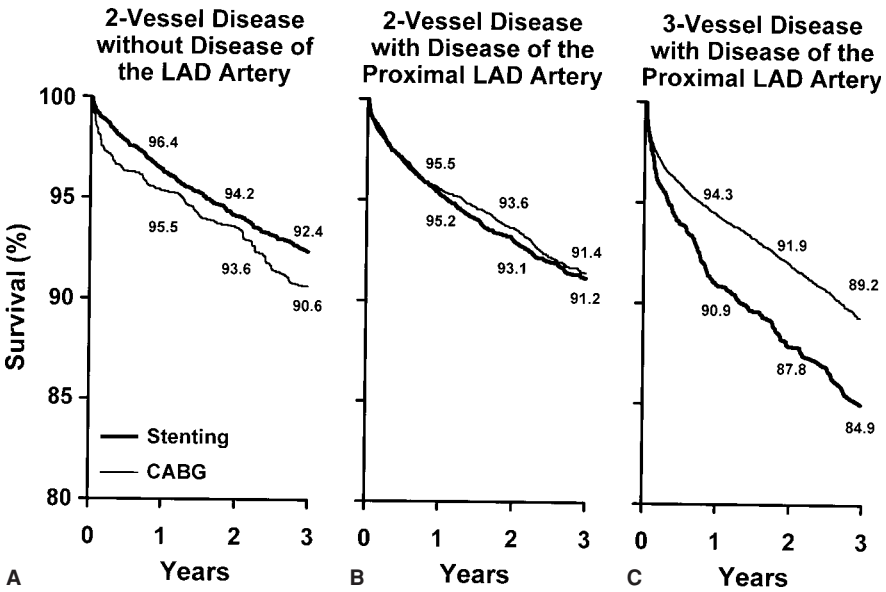

Figure 20-8. Unadjusted Kaplein-Meier survival curves in patients with two-vessel disease without involvement of the LAD artery (A); patients with two-vessel disease with involvement of the proximal LAD artery (B); and patients with three-vessel disease with involvement of the proximal LAD artery (C). *(Reproduced with permission from Hannan E, Racz M, Walford G, et al: Long-term outcomes of coronary-artery bypass grafting versus stent implantation. N Engl J Med 2003;352:2174.)*

chronic stable angina or new-onset angina. Approximately 5.6 million Americans have chronic angina, and about 350,000 develop new-onset angina each year.[101] Unstable angina develops in approximately 750,000 Americans each year and is associated with subsequent MI in approximately 10%. Postinfarction angina is defined as the presence of angina or other evidence of myocardial ischemia in a patient with a recent (1 to 2 weeks) Q-wave or non-Q-wave MI.

Unstable angina and postinfarction angina are classified into subsets according to the triggering stimulus (A to C) and frequency of pain (I to III).[102] Class A indicates angina precipitated by an extracardiac or indirect stimulus such as an arrhythmia or hypotension that can be reversed by medical management. Class B indicates angina without such an extracardiac or indirect stimulus, and class C indicates angina in the presence of acute MI. Class I is new or accelerated angina without rest pain. Class II is angina occurring at rest within 1 month but not within 48 hours of ACS. Class III is angina at rest within 48 hours of an ACS.

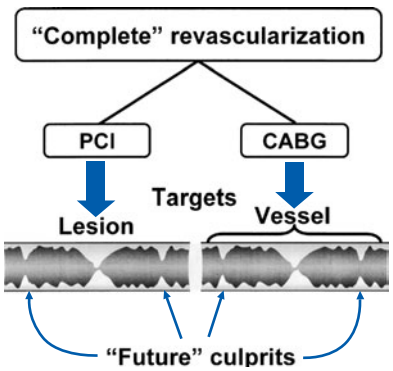

Figure 20-9. PCI is directed against specific culprit lesions. By bypassing diseased vessels, CABG treats both culprit lesions and future culprit lesions. *(Reproduced with permission from Opjie LH, Commerford PJ, Gersh BJ: Controversies in stable coronary artery disease. Lancet 2006; 367;69.)*

The initial approach to the patient with non-ST-segment-elevation ACS (NSTEMI) is pharmacologic stabilization, followed by risk stratification. The latter is based on multiple clinical, demographic, and electrocardiographic variables in addition to the use of serum biomarkers. In institutions with facilities for early angiography, patients at intermediate or high risk (the majority) undergo early angiography with a view toward revascularization. In many parts of the world, however, angiographic facilities are limited, and an alternative approach based on pharmacologic stabilization followed by mobilization and risk stratification using stress testing is employed.

The most recent randomized, controlled trials of aggressive versus conservative approaches to non-ST-segment-elevation ACS are the FRISC2, TACTICS, and VINO trials.[103–105] Despite differences between these trials, the results favor an aggressive strategy with a view toward revascularization in the majority of patients shown to be at high risk (e.g., older patients, diabetics, those with ST-segment depression on ECG, and those with elevated CPK-MB or serum troponins).

CABG versus medical therapy in ACS

The technical advances in PCI in the setting of ACS have relegated CABG largely to a secondary position in most cases. The special circumstances of postinfarction mechanical complications of papillary muscle rupture, ventricular septal defect, and shock are addressed specifically in other chapters of this text. It should be noted here, however, that two multicenter trials and one single-center randomized trial involving a total of 823 patients have evaluated the relative merits of CABG and medical therapy in unstable angina during the 1970s.[106–108] Patients with left main disease, poor LV function (ejection fraction $<30\%$), and age greater than 70 years were not included. In the VA cooperative study, improved survival and a lower rate of recurrent angina were shown with surgery,

and at both 5 and 8 years, there were fewer subsequent hospitalizations for cardiac reasons in the surgical group.[109] Interestingly, there was no difference in progression to Q-wave MI between medical and surgical groups.[109] Like the VA study, the National Cooperative Study Group Trial[106] showed no difference in progression to Q-wave MI but less severe subsequent angina with operation. Unlike the VA study, however, there was no survival difference at 2 years (90% in both groups). Of note, 32% of the medical group crossed over to surgery by 24 months. Since current medical therapy was not available to these patients, there is significant difficulty in extrapolating the results of these trials to current clinical practice. Finally, Bertolasi and colleagues reported a single-center study of 113 patients that demonstrated less subsequent angina, fewer infarctions, and a survival benefit for surgery in short-term follow-up.[107]

In the TIMI-IIIB trial, medical management followed by earlier delayed PCI or CABG resulted in 6-week mortality and nonfatal MI rates of 2.1% and 6.1% among 1473 patients with unstable angina or non-Q-wave MI (NQWMI).[108] This study compared the results of a strategy of initial stabilization followed by aggressive treatment involving routine angiography followed by revascularization in the presence of suitable anatomy with a conservative arm reserving angiography for those with recurrent angina or a positive stress test. At 42-day and 1-year follow-up, there was no difference in death or MI between the two groups. Subsequent subset analyses have demonstrated a trend in favor of an aggressive approach to revascularization over medical therapy in patients at higher risk, as characterized by an elevated CPK-MB fraction (NQWMI).[109] In the end, revascularization rates were similar, with only the timing of that revascularization event being different.

The Veterans Affairs Non-Q-Wave Infarcts and Strategies in Hospitals (VANQWISH) trial[111] was a similar design to TIMI-IIIB. A higher early mortality rate was observed in the invasive group than in the medical group possibly owing to the extraordinarily high perioperative mortality rate of 7.7% in the CABG group. The opposite result was found in the second Fragmin and Fast Revascularization during Instability in Coronary Artery Disease trial (FRISC II).[103] These investigators found a benefit with early revascularization, particularly among patients with elevated troponins. The reason for such different results among these studies is likely due to differences in patient populations studied. It is likely that higher-risk patients benefit from an aggressive approach, whereas lower-risk patients have less to gain and so are more likely to suffer adverse consequences.

The Angina with Extremely Serious Operative Mortality Evaluation (AWESOME) was reported in 2004,[112] comparing results from PCI and CABG. Patients were enrolled who had increased risk of adverse outcomes with CABG, including greater than one risk factor, prior CABG; ACS within 7 days; left ventricular ejection fraction (LVEF) $< 35\%$; age > 70 years; or intra-aortic balloon pump. Results suggested that PCI and CABG have similar outcomes for patients with ACS, even in those with low ejection fractions.

PCI for acute MI

Because of the rapidity with which vessel patency can be restored using percutaneous techniques, PCI has all but replaced CABG in the setting of acute ST-segment-elevation MI (STEMI). Both thrombolytic therapy and direct or primary angioplasty can restore coronary artery patency and flow during acute STEMI. In the absence of hemorrhagic concerns, however, thrombolytic therapy is more widely available and is standard early therapy for acute transmural MI when immediate angioplasty is unavailable.

In the few instances in which surgical revascularization must be undertaken following thrombolysis or acute angioplasty, perioperative bleeding is increased. Bleeding has been shown not to be excessive if glycoprotein IIb/IIa inhibitors are discontinued at least 2 hours preoperatively[113] or if a platelet transfusion is provided in the presence of abciximab.[114] Clopidogrel should be held for 5 days prior to surgery if possible.[115]

Several early myocardial reperfusion trials have assessed the role of routine adjunctive angioplasty given that not all arteries can be reopened by thrombolysis, that reocclusion occurs in some arteries opened initially, and that reocclusion is associated with increased morbidity and mortality.[116,117] In these studies, the addition of routine angioplasty to thrombolytic therapy did not enhance patency, improve left ventricular function, or reduce early mortality compared with a more conservative approach of ischemia-driven angiography, but did increase expense and vascular bleeding problems.[118–120] A meta-analysis of adjunctive PCI and thrombolysis versus thrombolysis only showed no early benefit of PCI except in patients who have clinical indications for early revascularization (e.g., postinfarction angina).[121] These studies were performed in an early phase of PCI, however, and the addition of stents as well as glycoprotein IIb/IIIa inhibitors and new lytics have renewed interest recently in a combined strategy.

Asymptomatic Coronary Artery Disease

The role of revascularization either by PCI or CABG versus medical therapy in the setting of asymptomatic CAD has been studied in the Asymptomatic Cardiac Ischemia Pilot (ACIP) trial.[122] Of 558 patients with CAD and medically controlled angina, treatment was randomized to either revascularization or medical therapy directed toward eliminating angina or eliminating ischemia during an ambulatory ECG. Revascularization was more effective than medical therapy in relieving ischemia, and CABG was superior to PCI (70% freedom from ischemia versus 46%; $p < .002$). Mortality at 1 and 2 years was superior for revascularization as compared with angina-directed medical therapy but not superior to ischemia-directed medical therapy.[57,123] The greatest benefit was among patients with the most severe disease. Importantly, many of these patients with "silent ischemia" on ambulatory ECG monitoring did have symptomatic angina at other times and thus were not truly asymptomatic.

The documentation of ischemia, however, is critical. Several studies emphasize the flaws in the assumption that one can identify future culprit lesions in the absence of symptoms or documentation of ischemia.[124] Among patients undergoing serial coronary arteriography who subsequently developed acute MI or unstable angina, the severity of stenosis at the time of initial angiogram is poorly predictive of the culprit lesion causing the acute ischemic syndrome.[124–127] In most cases, the severity of the lesion responsible for subsequent ischemia was less than 50%, and in many patients it was not present at all on the initial angiogram. The lack of benefit of prophylactic revascularization incidentally raises concern regarding the number of patients undergoing angioplasty who have not undergone stress testing to document objective evidence of ischemia when severe symptoms at the time of presentation were absent.[128] Bech and associates have demonstrated that fractional flow reserve exceeded 0.75 in 91 of 325 patients planned for PCI without noninvasive evaluation of ischemia and that among those patients, angioplasty had no impact on event-free survival or angina.[129]

The Elderly

Age is a predictor of operative risk in most models but is also a predictor of poor outcome with medical therapy in the presence of CAD. In the Swiss Multicenter Trial of Invasive versus Medical Therapy in the Elderly (TIME), briefly noted earlier, 301 patients over the age of 75 with chronic angina were randomized to medical therapy with or without invasive evaluation.[59] Of those undergoing angiography, two-thirds had revascularization. At the 1-year follow-up interval, there was no statistical difference in death or nonfatal MI rates. Symptoms and quality of life also were similar. However, there was a substantial increased risk of rehospitalization with revascularization in those who had undergone medical treatment. These data suggest that invasive evaluation should be offered to the elderly who are symptomatic only after adequate medical therapy.

The choice of mode of revascularization will be particularly affected in this group of patients by the presence of comorbidities that may increase the risk of surgical intervention, such as cerebrovascular disease, renal dysfunction, and pulmonary disease. The impact of a reduction in operative morbidity through off-pump coronary artery bypass (OPCAB) on this choice is as yet unclear. There are an increasing number of studies to suggest that it is in just this group of patients with comorbid conditions that off-pump surgery offers its greatest advantage over conventional surgery (see Chap. XX). The majority of these studies are not randomized, however, making their results less conclusive than one would hope. There are two retrospective and nonrandomized trials reviewing elderly patients who underwent OPCAB. There were more grafts in the standard CABG for both studies, but there were fewer strokes, incidences of prolonged respiratory failure, bleeding, and transfusions in the OPCAB group, and both ICU and hospital length of stay were reduced. Reoperations for bleeding, MI, renal failure, wound infections, and operative mortality were not significantly different.[130,131] Among the randomized trials, there has been no consistent advantage to OPCAB with respect to neurocognitive outcomes, a particularly important endpoint in the elderly.[132] A meta-analysis of both randomized and observational studies of OPCAB and standard on-pump CABG in diverse populations[133] has failed to demonstrate any difference except for a reduction in atrial fibrillation in the OPCAB group [odds ratio (OR) 0.59 (0.46–0.77)]. The impact, therefore, of newer technologies on modifying the indications for CABG in the elderly is as yet unclear.

Severe Left Ventricular Dysfunction

Left ventricular dysfunction is a predictor of increased operative risk for most cardiac surgical procedures, and in the early days of coronary revascularization, these patients were not offered CABG. As with age, however, LV dysfunction is also a strong predictor of poor outcome with medical therapy. Accordingly, more recently, significant LV dysfunction has been considered an indication rather than a contraindication for surgical revascularization. In some patients, LV function has been shown to improve—sometimes dramatically so—after revascularization, leading to the concept of a "hibernating" or "stunned" myocardium.[134–137] The identification of viable myocardium, which is potentially recoverable, depends on identification of preserved metabolic activity by positron-emission tomography (PET), cell membrane integrity by thallium-201 or technetium-99m single-photon-emission computed tomography (SPECT), or dobutamine stress echocardiography.[10,137,138]

Thus far, no prospective, randomized trials of medical versus surgical therapy in patients with severe LV dysfunction have been reported, although the National Institutes of Health (NIH)–sponsored trial entitled the Surgical Treatment for Ischemic Heart Failure (STICH) trial is underway. A number of retrospective analyses of the impact of revascularization on outcome in patients with LV dysfunction with or without demonstrable viability have been reported[139] (Fig. 20-10). Recently Allman and colleagues reported the results of a meta-analysis of these studies.[140] Their analysis demonstrated a 79.6% reduction in annual mortality (16 versus 3.2%; $p < .0001$) when patients with severe three-vessel disease and severely depressed LV function with evidence of viability underwent surgery versus medical therapy. Among those patients without demonstrable viability, the mortality rates were similar (7.7 versus 6.2%; p = NS). This study is subject to all the limitations of a retrospective surgical series, however, including, perhaps most important, the unaccountable effect of clinical judgment employed in selecting patients for one therapy versus another. The results, however, have been remarkably consistent over the years among virtually all studies, with the greatest benefit of surgical revascularization being sustained by the patients with the worst ventricular function.

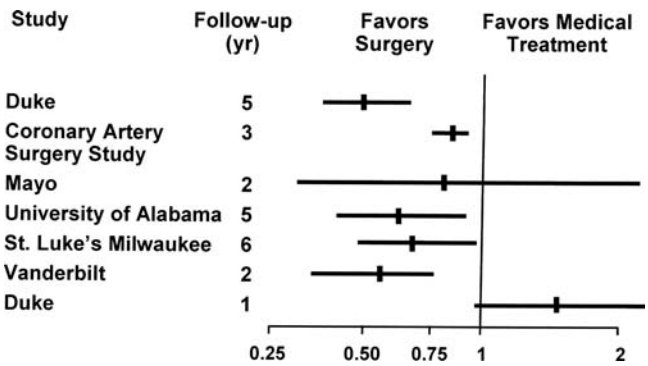

Figure 20-10. Relative risk of mortality for CABG compared with medical therapy in moderate to severe left ventricular systolic dysfunction, ranked in order of study quality. *(Reproduced with permission from Chareonthaitawee P, Gersch BJ, Araoz PA, et al: Revascularization in severe left ventricular dysfunction: The role of viability testing. J Am Coll Cardiol 2005; 46;567.)*

The relative roles of CABG and PCI in this population are not clearly defined despite the number of trials of angioplasty versus surgery. Patients with LV dysfunction may be at higher mortality risk following revascularization by PCI than by CABG, but the potential survival benefits of CABG have not been demonstrated, perhaps because these patients are underrepresented in these prospective, randomized studies. In a multicenter study of patients with LV dysfunction (ejection fraction <40%), slightly more than one-quarter of the patients were dead in the 2 years following multivessel angioplasty.[141] Similar results have been reported from other studies of PCI in patients with multivessel disease and LV dysfunction. Overall, the outcome with PCI appears less favorable than that obtained after CABG[61] possibly as a function of more complete revascularization in surgical patients.[142]

Completeness of revascularization may be particularly important in patients with LV dysfunction. An analysis of data from the CASS registry demonstrated that among patients with triple-vessel disease, 4-year survival depended on the number of vessels bypassed, particularly among those with more severe angina and those with worse ventricular function.[142] For PCI, completeness of revascularization of target arteries ranged from 57 to 61% in the prospective, randomized trials in which complete revascularization was not a protocol requirement (e.g., BARI, EAST, and CABRI). In the GABI and RITA trials, complete revascularization by PCI was targeted and was achieved in 86% in GABI and in 81 and 63% of patients with two- or three-vessel disease in RITA.[85,86]

Total Occlusions

In most patients with chronic, totally occluded coronary arteries, revascularization is not possible, although the advent of stent technology has offered some improvement in this area. In the randomized trials of multivessel PCI versus CABG, 35 to 37% of patients were excluded because of the presence of a chronic total occlusion of a coronary artery serving viable myocardium. Thus, the high proportion of trial patients with less than three-vessel disease, well-preserved ventricular function, and absence of chronically occluded arteries produces a study population that favors a higher incidence of complete revascularization by PCI and attenuated consequences of incomplete revascularization than expected in community practices. Among patients with severe angina, triple-vessel disease, and ventricular dysfunction, survival is greater in those with three or more coronary arteries bypassed than in those with only two vessels bypassed.[49,142] CABG improves survival in patients with three- and two-vessel disease with LV dysfunction compared with medical therapy. Although angioplasty may have a similar survival benefit, its influence on this high-risk subgroup has not been fully tested or reported.

Diabetes Mellitus

It has been recognized for many years that patients with diabetes mellitus are at higher risk following percutaneous[143] or surgical[144–146] revascularization. The BARI trial was the first trial large enough to identify significant differences in outcome between diabetic and nondiabetic patients. In this study, which included 353 diabetic patients, a survival benefit was observed among insulin-dependent patients undergoing CABG with an ITA graft as compared with those undergoing PCI. The explanation for this is not entirely clear, although an intriguing observation is that while the incidence of subsequent MI is similar between groups, survival following MI is superior among those who have undergone surgical revascularization.[147] In fact, diabetics suffering spontaneous Q-wave MI were more than 10 times as likely to die of their infarction if they had been treated with PCI compared with CABG. No such protective effect was seen among nondiabetic patients either with or without Q-wave MI. This survival difference was even more pronounced at 7 years, with 76.4% of diabetics in the surgical arm alive compared with 55.7% in the angioplasty arm.[148]

The physiologic basis for this difference remains a matter of speculation, although the completeness of revascularization may be a factor. Because of the significant incidence of restenosis after PCI in diabetics, Van Belle and colleagues[149] analyzed ejection fraction at 6 months and long-term cardiac mortality and morbidity among 513 diabetic patients stratified according to the presence of occlusive restenosis ($n = 94$), nonocclusive restenosis ($n = 257$), and no restenosis ($n = 162$). The mortality rose with restenosis (24% without restenosis, 35% with nonocclusive restenosis, and 59% with occlusion), and ejection fraction fell with occlusion (decrease of 4.8 $\pm$ 12.6%). Coronary mortality was strongly predicted by coronary occlusion by multivariate analysis.

The results of the BARI trial prompted retrospective post hoc analyses of several earlier trials. The results have been variable. An analysis of diabetic patients from the CABRI trial at 8 years demonstrated a mortality rate of 3.5% for CABG patients versus 15.6% for PCI patients.[150] There

also was a nonsignificant trend for better survival among diabetic patients treated surgically in the EAST trial.[151] A meta-analysis of pooled data pertaining to diabetic patients from CABRI, EAST, and RITA, however, found similar 5-year mortality rates following CABG or PCI.[152]

Several other data bank studies also have been conducted. The Northern New England Cardiovascular Disease Study Group evaluated survival 5 years after treatment among 7159 diabetic patients with multivessel disease who were treated with CABG or PCI between 1992 and 1996.[153] Of this group, 38.6% of patients were clinically and angiographically similar to those randomized in BARI. Patients were treated according to physician preference. Those undergoing CABG were more likely to have three-vessel disease and tended to be older with greater degrees of ventricular impairment and obstructive lung disease. There were more women and more urgent interventions in the PCI group. After adjusting for these variables, PCI was associated with a significantly greater mortality rate at 5 years [risk ratio (RR) 1.49, 95% confidence interval (CI) 1.02–2.17; $p = .037$) and particularly among diabetics with three-vessel disease [hazard ratio (HR) 2.01, 95% CI 1.04–3.91; $p = .038$].

Diabetes is a condition characterized biologically by an inflammatory, proliferative, and prothrombotic state. This may account in part for the increased risk of restenosis and occlusion. Since diabetics tend to have more diffuse disease, the importance of complete revascularization, which is achieved more often surgically than percutaneously, may be enhanced. Another explanation may have more to do with patient selection than vascular biology. It has long been recognized from the previously cited studies that the survival advantage of CABG over medical therapy is greater the more extensive the coronary disease, and more recent studies of PCI versus CABG have demonstrated similar trends. Diabetic patients tend to have more extensive disease, and in BARI, diabetic patients had a higher frequency of three-vessel disease, diffuse disease, proximal LAD artery disease, and LV dysfunction.

In this respect, it is interesting to note that in community studies[154] and the BARI registry, although diabetic patients have a poorer outcome with both PCI and CABG in comparison with nondiabetic patients, there were no significant differences in outcomes between these therapies in the diabetic patient subgroup. It must be emphasized that in these nonrandomized trials in which the selection of therapy was at the discretion of the physician and the patient, a very clear trend was noted. The "sicker" patients with left ventricular dysfunction and triple-vessel disease were far more likely to undergo CABG than patients with double-vessel disease and preserved LV function. Therefore, these registry studies suggest that although the differences between CABG and PCI in diabetic patients may be due to altered vascular biology, these differences are magnified by the process of randomization, in which patients who probably would have been treated with CABG in clinical practice were randomized to PCI.

From a clinical standpoint with regard to patient selection for coronary revascularization and the method of revascularization, the assessment of diabetic patients should be made on standard principles, namely, the severity and extent of coronary disease, the potential for complete revascularization, the presence or absence of LV dysfunction, and the technical suitability of the lesions for PCI. The results of the aforementioned studies suggest that a preference for surgical over percutaneous revascularization is, at this time, appropriate among diabetic patients—at least those with extensive disease and/or ventricular dysfunction. This recommendation may change if new technologies such as DESs and antiplatelet agents are successful in reducing the risk of restenosis and occlusion. DESs are being used with greater frequency owing to subset analysis of the TAXUS IV and SIRIUS trials showing a significant decrease in restenosis. However, these studies were not powered to determine restenosis rates in diabetic patients, and results may have been due to chance alone.[155–157] Furthermore, the potential impact of risk-factor reduction may alter the risk:benefit balance in the future in this important and increasing subset of patients presenting with CAD. Current data suggest that the decreased incidence of repeat revascularization, cardiac rehospitalization, and recurrent angina can be reduced to the level of nondiabetic patients if diabetic patients maintain optimal glycemic control (HbA1c $\leq$ 7%).[158] Irrespective of the mode of therapy, an aggressive approach to risk-factor modification is required.

End-Stage Renal Disease

End-stage renal disease (ESRD) is a growing problem. Cardiovascular disease is the most common cause of death among those with ESRD, and therefore, there likely will be high rates of revascularization required in these patients in the future.[159] Comorbidities complicating surgical or percutaneous revascularization, such as diabetes, hypertension, and calcified vessels, are more common in patients with ESRD, increasing the risk of intervention. A study conducted by the Northern New England Consortium found dialysis-dependent patients with renal failure to be 3.1 times more likely to die after CABG after adjusting for known risk factors [OR 3.1 (2.1–3.7); $p < .001$].[160] This study also found significantly increased rates of mediastinitis (3.6 versus 1.2%) as well as postoperative stroke (4.3 versus 1.7%).[160] The long-term survival also was decreased, with renal failure found to be a highly significant predictor of mortality after adjustment.[161] Despite these risks, the prognosis without surgical correction of CAD is poor. Revascularization in patients with ESRD is associated with improved survival compared with medical management.[162]

Carotid Artery Disease

Stroke is a devastating complication of cardiac surgery. The mortality rate among individuals suffering a postoperative cerebrovascular accident has been reported to be as high as 24.8% with a mean hospital stay of 28 days.[163] The source of perioperative stroke may be thromboembolic from the heart

itself, atheroembolic from the aorta, or a result of carotid artery disease. Among these, carotid artery disease is perhaps the most readily addressed surgically. Accordingly, current AHA/ACC guidelines recommend carotid artery screening for patients older than 65 years of age and those with left main coronary artery stenosis, peripheral vascular disease, a history of smoking, a history of transient ischemic attack or stroke, or carotid bruit on examination.[22] Conversely, uncorrected coronary artery disease is the most common source of mortality and morbidity after successful carotid endarterectomy.[164] Hence, the management of combined carotid artery and coronary artery disease is a topic of profound clinical importance encountered with significant frequency.

The clinical implications of carotid artery disease reflect the degree of atherosclerosis present. In a recent meta-analysis, perioperative stroke risk rises from 2% when a carotid stenosis is less than 50% up to 12% among patients with a unilateral occlusion.[165] Among those with bilateral high-grade stenoses (50 to 99%), the stroke risk has been estimated to be approximately 5%.[165]

While the benefits of carotid endarterectomy (CEA) are clearly established in symptomatic carotid artery stenoses in both the North American Symptomatic Carotid Endarterectomy Trial (NASCET)[166] and the European Carotid Surgery Trial (ECST),[164] the management of asymptomatic carotid artery disease is an ongoing controversy. The Asymptomatic Carotid Atherosclerosis Study (ACAS)[167] and the Asymptomatic Carotid Surgery Trial (ACST)[168] are large trials that enrolled 1662 and 3120 patients, respectively. ACAS did not demonstrate a significant reduction in the absolute risk of disabling or fatal stroke with surgery, whereas ACST reported a statistically significant absolute risk reduction of 2.5%. A recent *Cochrane Review*[169] concluded that despite a 3% perioperative stroke or death rate, CEA for asymptomatic carotid stenosis reduces the risk of any stroke by approximately 30% over 3 years. In a natural history study of patients undergoing cardiopulmonary bypass, 582 patients were screened with carotid artery ultrasound. Despite the exclusion of patients with recent neurologic symptoms, 70 patients (12%) had one carotid artery stenosis equal to or greater than 80%, and 50 patients (8.6%) had bilateral lesions of at least 50%.[170] Thus, this issue will continue to be debated in the future because its relevance to cardiac surgery is of obvious importance.

The AHA/ACC guidelines currently recommend CEA before or concomitant with CABG in patients with any symptomatic carotid stenosis. CEA is also recommended for asymptomatic patients with a unilateral or bilateral internal carotid stenosis of at least 80%.[22]

Gaudino and colleagues have shown an improvement in freedom from late stroke and TIA after combined CEA-CABG in patients with asymptomatic, unilateral high-grade stenoses from 75 to 98% at 10 years.[171] Similarly, among patients undergoing concomitant CEA and CABG, Akins and colleagues[172] and Kolh and colleagues[173] have reported 10-year actuarial event-free survivals of death (40 and 50%), MI (87 and 84%), and stroke (82 and 93%).

While the value of addressing both cardiovascular and cerebrovascular conditions is demonstrable, the superiority of a combined versus sequential approach remains controversial. Some centers perform CEA followed by CABG 1 to 5 days later, whereas others perform concomitant procedures. In a review, the cumulative risk of 8.4% for a combined endpoint of stroke and death of a staged procedure is not statistically different from the risk of a combined procedure (7.4%).[174] The increased operative risk associated with patients with carotid disease is attributable to the comorbidities of those patients with carotid disease rather than to the procedure itself.[175] Thus, the timing of CEA and CABG should be chosen based on patient and center preference. The recent advent of carotid artery stenting complicates matters further, with the place of this new technology in this setting still undefined.[176]

CHAPTER 21

Myocardial Revascularization with Percutaneous Devices

James M. Wilson • James T. Willerson

The increased popularity of surgical coronary revascularization was accompanied by the improved performance of diagnostic coronary angiography. As the diagnostic technique evolved to a safe and easily performed procedure, engineering advances offered the possibility of improving coronary blood flow capacity using catheter-based transluminal methods. In 1974, Andreas Gruentzig developed the double-lumen balloon catheter that was later miniaturized for use in coronary arteries.[1,2] Soon afterward, techniques for percutaneous transluminal coronary angioplasty (PTCA) expanded as technical breakthroughs were applied to subselective catheters, devices, guidewires, and balloon materials. Undoubtedly the most important advance in percutaneous revascularization has been the coronary stent, an expandable metal buttress that reinforces a balloon-dilated vessel. Not only does the stent provide mechanical support, preventing early vascular recoil and closure, but it also provides a platform for local drug delivery. The proliferation of techniques for expanding a coronary lumen has produced a more broadly encompassing nomenclature, namely, percutaneous coronary intervention (PCI) or percutaneous coronary revascularization (PCR).

BALLOON ANGIOPLASTY

Principles

Early balloon angioplasty procedures used a bulky balloon catheter with a small length of steering wire attached to its tip. However, severe technical limitations restricted percutaneous techniques to low-risk patients with proximal discrete coronary artery stenoses, and their outcomes lacked predictability. Predicated on the advances made in guiding catheters, guidewires, lumen-expansion tools, and antithrombotic therapy, higher-risk patients became candidates for percutaneous therapy. Therefore, a protocol for safe, successful vascular manipulation was required. Over time, because of the more complex, challenging cases that cardiovascular surgeons have treated, several principles have been recognized (Table 21-1).

Tools

Guiding catheter

The guiding catheter differs from diagnostic catheters in both shape and construction. A wire-braid-supported thin catheter wall allows for a larger central lumen and maintains sufficient mass, rigidity, and support to allow the advance of subselective catheters to the distal regions of the coronary bed. Slight modification in guiding catheter shape enables coaxial alignment of the catheter with the treated vessel while simultaneously maintaining contact with the opposing wall of the aorta or aortic cusp. The anatomy of the ascending aorta and origin of the treated coronary artery determine the shape of the guiding catheter that will provide the most secure positioning (Fig. 21-1). The choice of guiding catheter often is the deciding factor for success when approaching challenging anatomy or when complications increase procedural difficulty. Guiding catheter manipulation is a common cause of procedural complications that necessitate urgent coronary artery bypass surgery.

Guidewire

The guidewire represents an avenue of access to all points traversed. Therefore, when the guiding catheter position remains secure, the guidewire allows control of the distal vessel. The many different wires vary in stiffness, coatings, diameter, and design of the distal steering tip. For most procedures, the chosen wire is a 190- to 300-cm monofilament that is 0.0254 to 0.0356 cm in diameter with either a graded tapering segment welded to the tip or a gradual taper of the monofilament. The long body of the wire allows applied

Table 21–1.

Principles of Percutaneous Coronary Intervention

1. The patient's outcome is a function of age and comorbidity.
2. The procedure's outcome is a function of anatomy and proper planning (i.e., sequence and equipment choices such as guidewires and device).
3. Proximal and distal control of the treated vessel are maintained.
   a. Choose proper guide catheter support.
   b. Maintain distal wire position.
   c. Keep the guide, device, and distal wire tip visible during any movement.
4. Needs and limits to treatment options such as devices, adjuvant medical therapy, contrast use, and circulatory support are determined by
   a. Vascular access
   b. Clinical setting (e.g., stable angina or acute myocardial infarction)
   c. Ventricular function
   d. Comorbidity: diabetes mellitus, renal insufficiency
5. The following factors can lead to failure:
   a. Incomplete understanding of the three-dimensional anatomy of the course to be taken and lesion to be treated
   b. Unrealistic interpretation of
      i. The capacity of available techniques to achieve success
      ii. The allowance of specific anatomy to accept percutaneous manipulation
      iii. Ignorance or inattention to technique in subselective device movement
   c. Inattention to anticoagulation
   d. Inattention to catheter hygiene (minimizing blood and contrast stagnation within the guiding catheter or other devices)

torque to be transmitted to the distal steering tip. The central wire core at the tip is "plastic," or malleable, and may be shaped by the operator. In many wire designs, a wire coil wrapped around the central filament projects a blunter, less traumatic tip to the vessel that it must traverse. In addition, this superficial coil proffers elasticity to the shape created by the operator, preventing the filament's deformation during attempts to guide the wire to its desired destination. This shaped, soft steering tip eases access to tertiary branches of the coronary tree. This easily deflected wire is the safest choice but may lessen the probability of successfully crossing certain types of lesions, such as a total occlusion, particularly when an occlusion has been present for more than a month.[3,4] In these settings, a stiffer wire tip with a bonded, hydrophilic coating, rather than the wire coil, frequently is chosen. While increasing the likelihood of crossing the lesion successfully, these stiffer, "slicker" wires also increase the risk of such complications as creation of a subintimal wire course and dissection or perforation of the vessel (Fig. 21-2). Variations in the body wire's stiffness influence support for subselective device delivery in a challenging or tortuous anatomy.

Tools for lumen expansion

The vast bulk of subselective devices for coronary artery manipulation are balloon inflation catheters or some variation of this theme. The components of the balloon catheter are the proximal shaft, the distal shaft on which the balloon is placed, and the tip. The proximal shaft is made as rigid as possible to allow sufficient transmission of force applied by the operator to the distal aspect of the device. The balloon shaft generally is made of thinner material and is thus more deformable with a lower profile. The device tip must offer the lowest possible profile while advancing into the coronary arteries to minimize friction that could oppose its advance. A central lumen allows the device to track along the guidewire.

Balloon catheter designs vary in the placement of the proximal opening of the central lumen. The "on the wire" design has a central lumen extending the length of the catheter. This design affords the best traceability and capability to maneuver through difficult anatomy but requires an assistant to manipulate the wire during device advance. The "monorail" design has a central lumen extending only through the distal balloon shaft of the catheter. The remaining catheter shaft communicates only with the balloon lumen. This design, though less traceable, allows the procedure to be performed without the requirement for an assistant.

Properties of the angioplasty balloon include compliance, maximally tolerated pressure, profile, and friction

coefficient. Compliance, or growth under pressure, and maximally tolerated pressure are a function of balloon wall thickness and material. Compliance is divided into three categories: noncompliant, semicompliant, and compliant. Noncompliant balloons typically are made from polyvinyl chloride (PVC), polyethylene terephthalate (PET), and high-density polyethylene and polyolefin copolymer (HDPE/POC). Polyolefin copolymer balloons are compliant and vary up to 15% in diameter when exposed to nominal inflation pressure. PET balloons are the most noncompliant, with less than 5% variation even at high pressure. The thin-walled, compliant balloon has the lowest deflated profile,

allowing the device to pass through the most severely occluded vessels. However, the balloon may expand nonuniformly or lengthen when exposed to high pressures, such as pressures in excess of 20 atm (15,200 mm Hg), which are required to dilate hard and heavily calcified stenoses or stents. A variety of balloon coatings may be used to reduce the friction coefficient or protect from abrasion (as in passing a stent).

Antithrombotic therapy

During an angioplasty procedure, blood may stagnate in the guiding catheter or near the treated lesion when a wire or device is placed within the lumen of the target lesion. In addition, metallic components of the guidewire or other devices attract fibrinogen, thus stimulating thrombosis. Therefore, a thrombus may form easily unless prevented with intense anticoagulation therapy (Table 21-2). Most

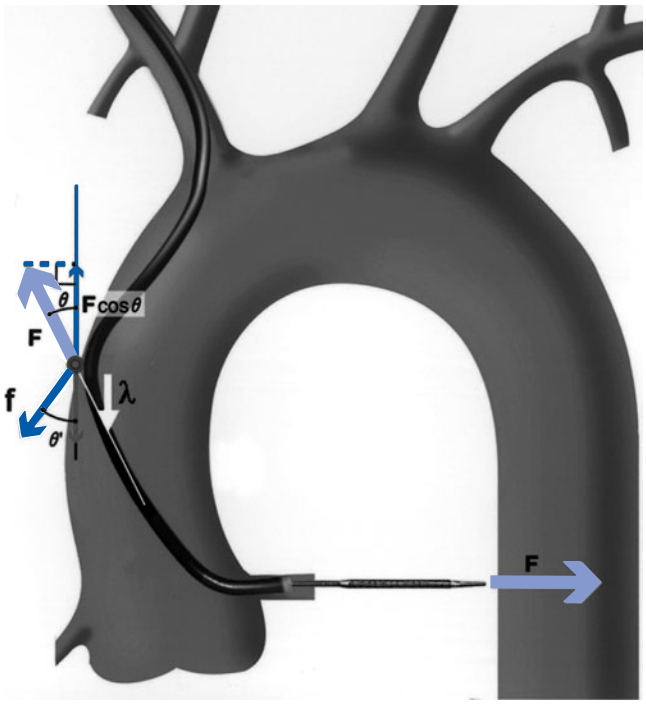

Figure 21-2. Support for subselective device introduction into the coronary vessels is determined primarily by the shape of the guiding catheter in relation to the anatomy of the ascending aorta and origin of the left main coronary artery. Shown graphically, advance of the device forces the catheter backward. This movement is opposed by the alignment of the catheter with the coronary artery and by friction developing through contact between the primary curve of the catheter and the opposing wall of the aorta. J Invas Cardiol 2005;17:636*)

angioplasty procedures are performed with unfractionated heparin anticoagulation titrated to an activated clotting time (ACT) value of more than 300 seconds.[5] Alternative anticoagulants such as low-molecular-weight heparins and direct antithrombin antagonists may be used.[6–10] However, none of these agents has proven to be superior to unfractionated heparin. Antiplatelet therapy also reduces the risk of thrombosis at the treated lesion. In addition to aspirin and thienopyridines, glycoprotein IIb/IIIa complex (Gp IIb-IIIa) inhibitors may be employed in specific circumstances. Gp IIb/IIIa complex inhibitors are unique in their ability to impair platelet-platelet aggregation regardless of the type or intensity of stimulus. Anticoagulation is titrated to a lower intensity, an ACT of 200 to 250 seconds, when Gp IIb/IIIa inhibitors are used. When this reduced-intensity anticoagulation regimen is used in conjunction with Gp IIb/IIIa inhibitors, hemorrhagic complications are less frequent without increased thrombotic complications.[11]

Two types of Gp IIb/IIIa inhibitors are available: an antibody derivative with high receptor affinity (e.g., abciximab) acting as a noncompetitive inhibitor with a long duration of effect and small-molecule competitive antagonists (e.g., eptifibatide or tirofiban) with a short duration of effect. The ability of these drugs to induce a temporary thrombasthenic state has proved remarkably effective in reducing the risk of percutaneous revascularization in the setting of unstable angina or acute myocardial infarction (MI).[12–15]

Mechanisms

Balloon angioplasty transmits increased intraluminal pressures circumferentially to the rigid intimal surface of the diseased vessel. Since atherosclerotic lesions typically are heterogeneous in their circumferential distribution and physical characteristics, the nondiseased or less diseased wall may be overstretched during balloon inflation. In most instances, the lesion segment with the greatest structural integrity is a focal point for applied stress. Adjacent regions of the vascular wall shift, and the diseased, inelastic intima fractures. Although this mechanism allows balloon expansion and an increase in luminal diameter, extension of the fracture into the intima-media border creates a dissection plane whose growth will be determined by the mechanical characteristics of the lesion and the amount of force applied. If growth of the dissection plane results in significant displacement of the diseased intima, the vessel will close. This event, termed *abrupt* or *acute occlusion*, complicates about 10% of balloon angioplasty procedures. Overstretching the minimally diseased or nondiseased wall without creating plaque fracture typically results in early recoil of the treated lesion to its original state. Occasionally, percutaneous angioplasty produces an angiographic appearance of near-total resolution of coronary artery stenosis with limited, invisible fracture of the intima. In the majority of instances, however, a small dissection may be visible, and 30 to 50% of stenosis remains.

After balloon deflation, the lesion, whose diseased endothelium may have been sparse to begin with, is now devoid of protection and rich in thrombogenic material. Platelet accumulation and thrombus formation are limited by flow and intense antithrombotic therapy. The small amount of thrombus that accumulates provides the stimulus and framework for colonization by inflammatory cells and myofibroblasts. Under the guidance of locally produced cytokines, myofibroblasts colonize, multiply, and deposit ground substance, creating the histologic appearance of intimal hyperplasia. Cell multiplication slows as the lesion is covered by endothelium, and ground substance is replaced by collagen-rich connective tissue. In addition, mechanical injury to the media and adventitia results in scar formation whose contracture may reduce vessel cross-sectional area, a phenomenon termed *negative remodeling*.[16,17] Encroaching intimal hyperplasia that peaks in volume about 3 months after the inciting injury, combined with negative remodeling, results in restenosis after 40 to 50% of balloon angioplasty procedures.[18–20]

Outcomes

In approximately 2 to 10% of balloon angioplasty procedures, intimal dissection, thrombosis, and perhaps medial

Infection	1.7%

PTCA = percutaneous transluminal coronary angioplasty.

smooth muscle spasm combine to produce abrupt closure.[21,22] Abrupt closure may be treated successfully with repeat balloon inflation but is treated more commonly with stent implantation.[23] The specter of abrupt closure and MI or emergency bypass surgery and its complications historically has limited the application of balloon angioplasty.

In patients with stable angina, the mortality rate from a balloon angioplasty procedure is 1% at 1 month.[24] About half the deaths are the result of a procedural complication, and most are related to low cardiac output[25] (Table 21-3). Although the incidence of restenosis (>50% diameter stenosis during follow-up) is 40 to 50% within 6 to 9 months of a PTCA procedure,[19,20,26] only 25% of patients report recurrent angina that warrants further investigation.[27] Patients with restenosis suffer an increased risk of MI and coronary artery bypass surgery.[28]

DEVICE-ASSISTED ANGIOPLASTY

Stent

Two major failings that hamper balloon angioplasty are abrupt closure and restenosis. These failings stimulated the development of a myriad of devices with the goal of reducing either the risk of the procedure, the risk of restenosis, or both. Only the coronary stent has been shown to have an advantage over balloon angioplasty, except in the case of lesions with severe calcification (Table 21-4). There are numerous coronary stent designs, but the majority of those in current use consist of a stainless steel (or alloy such as cobalt chromium) cylinder that has been "carved," creating a so-called slotted-tube design. Expansion of the stent creates a series of interlocking cells, resembling a cylindrical meshwork (Fig. 21-3). The stent thus is deformable, but when expanded, it maintains sufficient rigidity to act as scaffolding after deflation of the angioplasty balloon. Intimal disruption thus is contained and far less likely to propagate and occlude the treated vessel. In addition, the rigid framework left behind becomes part of the vessel wall, addressing the issue of remodeling, one of the mechanisms of restenosis.

A stent allows safe expansion of the vessel beyond that typically achieved with PTCA at the time of balloon expansion; however, stent use increases thrombotic and inflammatory responses of the vessel wall. The increased injury and a foreign-body response to stent struts result in a more intense and prolonged local inflammatory response.[29] As a result,

Table 21–4.

Devices Used for Coronary Angioplasty

	Experience	Ease of use	Complications	Efficacy	Lesion type
POBA	++++	++++	+	+++	Any
Cutting balloon	+	++	++	+++	Calcified lesion, ISR, bifurcation
Rotational atherectomy	+++	+	+++	+++	Heavily calcified, nondilatable ISR
Directional atherectomy	+	+	+++	+	Bifurcation, ostial lesion
Laser atherectomy	++	++	++	++	Calcification, ISR, thrombus
Aspiration (mechanical)	++	+	+	++	Thrombus
Aspiration (manual)	+	+++	+	++	Thrombus

POBA = plain old balloon angioplasty; ISR = in-stent restenosis.

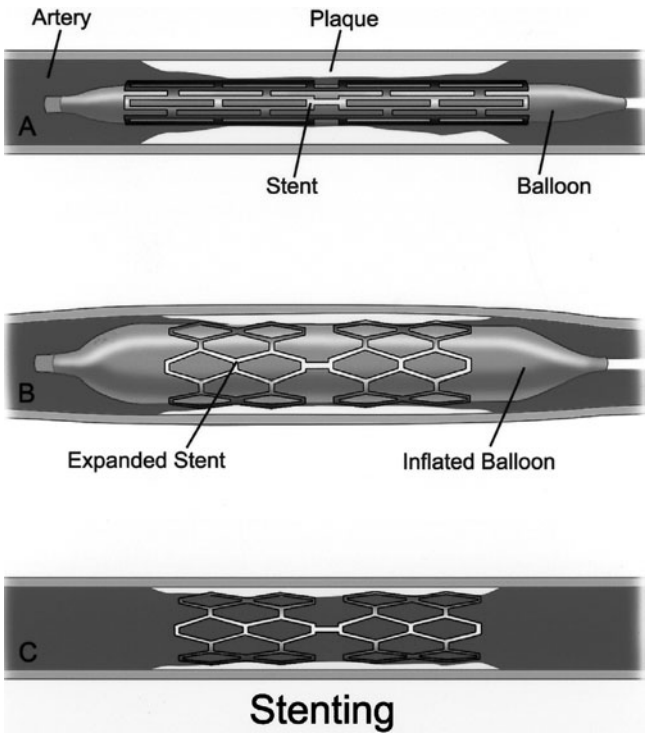

Figure 21-3. The coronary stent is a metallic "meshwork" that increases its rigidity when coldworked by balloon expansion. Buttressing of the vascular wall, propagation of dissection, and early vascular recoil are reduced significantly. (*Reprinted by permission from Texas Heart Institute, www.texasheart.org.*)

stent placement paradoxically exacerbates intimal hyperplasia.[30,31] Using the late (6 or 9 months) loss in lumen diameter after stent implantation as a measure of intimal hyperplasia, even the most modern stent designs fall within a range of about 0.8 mm, more than twice the loss incurred after PTCA (0.32 mm). As a result, when examining restenosis after angioplasty, the impact of stent PCR is rather small in comparison with that of PTCA.[30,31] The bulk of intimal hyperplasia and risk of restenosis are functions of the size of the treated lumen on completion of the procedure, the length of the treated lesion, and the presence of unstable angina, hypertension, and diabetes mellitus[32–35] (Table 21-5). Generally, for a 3-mm artery with a lesion length of 20 mm or less, the risk of restenosis at 6 months is 15 to 30%.[30,31,36–38] Long-term follow-up studies suggest that a stent that does not reocclude during the first 6 to 9 months after implantation is not subject to late, rapid disease progression.[37–41]

By reducing the likelihood of both abrupt closure requiring emergency coronary artery bypass surgery and restenosis, stent-assisted angioplasty is more effective than routine balloon angioplasty for virtually any type of coronary artery lesion. However, coronary artery stents were not proven to be safer than PTCA when stent placement was used as a "bailout" option in randomized clinical trials.[42] Nonetheless, registry data describe a risk for emergency surgery of only 0.3 to 1.1% and a procedural mortality of less than 1%.[43–46] The likelihood of a procedural complication

Table 21–5.

Approximate Risk of Restenosis Based on Final Lumen Diameter and Stent Length

	Final lumen diameter (mm)				
	2.0	2.5	3.0	3.5	4.0
Stent length (mm)	**Percent risk**				
15	32%	22%	14%	8%	4%
30	42%	30%	20%	11%	7%
45	52%	39%	28%	15%	10%
60	60%	47%	35%	20%	13%

Summarized and modified from ref. 34.

may be estimated based on lesion characteristics[47] (Table 21-6). Depending on lesion characteristics and the number of lesions treated, after 1 year, 5 to 10% of patients will require coronary artery bypass surgery, and 15 to 20% will undergo a second PCR procedure.[48–51] After 5 years, 10 to 15% of patients require another revascularization procedure because of the development of severe stenosis at an untreated site.[40] Diabetes increases the risk for adverse outcomes by increasing the risk of restenosis and disease progression at untreated sites.[52–54]

As noted previously in the description of the guidewire, iron components of stent struts attract fibrinogen and offer a site for platelet attachment and thrombosis. The increased risk of thrombosis at the treated site persists until endothelialization is complete. As a result, more intense antithrombotic therapy is required during the procedure and for up to 1 year afterward.[55,56] Before the use of preprocedural thienopyridine antiplatelet drugs, an intense antithrombotic regimen was used consisting of a Gp IIb/IIIa inhibitor and postprocedural warfarin anticoagulation in combination with aspirin.[11,30,31] However, the addition of thienopyridine antiplatelet drugs to aspirin therapy has proved more effective than warfarin anticoagulation. When given before the procedure, antiplatelet therapy provides sufficient protection so as to allow stent implantation in a stable patient without the need for Gp IIb/IIIa inhibitor therapy.[57–60]

A stent may be used as a drug-delivery system. However, rather than simply applying a drug to the stent surface, from which it will dissipate quickly, drug delivery is controlled by using a surface polymer or by altering the design or the material used to construct the stent.[61] This method of drug delivery, called a *drug-eluting stent* (DES), allows the drug to be applied at high concentrations at the site of interest and reduces the probability of systemic toxicity.

Table 21–6.

Risk Factors for Ischemic Events After Stent Placement[47]

Strongest correlates		
Nonchronic total occlusion		
Degenerated SVG		
Moderately strong correlates

Highest risk	Either of the strongest correlates	12.7%
High risk	≥3 moderate correlates	8.2%
Moderate risk	1–2 moderate correlates	3.4%
Low risk	No risk factors	2.1%

SVG = saphenous vein graft; MI = myocardial infarction; CABG = coronary artery bypass graft surgery.

A number of drugs have been studied. To date, the most effective drugs prevent replication of myofibroblasts that colonize the treated lesion.[62–64] Drug-eluting stents reduce the primary determinant of restenosis by 50 to 100%, as determined by quantitation of late lumen loss after angioplasty (Fig. 21-4). In large-scale clinical trials, this reduction corresponds to an angiographic restenosis rate of 4 to 6%, with a very low likelihood of a repeat procedure on the same lesion.[62,63,65] Studies examining the efficacy of the DES introduced new nomenclature to the follow-up endpoints. The most useful follow-up endpoint is termed *target vessel failure* (TVF), signified by cardiac death, MI, or repeat revascularization of the treated vessel. One year after the procedure, TVF is reduced from 19.4 to 21% with a bare-metal stent (BMS) to 8.8 to 10% with a paclitaxel or sirolimus DES.[50,51]

DES placement reduces the risk of angiographic restenosis and the need for repeat revascularization procedures for native coronary artery lesions, small vessels, chronic total occlusion, and saphenous vein grafts in patients with MI and diabetes mellitus[50,66–71] (Table 21-7). In fact, reduced rates of repeat intervention after DES placement have been reported for every type of lesion studied, except bifurcation lesions, where the risk of restenosis remains significant, and the risk of potentially fatal early thrombosis is as high as 3.5%.[69,72,73] However, the impact of DESs on failure of long-term treatment and repeat procedures does not translate to a reduced risk of procedure-related complications.[74] Because of the effect of the eluted drug or perhaps the polymer itself, endothelialization is delayed after DES implantation, peristent inflammation is prolonged, and local production of tissue factor may be enhanced.[75–78] After 1 month, thrombosis caused by DES placement is seen in approximately 0.3 to 0.7% of patients.[73,79,80] Late thrombosis is associated with the treatment of complex lesions, diabetes mellitus, renal failure, depressed left ventricular ejection fraction (LVEF), and withdrawal of dual antiplatelet therapy.[73,79,80] The treatment time required for dual antiplatelet therapy using aspirin and a thienopyridine after DES is

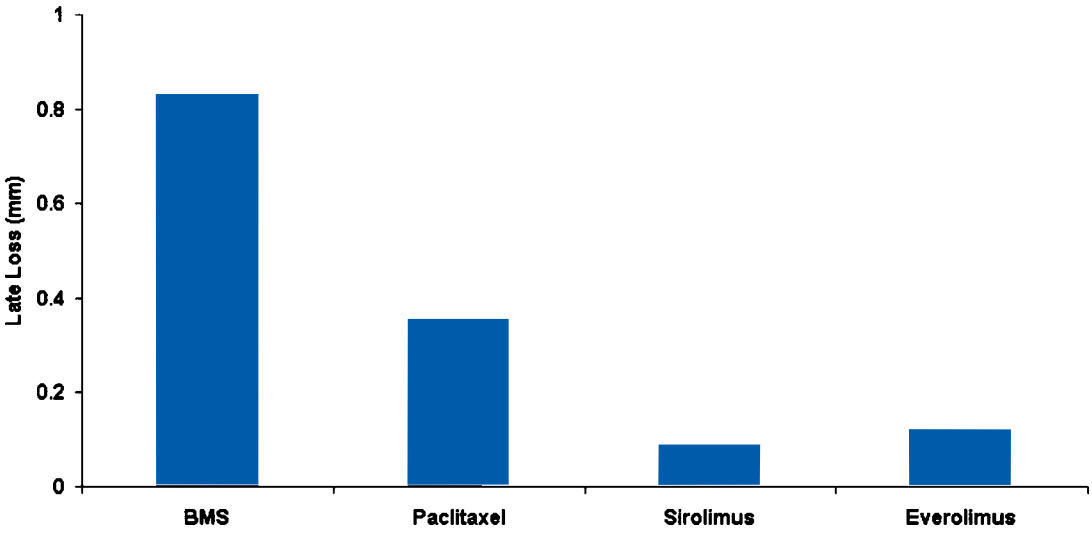

Figure 21-4. The effect of various stents on intimal hyperplasia in randomized trials is shown. A bare-metal stent's intimal hyperplasia thickness, or late loss, shown on the left, is compared with the late loss of drug-eluting stents shown at the right. BMS = bare-metal stent.

much longer than after BMS implantation. Current guidelines call for dual therapy for 3 months after sirolimus DES and 6 months after paclitaxel DES. However, clinical trial evidence that is not device-specific suggests that dual therapy should be continued for up to 1 year after any stent-related coronary revascularization.[55,56] The prolonged need for dual antiplatelet therapy has raised concerns about the timing of noncardiovascular surgeries following DES implantation.

Other Devices

Perfusion balloons

Before the routine use of coronary stents, abrupt closure owing to dissection could be treated with repeat balloon inflation and, if unsuccessful, with coronary artery bypass surgery. Prolonged balloon inflation generally was necessary for successful restoration of patency, but in the event of

Table 21–7.

The Clinical Impact of Drug-Eluting Stents

Population	Endpoint	BMS (%)	DES (%)
Total[50,51]	TVF	20–24.1	9.9–10.8
Diabetes mellitus[212]	MACE 9 mos.	27.2–36.3	11.3–15

Saphenous vein graft lesion[69]	MACE 6 mos.	28.1	11.5

BMS = bare-metal stent; DES = drug-eluting stent; TVF = target vessel failure; MACE = major adverse cardiac event; TVR = target vessel revascularization; TLR = target lesion revascularization.

failure, transport for emergency surgery often was accompanied by severe ischemia of the treated territory. As a result, balloon catheters with a short third-lumen opening just proximal and distal to the balloon were developed. These catheters, or "perfusion balloons," allowed for prolonged balloon inflation with far less ischemia and could be used to ameliorate the severity of ischemia during transport for surgery after an unsuccessful procedure.[81] Since the introduction of the coronary stent, perfusion balloons are used rarely.

Atherectomy

When introduced, the concept of reducing the bulk of the obstructing atheroma was quite attractive. The idea was to reduce vessel wall thickness or "debulk," allowing for balloon expansion at lower pressure. With less force applied for lumen expansion, theoretically the likelihood of abrupt closure would be reduced, as would the degree of arterial injury at the time of treatment. In some instances, balloon angioplasty even could be avoided. Several devices used to debulk have been developed and studied, including directional coronary atherectomy, high-frequency rotational atherectomy, percutaneous transluminal rotational ablation, and laser ablation. Unfortunately, when subjected to rigorous examination, debulking devices provide no incremental gain over plain balloon angioplasty in achieving procedural success or avoiding restenosis.[82–85] Although each device has developed a specific niche (see Table 21-4), their routine use generally is associated with an increased risk of procedural complications, including perforation and MI.[84,86,87]

Directional atherectomy

Directional coronary atherectomy is a procedure that uses a metal cylinder containing an opening, or "cutting window," opposing a balloon. When placed over a lesion, balloon inflation forces the cutting window into contact with the atheroma. The surface of the atheroma is lathed into a metallic reservoir. The SilverHawk atherectomy catheter (SilverHawk Technology, Redwood City, CA), a more recent iteration of directional atherectomy, uses the shape and orientation of the catheter (SilverHawk) to better orient the atherectomy. Directional atherectomy is limited by a modest degree of lumen enlargement, a frequent need for adjunctive angioplasty, and high rates of restenosis and complications. Thus directional atherectomy offers no advantage over conventional balloon angioplasty.[87]

Rotational atherectomy

The Rotablator (Boston Scientific Corporation, Natick, MA) is an olive-shaped device that is coated with diamond chips. The Rotablator is attached to a flexible shaft that is attached to an electrical motor. The motor creates rotation of the device or "burr" at very high speeds. The device is designed to abrade a rigid atherosclerotic intima, creating microemboli that are small enough to pass through the coronary microcirculation without incident.

Abrasion and microembolization are effective means of facilitating balloon angioplasty or stent implantation in heavily calcified lesions. However, the concept is not without failings. Impaired microcirculatory flow after rotational atherectomy is substantially more common than after plain balloon angioplasty.[88,89] Microembolization is likely to exacerbate ischemia and therefore is contraindicated when there are thrombotic lesions or impaired microcirculatory flow associated with recent MI. Use of this device is also associated with an increased risk of perforation in highly angulated lesions. It is, however, useful as an initial treatment method for very rigid, heavily calcified lesions because the procedure allows stent implantation where it otherwise would not have been possible.

Laser ablation

Lasers have been used to heat a catheter tip, to heat tissue abutting the angioplasty balloon, and to assist wire passage through chronic total occlusions, as well as for direct application to the lesion, for vaporizing tissue, and for direct application to myocardium.[90–95] Similar to the atherectomy devices, laser phototherapy devices are intended to perform safe and effective lesion debulking and to reduce the thrombus burden. With the exception of severely calcified lesions and, perhaps, lesions with a heavy thrombus burden, laser therapy is similar to atherectomy in offering little benefit over balloon angioplasty because laser therapy increases the risk of procedural complications.[85,87,93,96,97] Percutaneous transmyocardial laser revascularization yields no clinical improvement and promotes an additional risk of MI.[95] Also as in rotational atherectomy, specific lesions or circumstances may warrant its use (Fig. 21-5).

Aspiration devices

A number of coronary aspiration devices are available to reduce the risk of distal embolization and to diminish the local concentration of prothrombotic and vasoactive substances. These devices range from a simple end-hole catheter attached to a syringe to a complex suction catheter with or without an associated mechanical disrupter. These devices forcibly extract components of the thrombus or atheroma.[98] Their use may improve flow after treatment of thrombus-laden lesions or saphenous vein grafts[99] (Fig. 21-6). However, this effect has not been established with certainty.[100]

Embolic protection devices

During balloon angioplasty, mechanical dissolution of thrombus, if present, may result in macroembolization and distal vessel occlusion. The high-pressure manipulation of an atheromatous lesion also may free cholesterol crystals and other components of the lesion, resulting in distal microembolization, thrombosis, and slow- or no-reflow phenomenon.[101–105] Several devices have been developed to reduce the frequency or impact of distal embolization. These devices may be placed distal or proximal to the treated lesion. Distal devices are mounted on the guidewire

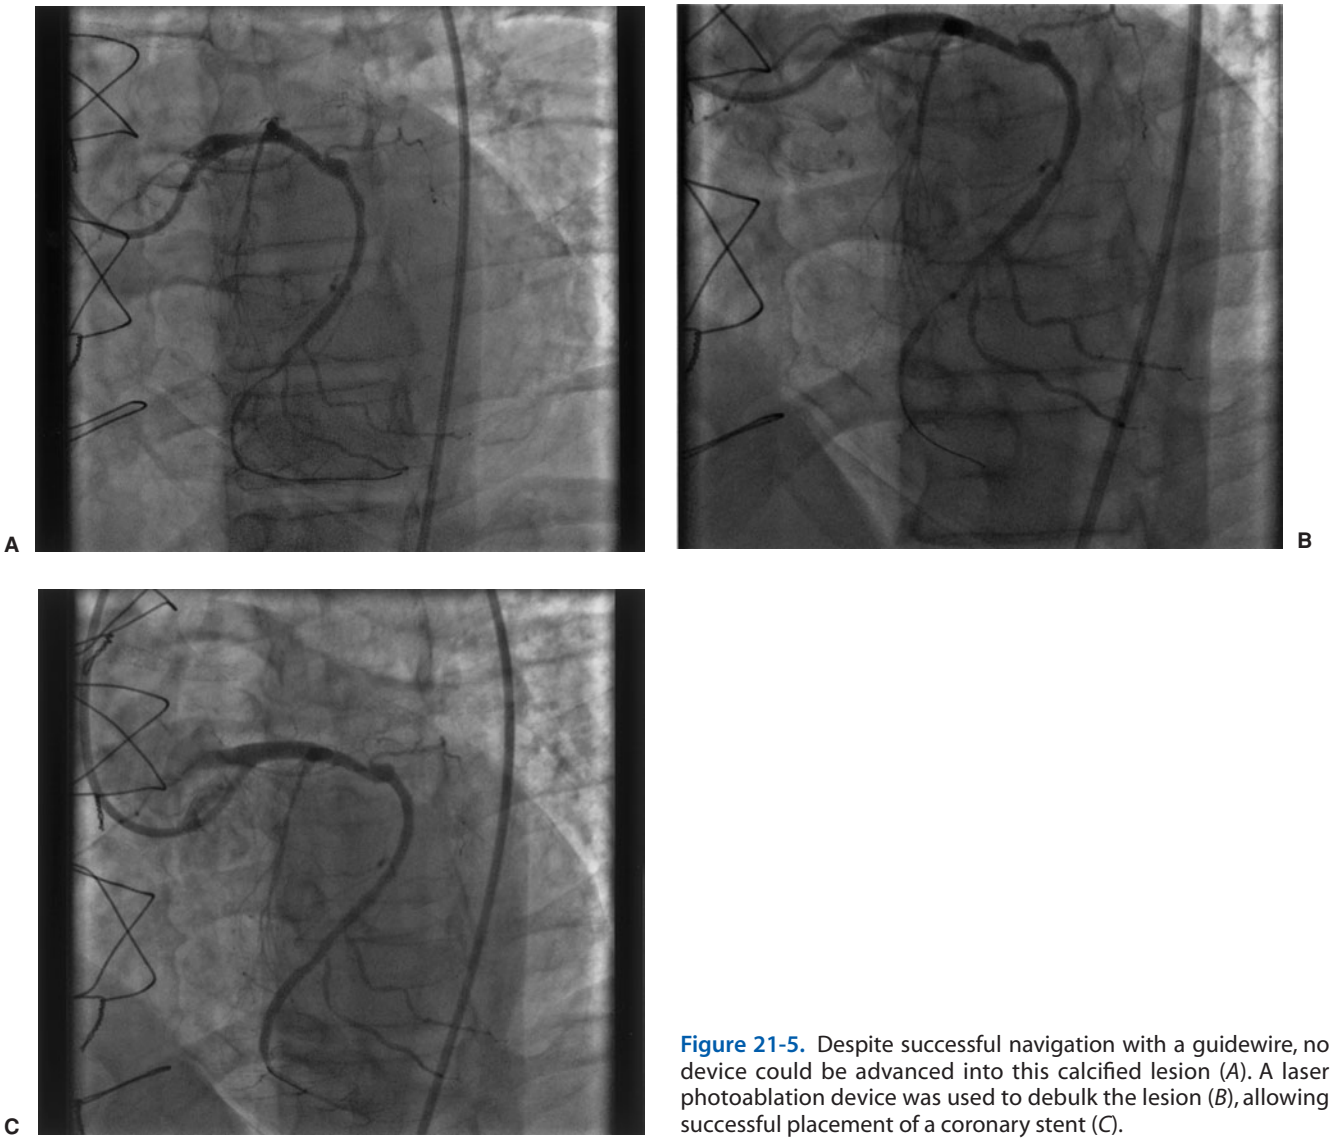

Figure 21-5. Despite successful navigation with a guidewire, no device could be advanced into this calcified lesion (*A*). A laser photoablation device was used to debulk the lesion (*B*), allowing successful placement of a coronary stent (*C*).

and use either a suspended micropore filter to trap particulate matter of 100 to 150 μm or larger or balloon occlusion of the treated vessel with posttreatment aspiration to capture embolized material. Proximally placed devices temporarily interrupt flow and aspirate the treated vessel. The PercuSurge GuardWire Plus (Medtronic, Minneapolis, MN) is a balloon occlusion and aspiration device that underwent testing in vein grafts in the Saphenous Vein Graft Angioplasty Free of Emboli Randomized (SAFER) trial. The trial demonstrated a 42% reduction in creatine kinase (CK) elevations and more than a 50% reduction in the no-reflow phenomenon.[106] Unfortunately, these results did not apply to patients with MI.[107]

The FilterWire EX (Boston Scientific, Natick, MA) has a self-expanding wire loop attached to the guidewire (Fig. 21-7). This self-expanding loop suspends a micropore filter shaped somewhat like a windsock and ensures good apposition to the wall of the treated vessel. Theoretically, smaller particles, cytokines, and procoagulant molecules may pass through the filter. However, a direct comparison between the filter wire and guardwire revealed no difference in the degree of protection against distal embolization.[108]

Imaging devices

Angiographic imaging allows imaging of the coronary lumen but may be unreliable in the setting of severe calcification, difficult branching patterns, or previously placed coronary stents. Furthermore, a thrombus that may increase the risk of PCR may go undetected by standard angiographic imaging. Therefore, a number of alternative imaging methods have been developed to improve diagnosis, to plan revascularization efforts, and to evaluate the success of

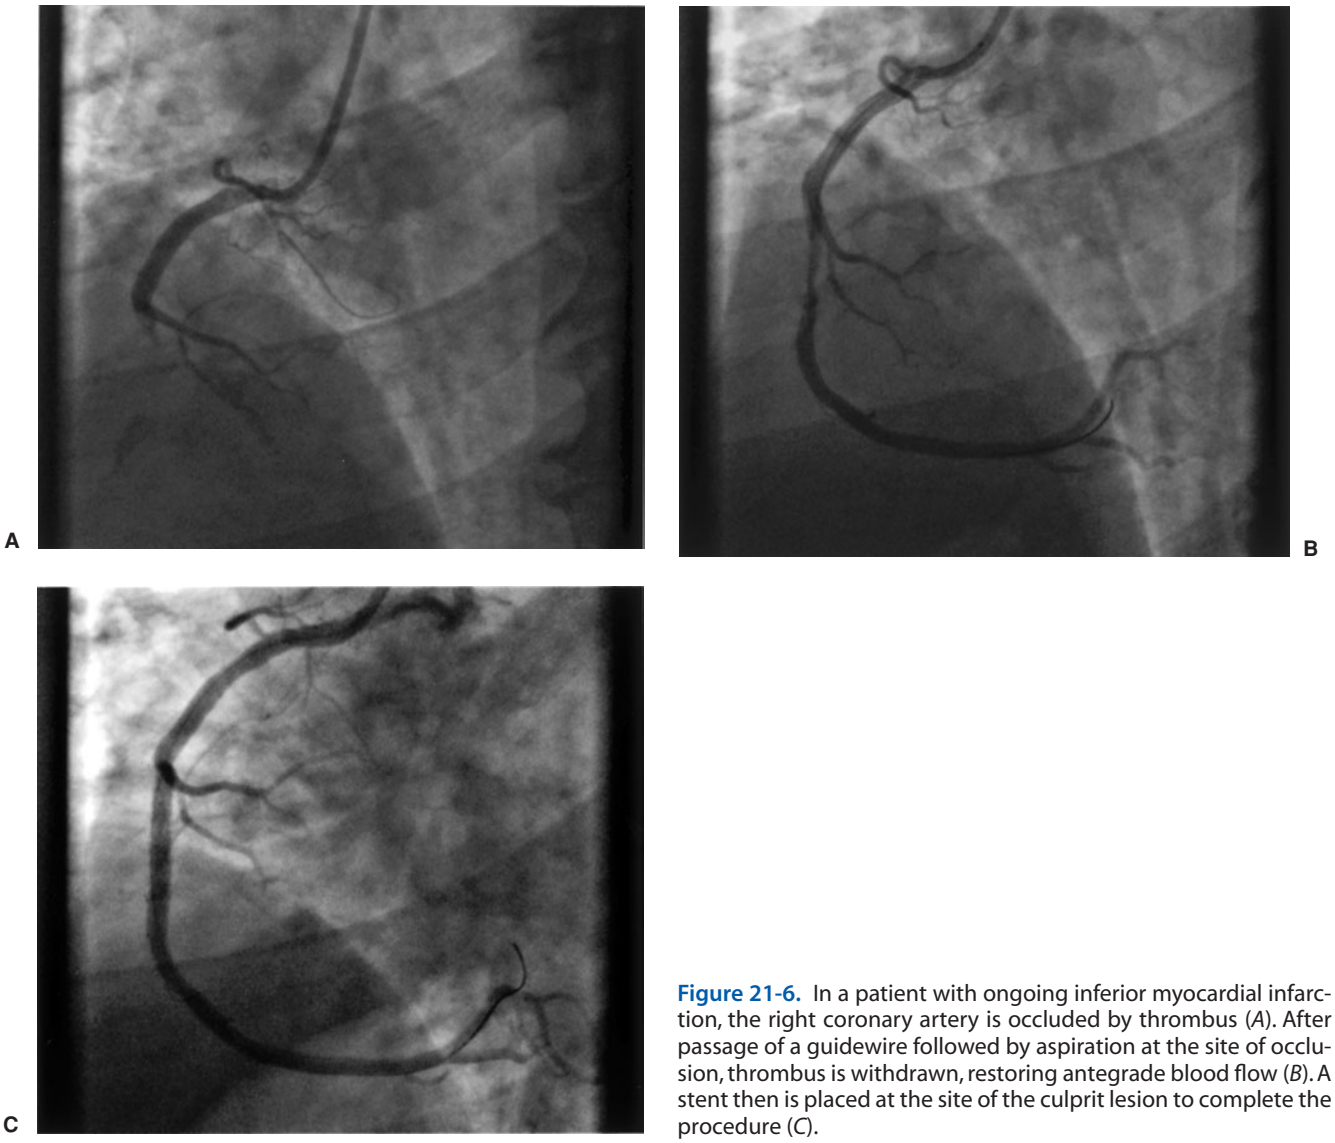

Figure 21-6. In a patient with ongoing inferior myocardial infarction, the right coronary artery is occluded by thrombus (*A*). After passage of a guidewire followed by aspiration at the site of occlusion, thrombus is withdrawn, restoring antegrade blood flow (*B*). A stent then is placed at the site of the culprit lesion to complete the procedure (*C*).

such efforts. Angioscopy or fiberoptic imaging requires occlusion of the imaged vessel and perfusion with saline. While a useful tool to investigate the presence or components of thrombus within coronary vessels, angioscopy has not been a useful adjunct to PCR.[109] In contrast, intracoronary ultrasound imaging has proved especially useful. Ultrasound imaging allows accurate determination of vessel size, luminal reduction, lesion components, and progress associated with revascularization attempts. Ultrasound guidance for stent implantation is associated with a greater than 30% reduction in the need for repeat procedures.[110] Of equal importance, intracoronary ultrasound is an invaluable research tool used to investigate the accuracy of contrast angiography and the impact of mural lesion components on complications and outcomes after angioplasty. Intracoronary ultrasound also provides precise, accurate information about the impact of various DESs on intimal hyperplasia.[111,112]

Devices that measure lesion severity

The hemodynamic significance of coronary lesions, the appropriateness of a treatment, and the success of treatment may be determined by the following two means: a guidewire that measures the velocity of blood flow within coronary arteries or a calculation that measures pressure distal to a coronary lesion.

A miniaturized Doppler-equipped guidewire with a 12-MHz transducer uses a pulsed interrogation that samples 5.2 mm beyond the guidewire tip at an angle of 14 degrees on either side. Assuming that the cross-sectional area of the

C

Figure 21-7. In this aged and degenerated saphenous vein graft, any manipulation is likely to result in distal microembolization, slow flow, and infarction (*A*). Placement of a distal filter wire may prevent embolization proximal to the device during placement of a stent (*B*). The self-expanding ring can be seen closely apposed to the walls of the saphenous vein graft, allowing flow through the centered filter (*C*).

interrogated vessel remains constant during all measurements, the ratio of velocities measured reflects the ratio of blood flow between any two measurements. The most important and reliable parameter that a flow probe measures is the ratio of resting flow to vasodilated coronary flow, a value known as *coronary flow reserve*. When measured using the Doppler probe, the value is termed *coronary velocity reserve* (CVR). As a coronary lesion becomes flow-limiting, attempts to normalize tissue perfusion by autoregulation result in arteriolar dilatation at rest. Therefore, the administration of an arteriolar vasodilator such as adenosine will have little additional effect on flow velocity. The absence of an appropriate increase in velocity during adenosine- or dipyridamole-induced arteriolar vasodilation produces abnormal flow reserve. A CVR greater than 2.0 indicates hemodynamically significant lesions.

CVR measurement reflects changes in flow relative to an assumed normal baseline state but is subject to error when baseline flow is abnormal. Examples of abnormal states include left ventricular (LV) hypertrophy, fibrosis, and perhaps anemia. In addition, abnormally large or small driving pressure gradients may fall outside the range of normal coronary autoregulation, altering the basal-to-hyperemic ratio. Failure to achieve arteriolar dilatation in response to adenosine or dipyridamole will produce an abnormal calculated flow reserve. Examples that affect arteriolar dilatation include diabetes mellitus, amyloidosis, and recent caffeine or theophylline ingestion.

Under normal conditions, epicardial vessels present little detectable resistance to flow. Therefore, driving pressure (P_{Ao}) and arteriolar resistance pressure (P_{RA}) determine maximal coronary blood flow. The presence of a flow-limiting coronary lesion will cause some of the driving pressure to be lost, so maximal flow will depend on the distal coronary pressure (P_d)-to-P_{RA} gradient and arteriolar resistance. Therefore, the fraction of maximal basal flow that remains possible in the presence of the lesion is

$$\dot{O}_{lesion}/\dot{O}_{no\ lesion} = (P_d - P_{RA}/R_{basal})/-(P_{Ao} - P_{RA}/R_{basal})$$

Canceling resistance and assuming that right atrial pressure remains constant results in a very simple relationship:

$$\dot{O}_{lesion}/\dot{O}_{no\ lesion} = P_d/P_{Ao}$$

This ratio, called the myocardial *fractional flow reserve* (FFR), is obtained after the administration of adenosine. An FFR of 0.75 or less identifies a hemodynamically significant lesion.[113]

BRACHYTHERAPY

Prior to the advent of the DES, restenosis after angioplasty or stent implantation could be treated by medical therapy, by repeat angioplasty, or by coronary artery bypass surgery. The frequency of restenosis led to a large population of patients with multiple treatment failures, intractable symptoms, and prohibitive risks for surgical treatment. Because a proportion of the cell population colonizing a treated lesion and contributing to restenosis arose from the media of the treated lesion, radiation therapy to prevent colonization and cell replication was proposed. The well-recognized dangers of high-dose, external-beam radiation limited dosing to local application, but this therapy still was seen as a substantial risk. When used as a treatment for de novo coronary lesions, radiation brachytherapy increased both short- and long-term complications.[114] However, for the treatment of refractory in-stent restenosis, limited successes have been observed.[115,116]

Radiation sources may be classified according to the energy of the emitted particle. Gamma radiation, at the high end of the electromagnetic spectrum, refers to an emitted photon with short wavelength and high energy that is able to penetrate deeply into tissue and surrounding structures. Therefore, short-term application of gamma radiation may allow for delivery of a significant tissue dose. Beta radiation refers to lower-energy and less penetrating electrons released from a radioactive isotope. Both forms of radiation have been used for coronary brachytherapy to prevent repeat stent restenosis. However, beta-radiation sources are handled more easily and may be applied to coronary stents for local delivery over a long period of time. Gamma-radiation sources are dangerous to handle, require special training, and may be applied only briefly in specially shielded catheterization laboratories. Beta-radiation sources include strontium-90, yttrium-90, and phosphorous-32. Strontium and yttrium are metallic and may be delivered to the site of interest as a "wire." Phosphorous-32 may be incorporated into a coronary stent. Gamma sources are limited to iridium-192, which must be delivered as pellets advanced through a specially designed catheter.

Radiation brachytherapy reduces the risk of repeat in-stent restenosis from 54 to 58% and, after 6 months, reduces restenosis from 17 to 27% in native vessels and saphenous vein grafts.[117–120] Treated patients have a greater risk of restenosis and repeat intervention during long-term follow-up, suggesting a catchup phenomenon, but an advantage over placebo is maintained through 5 years.[119,121–124] Unlike gamma radiation, the localized delivery of beta radiation also causes vigorous intimal hyperplasia to form adjacent to the treated site, creating a "candy wrapper" restenosis appearance.[125] The local effects of radiation create a prothrombotic state and an increased risk of thrombosis at the treated site.[115,126–128] Therefore, dual antiplatelet therapy is required for at least 1 year after the procedure.[129] This form of therapy likely will be abandoned with the advent of DESs, whose efficacy probably is equal to or greater than that of radiation.

CIRCULATORY SUPPORT

Performance of a percutaneous revascularization procedure includes an obligatory period of ischemia in the treated region. The duration of ischemia may be prolonged in the event of abrupt closure or distal embolization, and recovery may be incomplete or delayed for a period of days, as in the treatment of acute MI. For patients with depressed LV systolic function or for those in whom the treated territory is large, there is a risk for developing cardiogenic shock during and after the procedure. This risk substantially increases the possibility of acute renal failure, stroke, and death. The likelihood of shock complicating an angioplasty procedure may be predicted by using a scoring method that incorporates the extent and severity of systolic dysfunction present before the procedure and the extent that can be expected as a result of the procedure[130–132] (Table 21-8). Elective placement of

Table 21–8.

A Score Predicting the Need for Circulatory Support[132]

Six arterial segments	**LAD, D_1, S_1, OM, PLV, PDA**
Score 1	Target lesion or any additional lesion >70% diameter stenosis
Score 0.5	Subtended region is hypokinetic but has no stenosis
For a score >3	Consider IABP

LAD = left anterior descending artery; D_1 = first diagonal branch; S_1 = first septal branch; OM = obtuse marginal branch; PLV = posterior left ventricular artery; PDA = posterior descending artery; IABP = intra-aortic balloon pump.

an intra-aortic balloon pump (IABP) is associated with a reduced risk of hypotension and major complications.[133]

Intra-aortic balloon counterpulsation has been used to assist the performance of percutaneous angioplasty for a number of years, but the assistance provided by an IABP may be insufficient for patients with severely impaired systolic function or for those who develop cardiogenic shock after MI. The percutaneous left ventricular assist device (PLVAD) is a miniaturized axial-flow pump that is being used increasingly for support of patients in shock or during high-risk angioplasty procedures.[134] The PLVAD is capable of providing up to 4 L of additional blood flow per minute. Although it can providing superior circulatory support, the PLVAD has not shown any survival advantage when compared with the IABP, and vascular access-site complications are more frequent with the PLVAD.[135]

COMPLICATIONS OF PCR

In addition to abrupt closure and restenosis, there are several other potential complications of PCR that may influence the risk:benefit ratio for an individual patient. These complications include bleeding, vascular access-site complications, stroke, radiocontrast nephropathy, and MI owing to distal embolization.

Hemorrhage

During the introduction of coronary stent implantation, heparin therapy often was maintained after sheath withdrawal, resulting in groin access-site complications in as many as 16% of patients.[136] Modifications in groin access technique, pharmacologic therapy, and sheath withdrawal have reduced this risk substantially. Bleeding that requires transfusion or results in hemodynamic instability occurs in 0.5 to 4% of PCR procedures, depending on patient variables (e.g., age, gender, and peripheral vascular disease), procedural variables (e.g., location of femoral arteriotomy and duration), and pharmacologic variables (e.g., intensity of antithrombotic therapy).[5,137,138] Risk factors for vascular access-site complications potentially requiring surgical repair (e.g., pseudoaneurysm, arteriovenous fistula, laceration, and retroperitoneal hematoma) are similar to risk factors for bleeding.[139–141] A number of devices have been designed to improve femoral hemostasis after sheath removal, but none has proven superior to standard compression hemostasis.[142]

Because of the size of equipment used for angioplasty procedures, femoral access has been and remains the preferred approach. However, with the availability of lower-profile equipment, the radial artery is being used with greater frequency, which results in a reduction in bleeding and access-site complications.[143]

Ischemia

Stroke complicates approximately 0.18% of PCR procedures.[144] Its occurrence is associated with increased age, depressed LVEF, diabetes mellitus, saphenous vein graft intervention, and complicated or prolonged procedures requiring the placement of an intra-aortic balloon pump.[145]

MI complicates 5 to 30% of PCR procedures, depending on the definition of infarction.[146] Using a definition of new Q wave, the incidence is 1%.[147] When any elevation of MB fraction of CK (CK-MB) is used as the definition, as many as 38% of patients have periprocedural MI.[146] Use of more stringent definitions of infarction, such as greater than three or 10 times the upper limit of normal, reduces the reported values to 11 to 18% or 5%, respectively.[147–149] Actually, any elevation carries prognostic significance, but elevation above three times the upper limit of normal is accepted as a definition of periprocedural MI. Elevated levels of troponin I (23 to 48%)[149–151] after PCR are even more frequent, although the prognostic significance of minor elevations is questionable.

Transient coronary occlusion during PCR may result in a periprocedural MI. However, elevated markers of myocardial injury may be seen following apparently uncomplicated procedures.[146] One mechanism for such events is microscopic distal embolization. When severe, microscopic distal embolization of a coronary artery creates an angiographic appearance of slow vessel filling termed *no-* or *slow-reflow*. No-reflow is seen most often in the setting of saphenous vein graft angioplasty but also may complicate rotational atherectomy and primary PCR for acute MI. Methods of quantifying abnormal flow following PCR include a subjective estimation of flow velocity, the Thrombolysis in Myocardial Infarction (TIMI) flow rate (III, normal; II, slow; I, minimal contrast material flow beyond the treated site; and 0, no flow), and the more objective method of corrected TIMI frame count. Individual frames of the angiographic image are counted from the time of contrast material entry into the treated vessel until a predetermined distal landmark is reached. Because of somewhat slower flow in the longer left anterior descending artery, flow in this vessel is modified mathematically, or "corrected," in order to normalize values with the right and circumflex coronary arteries.[152]

No-reflow may be a brief and self-limiting phenomenon, but when prolonged, it is associated with increased mortality.[153] Pharmacologic manipulations, including intracoronary verapamil,[154] adenosine,[155] and nitroprusside,[156] may be used in an attempt to prevent or treat no-reflow phenomenon (see Table 21-2).

Perforation of the coronary artery complicates 0.5% of angioplasty procedures,[157–159] and its frequency increases almost 10-fold when ablation devices are used (ablation 1.3% versus PTCA 0.1%; $P < .001$).[157] Coronary artery perforation occurs more frequently in elderly and female patients.[157,159] Perforations are classified by severity as type I (a visible extraluminal crater without extravasation), type II (pericardial or myocardial blushing; Fig. 21-8), and type III (1 mm diameter perforation with contrast material streaming). Type I and II perforations typically are the result of improper guidewire manipulation or placement. Type I perforations (26%) may be treated nonsurgically 95% of the

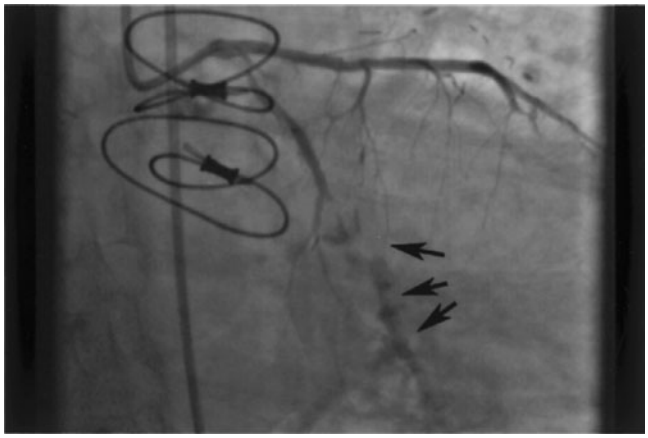

Figure 21-8. In the setting of early saphenous vein graft closure with myocardial infarction and postinfarction angina, attempts to access the culprit native vessel with a stiff guidewire have led to coronary perforation. Shown in this injection of the left coronary artery are occlusions of the left anterior descending and left circumflex coronary arteries. Staining is seen (*arrows*) in the region of the attempted recanalization of the left circumflex coronary artery identifying perforation (type II). The patient was treated successfully with reversal of anticoagulation and temporary occlusion of the circumflex using the PTCA balloon. PTCA = percutaneous transluminal coronary angioplasty.

time and are rarely fatal. Type II perforations (50%) require surgery 10% of the time and are associated with a 13% mortality rate. Type III perforations (26%) carry a mortality rate of 63%.[157]

Pericardial tamponade is frequently but not invariably associated with coronary artery perforation. The overall incidence of tamponade after PCI is 0.12% and doubles when ablation devices are used. PCI-associated tamponade is recognized 55%[160] of the time during or after the procedure while the patient is still in the catheterization laboratory and 45% of the time after the patient leaves the laboratory. A minority of episodes of late tamponade (13%) are associated with recognized coronary artery perforation. Tamponade requires surgical treatment in 39% of patients, is closely associated with MI complicating PCR, and carries a mortality rate of 42%.[160]

The covered stent that was developed for, but failed to reduce the risk of, saphenous vein graft restenosis[161] presently is used as a rescue device after coronary artery perforation or for the treatment of coronary or saphenous vein graft aneurysms[162] (Fig. 21-9). When a covered stent is used for the treatment of coronary artery perforation, the need for emergency surgery is reduced, and the outcome of coronary artery perforation is improved. A small number of patients, however, still will require surgery.[163]

Toxicity

Acute renal failure following exposure to radiocontrast material, or *radiocontrast nephropathy* (RCN), is poorly understood. Its occurrence is a function of age, congestive heart failure, hemodynamic instability, diabetes mellitus, preexisting renal insufficiency, anemia, peripheral vascular disease, and the amount of contrast material administered.[164–166] The incidence of RCN after coronary angiography is 5 to 6%, with the nadir of renal function occurring 3 to 5 days after the procedure.[167] Even a transient decline in renal function leads to an increased risk of ischemic cardiovascular events during follow-up, and renal failure requiring hemodialysis is seen in about 10% of patients with RCN, increasing both short- and long-term mortality.[164,166,168]

Attempts to limit the incidence of RCN have included the use of calcium channel antagonists, aminophylline, *N*-acetylcysteine, fenoldopam, dopamine, atrial natriuretic peptide, sodium bicarbonate, hemofiltration, and iso-osmolar nonionic contrast material and maintenance of brisk urine flow with crystalloid solution and diuretics.[167,169–177] Unfortunately, few of these methods have produced the desired result.

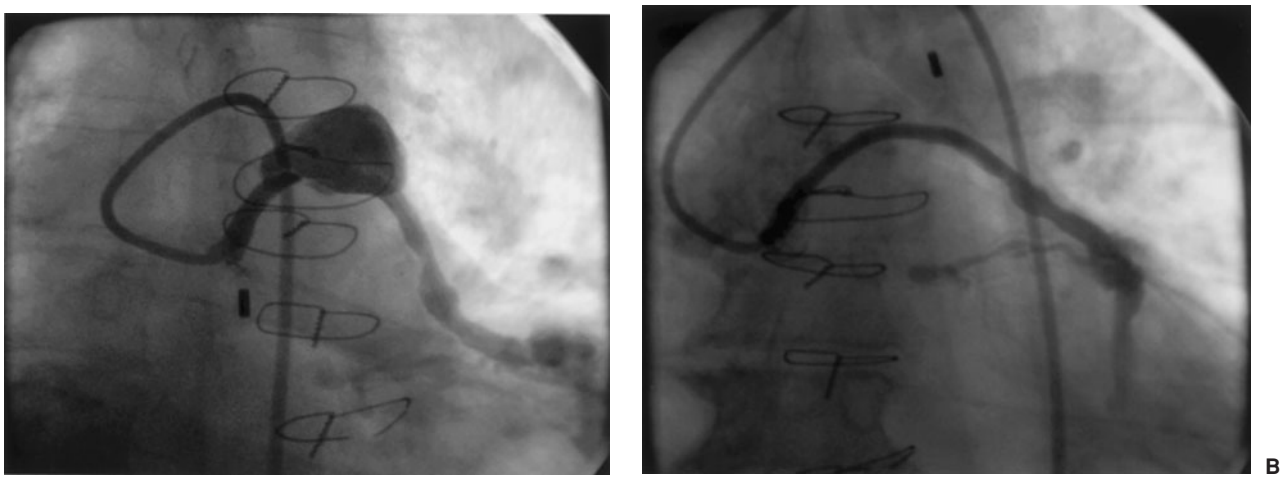

Figure 21-9. A large saphenous vein graft aneurysm (*A*) is treated with a covered stent (*B*).

Iodixanol, an iso-osmolar nonionic contrast agent, reduced the incidence of RCN following noncardiac angiography.[177] Giving four oral doses [600 mg each of *N*-acetylcysteine (two doses on the day before and two on the day of the procedure)] has met with varied outcomes in several studies but appears to be beneficial.[172,178] Administering crystalloid solution in volumes sufficient to maintain brisk urine flow, perhaps aided by alkalinization of urine pH, is the most effective intervention to ensure an adequate volume state.[167,170,171] Forced diuresis with diuretics is of minimal or no additional value, and the use of dopamine to reduce the likelihood or duration of RCN may be harmful.[170,175]

SPECIAL CIRCUMSTANCES

Acute Coronary Syndromes (ACS)

Successful PTCA within the first 6 hours of ST-segment-elevation MI is at least as effective as, and perhaps more effective than, thrombolytic agents in limiting myocardial damage and improving in-hospital survival. The incidence of recurrent ischemia is reduced, LV function may be better preserved, and there is no significant risk of intracranial hemorrhage.[179,180]

Patients undergoing urgent PTCA have a 20 to 40% risk of experiencing recurrent angina, restenosis, or repeat revascularization. Stents are more effective than PTCA, especially when used in combination with a potent antiplatelet regimen.[181–183] Their comparison with thrombolytic therapy has been far more favorable in both early and late outcomes.[180,184,185] The routine use of coronary stents for acute MI is associated with a restenosis rate of 17% and a 6-month event-free survival of 83 to 95%.[186–190] DESs are safe for use in patients with acute coronary syndromes[67,191,192] and reduce the risk of any adverse event from 17 to 9.4% at 300 days.[67]

Routine angioplasty following full-dose thrombolytic therapy was associated with an increased risk of complications owing to rethrombosis, bleeding, and intramural coronary artery hematoma, which could produce abrupt vessel closure. However, with the use of stents and Gp IIb/IIIa antagonists, there is no longer an increased complication risk associated with PTCA, and repeat hospitalization for revascularization has been reduced substantially.[193,194] After failed attempts at thrombolysis or for patients with cardiogenic shock who received thrombolysis, stent revascularization increases myocardial salvage and reduces the risk of death, heart failure, or reinfarction.[195–197]

Prior Coronary Artery Bypass

Stent implantation with the assistance of embolic protection devices is the preferred method for percutaneous treatment of saphenous vein grafts.[106,198] The use of distal embolic protection reduces the risk of periprocedural MI from 14.7 to 8.6%.[106] Unfortunately, diseased grafts have a high probability of developing new lesions, reducing the long-term event-free survival rate. After stent implantation, overall survival is 79% at 4 years, but survival free of MI or another revascularization procedure is only 29%.[199–203] DESs reduce the risk of restenosis after saphenous vein graft PCR but will not affect the likelihood of progression elsewhere in the diseased graft.[69]

THE FUTURE

The future of interventional cardiology lies in reducing procedural risk and extending treatment durability. For many patients, the goal of providing durable treatment success has been very nearly achieved with the introduction of DESs, an approach that has yet to be fully explored. However, a DES does not reduce procedural risk, and problems remain for patients with diffuse atherosclerosis, diabetes mellitus, bifurcation lesions, and acute coronary syndromes.

Ironically, the goal of reducing procedural risk has been pursued most effectively for saphenous vein graft revascularization with the development of distal embolic protection devices. However, for native-vessel intervention, particularly during acute coronary syndromes, further advances likely will be pharmacologic rather than technical. Drawing on observations made in ischemic preconditioning, modification of myocardial energy metabolism with drugs such as ranolazine, perhexeline maleate, and others represents a means of improving the heart's ability to withstand ischemia, thus temporizing the impact of temporary vascular occlusion and macro- or microembolization.[204–206] In addition, inhibitors of the protein kinase family of enzymes, central to intracellular signaling, also may improve the heart's ability to withstand ischemia as well as reduce the severity of reperfusion injury.[207–209]

Local drug delivery has met with great success in reducing the problem of restenosis. However, there are numerous methods of modifying the physiology driving intimal hyperplasia after stent implantation. New DES platforms offer the alternative of eluting multiple drugs at different rates, reducing the need for systemic medical therapy such as prolonged dual antiplatelet therapy. One active area of research is the development of stents capable of delivering drug therapy without dependence on a coating polymer. In addition, complex molecules that can be absorbed by the body are being developed as stent platforms. The use of such a stent, one that delivers antithrombotic and antiproliferative drug therapy, could, conceivably, allow PCR protection from acute closure, recoil, thrombosis, and restenosis without contributing to vessel rigidity—which increases the difficulty of subsequent procedures.

A growing number of patients who are surviving long-term with severe multivessel coronary artery disease remain hampered by severe angina pectoris. In many instances, years of slow, steady disease progression have left extensive collateral vessels that prevent infarction and the near or complete loss of major branch vessels. These patients currently have no option for percutaneous or surgical revascularization.

The promise of direct myocardial revascularization remains unfulfilled, and percutaneous attempts appear to be harmful.[210] The modification of vascular growth and remodeling that was hoped for with the administration of specific growth factors proved too complex to achieve predictable results. However, the use of stem cells, perhaps the most efficient producers of cytokines and growth factors in their proper sequence, has met with early success. Direct injection of stem cells into regions of ischemic myocardium improves walking time and reduces the frequency of angina attacks.[211]

CHAPTER 22

Myocardial Revascularization with Cardiopulmonary Bypass

Enrique Góngora • Thoralf M. Sundt, III

Coronary artery disease (CAD) remains the single largest killer of Americans. Accounting for almost half a million deaths per year, CAD imposes a particular burden on the elderly, with more than 80% of all CAD deaths occurring in those over age 65.[1] Given projections that the number of Americans older than 65 years of age will double from 30 million currently to 62 million over the next 25 years,[2] and the anticipated increase in the prevalence of important risk factors for CAD such as diabetes mellitus and obesity,[3] the need for coronary revascularization in the next two decades can be expected to increase.

The role of surgical revascularization vis-à-vis percutaneous coronary interventions (PCI) continues to mature, as the latter field has evolved from balloon angioplasty to near routine coronary stenting complemented by "cutting balloon" angioplasty, rotational atherectomy, directional atherectomy, laser angioplasty, and radiation brachytherapy. Between 1999 and 2002 the use of percutaneous techniques increased at a rate of 6.8% annually with a 1.9% annual decrement in the number of coronary artery bypass graft (CABG) procedures performed.[4] In 2002, an estimated 959,000 Americans required coronary revascularization, according to the Centers for Disease Control and Prevention. Revascularization was achieved by CABG in 31% of patients and in 69% of patients with percutaneous interventions. A total of 709,000 open heart surgery procedures were recorded during the same year, with CABG procedures performed in 306,000 patients.[5] Despite progress in reducing the rate of target vessel restenosis, particularly with the advent of drug-eluting stents, reintervention rates remain higher and angina relief lower following PCI rather than CABG. Furthermore, CABG procedures can be carried out today with remarkably low periprocedural mortality and morbidity and excellent long-term results despite an increasing risk profile.[6] There are also mounting data to suggest a late mortality benefit with CABG over PCI,[7–9] although a complete discussion of this topic is beyond our scope here. It is sufficient to note that surgical revascularization will undoubtedly continue to play a significant role in the management of CAD for the foreseeable future.

There has been considerable interest of late in performing CABG without use of cardiopulmonary bypass as discussed in detail in a separate chapter. "Off-pump" CABG is technically demanding, however, and is likely not applicable to every patient. Excellent short- and mid-term results have been achieved by centers with special interest in this technique; however, concerns about graft patency with off-pump techniques still exist, and long-term outcomes as well as graft patency studies are eagerly awaited. Currently, 80% of surgical myocardial revascularizations (MRs) in the United States are performed with the aid of cardiopulmonary bypass.[4] At this time MR with cardiopulmonary bypass remains the gold standard against which newer techniques must be compared. In the foreseeable future MR with cardiopulmonary bypass will continue to be a cornerstone of the management of patients with CAD.

HISTORY OF CORONARY ARTERY BYPASS GRAFTING

Indirect methods to restore blood supply to the ischemic myocardium were pioneered by Claude Beck,[10] who reported in 1935 on the placement of a pedicled pectoralis muscle flap on the abraded pericardium. In 1951 Vineberg described direct implantation of the internal thoracic artery (ITA) into the myocardium,[11,12] and Sen described "myocardial acupuncture" in 1968.[13] Gibbon's development of the cardiopulmonary bypass machine and its successful clinical application by Kirklin at the Mayo Clinic and Lillehei at the University of Minnesota[14–16] made direct coronary revascularization technically feasible. Bailey

in 1957 reported the first successful coronary endarterectomy, and in 1958 Longmire reported a mammary-to-coronary anastomosis performed after a surgical misadventure with a coronary endarterectomy.[17,18] Goetz in 1960 performed the first successful planned coronary artery bypass operation, employing a metal cannula to connect the right ITA to the right coronary artery (RCA), with angiographic patency confirmed 2 weeks after operation.[19,20] The first reported use of a saphenous vein aorto-coronary bypass was reported by Sabiston in 1962; however, the postoperative death of the patient dissuaded repetition of the procedure.[21,22] The Russian surgeon Kolessov is credited with the first successful planned sutured internal mammary-to-coronary anastomosis in 1964.[23,24] Garrett and DeBakey reported a 7-year follow-up of a bypass with venous conduit performed also in 1964.[25]

It was, however, the development of coronary angiography by Mason Sones at the Cleveland Clinic in 1957 that opened the door to the elective treatment of coronary atherosclerosis by means of direct revascularization.[26] Initial studies by Rene Favaloro and Donald B. Effler with venous and arterial conduits, and their systematic application of these techniques to treat clinical events associated with stenotic lesions of the coronary arteries, culminated in the first large series of aorto-coronary grafts with venous conduits reported in 1968.[27–30] Simultaneously Dudley Johnson of Milwaukee published a series of 301 patients undergoing coronary bypass with venous conduits in 1969.[31] The success of these techniques was soon demonstrated in larger series,[32] initiating the modern era of coronary artery surgery.

One of the most striking features of the history of CABG is the extent to which the procedure was subjected virtually from the outset to prospectively randomized study. Surgical revascularization was demonstrated to provide excellent relief of symptoms as well as improved survival among patients with the most severe forms of atherosclerotic coronary involvement.[33–35] The subsequent establishment of large databases has allowed advances in risk stratification, mortality prediction, and long-term follow-up, making CABG arguably the most data-driven, evidence-based medical procedure performed today.

INDICATIONS FOR SURGICAL CORONARY REVASCULARIZATION

The indications for CABG are reviewed in detail in a separate chapter. In brief, the indications established by the American Heart Association and American College of Cardiology (AHA/ACC) consensus panel[36] are based predominantly on the results of trials comparing surgical revascularization with medical therapy for patients with chronic stable angina. Between 1972 and 1984 several randomized trials compared medical and surgical therapy for the treatment of atherosclerotic CAD. The three major trials, the Coronary Artery Surgery Study (CASS),[34,37] the Veterans Administration Coronary Artery Bypass Cooperative Study Group,[35] and the European Coronary Surgery Study (ECSS),[33] and three smaller randomized trials,[38–40] demonstrate the greatest survival benefit of revascularization to be among those patients at highest risk as defined by the severity of angina and/or ischemia, the number of diseased vessels, and the presence of left ventricular dysfunction.[35,41–43] It is widely accepted that there is a survival advantage for surgical revascularization over medical therapy in patients with left main disease,[44] and those with triple-vessel disease and left ventricular dysfunction.[45,46] There is also significant evidence supporting a survival advantage with CABG for those with two-vessel disease and proximal left anterior descending (LAD) disease,[33] and in patients with severe ischemia and multivessel disease.[47,48] More recent progress in both PCI and medical therapy, however, has raised intriguing questions as reviewed in the aforementioned chapter.

PREDICTION OF OPERATIVE RISK

The ultimate decision whether or not to proceed with CABG in an individual patient can only be made with an estimate of the individual's risk. Formal prediction of risk-adjusted outcomes permits both the surgeon and the patient to weigh the risks against potential benefits and realistic expectations, thereby permitting the patient to give a true informed consent prior to coronary surgery. Accurate risk-adjusted prediction of postoperative morbidity and mortality also provides an important quality improvement tool to understand and examine the variability in institutional and individual surgeon performance.

Operative Mortality

A number of large single-center and multicenter cardiac surgery databases have been used to develop risk models for predicting operative mortality in patients undergoing CABG.[36,49–51] The most accurate assessment of individual operative risk is likely that derived using the Society of Thoracic Surgeons (STS) database (Table 22-1). Database participants have access to a desktop program into which they are able to enter individual patient variables to obtain an actual percent of predicted risk. The precise STS risk algorithm is proprietary, however, and demands database participation as well as access to the computer program.[52–55]

A practical "seat of the pants" sense of risk can be more simply derived simply from an understanding of the core variables most predictive of risk in the aforementioned data sets. The strongest predictors of operative mortality include nonelective surgery, low ejection fraction, and prior heart surgery.[36] Jones and associates examined seven large datasets, with more than 172,000 patients undergoing isolated CABG, to assess the predictive power of certain preoperative values

Table 22–1.

Independent Variables Associated with Mortality After Isolated Coronary Artery Bypass Graft (CABG) Surgery

Variable	Odds ratio	95% Confidence interval
Multiple reoperations	4.19	3.61–4.86
First reoperation	2.76	2.62–2.91
Shock	2.04	1.90–2.19
Surgery status	1.96	1.88–2.05
Renal failure/dialysis	1.88	1.80–1.96
Immunosuppressants	1.75	1.57–1.95
Insulin-dependent diabetes mellitus	1.5	1.42–1.58
Intra-aortic balloon pump use	1.46	1.37–1.55
Chronic lung disease	1.41	1.35–1.48
Percutaneous transluminal coronary angioplasty, 6 hours	1.32	1.18–1.48)

Data were collected from 503,478 patients undergoing isolated CABG in the U.S. from 1997 to 1999 from Society of Thoracic Surgeons' database. Variables are listed in decreasing order of importance.
Source: Data from Shroyer AL, Coombs LP, Peterson ED, et al: The Society of Thoracic Surgeons: 30-day operative mortality and morbidity risk models. Ann Thorac Surg *2003;75:1856.*

on operative mortality. Seven variables were found to be predictive of mortality in all datasets. These seven core variables included urgency of operation, age, prior heart surgery, gender, left ventricular ejection fraction (LVEF), percentage of stenosis of the left main coronary artery, and number of major coronary arteries with >70% stenosis. The variables with the greatest predictive power related to urgency of operation, age, and reoperative surgery, while variables that described coronary anatomy had the least predictive power.[56] Chronic comorbidities have also been found to be associated with an increased operative mortality after coronary bypass, including treated diabetes,[57] peripheral vascular occlusive disease,[58] chronic renal insufficiency,[59] and chronic obstructive pulmonary disease (COPD).[53,60]

Operative Morbidity

Of nearly equal concern to patients and physicians alike are the risks of significant morbidity following CABG surgery. Perioperative morbidities are linked to increased operative mortality, reduced long-term survival, and increased cost of care.[61,62] Accordingly there has been considerable interest in the development of risk models to predict a variety of postoperative complications.[36,54] The Northern New England Cardiovascular Disease Study Group initially developed a scoring system to calculate the risk of cerebrovascular accident (CVA) and mediastinitis following isolated CABG. A score is assigned to each independent variable according to its strength of association. Variables used to predict CVA risk in decreasing order of importance included: emergency surgery, increasing age, chronic renal failure with or without dialysis dependence, previous CVA, peripheral vascular disease, diabetes, female gender, and LVEF <40%. Variables used to predict mediastinitis risk in decreasing order of importance included: severe obesity (body mass index >37 kg/m^2), dialysis dependence, obesity (body mass index 31 to 36 kg/m^2), COPD, emergent or urgent surgery, age >80 years, diabetes, LVEF <40%, and age >70 years. The reader is referred to the AHA/ACC consensus panel guidelines for a more detailed review of these scoring systems.[36]

More recent data have been provided by the STS. The STS risk model for postoperative complications is based on data collected from 503,478 patients undergoing isolated CABG in the United States from 1997 to 1999. The 30-day operative death and major complication rates for STS CABG procedures were 3.05 and 13.4%, respectively, including stroke (1.6%), renal failure (3.5%), reoperation (5.2%), prolonged ventilation (5.9%), and sternal infection (0.63%).

Table 22–2.

Variables Associated with Development of a Major Complication After Isolated Coronary Artery Bypass Graft Surgery (CABG)

Variable	Odds ratio	95% Confidence interval
Renal failure/dialysis	2.49	2.41–2.58
Multiple reoperations	2.13	1.92–2.36
Shock	1.86	1.78–1.95
Intra-aortic balloon pump use	1.78	1.72–1.84
First reoperation	1.75	1.70–1.81
Insulin-dependent diabetes mellitus	1.59	1.54–1.64
Surgery status	1.58	1.53–1.63
Chronic lung disease	1.41	1.38–1.45
Immunosuppressants	1.34	1.26–1.43
Percutaneous transluminal coronary angioplasty <6 hours	1.33	1.23–1.43

Any major complication is defined as the composite outcome of stroke, renal failure, prolonged ventilation, mediastinitis, or reoperation. Data collected from 503,478 patients undergoing isolated CABG in the U.S. from 1997 to 1999 from the Society of Thoracic Surgeons' database. Variables are listed in decreasing order of importance.

Risk models were developed using multivariate analysis to stratify the strength of the association from among 30 potential preoperative risk factors for mortality and major complications as shown in Tables 22-2 and 22-3. Except for deep sternal wound infection, the development of any of these complications correlated with an increased risk-adjusted operative mortality.[54]

PREOPERATIVE ASSESSMENT

Patient Evaluation

Regardless of the risk model applied, there is no substitute for clinical evaluation of the patient. Particular attention should be paid to the history of the nature, duration, and severity of ischemic symptoms, as well as signs and symptoms of congestive heart failure (CHF). Evidence of coexisting cardiovascular disease, including cerebrovascular and peripheral vascular disease, will impact both formal risk models and the "foot-of-the-bed" estimate of operative risk, as will COPD disease, diabetes mellitus, and renal or hepatic insufficiency. Recent gastrointestinal hemorrhage may pose a particular risk perioperatively, given both the aggressive anticoagulation required intraoperatively and the general physiologic stress to which the patient will be subjected. The most accurate predictor of excessive perioperative bleeding is a history of prior bleeding disorders. Although universal precautions demand that all patients be treated as if they were carriers of blood-borne transmissible disease, knowledge of active hepatitis or human immunodeficiency virus infection may serve to reinforce to caregivers the importance of using caution in handling sharps and other materials contaminated with the patient's blood. Likewise, identification and treatment of acute medical issues may minimize postoperative morbidity. Review of current medications and dosages with special attention paid to antiplatelet agents such as clopidogrel or anticoagulation with warfarin may impact the technical aspects of surgery and the decision to use antifibrinolytic agents or aprotinin.

Particularly important aspects of the physical examination may be overlooked by our medical colleagues. These include: the adequacy of presternal soft tissues to permit adequate healing, particularly in patients with a history of mediastinal irradiation, cachectic elderly patients, and women who have undergone prior mastectomy. Evidence of venous varicosities, or even prior vein stripping, may alter

Table 22–3.

Variables Associated with Development of a Specific Postoperative Complication

Stroke	Renal failure	Prolonged ventilation	Mediastinitis	Reoperation
Variable, odds ratio (95% confidence interval)				
PVD/CVD, 1.5(1.44–1.56)	Renal failure/dialysis, 4.3 (4.09–4.52)	Multiple reoperations, 2.3 (2.01–2.64)	IDDM, 2.74 (2.47–3.03)	Multiple reoperations, 1.69 (1.49–1.97)
Renal failure/dialysis, 1.49 (1.37–1.62)	IDDM, 2.26 (2.16–2.37)	IABP, 2.26 (2.17–2.36)	Chronic lung disease, 1.62 (1.47–1.78)	Shock, 1.46 (1.37–1.56)

one's plans for conduit. An Allen test may be performed to determine the availability of a radial artery as an alternate conduit.

At a minimum, radiologic evaluation should include a recent chest x-ray to rule out concomitant neoplasm or active pulmonary infection. Coronary angiography must be reviewed and potential graft targets identified preoperatively. Hemodynamically significant lesions reduce coronary blood flow under conditions of increased demand, resulting in myocardial ischemia. A 75% reduction in cross-sectional area, which correlates with a 50% loss of arterial diameter, is sufficient to impair coronary blood flow reserve and distal coronary pressure, and is accepted as a significant stenosis by the AHA consensus and the Bypass Angioplasty Revascularization Investigation (BARI) study investigators.[36,63] In general, lesions with this magnitude of obstruction should be considered for bypass, provided that the distal vessel is of adequate size and quality. A loss of 90% of the luminal area, which correlates with a 75 to 80% loss in diameter, will result in reduced blood flow at rest.[64] It should be noted, however, that bypassing less-than-significantly stenotic lesions creates a state of competitive flow between the graft and the native vessel, predisposing to low flow in the bypass conduit and increasing the risk of graft occlusion regardless of the conduit used.[65–68]

Finally, it is critical that the surgeon discuss in detail the risks, benefits, and alternatives to surgery with the patient to permit the patient to make a truly informed decision. Ideally, this discussion is held in the presence of friends or family of the patient, since patients often have difficulty absorbing the details of the discussion at the time of first meeting a surgeon. The patient and family should be given the details of the planned operation, anticipated perioperative events, and estimate of the need for postoperative rehabilitation, as well as the tempo and time course of recovery. A clear understanding

of the expectations for the perioperative period will reduce the patient's anxiety about surgery, promote early recovery, and is the physician's best protection from litigation should untoward events occur.

BYPASS CONDUITS

Internal Thoracic Artery

The use of the left internal thoracic artery (ITA) as a bypass graft to the LAD artery has been proven to provide superior early and late survival, and better event-free survival after coronary artery bypass (CAB).[69–74] The superior biologic characteristics, unparalleled long-term patency, and better clinical outcomes associated with the use of the ITA make it the conduit of first choice for MI.

Characteristics

The ITA demonstrates remarkable resistance to development of atherosclerosis. This may be in part attributable to a greater resistance of its endothelium to harvest injury as compared with the saphenous vein; under electron microscopy thrombogenic intimal defects are essentially nonexistent in the ITA, but are commonly detected in venous grafts.[75] Perhaps more significantly, however, is the nonfenestrated internal elastic lamina of the ITA that may inhibit cellular migration, thereby preventing initiation of intimal hyperplasia. In addition, the medial layer of the ITA is thin, with fewer smooth muscle cells that exhibit a lesser proliferative response to known mitogens such as platelet-derived growth factor and pulsatile mechanical stretch.[76,77]

The endothelium of the ITA is itself unique as well. With a significantly higher basal production of the vasodilators nitric oxide and prostacyclin,[78–82] the ITA demonstrates a favorable response to pharmacologic agents commonly used in the postoperative period. The ITA vasodilates in response to milrinone and does not vasoconstrict in response to norepinephrine.[83] Nitroglycerin causes vasodilation in the ITA, but not in the saphenous vein.[84] The endogenous secretion of such vasodilators may also have a "downstream" effect on the coronary vasculature, explaining the common observation that the coronary target itself appears relatively protected distal to the anastomosis. Finally, the ITA exhibits remarkable remodeling over time, adapting to the demand for flow by often increasing in diameter over time as observed on late postoperative angiograms. The ITA increases its flow in the same way as normal coronary arteries, through an increase in velocity and caliber mediated by the endothelium.[85]

Surgical anatomy of the internal thoracic artery

The ITA arises from the undersurface of the first portion of the subclavian artery opposite the thyrocervical trunk. The left ITA (LITA) originates as a single artery in 70% of the time and as a common trunk with other arteries in 30%, in contrast the right ITA (RITA), which originates as a single artery in 95% of cases.[86] At the level of the clavicle and the first rib, the ITA passes at first downward and medially behind the subclavian vein and lateral to the innominate vein. In this area the phrenic nerve crosses the ITA, from its lateral to its medial side, before contacting the pericardium. The distance between the origin of the ITA and the intersection with the phrenic nerve is 1.9 $\pm$ 0.7 cm on the left and 1.5 $\pm$ 0.7 cm on the right side. The phrenic nerve crosses anterior to the ITA 66% of the time on the left and 74% of the time on the right.[86] It is important to keep these relations in mind to avoid phrenic nerve injury during ITA harvest, especially when dissecting the most proximal 3 cm of the vessel.

Below the first costal cartilage the ITA descends almost vertically and slightly laterally at a short distance from the margin of the sternum. The ITA lies posterior to the cartilages of the upper six ribs and the intervening internal intercostal muscles. In the upper chest there is a bare area of variable length where the ITA is covered only by the endothoracic fascia and parietal pleura. Below this level the transversus thoracis muscle covers the posterior surface of the ITA. The mean distance of the LITA from the sternal margin at the level of the first intercostal space is 10.5 $\pm$ 3.2 mm, whereas at the level of the sixth intercostal space the distance increases to 20.0 $\pm$ 6.7 mm. The RITA is slightly closer to the sternal margin than the LITA. At the level of the sixth rib the ITA bifurcates into its terminal branches: the musculophrenic and superior epigastric arteries. The length of the ITA ranges from 15 to 26 cm, with a mean of 20.4 $\pm$ 2.1 cm; the LITA is slightly longer than the right.[86] A pair of internal mammary veins accompanies the ITA, at the most superior portion these veins form a single vessel, which runs medial to the artery and drains into the innominate vein.

The ITA supplies blood to the pericardium, phrenic nerve, sternum, anterior chest wall, the pectoralis major, the mammary gland, the anterior abdominal wall, and the diaphragm. The pericardiophrenic artery arises from the ITA in 90% of individuals. It runs parallel to the phrenic nerve, and its division may cause devascularization of the nerve. A large lateral costal artery branches from the ITA in 15% of cases, and some have argued that if left undivided it may create a steal phenomenon following CABG, although this remains unproven and seems unlikely in the absence of a proximal ITA stenosis.[86] The smaller parietal branches of the ITA can arise as single vessels or as a trunk from the ITA. The sternal, intercostal, and perforating arteries typically arise respectively from the medial, lateral, and anterior aspects of the ITA at the superior and inferior margin of the costal cartilages.[87] The sternal/intercostal branches and sternal/perforating branches arise by a common trunk and then divide at a variable distance from the ITA. Theoretically, division of a common trunk close to its ITA origin would allow collateral circulation to the sternum from intercostal and thoracoacromial sources. These potential sources of collateral blood flow are not as common as vessels with a single origin (ratio of 2:5), and only a few of them (14%) are encountered in the distal two-thirds of the sternum.[87]

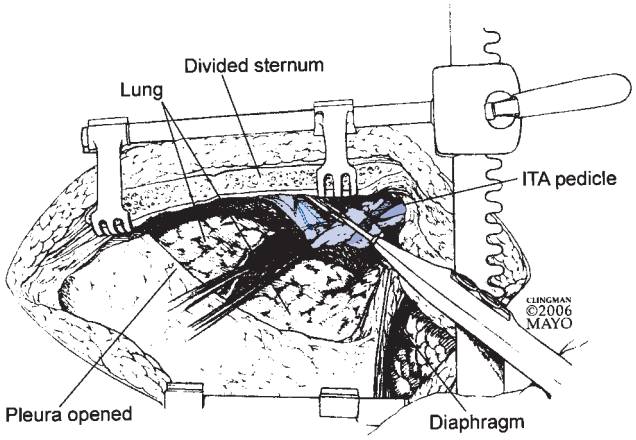

Figure 22-1. Internal thoracic artery (ITA) harvest. A self-retaining mammary retractor is used for exposure of the ITA bed. The left pleura is dissected away from the mammary pedicle and opened along the course of the ITA. The endothoracic fascia is incised medial and lateral to the ITA pedicle. The pedicle is carefully separated with blunt dissection from the underside of the rib. Gentle traction on the pedicle exposes arterial and venous branches at the level of the intercostal spaces; vessels are clipped on the ITA side and cauterized or clipped on the chest wall side. The proximal dissection is carried to the inferior border of the subclavian vein; the distal dissection is then carried to the level of the ITA bifurcation. The transversus thoracis muscle must be divided to expose the ITA bifurcation. The ITA is divided after full heparinization, either at the end of harvest or just prior to grafting of the left anterior descending (LAD) artery.

Pedicled harvest technique

After the sternum is divided, the LITA is harvested (Fig. 22-1). A self-retaining internal mammary retractor is utilized for exposure of the internal mammary bed. A variety of retractors are available including table-mounted models providing a combination of upward and lateral retraction, as well as modified sternal retractors providing simultaneous upward pull on the left and downward push on the right hemisternum. Excessive retraction can cause costal fractures or dislocation of the costosternal joints, resulting in severe postoperative pain as well as brachial plexus injury. The parietal pleura and loose connective tissue with accompanying fat is pushed away from the chest wall. The left pleural space can be entered or left intact at the surgeon's discretion. Opening the pleural space allows easier exposure of the ITA, especially in its most proximal aspect, and permits the ITA to fall into a more lateral and posterior path on its way to the heart. Slightly rotating the operating table to the patient's left and decreasing the patient's tidal volume can aid in the visualization of the mammary bed. The ITA is identified lateral to the border of the sternum by inspection of the bare area or by palpation in the area of artery covered by muscle. The ITA can then be harvested using either a pedicled, semiskeletonized, or a skeletonized technique.

In the pedicled technique the dissection plane is started in the bare area of the ITA at the level of the third or fourth rib; the intercostal space is avoided since it contains branches of the vessel. The endothoracic fascia is incised medial and lateral to a 1 cm pedicle that includes the ITA and accompanying veins. The first portion of the pedicle is carefully separated with blunt dissection from the rib. Exposure can be obtained by pushing the pedicle away with closed forceps or by gently grasping the fascia; the conduit must never be grasped with the forceps. Gentle traction on the pedicle allows exposure of arterial and venous branches; larger vessels should be clipped on the ITA side and cauterized or clipped on the chest wall side; cauterizing vessels close to the ITA must be avoided since thermal injury may occur. After the pedicle is partially developed, the dissection is continued proximally and distally. The transverse thoracic muscle must be divided in order to identify the distal pedicle and the dissection is then carried to the level of the ITA bifurcation. The proximal dissection is carried to the inferior border of the subclavian vein; special attention should be given to avoid injury to the phrenic nerve in this location. Once the pedicle is completed, the patient is heparinized and the pedicle is divided distally just proximal to the bifurcation. The distal vessel is ligated with a 2-0 silk suture and reinforced with a metal clip. A small plastic bulldog clamp is applied to the distal end of the artery and the pedicle is sprayed with papaverine solution or wrapped in a papaverine-soaked sponge. Alternatively the pedicle may be left in situ and transsected just prior to using the conduit.

Skeletonization of the internal thoracic artery

Sternal ischemia is a consequence of ITA harvest. Sternal blood flow decreases significantly after pedicled ITA harvest.[87,88] Skeletonization of the ITA reduces the degree of sternal ischemia produced by ITA harvest. Two small prospective randomized studies have assessed sternal blood supply using bone scan with single photon emission computed tomography after skeletonized and pedicled ITA harvest. Pedicled ITA harvest resulted in a steep decrease in sternal vascularity, while skeletonization of the ITA resulted in minimal change in sternal blood supply, and multivariate analysis found the harvesting technique to be the only factor responsible for postoperative sternal ischemia.[89,90]

Excellent results have been reported using skeletonization in the setting of bilateral ITA harvesting. Matsa and associates reported a deep sternal wound infection rate of 1.7% in 765 patients using bilateral skeletonized ITAs. Sternal complications occurred in only 2.6% of 231 diabetic patients in this study, and the incidence was not significantly different from that of the nondiabetic patients.[91] In Calafiore and coworkers' review of 842 patients undergoing skeletonized bilateral ITA grafting compared with a historical nonskeletonized bilateral ITA control group, skeletonization was associated with a reduced incidence of sternal wound complications (4.5 versus 1.7%). The diabetic patients in this study derived the greatest benefit from skeletonization of the ITAs (10 versus 2.2%).[92]

Using the skeletonization technique of ITA harvest, only the artery itself is mobilized, leaving the internal thoracic venous plexus intact. In the semiskeletonization technique, both the ITA and the two adjacent veins are mobilized with no other surrounding tissue. Skeletonization of the ITA offers multiple advantages: It increases luminal diameter and free flow compared to a pedicled graft, and also provides a longer conduit which allows a greater number of sequential anastomoses, maximizing the targets for arterial revascularization.[92] Skeletonization of the ITA is a technically more demanding and time-consuming procedure. Some surgeons have expressed concerns regarding functional integrity, vasoreactive profile, and early and long-term patency. Noera and colleagues, however, found no difference in endothelial damage assessed by light microscopy between pedicled or skeletonized ITAs in a retrospective analysis.[93] In prospective randomized studies, Gaudino and associates found no difference in endothelial integrity by light and electron microscopy, and no difference in regard to endothelial-dependent or neurogenic-dependent vasoreactivity between skeletonized and pedicled ITAs.[94,95] Unfortunately, there are as yet no randomized studies comparing long-term patency differences between skeletonized and pedicled grafts, although review of current evidence suggests that early and mid-term patency is similar to those of pedicled grafts.[96,97]

Patency

The superior late patency of an ITA graft to the LAD coronary artery compared to a saphenous vein graft (SVG) was initially demonstrated by Barner and colleagues in the 1980s.[98] Superior patency translates into improved 10-year survival (LITA-to-LAD artery 82.6% versus saphenous vein graft-to-LAD artery 71%), and less incidence of myocardial infarction (MI), hospitalization for cardiac events, and cardiac reoperations.[73] The superior performance of ITA grafts appears to persist in the current era despite the use of agents to improve vein graft performance; in the BARI trial the patency rate of ITA grafts was 98% at 1-year, while that of vein grafts was 87%. At 4 years the patency rate for ITA grafts was 91% and 83% for venous grafts.[99,100] The superior patency of the ITA becomes even more prominent with longer follow-up. In a recent angiographic study of 1408 symptomatic post-CABG patients, patency rates for the LITA at 10 and 15 years were 95 and 88%, respectively, while SVG patencies were 61 and 32% at the same time intervals.[101]

Radial Artery

The use of the radial artery (RA) as a conduit for coronary bypass was originally described by Carpentier and associates in the early 1970s.[102] Spasm of the artery was common during surgery and was managed by mechanical dilation. The initial results were disappointing, with 32% of grafts occluded at 2 years.[103] Accordingly, the RA was abandoned as a conduit for CABG. Acar and colleagues revived the use of the RA after a number of grafts, angiographically demonstrated to be "occluded" early postoperatively, but that were found to be fully patent 15 years later. Acar postulated that harvest injury was responsible for the spasm/graft occlusion.[103,104] Proponents of the RA have demonstrated encouraging mid- and long-term results with a pedicled harvesting technique and pharmacologic manipulation to prevent radial artery vasospasm.[105–107] As a result, this conduit has enjoyed a remarkable resurgence of interest as a supplementary arterial conduit for coronary revascularization. Randomized data on comparison with other conduits are scarce, and an undeniable superiority to the saphenous vein remains unproven.

Characteristics

Histologically, the RA has a fenestrated internal elastic lamina, and a thicker wall than the ITA with a higher density of myocytes in its media.[108] The RA is also more likely to have atherosclerotic changes at the time of harvest than the ITA, with 28% of RAs having some degree of demonstrable atherosclerosis, as compared with only 6% of ITAs. Whether these differences indicate that the RA will prove more susceptible to graft atherosclerosis remains unknown.[109]

Physiologically, the RA is equally sensitive to norepinephrine as the ITA; however, given its greater muscle mass it generates a higher force of contraction, accounting for its well recognized propensity for spasm.[110] Fortunately, the RA also readily responds to a variety of vasodilators including calcium channel blockers, papaverine, nitrates, and milrinone.[111–114] In vitro, nitroglycerine appears to be the most effective agent for inhibiting and reversing RA spasm.[115] Additionally, nitroglycerin has been shown to be better tolerated clinically, equally effective, and less expensive than diltiazem in prophylaxis of RA spasm after CABG in a prospective randomized trial.[116]

Surgical anatomy of the radial artery

The RA originates from the brachial artery just proximal to the biceps tendon. In the proximal forearm the RA courses underneath the brachioradialis muscle. As it courses distally, it emerges from the lower surface of the muscle, becoming more superficial, and runs beneath the antebrachial fascia between the tendon of the brachioradialis muscle and the flexor carpi radialis muscle and anterior to the radius and pronator quadratus muscle. The radial recurrent artery originates from the lateral aspect of the RA soon after its origin from the brachial artery. Multiple small muscular branches emerge from the deep and lateral surfaces of the artery. At the wrist the RA gives rise to the palmar carpal branch, the dorsal carpal branch, the superficial palmar branch, and the deep palmar branch, that join similar branches from the ulnar artery to form the palmar arches.[113] Throughout its course the RA is accompanied by a rich plexus of venae comitantes. The average length of the RA ranges between 18 and 22 cm with an inner diameter of 2 to 3 mm.[117]

Harvest technique

It is most common to consider the patient's nondominant arm for harvest, partially out of concern for the impact of even subtle neurologic changes, and partially given the convenience of harvesting the left radial artery simultaneously with the LITA. The extremity of interest must have adequate ulnar collateral circulation to ensure viability of the hand. Assessment of collateral circulation is performed clinically with an Allen test. Patients with positive or equivocal results may undergo noninvasive duplex ultrasonography.[118,119] The RA of the dominant hand can also be harvested. Tatoulis and associates reported 261 patients undergoing bilateral RA harvesting with safe functional outcomes of both extremities.[120]

The arm is prepped circumferentially and the hand wrapped in a sterile fashion. The upper extremity is place on an arm board perpendicular to the long axis of the operating table. As shown in Fig. 22-2, a medially curved incision is made on the skin overlying the RA from a point 2 cm proximal to the styloid process of the radius to a point 2 cm distal to the elbow crease and 1 cm medial to the biceps tendon. The subcutaneous tissue is divided with the cautery. The dissection can be initiated at either end depending on the surgeons' preference, although most surgeons would start the dissection at the distal end. The deep fascia of the forearm is incised directly over the RA. The RA is harvested as a pedicle with minimal manipulation using sharp dissection, diathermy, or the harmonic scalpel. There are some data to suggest that early graft flow is superior when the harmonic scalpel is used.[121] On the proximal half of the forearm lateral gentle retraction of the brachioradialis muscle aids in the exposure. At the distal end of the dissection the satellite veins are identified and clipped individually. The proximal end of the dissection is marked by the radial recurrent branch and a large venous plexus in the medial aspect of the RA. It is our routine to leave the recurrent radial branch intact. Once the pedicle is free and systemic heparin has been administered, the artery is divided proximally and distally and stored in a solution of 1% papaverine in heparinized arterial blood at room temperature. An alternative approach is division of the artery distally during the dissection and injection of 5 mL of 1% papaverine in heparinized arterial blood intraluminally with a 1-mm blunt-tipped cannula. The distal end is occluded with a clip, allowing the radial artery to distend under arterial pressure while the more proximal dissection is completed. After the RA is removed from the forearm, hemostasis of the operative field is obtained and the arm is closed in multiple layers. A closed suction drain may be placed to prevent seroma/hematoma formation. The arm is then abducted and secured to the table. Reports of endoscopic RA harvest are beginning to emerge with good functional and cosmetic results; nonetheless the impact of the technique on graft patency is unknown.[122,123]

Two nerves must be protected during RA dissection. The lateral antebrachial cutaneous nerve lies superficial to the belly of the brachioradialis muscle and runs close to its medial border. Placing the skin incision medial to the edge of the brachioradialis prevents potential injury. Damage to this nerve will produce paresthesias and numbness of the radial

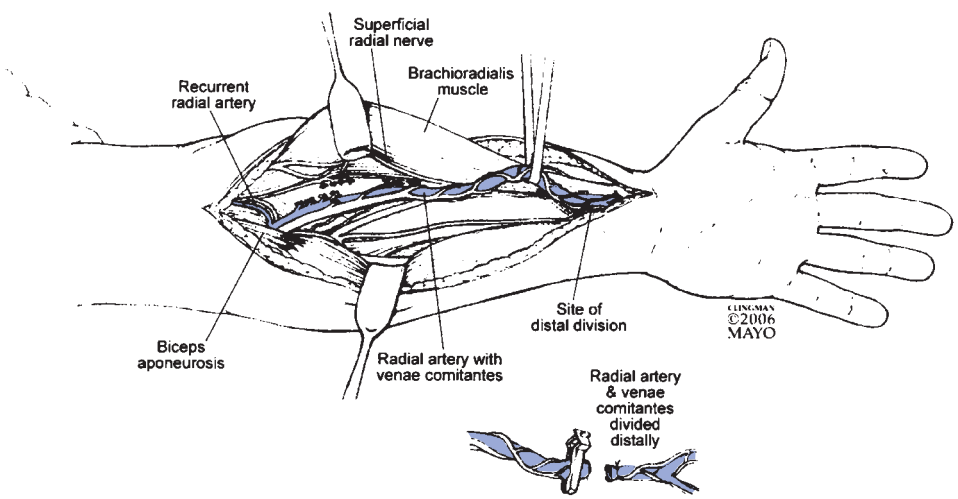

Figure 22-2. Radial artery harvest. A medially curved incision is made on the forearm over the artery. The deep fascia of the forearm is incised directly over the artery. The brachioradialis muscle is retracted laterally. Dissection is begun at the distal end and the satellite veins are divided. The RA is harvested as a pedicle with minimal manipulation. The proximal end of the dissection is marked by the radial recurrent branch which is left intact. After the pedicle is free and heparin has been given, the artery is divided proximally and distally and stored in a solution of 1% papaverine in heparinized arterial blood at room temperature. Hemostasis of the operative field is obtained and the arm is closed in multiple layers. A closed suction drain may be placed.

aspect of the volar forearm. The superficial branch of the radial nerve lies under the brachioradialis muscle and in the proximal two-thirds of the forearm runs parallel to the RA. Injury to this nerve will result in paresthesias and numbness of the thumb and the dorsum of the hand. This nerve can best be protected by avoiding excessive lateral retraction on the brachioradialis muscle.[113,124] Transient paresthesias, numbness, and thumb weakness are reported by almost a third of patients after RA harvest; however, they gradually resolve with time so that after 1 year only 10% of patients still have residual symptoms, and only 1% report their symptoms as severe.[125–127]

Patency

Acar and associates in 1992 reported on 122 radial grafts with a 100% patency rate at 2 weeks and 93% patency at 9 months.[111] A number of authors since then have also reported satisfactory mid- and long-term patency for RA grafts. The reported 5-year patency ranges from 83 to 95%; lower patency rates were found in series in which angiograms were performed only on symptomatic patients, and higher patency rates in series with protocol-directed angiography.[104–107,128] The RA patency appears not to be affected by the site of the proximal anastomosis,[105] but its performance seems to be very susceptible to competitive flow. The graft failure rate is higher if the target vessel stenosis is less than severe, and on the right coronary system.[66,106,129]

The most solid data we have on the performance of the RA comes from the Radial Artery Patency Study, a prospective randomized trial comparing the patency rate of the RA compared to the SVG at 1 year.[130] In this study, complete graft occlusion occurred less frequently with RA grafts than with SVGs (8.2 versus 13.6%); however, string signs occur more commonly with RA grafts than with SVGs (7 versus 0.9%). More severe target coronary lesions were associated with a lower rate of occlusion (>90% obstruction 5.9% versus 70 to 89% obstruction 11.8%), and string sign in the RA grafts (>90% obstruction 3.7% versus 70 to 89% obstruction 12.4%). A second important study, the Radial Artery Patency and Clinical Outcomes study, reported interim results on the 5-year patency and cardiac event-free survival of the RA graft as a second graft with that of the free RITA in younger patients (<70 years), and that of the SVG in older patients (>70 years).[131] Unfortunately, only a quarter of the patients enrolled in the study (114/396) underwent protocol-directed angiography regardless of symptoms. The 5-year RA graft patency was 95% compared to 100% for the RITA in the younger group, and the 5-year graft patency was 86% for RA and 95% for SVG in the older group. These differences were not statistically significant.

Gastroepiploic artery

The use of the right gastroepiploic artery (RGEA) as a pedicled coronary graft conduit was described in the early eighties by Pym and Suma and their coworkers.[132,133] The gastroepiploic artery (GEA) may be utilized in reoperative surgery in the absence of other suitable conduits,[134,135] or as a secondary or tertiary arterial conduit in an attempt to provide all-arterial revascularization.[136–140] Despite the enthusiastic support of a small cohort of surgeons, the widespread use of the GEA as a coronary conduit has been limited by increased operative time required to harvest the conduit, the potential for perioperative and long-term abdominal complications, and the lack of consensus on the long-term benefit for total arterial revascularization.

Characteristics

The GEA is a muscular artery with a thin intima and a fenestrated internal elastic lamina. The medial layer is less developed than that of the RA and has similar thickness to the ITA.[141,142] Compared to the ITA, the media of the GEA generates a greater contractile force; however, the GEA demonstrates endothelial-dependent relaxation, prostacyclin production, and response to clinically used vasoconstrictors similar to that of the ITA.[143–145] The GEA may not be suitable for use in all patients. Its use is contraindicated in patients with previous gastric resection, prior endovascular instrumentation of the artery, or documented mesenteric vascular insufficiency. Any patient suspected of having preoperative mesenteric vascular insufficiency must have angiographic evaluation of the celiac axis and GEA patency before harvest of the conduit.

Surgical anatomy of the gastroepiploic artery

The gastroduodenal artery, a branch of the common hepatic artery, gives rise to the superior pancreaticoduodenal artery and the RGEA. This division occurs soon after the gastroduodenal emerges from behind the first portion of the duodenum. The RGEA then runs superiorly and laterally, following the greater curvature of the stomach approximately 2 cm from the gastric wall accompanied by small satellite veins running its entire course between the layers of the gastro-colic omentum. Proximally the RGEA gives several small branches to the head of the pancreas, duodenum, and pylorus. The RGEA gives off inferior branches to the greater omentum and superior branches then run into the body of the stomach at 1 to 2 cm intervals. On its distal portion the RGEA fans out into multiple small gastric branches and finally anastomoses with the left gastroepiploic artery at approximately the junction of the proximal and distal half of the greater curvature. In an anatomic study of the RGEA, the mean internal diameter at the anastomotic sites was 2.20 mm (range 1.5 to 4.0 mm) with a mean pedicle length of 19.2 cm (range 16 to 26 cm).[146]

Harvest technique

The GEA is usually harvested after the ITA dissection is completed. The median sternotomy incision is extended inferiorly to a limited upper midline laparotomy. Nasogastric decompression is established. The greater curvature of

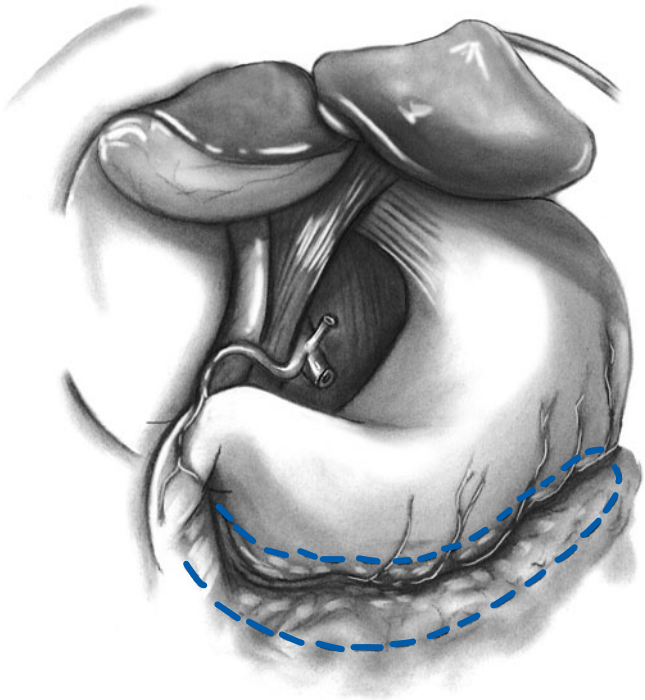

Figure 22-3. Right gastroepiploic artery (RGEA) harvest. The greater omentum outside the gastroepiploic arcade is divided with careful preservation of the artery. The GEA is palpated to assess patency. A pedicle of the RGEA and associated veins is circumferentially dissected free of the greater omentum and of the wall of the stomach. All side branches should be carefully ligated. Avoid leaving any uncontrolled branches since large mesenteric hematomas may develop. Proximally the dissection is carried to the level of the pylorus. Distally the dissection is carried along the greater curvature toward the spleen until the left gastroepiploic artery is encountered. After systemic heparinization, the artery is transsected and flow is assessed. A soft vascular bulldog clamp is applied to its distal end. Placement of the pedicle anterior to the stomach and duodenum minimizes tension on the conduit if gastric distention should occur, but places the conduit at risk if a future laparotomy is necessary; placement posterior to the stomach provides the opposite trade-off.

the stomach is exposed by division of the greater omentum outside the gastroepiploic arcade with careful preservation of the artery (Fig. 22-3). The GEA is palpated to assess patency. A pedicle of the RGEA and associated veins is circumferentially dissected free of the greater omentum and of the wall of the stomach. Electrocautery, surgical clips, or a harmonic scalpel can be used to divide small lateral branches. Great care should be taken to avoid leaving any uncontrolled branches since large mesenteric hematomas may develop. Proximally the dissection is carried to the level of the pylorus. Distally the dissection is carried along the greater curvature toward the spleen until the left gastroepiploic artery is encountered.[147] After systemic heparinization, the RGEA is transsected and adequacy of flow is assessed. A small soft vascular bulldog clamp is applied to its distal end. Topical anti-spasm measures similar to those described for RA harvesting should be used. Placement of the pedicle anterior to the stomach and duodenum minimizes tension on the conduit if gastric distention should occur, but places the conduit at risk if a future laparotomy is necessary; placement posterior to the stomach provides the opposite trade-off.[148] The best route prior to entry into the pericardium will depend on the length of the pedicle, the coronary target, and the size of the left lateral segment of the liver. The pedicle can be placed anterior or posterior to the liver in order to provide the best anatomic positioning. Several centimeters of conduit should be left inside the pericardium to provide a tension-free anastomosis and allow cardiac mobility. The GEA has been used to supply the RCA, the LAD artery, and the distal circumflex system.[134,149–151] If there is lack of conduit or inability to reach the target vessel, the GEA can be used as a free graft.

Patency

Suma and colleagues have reported a patency rate for GEA grafts of 96, 91, 80, and 62% at 1 month, 1 year, 5 years, and 10 years, respectively. The patency of the GEA is influenced by competitive flow, as is the case for other arterial grafts.[152] The perioperative risk after CABG with the use of the GEA is similar to that of other primary coronary operations, with a reported 30-day mortality ranging from 1.5 to 3.3% in large series.[136,138,149,151,153] Reported long-term clinical outcomes include actuarial survival of 88 to 92% at 5 years and 84% at 10 years, and freedom from any cardiac event of 85% at 5 years and 70 to 80% at 10 years.[140,151,152]

Other Arterial Conduits

A variety of arterial conduits have been used in patients in whom no other conduits are available. Anecdotal use of the ulnar, left gastric, splenic, thoracodorsal, and lateral femoral circumflex arteries as coronary graft conduits has been reported in the literature.[154–157] There has been interest in the past in the use of the inferior epigastric artery as well, and several series have demonstrated encouraging early clinical results with good early patencies.[158–161] The popularity of the RA, however, has in large measure superseded these options.

Greater Saphenous Vein

In spite of its shortcomings the saphenous vein continues to be one of the most commonly used conduits in coronary bypass grafting. Characteristics that have solidified the greater saphenous vein as a coronary conduit include its ease of harvest, ready availability, versatility, resistance to spasm, and thoroughly studied long-term results.

The loss of clinical benefit after CABG due to the time-related attrition of venous grafts has generated interest in pharmacologic strategies to maximize early and late venous graft patency. Prospective randomized trials have shown that early aspirin administration reduces vein graft occlusion in the first year after CABG.[162,163] Administration of aspirin within

48 hours after CABG also reduces early postoperative complications including mortality, MI, stroke, renal failure, and bowel infarction.[164] More recently it has been recognized that lipid-lowering agents reduce the progression of both native coronary artery and graft atherosclerosis, as well as subsequent cardiovascular events.[165–167] Aggressive use of statins to achieve a low-density lipoprotein cholesterol <100 mg/dL decreased by one-third the number of grafts affected with atherosclerosis at angiographic follow-up, and also decreased the need for repeat revascularization in The Post Coronary Artery Bypass Graft Trial Investigation.[165] Despite clear documentation of improved outcomes with these two pharmacologic strategies, there is evidence of underutilization of these therapies after CABG.[168,169] Systemic approaches to ensure their universal application are needed.[36] Finally, in the future gene therapy may allow modification of the venous vascular endothelium to avert development of intimal hyperplasia.[170,171] Unfortunately, the PREVENT IV trial, testing whether short-term angiographic vein graft failure could be diminished with treatment of saphenous vein prior to grafting with edifoligide (an oligonucleotide decoy that binds to and inhibits E2F transcription factors) demonstrated no impact of the treatment.[172] The concept remains a valid one, however, and gene therapy will continue to be an exciting area of investigation in the future.

Harvest technique

Some surgeons prefer to harvest vein from the lower leg because of a more appropriate caliber and wall thickness, as well as greater distance from the perineum (a potential source of infection). Others prefer to harvest vein from the thigh, arguing improved wound healing, particularly among patients with distal peripheral arterial occlusive disease. In patients with a history of previous vein stripping it is important to perform a complete duplex examination of the venous system of the lower extremities to assess remaining suitable greater and lesser saphenous veins.

Saphenous vein harvest can be performed with a completely open, bridged, or endoscopic technique. More extensive skin incisions allow harvest with the least amount of surgical trauma to the conduit at the risk of a higher rate of wound complications and postoperative pain, while bridged incisions may decrease pain and wound complications but increase surgical manipulation of the conduit. Open dissection can be started either in the upper thigh, above the knee, or at the ankle (Fig. 22-4). Identification of the vein is easiest at the ankle, just above the medial malleolus. An incision overlying the vein and extended directly over the trajectory of the vein is made, taking care not to create skin flaps. Sharp dissection is then used to free the vein from the surrounding tissue with all side branches ligated and divided in situ. Side branches on the vein should be

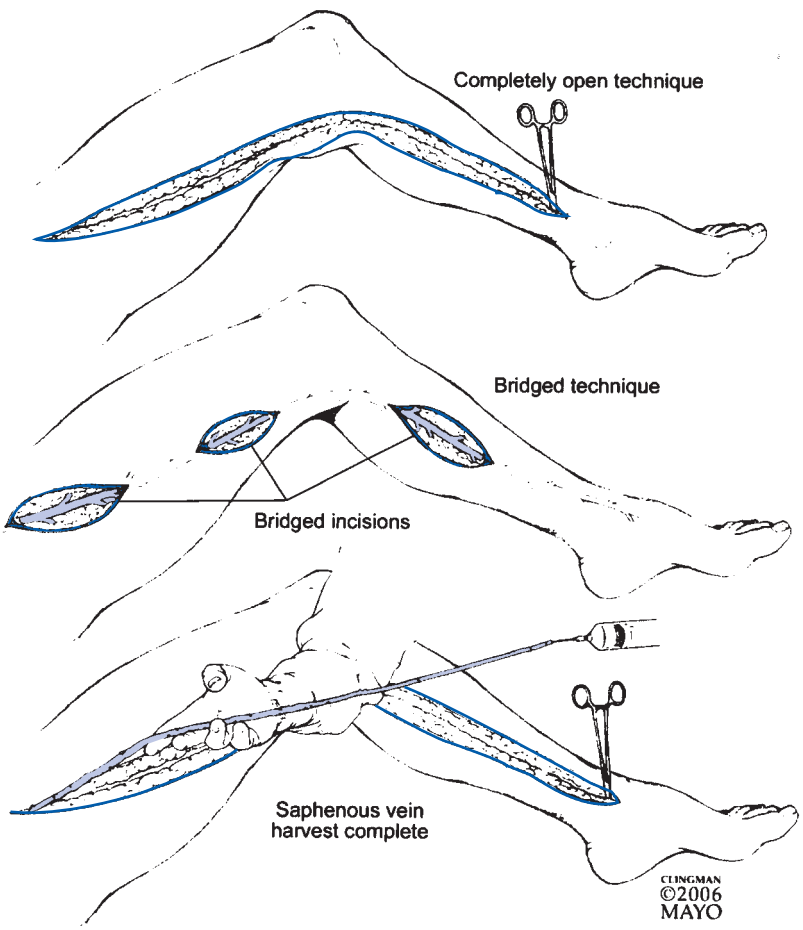

Figure 22-4. Saphenous vein harvest: open and bridged technique. Open technique (top): Dissection can be started in the upper thigh, above the knee, or at the ankle. Identification of the vein is easiest at the ankle, just above the medial malleolus. An incision is made overlying the vein and extended directly over its trajectory. The vein is dissected and all venous tributaries are ligated and divided in situ. Bridged technique (middle): Two- or three- step incisions are performed over the course of the vein. Dissection of the vein is carried in a similar fashion as the opened technique except that branches are divided in situ and ligated once the vein is explanted. Completed dissection (bottom): Once dissection is completed, the vein is ligated and divided proximally and distally. Stumps of side branches on the vein are left long and then are ligated flush with the vein, avoiding narrowing of the conduit. The vein is then gently flushed and stored in heparinized blood solution. The skin incisions are closed and the leg is wrapped with an elastic bandage.

left long and should be ligated flush with the vein, taking care to avoid narrowing of the conduit. In the lower leg, care should be taken to avoid trauma to the saphenous nerve, which is in close proximity to the vein. Once dissection is completed the vein is ligated and divided proximally and distally. The vein is then gently flushed with heparinized blood solution. A blunt-tipped cannula is placed in the distal end and the conduit stored in heparinized blood solution. The vein should not be grasped with forceps, stretched, or overdistended, since patency rates may be related to endothelial damage induced during harvest and preparation.[173–180] When using a bridged technique, two or three step incisions are performed over the course of the vein (see Fig. 22-4). Dissection of the vein is carried out in a similar fashion except that branches are divided in situ and ligated once the vein is explanted.

Minimally invasive harvest of the saphenous vein using an endoscopic technique is gaining popularity.[181] Compared to traditional harvest there appears to be no detrimental effects on vein morphology, endothelial structure, or function.[182–185] Endoscopic harvest decreases wound complication rates and produces an improved cosmetic result, although the operative time devoted to harvest is increased. The reported rate of conversion to open harvest ranges from 5 to 7%.[186–189] Despite an increased number of defects requiring suture repair with endoscopic techniques, the 3- and 6-month patency rates appeared similar to those of open harvest in two prospective randomized studies.[190,191] A 1.5 to 2.0 cm skin incision is made in the medial aspect of the extremity above or below the knee, depending on the length of vein required (Fig. 22-5). CO_2 insufflation for visualization and dissection is established. Harvesting is directed toward the groin region as far proximally as possible. Side branches are divided by using bipolar cauterizing scissors or clips. Once dissection is completed, a small puncture is made in the groin directly over the saphenous vein and the vein is exteriorized under endoscopic guidance. After removing the vein from the leg, side branches are ligated with 4-0 silk ties. If any branches have been avulsed, the vein is repaired with interrupted 6-0 polypropylene sutures. The skin incisions are closed with absorbable subcutaneous and subcuticular sutures and the leg is wrapped with an elastic bandage.

Other Venous Conduits

Alternative venous conduits such as the lesser saphenous and cephalic veins may be used in the setting of reoperative surgery when no other conduits are available. The lesser saphenous vein can be harvested in a supine position through a lateral approach by flexing the hip and medially rotating the knee or by an inferior approach with straight elevation of the extremity. A skin incision is usually started midway between the Achilles tendon and the lateral malleolus. Dissection is carried proximally along the leg. Attention should be paid to avoid injuring the sural nerve. The vein is otherwise managed similarly to the greater saphenous vein. The patency rate for arm veins is significantly lower than that of saphenous veins and they should be considered essentially conduits of last resort.[192,193] For cephalic vein harvest, the arm is prepared and positioned as during radial artery harvest. Incisions are placed along the medial and superior aspect of the arm. The vein is identified and harvested similarly to the

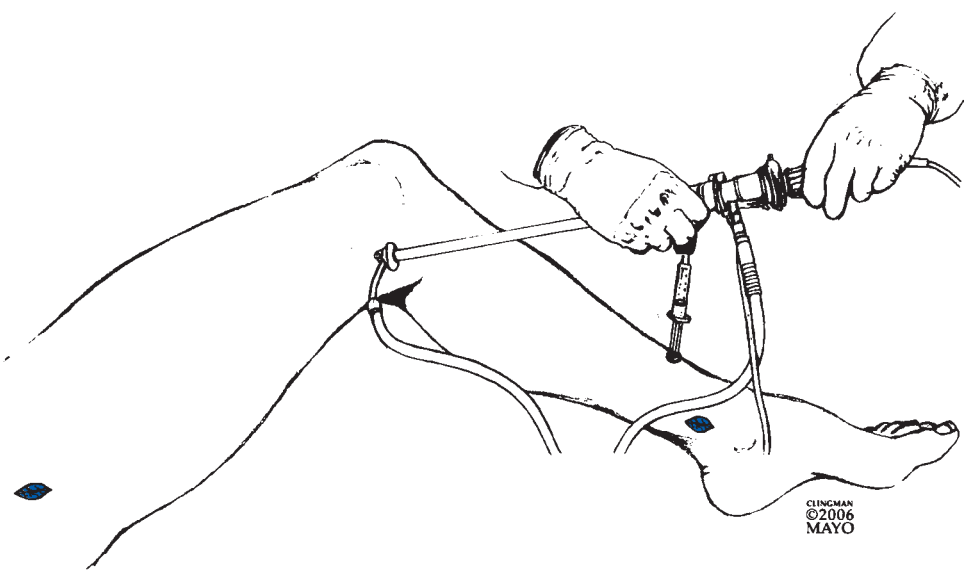

Figure 22-5. Endoscopic saphenous vein harvest. A 2.0 cm skin incision is made in the medial aspect of the knee. CO_2 insufflation is established. Harvesting is directed toward the groin region as far proximally as possible. Side branches are divided by using bipolar cauterizing scissors. Once dissection is completed a small puncture is made in the groin directly over the vein and the vein is exteriorized under endoscopic guidance. After removing the vein from the leg, side branches are ligated with 4-0 silk ties. If any branches have been avulsed, the vein is repaired with interrupted 6-0 polypropylene sutures.

greater saphenous vein. The cephalic vein is relatively thin-walled in comparison to the greater saphenous vein and extra care should be taken during harvest. The cephalic vein is also predisposed to aneurysmal dilatation.

CONDUCT OF THE OPERATION

Intravenous access is established through two large-bore peripheral venous lines and central venous access is via an internal jugular approach prior to the induction of general anesthesia. Monitoring lines typically include one or more arterial lines, including a femoral arterial line in patients for whom one anticipates that a perioperative intra-aortic balloon pump (IABP) may be required. Pulmonary artery catheters with or without oximetric capability are commonly used. There has been increasing use of intraoperative transesophageal echocardiography (TEE) as a routine adjunct,[194] although complications of intraoperative TEE have been reported.[195] The patient is positioned in the decubitus supine position with arms tucked at the side. Care should be taken to avoid peripheral nerve complications due to pressure injury. The lower extremities are positioned with a slight internal rotation and flexion of the knees. The operative field is prepped to include the lower neck, the chest, and abdomen between the anterior axillary lines and the lower extremities circumferentially.

Incisions

In most instances a midline sternotomy incision is performed, with the skin incision extending from a point midway between the angle of Louis and the sternal notch, to just below the tip of the xiphoid process. Either the scalpel or electrocautery is used to extend the incision through the subcutaneous tissues down to the sternum. Special attention should be devoted to identifying the middle of the sternum. In thin individuals this can be easily accomplished by palpating the sternal borders, in obese patients a pointed instrument may be used to identify the sternal edges. The middle of the sternal periosteum is marked with the electrocautery. Attention is then turned to the sternal notch where the interclavicular ligament is divided, allowing palpation of the posterior aspect of the sternal manubrium. The xiphoid process is identified and divided in the midline with heavy scissors or electrocautery. The sternum is divided in the midline either from the top down or bottom up depending on the surgeon's preference. Bleeding points in the sternal periosteum are selectively cauterized with care not to strip all of the periosteum away from the edges one hopes will heal after the operation. Harvest of the saphenous vein or the RA is initiated simultaneous with the sternotomy. Once the sternum has been divided, the ITA is harvested as previously described.

Cannulation and Establishment of Cardiopulmonary Bypass

The pericardium is divided vertically down to the diaphragm and the inferior attachment of the pericardium to the diaphragm is divided transversely. The remnant of thymic tissue and pericardial fat is divided in the midline until the inferior aspect of the left innominate vein is identified. Placement of pericardial retraction sutures to create a pericardial cradle improves exposure of the ascending aorta and right atrium. The distal ascending aorta is inspected and manually palpated for soft nonatherosclerotic areas suitable for cannulation and cross-clamping (Fig. 22-6). Systemic anticoagulation is achieved prior to arterial cannulation with intravenous administration of 300 to 400 U/kg of unfractionated heparin. Prior to aortic cannulation the systolic blood pressure should be reduced below100 mm Hg to minimize the risk of aortic dissection. Two partial-thickness concentric diamond-shaped purse-string sutures using 3-0 Tevdek or polypropylene suture are placed in the distal ascending aorta just proximal and to the left of the innominate artery origin; the size of the purse strings should be one-third greater than the aortic cannula tip. The ends of the sutures are passed through rubber tourniquets that will be used for tightening the purse strings. The aortic adventitia within the purse strings is divided in preparation for aortotomy. The adventitia just superior to the planned aortotomy is grasped with a forceps and an aortotomy equal in size to the cannula tip is created with a no. 11 blade. Bleeding is easily controlled with slight inferior traction of the forceps on the adventitia. The aortic cannula is inserted and properly

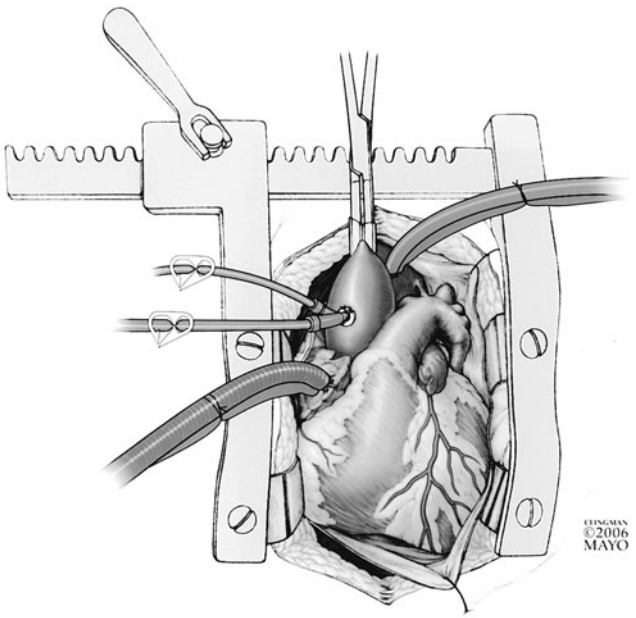

Figure 22-6. Cannulation. After full systemic heparinization, cannulation of the distal ascending aorta is performed with an appropriately sized curved or straight tip aortic cannula. A two-stage venous cannula is used for access to the right atrium, usually through the right atrial appendage. An aortic root cardioplegia/vent is placed. A retrograde cardioplegia cannula may be placed at the discretion of the surgeon. Patients with aortic regurgitation benefit from placement of a right superior pulmonary vent to avoid distention of the left ventricle from infusion of cardioplegia into the aortic root.

positioned, and the purse strings are tightened. The rubber tourniquet is secured to the aortic cannula with a heavy silk tie and then the cannula is secured to the skin. The aortic cannula is then de-aired and connected to the arterial end of the pump tubing. Intraluminal positioning of the cannula is confirmed by watching for the cannula to fill with arterial blood and by confirming a pulsatile waveform with the perfusionist.

Venous cannulation is accomplished with a two-stage venous cannula inserted in the right atrial appendage. A 2-0 Tevdek or polypropylene purse-string suture is placed around the tip of the right atrial appendage. The purse string should be wide enough for easy access of the selected venous cannula. An atriotomy is made with scissors at the tip of the appendage, both edges of the atrial appendage are grasped with forceps, and the incision is extended superiorly and inferiorly to a size appropriate for the venous cannula. Small bridging fibers of muscle are divided with scissors to permit easy entry of the cannula and the venous cannula is inserted. Some surgeons place a partial occlusion clamp on the right atrial appendage at the level of the purse-string suture to simplify preparation of the cannulation site, and once this is accomplished the clamp is removed and the cannula is inserted. The purse-string suture is tightened and the rubber tourniquet is secured to the venous cannula with a heavy silk tie. The tip of the venous cannula should be in the inferior vena cava. The venous line is then connected to the pump tubing. After ensuring that the appropriate activated clotting time target has been reached, cardiopulmonary bypass is initiated. An aortic root cannula for administration of cardioplegia and venting is placed in the ascending aorta. Some surgeons place this at the site of a planned proximal anastomosis. Retrograde cardioplegia may be used, particularly if there is aortic regurgitation, left main disease, severe proximal multivessel disease, or poor left ventricular function (LVF). Patients with aortic insufficiency that is not to be surgically addressed may benefit from the placement of a left ventricular vent catheter via the right superior pulmonary vein to avoid left ventricular distention.

Target vessels may be easier to identify before cardioplegic arrest while they are fully distended in their native state. Target locations are usually confirmed by visual inspection and epicardial examination with the location of planned distal anastomoses marked with a scalpel. Systemic cooling to between 28 and 34°C is preferred by many surgeons, although it is our practice to perfuse patients normothermically. Cardioplegia may be administered warm, tepid (25°C), or cold via antegrade or retrograde routes. Some surgeons even administer cardioplegia simultaneously both antegrade and retrograde. Adequacy of myocardial protection may be assessed with intraoperative monitoring of myocardial temperature or pH.[196,197] A substudy of the CABG Patch Trial investigated the effect of cardioplegia type, temperature, and delivery route in 885 CAD patients with low ejection fraction (EF) (<36%). Patients receiving crystalloid cardioplegia versus those receiving blood cardioplegia were found to have significantly more operative deaths (2 versus 0.3%), postoperative MIs (10 versus 2%), shock (13% versus 7%), and postoperative conduction defects (21.6 versus 12.4%). Despite a higher operative morbidity no significant difference was demonstrated in early or late mortality between crystalloid or blood cardioplegia. Furthermore, patients receiving normothermic blood cardioplegia had less postoperative right ventricular dysfunction (10%) than those receiving cold blood (25%), or cold blood with warm reperfusion (30%). There was also no significant difference in early or late mortality with regard to temperature of blood cardioplegia. Finally, combined antegrade and retrograde cardioplegia delivery was associated with significantly less inotrope use (71 versus 84%), right ventricular dysfunction (23 versus 41%), and postoperative balloon pump use (12 versus 19%) than antegrade cardioplegia delivery alone.[198]

DISTAL ANASTOMOSES

Location of Targets and Sequence of Anastomoses

Arteriotomy sites should be chosen proximal enough to offer the largest-sized coronary target and just distal enough to avoid the area of obstruction. Arteriotomies at bifurcations should be avoided. Diseased vessels with an intramyocardial course can often be localized by noting epicardial indentation, accompanying epicardial veins, or a whitish streak within the myocardium. Sharp dissection of overlying tissue is then required to identify the desired target site. The LAD coronary artery can be particularly difficult when it has an intramyocardial course, since one may inadvertently enter the right ventricular cavity while dissecting in the interventricular fat plane. Such a ventriculotomy can be closed with fine 6-0 polypropylene sutures, keeping in mind that the right ventricle is a low-pressure chamber and deep bites of myocardium are not necessary. If extreme difficulty is encountered in identifying an LAD artery, a fine probe may be passed retrograde via a small transverse arteriotomy into the LAD artery at the apex of the heart. One can then palpate the proximal target and cut down appropriately. The arteriotomy is then closed with an 8-0 polypropylene suture.

The distribution of cardioplegia is usually relatively uniform; however, the sequence of anastomoses may be planned based on ischemic regions if myocardial protection is a particular concern. Grafting the most ischemic area first will permit early antegrade delivery of cardioplegia through the graft. Alternatively, the sequence of anastomoses may be dictated by the quality of the conduit itself, matching the best conduit to the most important territories. It is customary to perform the left internal thoracic artery-to-LAD artery anastomosis last to avoid tension and potential disruption of the anastomosis.

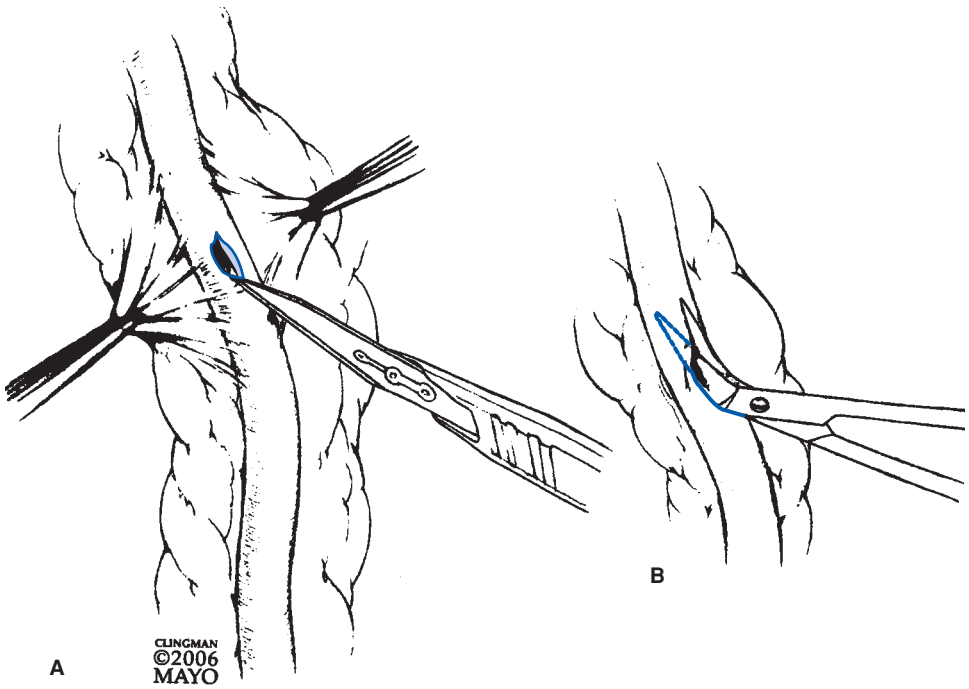

Figure 22-7. Distal anastomosis: Arteriotomy. (A) Arteriotomy sites should be proximal enough to offer the largest-sized coronary target, and just distal enough to avoid the area of obstruction. Intramyocardial vessels can often be localized by noting epicardial indentation, accompanying epicardial veins, or a whitish streak within the myocardium. Sharp dissection of overlying tissue is then required to identify the desired target site. The arteriotomy is then performed with a no. 11 blade. (B) The arteriotomy is extended with fine Pott's scissors proximally and distally. The arteriotomy should match the conduit diameter, and should be at least 1.5 times the diameter of the distal coronary.

Arteriotomy

The choice of the site of arteriotomy is critical. Opening into a plaque may force endarterectomy, while injury to the posterior wall with the knife transforms a straightforward anastomosis into a complex repair. Silastic tapes placed proximally and distally around the coronary artery may help to stabilize the vessel, although only a minority of surgeons employ this technique. The arteriotomy can be performed with a no. 11 or 15 blade and extended with fine Pott's scissors proximally and distally. The arteriotomy should match the conduit diameter, and should be at least 1.5 times the diameter of the distal coronary (Fig. 22-7).

Anastomotic Technique

The goal of the anastomosis is to join the conduit and the target vessel with precise endothelial approximation with minimal resistance to flow. The wall of the vessel should be handled with care, avoiding endothelial injury to prevent thrombotic complications. Coronary anastomoses are typically constructed with 7-0 polypropylene suture. Sutures should be evenly spaced to prevent leaks at the conclusion of the anastomosis. In order to increase anastomotic area we prefer to bevel the conduits at approximately 30° and notch them at the heel. Anastomoses may be performed either with a continuous running suture or in an interrupted fashion. We prefer a continuous, parachuting technique initiated at the lateral midpoint for virtually all anastomoses. We will describe an end-to-side anastomosis and a side-to-side sequential anastomosis.

The conduit is brought onto the field with a mosquito clamp on the adventitia at the toe of the conduit. An end-to-side anastomosis is accomplished with 12 sutures (Fig. 22-8). Starting at 3 o'clock on the right side of the vessel, the suture is passed outside-in on the conduit and then inside-out at the corresponding location of the target coronary vessel. Two more stitches are taken before the heel, one directly in the heel, and then two more on the left side of the anastomosis before parachuting the conduit down to the target vessel. The anastomosis is then completed by placing another six stitches evenly spaced in the same manner around the toe until the other thread is encountered. This technique encourages one to move out of the heel and toe of the anastomosis, minimizing the risk of narrowing the outflow. Care must be taken to prevent suturing the back wall of the coronary, and the proper amount of tension on the follow-through must be provided to avoid both leakage and a purse-string effect. To prevent anastomotic tension and torsion, pedicled conduits can be suture-fixated to the adjacent epicardium. This is particularly relevant when further manipulation of the heart is anticipated due to the need for concomitant procedures.

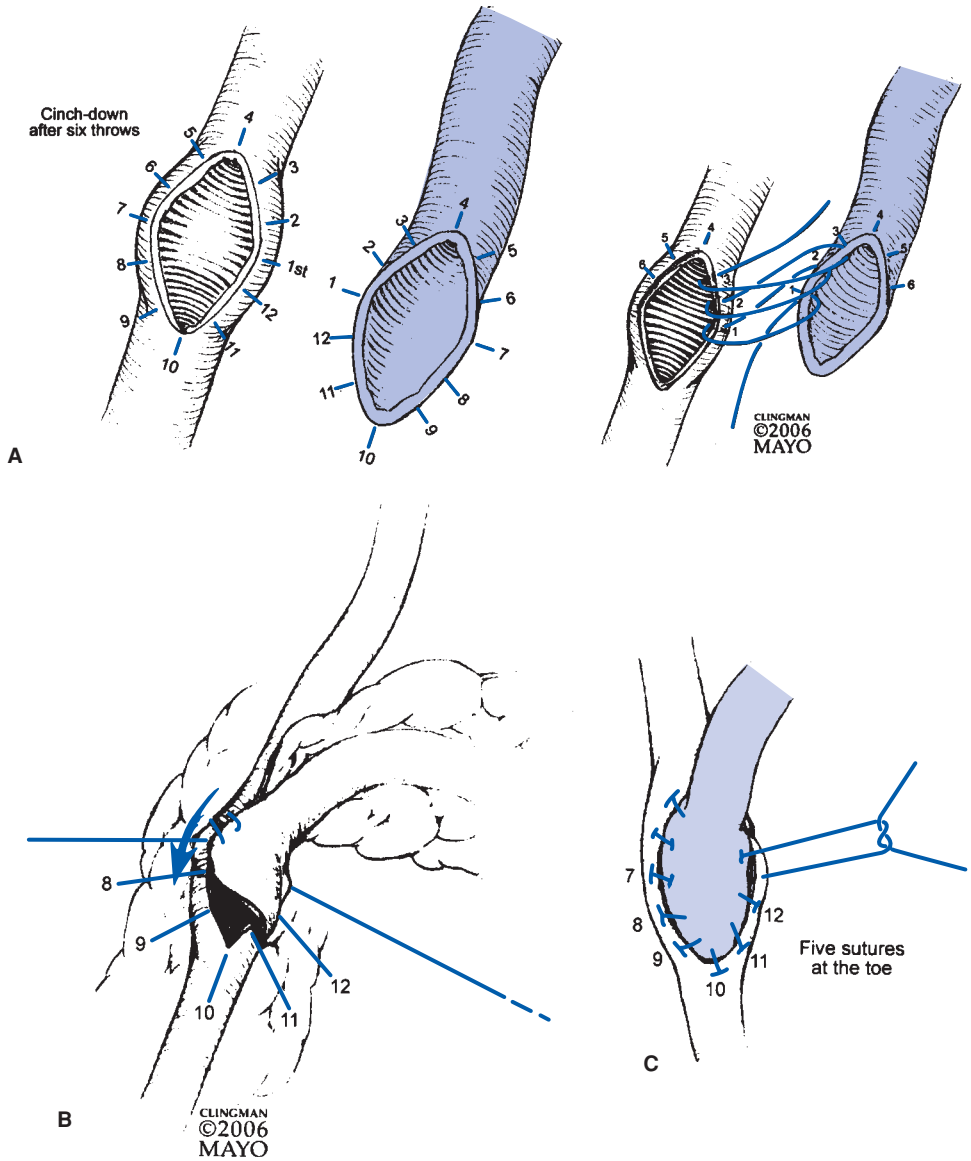

Figure 22-8. Distal anastomosis suture technique. (A) The conduit is beveled at 30° and notched at the heel. We use a continuous, parachuting technique with 7-0 or 8-0 polypropylene suture. The conduit is brought onto the field with a mosquito clamp on the adventitia at the toe of the conduit. An end-to-side anastomosis is accomplished with 12 sutures. Starting at 3 o'clock on the right side of the vessel, the suture is passed outside-in on the conduit and then inside-out at the corresponding location of the target vessel. (B) Two more stitches are taken before the heel, one directly in the heel, and then two more on the left side of the anastomosis before parachuting the conduit down to the target vessel. (C) The anastomosis is then completed by placing another six stitches evenly spaced in the same manner for the toe.

Sequential grafting permits efficient use of conduit, and when target vessels are small, increased flow in the conduit. When planning sequential anastomoses, the most distal anastomosis should be to the largest target vessel with the greatest outflow potential. If the reverse situation is created, the most distal anastomosis is at increased risk for failure, given the likelihood of preferential flow to the larger more proximal anastomosis.[199,200] A clear disadvantage of sequential grafting is the reliance of two or more distal targets upon a single conduit and proximal anastomosis, placing a potentially larger region of myocardium at jeopardy.[200] Although some surgeons avoid using the LITA for sequential grafting or as a donor for composite Y-grafting of other conduits because of concerns of compromising critical LITA-to-LAD flow, several series have demonstrated successful use of the ITA for sequential grafting of stenotic diagonal coronary arteries with excellent results.[201,202] The LITA has also been used for multiple sequential anastomoses to the circumflex territory

with grafting of the RITA to the LAD artery.[203] Sequential grafting has also been performed with the RGEA[204] as well as the RA.[205]

When constructing a sequential anastomosis, it is our preference in most instances to complete the distal anastomosis first and move proximally (Fig. 22-9). This facilitates determination of optimal intergraft spacing. In the case of the LAD-diagonal graft, however, it is easier to move from proximal to distal, performing the diagonal anastomosis first. Sequential side-to-side anastomoses may be perpendicular or longitudinal. When constructing perpendicular anastomoses, care must be taken not to make the arteriotomies too long, as there is risk of creating a "gull-wing" deformity and placing the graft at jeopardy. Arteriotomies in both the conduit and target are made in the direction of the long axis of the vessel. The two incisions are then aligned perpendicular to one another and an eight-stitch anastomosis is completed, creating a diamond-shaped anastomosis. The arteriotomy for longitudinal anastomosis may be made as long as necessary without risk of distorting the conduit. Typically the longitudinal anastomosis is begun at the heel and the far wall is completed open. It is then parachuted down and the front wall is completed.

CORONARY ENDARTERECTOMY

Coronary endarterectomy predated CABG as a direct surgical approach to relieving coronary occlusive disease.[17,18,206,207] Coronary endarterectomy has been relegated to a position of secondary importance, however, thanks to the reliable and reproducible results obtained with CABG. Recently there has been increased interest in endarterectomy techniques, as the patient population coming to CABG has a greater atherosclerotic burden due to diabetes, hyperlipidemia, and advanced age.[208] Most commonly the need for endarterectomy arises intraoperatively when no soft site can be identified for arteriotomy or a vessel has been inadvertently opened in an extensively diseased area not amenable to grafting. Occasionally, endarterectomy is undertaken electively in patients with diffuse and extensive coronary disease with no other choices except transplantation.

The perioperative risk of CABG with endarterectomy is higher than that for CABG alone in most studies.[209–211] Reported mortality rates range from 2 to 6% with perioperative MI rates of 5 to 10%.[212–215] There appears to be higher perioperative risk when multiple vessels require endarterectomy.[210,212,216] There has been controversy regarding the risk of endarterectomy of the LAD, with some studies showing increased risk[210] while others demonstrate no such increased risk.[215,217,218]

The late results of endarterectomy are inferior to those of routine CABG, with reported 3-year patency for ITA grafts to endarterectomized LAD targets ranging from 74 to 80%.[213,219] Despite this, angina relief is remarkably good initially. Unfortunately, the rate of recurrent angina is somewhat higher than after uncomplicated CABG; reported recurrence of angina varies from 9 to 35% at 5 years.[215,218–220] The reported 5-year survival following coronary endarterectomy ranges from 70 to 87%.[212–215] Among patients in whom bypass to more distal nondiseased segments is not possible, coronary endarterectomy with subsequent bypass offers a viable alternative to leaving a territory ungrafted.

The technique of endarterectomy requires that the central core be extracted adequately in order to relieve obstruction of the branch vessels. Patency of a graft to the endarterectomized vessel depends upon the adequacy of run-off, therefore the distal endpoints of the endarterectomy core must be smoothly tapered. If the core fractures leaving behind disease in side branches, distal counter-incisions may be needed to obtain a satisfactory result.

The RCA is the vessel most often endarterectomized, usually at the level of its bifurcation. A manual eversion endarterectomy is performed after entering at the vessel approximately 1 cm proximal to the crux. A circumferential plane of dissection between the core and the adventitia is developed with a fine coronary spatula. The core is transsected proximally and gently grasped with DeBakey forceps while the spatula is used to tease the adventitia away from the core. The core is regrasped hand over hand as distally as possible to avoid fracture. When the crux is reached, the posterior descending artery and the left ventricular branch are endarterectomized separately. If endarterectomy of the proximal segment of the RCA is needed, we prefer to use an open technique since it is difficult to obtain a nice tapering of the core at the take-off of the acute marginal branches with a retrograde eversion endarterectomy. The vessel wall is then reconstructed with a long hood created with the bypass conduit of choice.

We prefer open extended technique when the LAD is endarterectomized (Fig. 22-10). The vessel is opened as far proximal as possible if endarterectomy is anticipated. If the vessel has been opened in its mid-portion before it is apparent that endarterectomy is necessary, we extend the incision in the adventitia proximally before developing the endarterectomy plane. Retrograde eversion endarterectomy is dangerous because branch vessels will not be opened. Once the core is separated from the adventitia it is transsected proximally at the heel and the vessel is opened beyond the takeoff of the major diagonals to permit individual eversion endarterectomy of each of the branches. The segment is reconstructed with a long hood of the conduit of choice or a vein patch into which the ITA is anastomosed. The circumflex artery is the most infrequently endarterectomized vessel. Its rapid branching pattern makes satisfactory endarterectomy difficult. We tend to begin with an eversion technique focusing our efforts on opening the largest distal branches as much as possible.

PROXIMAL ANASTOMOSES

Proximal anastomoses of saphenous vein or RA to the aorta can be performed before or after the distal anastomoses. Construction of proximal anastomoses prior to the institution of cardiopulmonary bypass will minimize pump time but risks

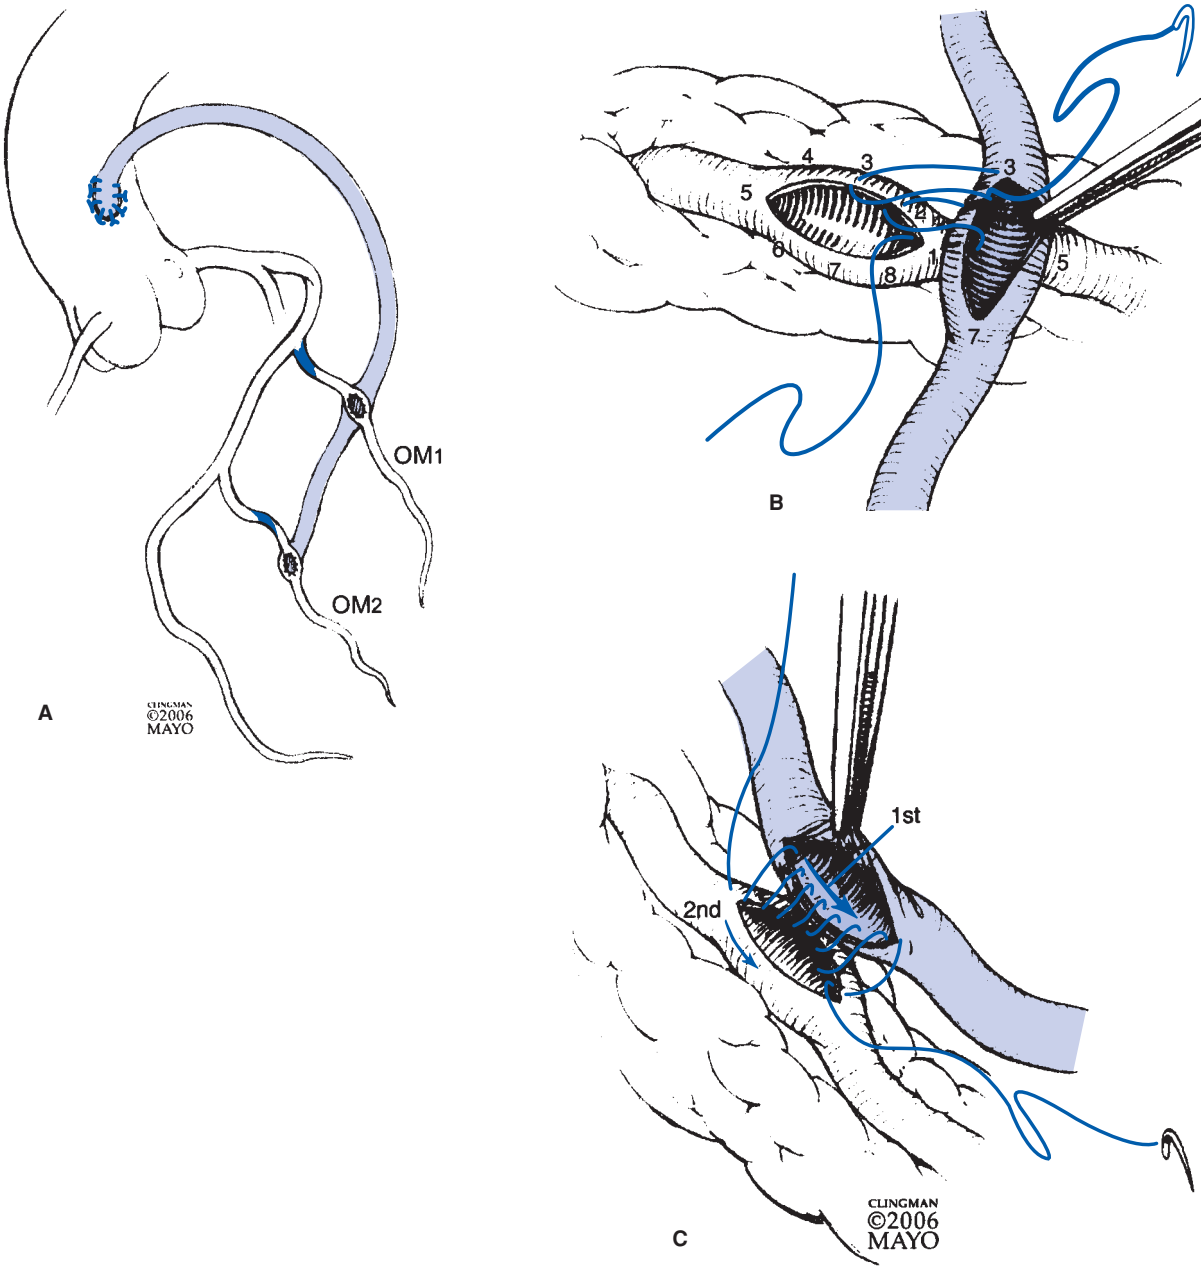

Figure 22-9. Sequential anastomosis. (A) Order of anastomoses: The order in which sequential anastomoses are performed is important to facilitate optimal intergraft spacing and avoid kinking. The distal anastomosis is completed first and the more proximal sequential anastomosis is performed second, except for an LAD-diagonal graft, in which the diagonal is performed first followed by the LAD. (B) Perpendicular sequential side-to-side anastomosis: Arteriotomies are made in the direction of the long axis of the coronary and the conduit. Care must be taken not to make the arteriotomies too long, since there is risk of creating a "gull-wing" deformity. The two incisions are aligned perpendicular to one another. The suture is passed starting inside-out at the apex of the target coronary and then outside-in at the mid-portion the conduit. An eight-stitch anastomosis is completed creating a diamond-shaped anastomosis. (C) Longitudinal sequential side-to-side anastomosis: The arteriotomy for longitudinal anastomosis may be made as long as necessary without risk of distorting the conduit. The anastomosis is begun at the heel and the far wall is completed open. It is then parachuted down and the front wall completed.

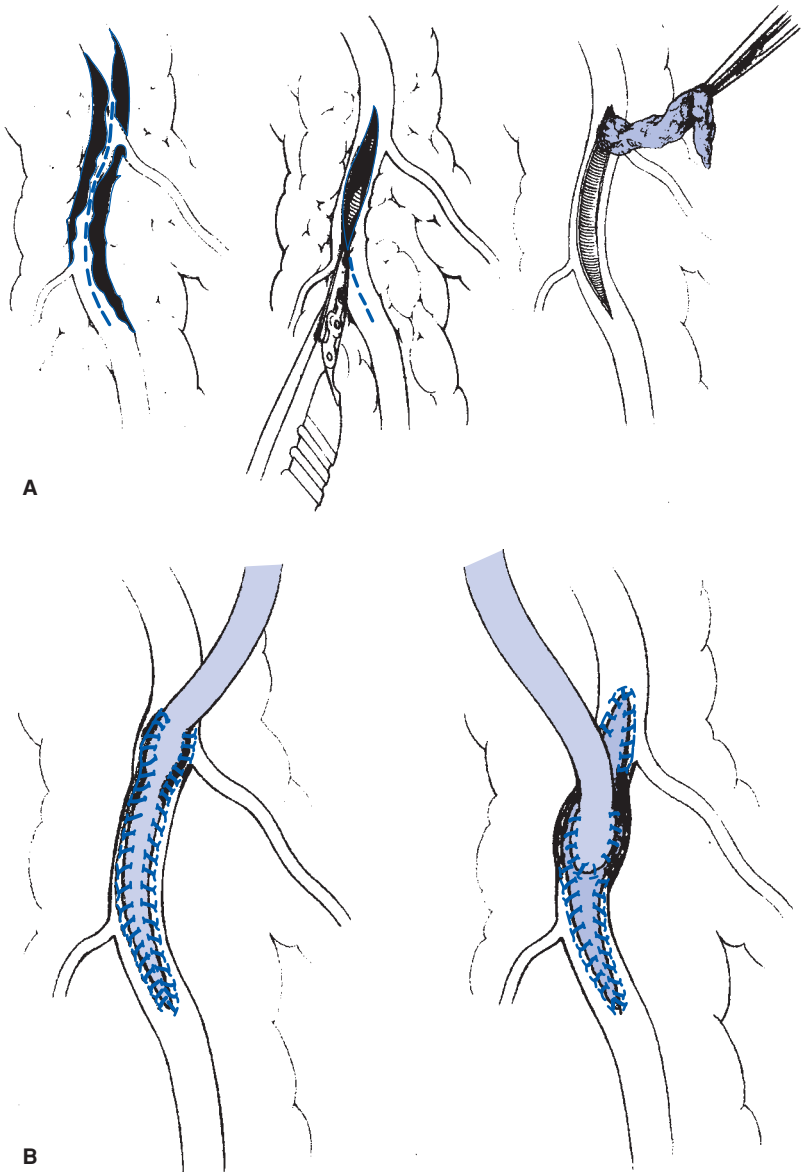

Figure 22-10. Coronary endarterectomy: Open extended technique. (A) The extent of disease is evaluated to plan the length of the arteriotomy and endarterectomy. The arteriotomy is performed and extended as proximal as needed before the circumferential plane of dissection between the core and the adventitia is developed with a fine coronary spatula. Once the core is separated from the adventitia it is transsected proximally at the heel and the vessel is opened beyond the takeoff of the major branches to permit individual eversion endarterectomy of each of the branches. (B) The segment is reconstructed with a long hood of the conduit of choice. The segment may be reconstructed with vein patch into which the ITA is anastomosed.

damage to the aorta due to application of the partial occlusion clamp to the pulsatile, pressurized aorta. Alternatively, proximal anastomoses may be constructed on bypass but before application of the cross-clamp with subsequent completion of distal anastomoses. If performed after the distal anastomoses, they may be constructed after completion of each distal anastomosis, or after all distals. The proximal anastomoses may be constructed under the same cross-clamp or with a partial aortic occlusion clamp. Use of a partial occlusion clamp limits ischemic cross-clamp time, but does require a greater degree of aortic manipulation and has been associated with a higher risk of stroke as compared with the single-clamp technique.[221]

Anastomotic Technique

Once an appropriate site for aortotomy is identified, the fatty tissue overlying the aorta is removed (Fig. 22-11). An arteriotomy is created with a no. 11 blade, and a 4 to 5 mm punch is used to create a circular aortotomy. The size of the punch will vary depending on the size of the conduit graft. The proximal aspect of the conduit is beveled and then notched at the heel. A running 5-0 polypropylene suture is used for a venous graft and a 6-0 polypropylene suture for an arterial conduit. The long axis of the graft is aligned at an appropriate angle to the ascending aorta. The anastomosis can be completed with eight stitches in most cases; symmetry in the spacing of sutures is paramount to obtain a hemostatic anastomosis. The site of anastomosis can be marked to facilitate future cardiac catheterization.[222] Free arterial grafts may be anastomosed directly to the aorta, or to the hood of a vein graft.

Composite Grafts

As an alternative to proximal anastomosis to the aorta, a free graft can be anastomosed proximally to the pedicled ITA

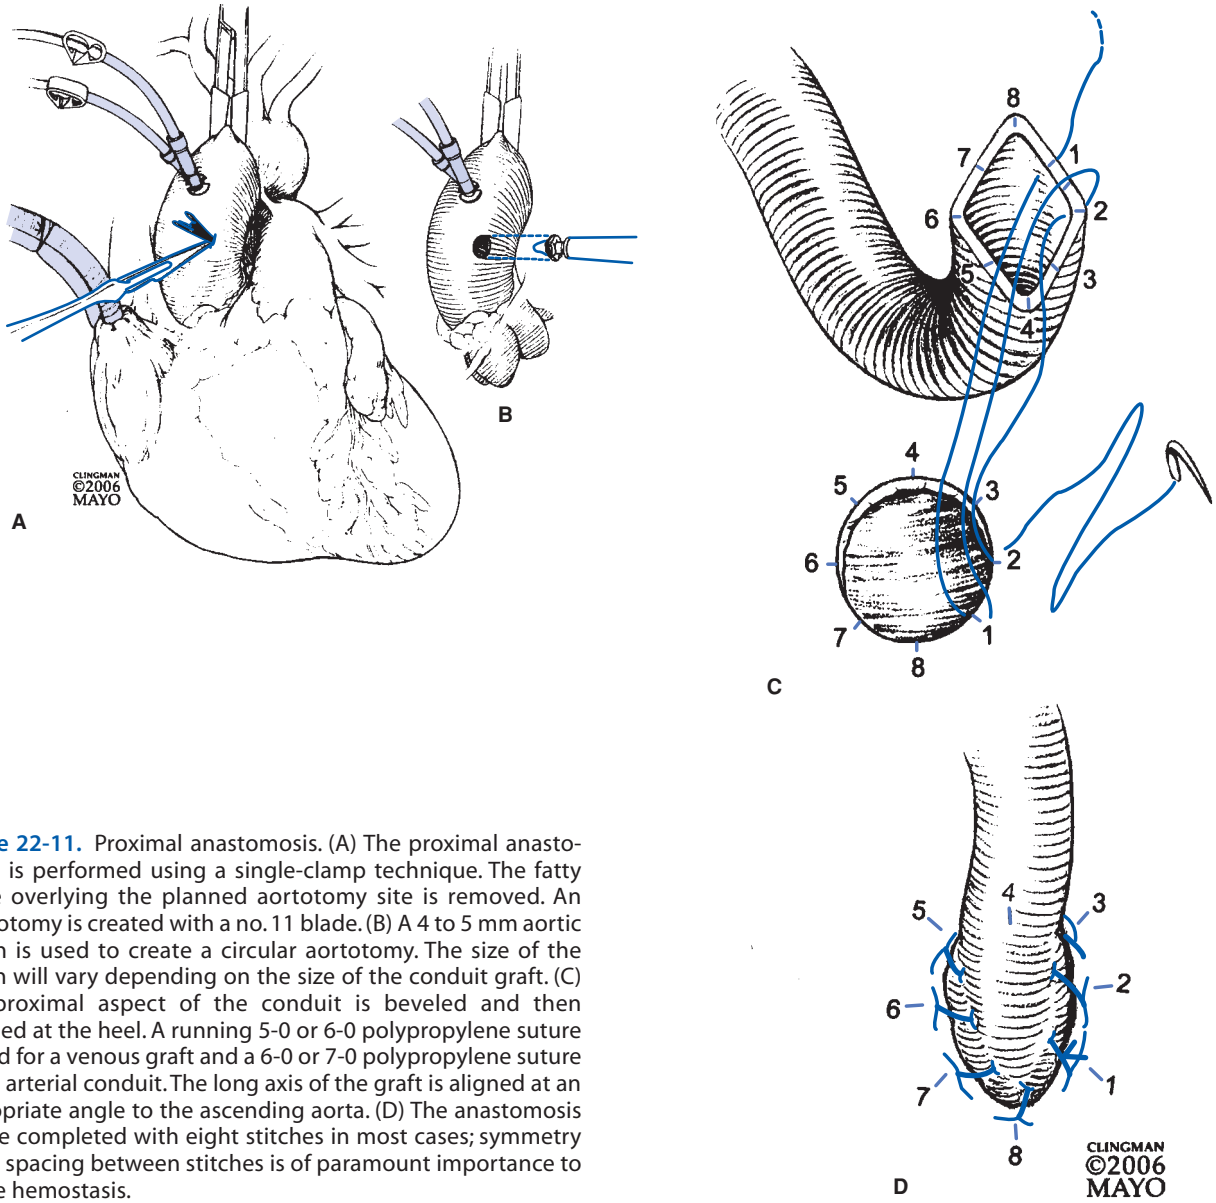

Figure 22-11. Proximal anastomosis. (A) The proximal anastomosis is performed using a single-clamp technique. The fatty tissue overlying the planned aortotomy site is removed. An arteriotomy is created with a no. 11 blade. (B) A 4 to 5 mm aortic punch is used to create a circular aortotomy. The size of the punch will vary depending on the size of the conduit graft. (C) The proximal aspect of the conduit is beveled and then notched at the heel. A running 5-0 or 6-0 polypropylene suture is used for a venous graft and a 6-0 or 7-0 polypropylene suture for an arterial conduit. The long axis of the graft is aligned at an appropriate angle to the ascending aorta. (D) The anastomosis can be completed with eight stitches in most cases; symmetry in the spacing between stitches is of paramount importance to assure hemostasis.

(Fig. 22-12). This technique has the theoretical advantage of providing a more physiologic arterial pressure waveform by attaching the conduit to a third-order vessel rather than to the aorta. Composite grafting is also a useful tool for the hostile, calcified ascending aorta or when there is a limited length of conduit available. It is also advantageous when there is a marked mismatch between aortic wall thickness and arterial conduit size.[223]

A combination of composite and sequential grafting allows the opportunity to perform complete arterial revascularization with only ITAs[224,225] or with a LITA and other arterial conduits.[226–229] Multiple configurations of Y- and T-grafts can be devised to best suit the anatomic characteristics of each patient.[230] The LITA has been shown to have more than sufficient flow reserve to supply flow to the entire coronary circulation.[231] The free right ITA, the RA, or other arterial conduit can be based in this manner.[159,232,233]

All-arterial Y-grafts are usually planned in advance and constructed prior to the initiation of cardiopulmonary bypass. Special care must be taken during construction of composite grafts to avoid tension, rotational torsion, or narrowing of the inflow anastomosis. Disadvantages include technical difficulty and reliance upon a single inflow source for two or more distal targets.

MANAGEMENT OF THE ATHEROSCLEROTIC ASCENDING AORTA

Ascending aortic atherosclerosis has been consistently identified as a very important risk factor for stroke in multiple series. Epiaortic ultrasound can be performed to define the extent of atherosclerosis of the ascending aorta and its likelihood of embolization.[234] Patients with severe atherosclerosis

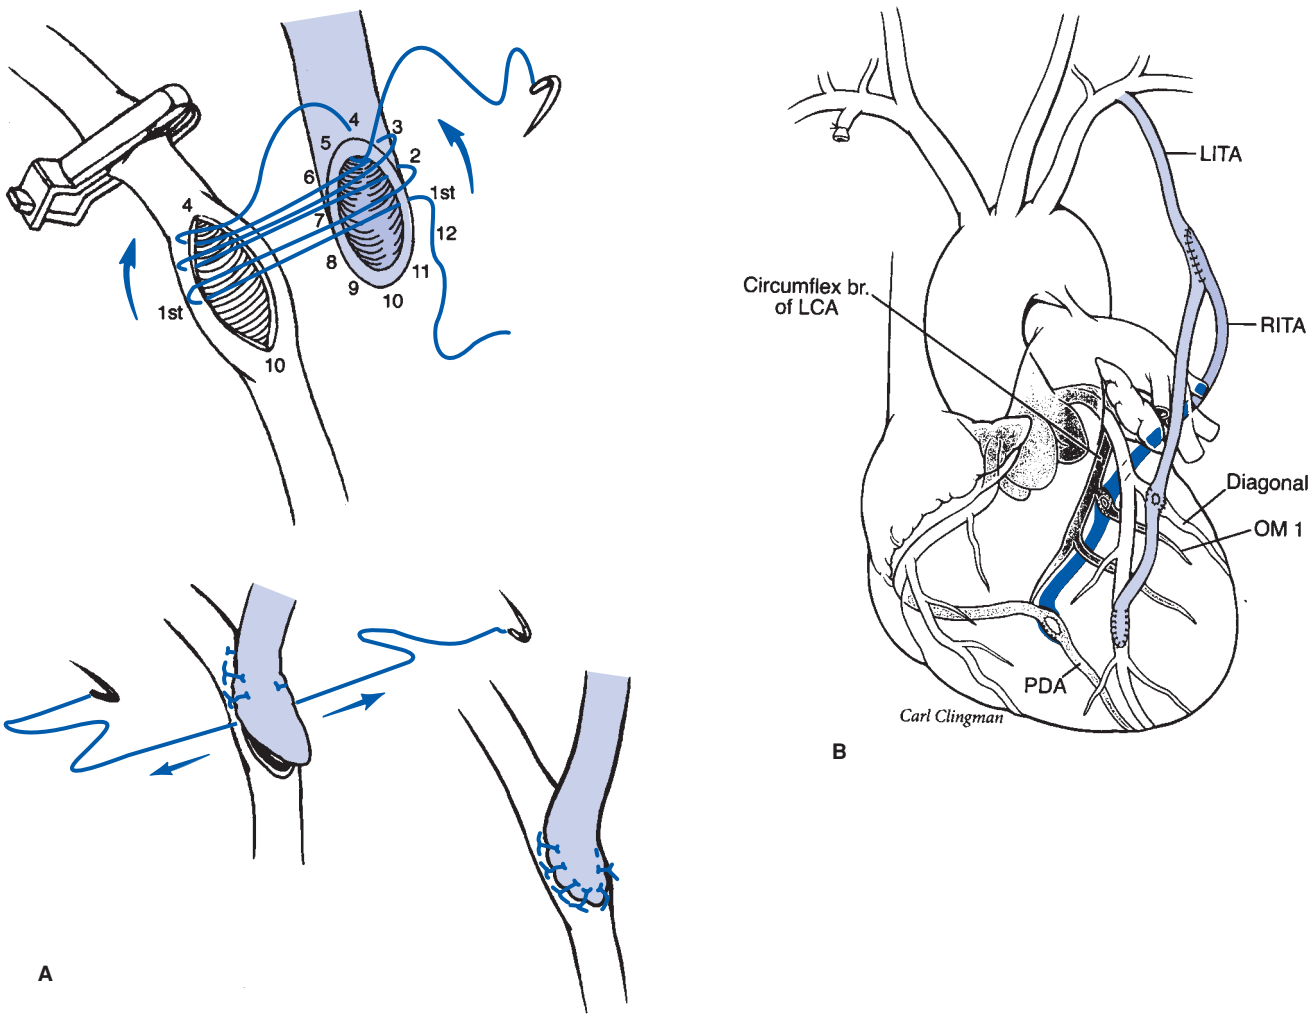

Figure 22-12. Composite Y graft. (A) Y-graft anastomotic technique: A coronary artery bypass graft (CABG) is used as a donor site for the proximal anastomosis of another conduit. An incision is created in the donor conduit. The proximal end of the recipient conduit is then anastomosed to the donor site in an end-to-side fashion as previously described for a distal anastomosis. The recipient conduit is then gently parachuted down onto the donor conduit. (B) Total arterial revascularization: As shown, arterial revascularization can be performed using the right internal thoracic artery (RITA) off the left internal thoracic artery (LITA) as a Y graft and liberal use of sequential grafting.

of the ascending aorta may require alternative strategies to prevent embolization of aortic atheroma. If the ascending aorta is hostile, cannulation can be performed at the aortic arch, innominate artery, axillary artery, femoral artery, or external iliac artery. Distal arch or innominate artery cannulation should be avoided if there are atherosclerotic changes in those regions. Femoral arterial cannulation avoids manipulation of a diseased ascending aorta, but will reverse the direction of flow in the descending thoracic aorta and arch toward the head, potentially embolizing atherosclerotic debris, especially in patients with atheromatous descending aortas or abdominal aortic aneurysms. Also, severe atherosclerotic changes may render the femoral or external iliac vessels unusable for cannulation. The axillary artery is a good option to achieve arterial inflow, either by direct cannulation or by using a chimney side graft, as dictated by the size of the artery. If needed, aortic clamping may be performed in areas free of atheroma, usually in the more proximal ascending aorta.

Coronary revascularization can be achieved with a variety of methods. Using a "no touch" technique, revascularization can be done using only pedicled arterial conduits, and if proximal anastomoses are required they can be based off pedicled conduits or brachiocephalic vessels. Distal anastomoses can be performed under cold fibrillatory arrest without aortic cross-clamping, and they also can be accomplished using off-pump techniques.[234–237] Proximal anastomoses can be performed under deep hypothermic circulatory arrest or after graft replacement of the ascending aorta if there are large mobile atheromas.[237,238]

Weaning from Cardiopulmonary Bypass

Upon completion of all anastomoses, the patient is prepared for transition from supported circulation to native circulation. Prior to separation from cardiopulmonary bypass, hemostasis of all possible surgical sites and appropriate de-airing is confirmed. The patient must be rewarmed to normothermia if cooled and the acid-base status and electrolyte abnormalities corrected. Weaning from bypass is otherwise the same as for other cardiac surgical cases. Issues particular to CABG include attention to avoid overdistention of the heart, which may place grafts on tension and disrupt anastomoses. If air has entered the heart, bubbles may pass into the aorta and down the bypass grafts. This may cause arrhythmias and regional wall motion abnormalities in the distributions supplied by the grafts.

OUTCOMES

Operative Mortality

The risk profile of patients requiring isolated CABG in the United States has changed significantly in the past decade. CABG patients are now older, with a greater number of comorbidities, decreased LVEF, and a higher burden of atherosclerotic disease; however, early outcomes after coronary artery bypass continue to improve. The STS database demonstrates that despite an increase in expected mortality from 2.6 to 3.4% (relative increase 30%) in the decade of the 1990s, the observed mortality has actually decreased from 3.9 to 3.0% (relative decrease 23%).[6] Similar observations have been made using the Veterans Affairs mandatory national database. The unadjusted mortality rate for isolated CABG in the Veterans Affairs database fell from 4.3% in 1989 to 2.7% in the year 2000.[239] In the private sector similar trends have been observed. In an analysis of outcomes of patients undergoing isolated CABG in the HCA system, a nationwide for-profit health care system involving 200 hospitals in 23 states, Mack and associates reported an ongoing decrease in unadjusted operative mortality among 51,353 patients, 80% of whom were operated on with cardiopulmonary bypass. In this study the operative mortality for on-pump CABG fell from 2.88% in 1999 to 2.24% in 2002.[4]

Causes of Death

In a multicenter prospective study performed by the Northern New England Cardiovascular Disease Study Group, 384 deaths in 8641 consecutive patients undergoing isolated CABG between 1990 and 1995 were analyzed with respect to the mode of death. The mode of death was defined as the seminal event that precipitated clinical deterioration and ultimately resulted in the patient's demise. Heart failure was judged to be the primary mode of death for 65% of the patients, followed in frequency by neurologic causes (7.3%), hemorrhage (7%), respiratory failure (5.5%), and dysrhythmia (5.5%). The greatest variability in mortality rates observed across surgeons in the study was attributable to differences in rates of heart failure.[240] Cardiac causes were also identified by Sergeant and colleagues as the most common causes of death in a series 5880 patients undergoing CABG at the Katholieke Universiteit Leuven, Belgium between 1983 and 1988.[72]

Operative Morbidity

Myocardial dysfunction

Postischemic myocardial dysfunction and cardiac failure after CABG may be related to preoperative ischemic injury, inadequate myocardial protection, incomplete revascularization, or postoperative graft failure. The spectrum of myocardial injury varies from subtle degrees of global myocardial ischemia to transmural infarction. The incidence of myocardial injury varies with the sensitivity of the method used for detection. Development of segmental transmural MI with development of new Q waves occurs in 1 to 5% of patients undergoing isolated CABG, and it results in a decrement in operative and long-term survival after coronary surgery.[241–245] Elevations of cardiac specific enzymes are ubiquitous after CABG,[246] and elevations in creatinine kinase-myocardial bound (CK-MB) greater than five times the upper limit of normal (ULN) value are considered significant.[247,248] In a prospective study of 2918 patients undergoing CABG, 38% of patients had a CK-MB >5 ULN and 17% had a CK-MB >10 ULN with an incidence of new Q-wave MI of 4.7%.[248] Troponin may be a more sensitive marker than CK-MB, but its role in large populations of CABG patients is still to be defined.[249–252] Prominent elevations of CK-MB and troponin have been associated with global ischemia, MI, low cardiac output, and increased operative mortality, as well as increased mid-term and long-term mortality.[247,248,250,253]

Postoperative myocardial dysfunction may be manifest clinically as low cardiac output syndrome as defined by the need for postoperative inotropic support or aortic counterpulsation to maintain a systolic blood pressure >90 mm Hg or a cardiac index >2.2 L/min. Transient myocardial dysfunction necessitating low-dose inotropic support for a short period of time is common after CABG. The reported incidence of low output syndrome, therefore, will vary depending on the defining criteria. For example, in one study in which low output syndrome was defined as the need for intra-aortic balloon (IAB) pulsation or inotropic support for >30 minutes, the incidence of low output was 9%, whereas in another series defining low output as the need of IAB pulsation or inotropic support for >8 hours, the incidence was 4.3%.[254,255] Low output syndrome has been shown to be a marker for increased operative mortality by 10- to 15-fold.[254,255] Independent predictors of low output syndrome in order of importance include: LVEF <20%, reoperation, emergency operation, female gender, diabetes, age older than 70, left main disease, recent MI, and triple vessel disease.

Adverse neurologic outcomes

Neurologic deficits after coronary surgery are divided into two types: type 1 deficits include major neurologic deficits, stupor, and coma; type 2 deficits are characterized by deterioration of intellectual function and memory. In a prospective multicenter study conducted by the Multicenter Study of Perioperative Ischemia Research Group, 2108 patients from 24 U.S. institutions were evaluated with regard to adverse cerebral outcomes after CABG: the incidence of type 1 deficits was 3.1% and type 2 deficits was 3%. The associated mortality rates were 21 and 10%, respectively, while the operative mortality in patients with no neurologic dysfunction was 2%.[256] Predictors of both types of deficits included advanced age (≥70 years of age), and history or presence of severe hypertension. Independent predictors of type 1 deficits included proximal aortic atherosclerosis, history of prior neurologic disease, use of IABP, diabetes, unstable angina, and perioperative hypotension. Predictors of type 2 deficits included history of alcohol consumption, dysrhythmias, prior CABG, peripheral vascular disease, congestive heart failure (CHF), and perioperative hypotension. Similar predictors of adverse neurologic outcomes have been observed in other studies.[256–258]

Deep sternal wound infection

Deep sternal wound infection occurs in 1 to 4% of CABG patients and carries a mortality rate of 25%.[259] Proven methods to reduce postoperative wound complications include the use of preoperative showers with chlorhexidine gluconate on the evening and morning before the procedure,[260] prophylactic intranasal application of mupirocin given on the evening and the morning before the procedure and twice daily for 5 days postoperatively,[261–263] hair clipping the morning of surgery,[264] and administration of intravenous prophylactic antibiotics prior to skin incision.[265–269]

Obesity and diabetes are strong independent predictors of mediastinitis. Insulin-dependent diabetics are especially susceptible to deep sternal wound infection.[270–272] Recent data suggest that tight glycemic control in the postoperative period decreases the risk of mediastinitis in the diabetic population.[273,274] Other preoperative variables independently associated with an increased incidence of deep sternal wound infection include reoperations, longer operative times, re-exploration for bleeding, and blood transfusions.[271,272,275]

The use of bilateral ITAs had been implicated as a risk factor for mediastinitis, especially in diabetics;[271,276] however, this risk appears to be mitigated in part by using a skeletonized ITA harvesting technique.[91,277–279] Bilateral ITA harvest must be avoided in obese diabetic women since they exhibit a prohibitively high risk of deep sternal wound infection, even with skeletonization of the IMAs.[91]

Acute renal failure

Acute renal failure ensuing after CABG with cardiopulmonary bypass is an ominous event. In a prospective observational study conducted at 24 university centers in the United States, 2222 CABG patients were evaluated with regard to postoperative renal dysfunction. Renal dysfunction not requiring dialysis occurred in 6.3%, and renal dysfunction requiring hemodialysis developed in 1.4%. Mortality was directly related to postoperative renal function. Patients with no renal dysfunction had 0.9% mortality, and postoperative renal dysfunction increased mortality to 19% if no dialysis was needed and to 63% if hemodialysis was required. Independent predictors of postoperative renal dysfunction included increasing age, CHF, reoperation, diabetes mellitus, chronic renal insufficiency, prolonged cardiopulmonary bypass time, and low cardiac output.[280] These findings were confirmed by a series of 42,733 patients with similar incidence and mortality associated with postoperative renal dysfunction.[281] One in four patients with preoperative chronic renal insufficiency (creatinine >1.6 mg/dL) will require renal replacement therapy post-CABG, and patients at highest risk are older than 70 years and have a baseline creatinine >2.5 mg/dl.[59]

Long-Term Outcomes

The long-term outcomes of surgical MR depend on the complex interaction of patient-related and procedure-related factors. Important patient-related factors include anatomic distribution of the CAD, the extent and severity of coronary atherosclerosis, the physiologic impact of ischemia on ventricular function at the time of the original operation, age, gender, overall health status, severity of atherosclerotic burden throughout the body, the presence and severity of associated comorbidities, development of operative complications such as stroke, and a need for permanent hemodialysis. The progression rate of native coronary atherosclerosis after surgery and the development of coronary bypass graft failure are of extreme importance in the development of post-CABG angina recurrence, MI, need for reintervention, and cardiac-related mortality. Procedure-related factors that influence long-term outcomes include completeness of revascularization, myocardial protection, and selection of bypass conduits.

Sergeant and colleagues at the Gasthuiberg University Hospital of the Katholieke Universiteit (KU) Leuven, Belgium have provided us with the most complete data set on clinical outcomes after MR. From 1971 to 1993, 9600 consecutive CABG patients were prospectively followed with special attention to clinical outcomes after surgical MR; the investigators achieved a 99.9% complete follow-up in this cohort. Clinical outcomes prospectively followed at the KU Leuven included mortality, return of angina, MI, and coronary reintervention.[282]

Sergeant defined return of angina as the first recurrence of angina of any intensity or duration unless it was associated on the same day with MI or death. The severity of this event was also recorded. At the KU Leuven the overall nonrisk adjusted freedom from return of angina was 95% at

1 year, 82% at 5 years, 61% at 10 years, 38% at 15 years, and 21% at 20 years. The data suggest that if followed long enough after CABG, the return of angina is almost inevitable, and at 12 years one-half of operated patients had return of angina. The initial episode of recurrent angina was rated as mild in 59% of patients.[283] In the Bypass Angioplasty Revascularization Investigation (BARI) trial of 914 patients with symptomatic multivessel disease randomly assigned to receive CABG, freedom from angina was 89% at 1 year and 82% at 5 years.[284]

The overall nonrisk adjusted freedom from MI after CABG at the KU Leuven was 97% at 30 days, 94% at 5 years, 86% at 10 years, 73% at 15 years, and 56% at 20 years.[285] The overall nonrisk adjusted freedom from a coronary reintervention, either PCI or reoperative CABG, was 99.7% at 30 days, 97% at 5 years, 89% at 10 years, 72% at 15 years, and 48% at 20 years.[286] In the BARI trial, freedom from subsequent coronary reintervention intervention at 7 years was 86.9%.[284]

Overall risk-unadjusted survival after CABG in the KU Leuven experience was 98% at 30 days, 92% at 5 years, 81% at 10 years, 66% at 15 years, and 51% at 20 years. Mortality after CABG was characterized by an initial period of high risk in the first month after surgery, then risk declined to its lowest at 1 year after the operation, and thereafter the mortality risk rose slowly and steadily for as long as the patient was followed. This slow and steady rise in the risk of death over time paralleled that of the general population when matched for sex, age, and ethnicity.[286] The occurrence of ischemic clinical events after CABG negatively influenced survival. Overall survival was lessened by return of angina, with an observed survival of 83% at 5 years and 54% at 15 years, the more intense the severity of angina at its return, the greater its influence on survival.[283] The occurrence of MI after CABG has a greater negative effect on survival. Observed long-term survival after post-CABG infarction at the KU Leuven was 80% at 30 days, 65% at 5 years, 52% at 10 years, and 41% at 15 years.[285]

Progression of disease in native coronary arteries

Progression of atherosclerosis in the native coronary arteries continues after CABG. Bourassa and associates studied the progression of atherosclerosis in the native circulation 10 years after surgery and found that progression of CAD occurs in approximately 50% of nongrafted arteries. The rate of progression of disease in nongrafted arteries was no different from that of grafted arteries with patent grafts; however, progression was more frequent in grafted arteries with occluded grafts. Progression of pre-existing stenoses in native coronaries was more frequent than appearance of new stenoses, and it was related to the severity of the pre-existing stenosis only in nongrafted arteries. Progression of native CAD was associated with deterioration in LVF. Native coronary atherosclerosis progressed at a similar rate to that of equally diseased arteries in nonoperated patients.[287] Low levels of high-density lipoprotein cholesterol and elevated levels of plasma low-density lipoprotein cholesterol correlated with native disease progression and development of new atherosclerotic lesions.[288,289] These findings underline the need for aggressive secondary prevention to diminish the progression of native coronary atherosclerosis.

Graft failure

Although the use of the saphenous vein helped popularize coronary bypass grafting, the propensity of the saphenous vein to occlude over time has been the Achilles' heel of the procedure. Three entities are responsible for saphenous vein graft failure: thrombosis, intimal hyperplasia, and graft atherosclerosis.[290]

Thrombosis accounts for graft failure within the first month after CABG, and graft occlusion is found on angiography in 3 to 12% of all venous grafts. Thrombosis of the graft may be related to endothelial injury and technical errors. Injury during conduit harvest may cause disruption of the intimal and even medial layers of the vessel. Endothelial injury can also occur with forceful distention of the conduit and nonphysiologic pH of the distending fluid. Endothelial damage creates a prothrombotic milieu in the conduit. Technical errors include poorly constructed anastomoses, graft kinking, and insufficient graft length that causes tension at the anastomosis. Graft-target size mismatch, poor vessel run-off, and competitive flow will produce low flow through the graft conduit and may also lead to early thrombosis.[77,290,291]

Intimal hyperplasia defined as the accumulation of smooth muscle cells and extracellular matrix in the intimal compartment, is the major disease process in venous grafts between 1 month and 1 year after implantation. Nearly all veins implanted into the arterial circulation develop further intimal thickening within 4 to 6 weeks, which may reduce the lumen by up to 25%. Intimal hyperplasia rarely produces significant stenosis per se. More importantly, however, it will provide the foundation for later development of graft atheroma. Progression of atherosclerosis in aortocoronary saphenous vein grafts is frequent and is the predominant cause of late graft closure after CABG. Vein graft atherosclerosis may begin as early as the first year, but is fully developed only after about 5 years. Ten years after surgery 50 to 60% of SVGs will be occluded and one-half of still patent grafts will show angiographic evidence of atherosclerosis; two-thirds of these lesions will have a luminal diameter reduction of 50% or greater.[287] Vein graft atherosclerosis is the leading cause for reoperation following CABG, more so than progression of disease in native coronary arteries.[292–295]

Extended use of arterial grafting

BILATERAL ITA: In contrast to the easily demonstrated survival benefit conferred by an ITA graft to the LAD artery, it was more difficult to demonstrate a survival benefit to a second arterial graft. Buxton and colleagues studied 1243 patients undergoing primary CABG with bilateral ITA grafts compared with 1583 patients with single ITA grafts.

This group demonstrated a 15% absolute improvement in actuarial survival rates 10 years after CABG with the use of bilateral ITA grafts, as compared with the use of a single ITA graft (10-year survival for bilateral ITA was 86 ± 3% versus 71 ± 5% for a single ITA).[296] Lytle and colleagues demonstrated an improvement in survival at 12 years (79 versus 71%), as well as superior reoperation-free survival (77 versus 62%) among 2001 bilateral and 8123 single ITA graft patients.[297]

COMPLETE ARTERIAL REVASCULARIZATION: The better long-term results achieved with the use of bilateral ITAs and the well-known time-related attrition in patency of venous conduits encouraged the exclusive use of arterial conduits for MR. Complete arterial revascularization can be achieved by a variety of strategies including composite grafting using exclusively ITAs or secondary arterial conduits such as the RA and the GEA. The use of sequential anastomotic techniques maximizes the utilization of arterial conduits. Although technically demanding, sequential grafting can be performed safely and with excellent long-term results. Dion and colleagues reported a 96% patency rate at 7.5 years of follow-up on1150 sequential ITA anastomoses.[298]

Tector has championed complete arterial revascularization using bilateral ITAs in a T configuration with end-to-side anastomosis of one ITA as a free graft to the side of the second ITA which is left as a pedicled graft, combined with liberal use of sequential anastomoses. In his series of 897 patients overall survival was 75%, and freedom from reintervention was 92% 8 years after revascularization.[225] Barner has reported similar encouraging results with composite grafting using one ITA and one RA.[232]

Data from randomized studies are beginning to emerge supporting improvement in early outcomes with complete arterial revascularization compared to conventional CABG. Muneretto and associates randomized 200 patients to complete arterial revascularization (left ITA to the LAD artery and composite grafts with the right ITA, RA, or both) versus conventional CABG (left ITA to the LAD artery and SVGs). In mid-term follow-up (20 months) superior event-free survival (freedom from nonfatal MI, angina recurrence, graft occlusion, need for percutaneous transluminal coronary angioplasty, and late death) was demonstrable in the complete arterial revascularization patients compared to conventional CABG.[299] The same group conducted a second randomized trial comparing complete arterial revascularization to conventional CABG (ITA to LAD artery and SVG) in 160 patients older than 70 years of age undergoing first time nonemergent CABG. Early mortality was similar, but at 16 ± 3 months, there were significantly fewer graft occlusions and recurrences of angina among the complete arterial revascularization group. Independent predictors of graft occlusion and angina recurrence were use of SVGs, diabetes, and dyslipidemia.[228] The result of longer follow-up of these trials is eagerly awaited.

CHAPTER 23

Myocardial Revascularization without Cardiopulmonary Bypass

Todd M. Dewey • Michael J. Mack

Coronary artery bypass grafting (CABG), while declining in overall numbers, continues to comprise the majority of open-heart procedures performed on a yearly basis in the United States. The efficacy of this procedure for survival, symptom improvement, and quality of life has been well documented in specific patient subgroups. Additionally, it has been a technique that can be performed reproducibly by a wide variety of operators with varying degrees of technical skill and acumen with generally good results. However, conventional bypass grafting using cardioplegic arrest continues to be associated with singular complications that may negate an otherwise successful procedure. Renewed interest in off-pump bypass grafting (OPCABG) in the mid-1990s presented surgeons with the option of revascularization without the potential complications of extracorporeal support. However, widespread acceptance and use of this technique remain sporadic. While this approach has been adopted as the primary mode of coronary revascularization by some, most surgeons still prefer to operate on an arrested heart. This is evidenced by the fact that off-pump surgery still only accounts for approximately 20 to 25% of all coronary artery bypass procedures performed in the United States.[1] For most surgeons, the transformation of this technique from compelling idea to standard therapy relies on scientifically demonstrating the following: (1) graft patency rates that are at least equivalent to conventional techniques, (2) reduced morbidity and mortality, especially in high-risk groups, (3) a rapid return to usual functional capacity, and (4) an economic benefit. Unfortunately, many of the results reported in the literature concerning outcomes with off-pump bypass grafting have been inconclusive as to the overall benefit of the technique. Most studies have suffered from the fact that they have been retrospective reviews with perceived patient selection bias, despite many times including sophisticated statistical risk adjustment. And while newer prospective studies continue to be published, questions regarding the ultimate benefit of this technique remain unanswered in the minds of many surgeons. Ultimately, it will be up to individual surgeons to decide whether to include this useful technique in their surgical repertoire.

PATIENT SELECTION

Patient selection for off-pump bypass grafting depends largely on the interaction between the experience level and technical skill of the operating surgeon and the angiographic coronary anatomy identified at the time of cardiac catheterization. Many decisions regarding a patient's suitability for an off-pump approach can be made prior to the patient going to the operating theater. Surgeons with little off-pump experience should concentrate on patients with less demanding revascularization requirements (Table 23-1). These would include patients with good-sized epicardial target vessels (>1.25 mm), coronary arteries with focal stenosis rather than diffuse disease, target vessels away from the atrioventricular groove, and vessels in which an endarterectomy is not required. Additionally, these procedures should be performed in nonemergent situations in which the patients are hemodynamically stable and have relatively well-preserved left ventricular function. These operations also should be primary revascularization procedures and not reoperations.

With experience, higher-risk and technically more challenging procedures can be undertaken. These include procedures on patients with marginal hemodynamics but who are otherwise stable, those requiring multiple grafts to the posterior and lateral walls or the atrioventricular groove, and those with enlarged right or left ventricles[2–6] (Table 23-2). Difficult patients most likely to benefit from off-pump surgery include those with severe left ventricular dysfunction, renal insufficiency, atherosclerotic disease of the ascending aorta, severe chronic obstructive

Table 23–1.

OPCAB Patient Selection in Early Experience

Anterior vessels
Limited number of bypasses (1–3)

pulmonary disease, and those grafted emergently after an acute myocardial infarction.[6–9] Patients presenting the most significant challenge include those requiring reoperations and those with small and diffusely diseased vessels.[10,11]

Patients who are unstable, either hemodynamically or electrically, may not tolerate the manipulation required for off-pump bypass grafting and therefore represent a population generally not considered candidates for OPCABG. Additionally, patients with moderate or greater aortic or mitral insufficiency may not tolerate extremes of positioning for revascularization. Excessive manipulation of the heart can worsen valvular incompetence, leading to ventricular distension and ultimately ventricular fibrillation. Close attention to hemodynamic parameters such as the pulmonary artery pressures, mixed venous oxygen saturation, and systemic blood pressure can give an early indication of impending problems and allow time for cardiac repositioning. Patients clearly not amendable to an off-pump approach can be revascularized safely by performing pump-supported beating-heart surgery. Patients are supported by the extracorporeal circuit to maintain hemodynamic stability, but global ischemia is avoided by performing the anastomosis using beating-heart techniques. The ability to apply these techniques when needed augments the armamentarium of the practicing surgeon.

Table 23–2.

Patients Most Likely to Benefit from OPCAB

Age >70 years
Low ejection fraction
Reoperative surgery
Patients with significant comorbidities Cerebral vascular disease Peripheral vascular disease Hepatic disease Bleeding disorders COPD Renal dysfunction
Atheromatous or calcified aorta
Patients who refuse blood products

COPD = chronic obstructive pulmonary disease; OPCAB = off-pump coronary artery bypass.

ANESTHESIA FOR OPCABG

The avoidance of extracorporeal circulation in association with off-pump revascularization requires modifying not only the anesthetic technique used in these patients but also the level of participation of the anesthesiologist, especially during construction of the distal anastomoses. Close collaboration with a familiar and involved anesthesiologist is vital to the performance of off-pump bypass grafting. Lines of communication between the surgeon and the anesthesiologist should be clearly established in order to provide appropriate responses to rapidly changing clinical situations.

The anesthetic technique for off-pump bypass grafting is tailored to provide hemodynamic stability during displacement of the heart, reduce the sequelae of regional myocardial ischemia, and allow early recovery of consciousness and extubation (Table 23-3). These techniques are predicated on the avoidance of long-acting agents and the use of short- and intermediate-acting narcotics.

Without the heat exchanger of the bypass circuit to control the patient's body temperature, maintenance of body heat by ancillary methods becomes necessary. The patient's temperature is maintained using warming mattresses, infusion of warmed fluids, warmed oxygen and anesthetic gases, and keeping the room temperature elevated. Immediate extubation of patients at the conclusion of the procedure should be the goal in the majority of off-pump cases. Several reports have confirmed the safety of immediate extubation after off-pump bypass grafting, provided that certain criteria are met, namely, (1) patients should be stable hemodynamically, (2) oxygenation and ventilation parameters should be satisfactory, (3) patients should have adequate return of muscular strength, (4) patients should have a

Avoidance of negative inotropes

OPCAB = off-pump coronary artery bypass.

level of consciousness sufficient to respond to simple commands, and (5) surgical bleeding should be controlled.[12] In one series, 514 patients of 548 (94%) undergoing off-pump bypass grafting were extubated successfully in the operating room, with a minimal number of patients requiring reintubation.[13]

All patients receive continuous oximetric pulmonary artery catheters and transesophageal echocardiography probes. These provide continuous hemodynamic monitoring and allow treatment to be directed toward specific alterations in the patient's cardiac function. Additionally, undiagnosed intracardiac abnormalities are identified intermittently that may require treatment and alteration of the operative plan. Nitroglycerine infusion for ischemic prophylaxis and volume loading are instituted at the beginning of the case. Patients are preload-sensitive during the manipulation that occurs when setting up the anastomoses, especially of the posterior circulation vessels. Cardiac displacement leads to right ventricular deformation and decreased pump function without valvular incompetence; this occurs secondary to inflow occlusion or outflow obstruction.[14–19] Volume loading and the use of Trendelenburg positioning increase preload, thereby augmenting right ventricular filling pressures and allowing patients to tolerate the distortion in anatomy and maintain adequate cardiac output and systemic blood pressure. Antiarrhythmics are instituted as needed but are seldom required. Pacing wires and intraluminal shunts are placed often when grafting poorly collateralized large right coronary arteries because hypotension and bradycardia are seen frequently with occlusion of these vessels.

Most surgeons believe that negative inotropic or chronotropic agents are to be avoided in off-pump surgery. They provide little in facilitating construction of the anastomoses while reducing cardiac performance enough to make some areas of the heart ungraftable. Use of positive inotropes can increase the force of myocardial contraction, accentuating cardiac motion and making target stabilization more difficult. During manipulation and positioning of the heart, volume infusion and small aliquots of pressor agents are used to support blood pressure and optimize cardiac output.

Anticoagulation is produced using 1.5 to 2.0 mg/kg of heparin in order to maintain an activated clotting time (ACT) of greater than 300 seconds. At the end of the procedure, the anticoagulation is reversed to varying degrees, depending on surgeon preference, with protamine sulfate. A bypass circuit is available routinely in the operative suite in the event that conversion to cardiopulmonary support is indicated. Conversion rates vary with surgeon experience but generally are less than 4%.[20]

SURGICAL TECHNIQUE

Incision

A median sternotomy is the most frequently used route for cardiac access when performing multivessel grafting. Isolated grafting of specific individual vessels can be performed using a variation of thoracotomy, anterior for the left anterior descending artery or lateral for access to the marginal vessels. The use of thoracotomy for multivessel grafting also has been reported. A median sternotomy allows the surgeon to visualize the operative field from an orientation that is familiar and similar to on-pump procedures. This facilitates target-vessel identification as well as harvesting of the internal mammary arteries for use as conduit. Additionally, should conversion to conventional bypass become necessary, a median sternotomy allows easy access for cannulation of the heart.

Once conduit is obtained, the retractor is positioned inferiorly in the sternal incision. This placement reduces traction on the brachial plexus and generally facilitates mobilization of the heart for positioning. Current retractors used for beating-heart surgery come with attachable devices to aid in positioning the heart as well as stabilizing the target artery (Fig. 23-1). The pericardium is opened in an inverted T-shaped incision. The lateral extensions are exaggerated to facilitate mobilization of the apex of the heart and to create increased space for the right ventricle during positioning. When dealing with hypertrophic hearts, it is often helpful to displace the heart into the right side of the chest to aid in exposure of the lateral wall vessels. This is accomplished by incising the right pleura parallel to and along the entire length of the sternotomy. Additionally, the pericardial incision is extended posteriorly toward the inferior vena cava along the right diaphragm (Fig. 23-2). This incision is stopped just prior to reaching the phrenic nerve to avoid

Figure 23-1. Custom off-pump sternotomy retractor. Note the suture holders and tracts for attachment of stabilizer and suction exposure device.

injury. Graft preparation is performed prior to manipulating the heart in order to reduce the amount of time spent with the heart in a nonanatomic position. All varieties of conduit used in conventional bypass grafting likewise can be used in beating-heart surgery.[21]

Patient Positioning

Standard positioning for OPCABG is to place the patient in a slight Trendelenburg position and also mildly rotated toward the operating surgeon. This position helps to maintain hemodynamic stability by augmenting cardiac output by increasing venous return to the heart. Additionally, rightward rotation enlists gravity to facilitate mobilization of the heart, thereby simplifying visualization of the coronary arteries of the lateral, posterior, and inferior walls. Extreme degrees of rotation may be necessary to obtain hemodynamically tolerable positions for some difficult anastomoses.

Target-Vessel Exposure and Stabilization

Optimal target-vessel exposure and three-dimensional stabilization are essential for successful off-pump bypass surgery. The most common technique used to manipulate the heart

Figure 23-2. Extension of the pericardial incision along the right diaphragmatic reflection to create room for the right ventricle during displacement.

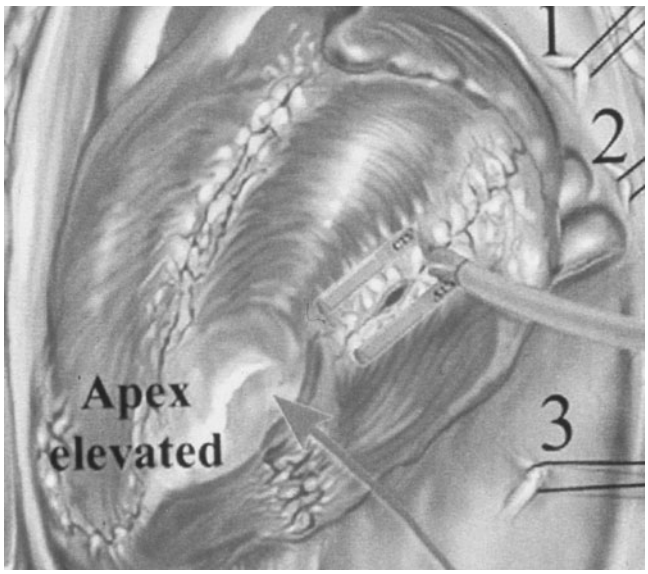

Figure 23-3. Placement of deep pericardial sutures for cardiac displacement during exposure of the posterior circulation.

and expose the coronary arteries is the use of deep pericardial sutures for cardiac distraction and exposure (Fig. 23-3) or, more commonly, apical suction devices. Apical suction devices allow distraction and manipulation of the heart by creating a vacuum-type seal to the epicardial surface (Fig. 23-4). These devices extend from reticulating arms that attach to the sternal retractor and allow the heart to be positioned for optimal vessel exposure. By applying suction and moving the apex of the heart toward the right sternum, the anterior descending, diagonal, and obtuse marginal vessels are presented. Suction applied to the acute margin of the heart with retraction toward the left shoulder exposes the distal right coronary artery and its branch vessels.

The advantage of these devices is that they maintain the normal geometry of the heart and avoid compression of the right ventricle. This improves hemodynamic stability when grafting difficult arteries, especially in patients with reduced ejection fractions, and allows the surgeon to be meticulous during construction of the anastomoses instead of hurried.

Stabilization of the target vessel for the anastomoses is obtained by using a two-armed suction stabilizer.[22] These stabilizers consist of pods of suction cups within the prongs of the stabilizer that immobilize the target area by creating a vacuum between the epicardial surface and the stabilizer arm (Fig. 23-5). This allows for construction of the anastomoses to take place in a motionless field, recreating the same visual image seen in an arrested heart.

Grafting Strategy

The sequence of graft construction is crucial to the success of the procedure (Table 23-4). In general, collateralized vessels should be grafted before collateralizing vessels. Additionally, a bloodless field is necessary to perform a precise distal anastomosis. Proximal control of the vessel selected for grafting is obtained with a soft Silastic tape mounted on a blunt needle (Quest Medical, Allen, TX) (see Fig. 23-5). This tape is placed circumferentially just proximal to the site of the anastomosis. Tension applied to the suture restricts blood flow by inflow occlusion and facilitates the anastomosis. A distal snare can be placed if backbleeding from collateralizing vessels is problematic. However, most surgeons avoid distal loops because of potential damage to the intima of the outflow portion

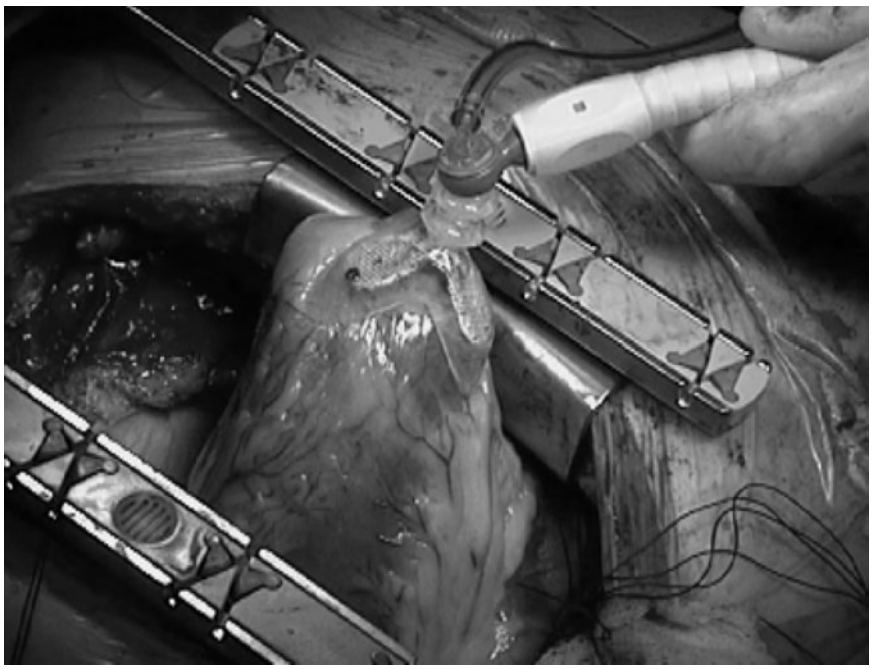

Figure 23-4. Attachment of an apical suction device to the epicardial surface to facilitate exposure of the posterior circulation without compression or distortion of the right ventricle.

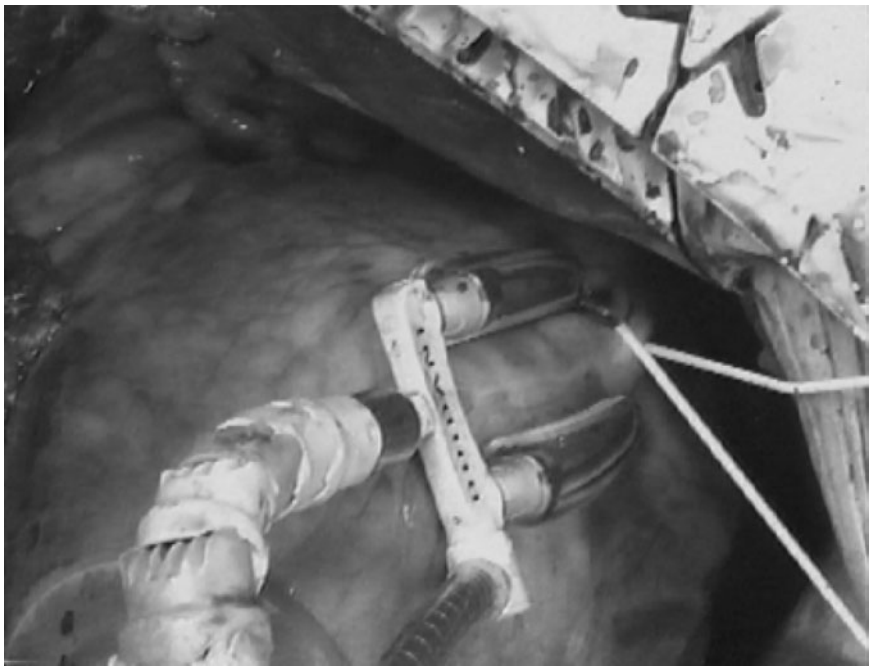

Figure 23-5. Suction stabilizer device placed adjacent to the obtuse marginal circumflex branch for local immobilization. Note the Silastic snare around the proximal vessel.

of the grafted artery.[23] A misted carbon dioxide blower also is employed to clear blood from the field and to open the arteriotomy during the anastomosis (Fig. 23-6). A heparinized, pH-balanced solution should be used in the blower.[24] The flow rate of carbon dioxide from the blower should be limited to the minimal level needed to perform the anastomosis because excessive gas jet velocity can injure the target coronary endothelium or the conduits.[24] Intracoronary shunts may be employed to provide distal vessel perfusion during the construction of the anastomosis if ischemia is a concern. Patience is rewarded when positioning the heart to expose the target vessels. Small changes in positioning can have profound hemodynamic effects. Avoidance of overreacting to pressure changes and close collaboration with the anesthesiologist generally allow the heart to be positioned with acceptable hemodynamics and exposure for the anastomoses.

Table 23–4.

Grafting Strategy for OPCAB—Easiest to Hardest

Collateralized vessels before collateralizing
Left anterior descending with LIMA
Proximal anastomosis before distals
Diagonal artery
Main right coronary artery
Posterior descending artery
Distal circumflex, second, third obtuse marginal vessels
Posterior lateral artery
Proximal obtuse marginal artery
Ramus intermedius artery

OPCAB = off-pump coronary artery bypass; LIMA = left internal mammary artery.

The left anterior descending (LAD) artery typically is the first anastomosis performed using the internal mammary artery. This vessel is the easiest to expose and access and allows revascularization of the septum and anterior wall prior to other provocative maneuvers. Exposure usually is obtained by placing a moist laparotomy pad behind the heart to bring the vessel to the midline. An exception to this strategy might occur if the LAD artery collateralizes a completely occluded right coronary artery (RCA), thereby providing the sole blood supply to the septum and anterior and inferior walls. In this circumstance, initial grafting of the RCA to limit the amount of myocardium made ischemic during occlusion of the LAD artery would be a reasonable approach. A stabilizer then is placed straddling the target area, and the vessel is exposed. An intramyocardially located LAD artery can be particularly challenging. This situation can be addressed successfully by careful attention to the details of exposure. The dissection is not initiated until the stabilizing foot is in place. A misted carbon dioxide blower is used to maintain a bloodless field. Exposure of the LAD artery begins distally, where it emerges onto the epicardial surface near the apex of the heart. Dissection then proceeds proximally by relocating the stabilizer until a segment of artery suitable for grafting is identified. Alternatively, one can locate the anterior descending artery by tracing a

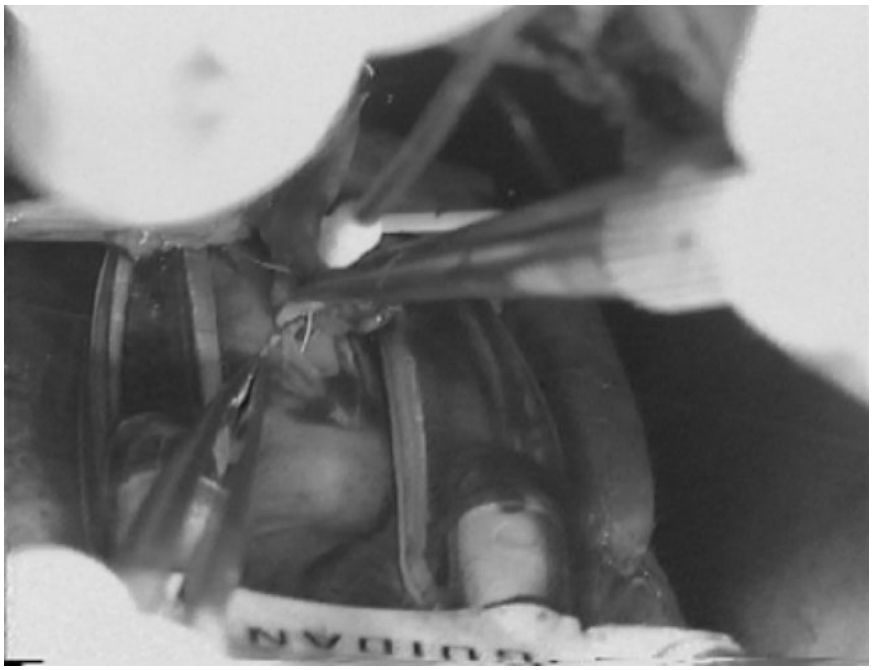

Figure 23-6. Creation of a motionless, bloodless operative field for a distal anastomosis to the left anterior descending coronary artery by use of a suction exposure device, a proximal Silastic snare, and a misted CO_2 blower (*arrow*).

diagonal artery back to its branch point with the LAD artery. Shed blood is scavenged using a Cell Saver (Haemonetics Corp, Braintree, MA). Intracoronary shunts can be used if the arteriotomy is centered over a septal perforator to reduce blood loss and aid in visualization or if preserved distal perfusion is required to maintain hemodynamic stability. After completion of the LAD anastomosis, a tacking suture is placed to secure the pedicle to the epicardium to eliminate torsion and tension on the anastomosis.

Grafting then is continued by performing the easier anastomoses prior to the more difficult ones. The diagonal arteries on the anterior surface of the heart are relatively straightforward to graft and can be exposed either by using a posteriorly placed laparotomy pad or by putting a suction device on the apex of the heart and moving the vessel to the midline. This position is well tolerated hemodynamically in most patients. Grafting then commences in standard fashion by placing the Silastic suture for inflow occlusion and stabilizing the target site.

The main RCA, while generally easy to demonstrate, can be problematic to graft. Problems occur most frequently when a large dominant, moderately stenotic RCA is to be bypassed proximal to the crux. Proximal occlusion causes ischemia to the atrioventricular node, thereby manifesting as bradycardia and heart block that can lead to ventricular distension and cardiovascular collapse. Helpful maneuvers, as noted previously, include placing atrial and ventricular pacing wires prior to making the arteriotomy, as well as placing an intracoronary shunt to preserve distal perfusion to the atrioventricular node. Trendelenburg positioning and suction distraction cephalad on the acute margin provide excellent exposure of the middle to distal RCA.

The posterior descending artery follows in degree of difficulty to expose and graft. A similar approach is used to that of exposing the distal RCA but with the angle of distraction oriented more toward the left shoulder of the patient. This positioning simplifies the anastomosis by placing the posterior descending artery on a level plane, thereby maintaining a consistent focal length for the surgeon. Bradyarrhythmias and hemodynamic problems are seen infrequently with occlusion of this vessel as opposed to the RCA.

The next most accessible vessels would include the middle to distal obtuse marginal branches and the posterior ventricular artery. The heart is positioned with the apex pointing toward the right midsternum using a suction device. The patient is placed in mild Trendelenburg position and also rotated to the right toward the surgeon to achieve adequate visualization of the target vessel. Release of right-sided pericardial stay sutures and/or opening of the pleura on the right side can help to avoid compression of the right ventricle and maintain acceptable hemodynamics during the anastomoses.

The ramus intermedius artery is challenging to expose owing to compression on the right ventricular outflow tract and pulmonary artery. The introduction of suction devices to position the heart has decreased the hemodynamic alterations associated with exposing this difficult part of the heart. The apex of the heart is retracted toward the patient's right hip, and the table is rotated toward the surgeon. This area of the heart tends to be tethered by the nearby pericardial reflection, reducing its mobility and making exposure difficult. Additionally, a large left atrial appendage can present visualization problems when grafting near the atrioventricular groove.

Rapid recovery of regional myocardial function prior to subsequent occlusion of other target arteries is essential for successful multivessel off-pump bypass grafting. Some

surgeons argue in favor of constructing the proximal anastomoses prior to performance of the distal anastomoses in order to provide immediate perfusion to the grafted artery and thereby decreasing regional ischemic impairment and promoting recovery of the grafted region. Other surgeons follow a sequence of grafting similar to an arrested-heart procedure, in that the distal anastomoses are completed prior to performing the proximal anastomoses. A third alternative is to provide perfusion-assisted blood flow down the grafts at the conclusion of the distal anastomoses.[25] This is done by attaching each completed vein graft to a perfusion pump that receives oxygenated blood from an aortic root cannula and delivers it to a standard multiperfusion catheter. This perfusion-assisted direct coronary artery bypass (PADCAB) technique (1) allows immediate blood flow to regionally ischemic myocardium, (2) provides the potential for including vasoactive substances or substrate-enhanced blood in the perfusate, and (3) can provide increased hemodynamic stability during multivessel grafting, particularly in patients with marginal hemodynamics or reduced left ventricular function. The saphenous vein grafts remain perfused until each is individually anastomosed to the ascending aorta. Excellent outcomes have been reported using each of the various techniques.[25]

The proximal anastomoses generally are constructed by using a partial occlusion clamp on a depressurized aorta. Many surgeons routinely use epiaortic scanning to survey the aorta for atheromatous disease that can escape even careful palpation.[26] Recent introduction of the HEARTSTRING Proximal Seal System (Guidant, Cupertino, CA) obviates the need for a partial occlusion clamp, thereby reducing the risk of atheromatous embolization or aortic dissection with placement of the clamp[27] (Fig. 23-7). This device creates a hemostatic seal with the inner surface of the ascending aorta that allows the creation of a hand-sewn angled take-off of the proximal vein graft.

On completion of the grafts, an assessment of the hemodynamic stability, the electrocardiogram (ECG), and the ventricular function of the patient is performed. Many surgeons do not routinely measure intraoperative graft flows but rely instead on ECG changes or wall motion abnormalities detected by transesophageal echo. Small drainage tubes (19 French Blake or Jackson-Pratt) are placed to facilitate immediate extubation. Pacing wires are placed according to the surgeon's discretion. The sternotomy is closed in standard fashion, and Cell Saver blood is returned to the patient.

PUMP-SUPPORTED BEATING-HEART SURGERY

The use of extracorporeal circulation for hemodynamic support while allowing the heart to beat remains a helpful tool in a surgeon's armamentarium. Patients taken to the operating suite who are unstable secondary to an acute myocardial infarction, severely reduced left ventricular ejection fraction, acute coronary artery closure or dissection, or other catheterization lab misadventure represent a difficult population for traditional beating-heart surgery. In these situations, standard positioning of the heart to achieve adequate exposure may worsen already marginal hemodynamics, leading to cardiovascular collapse and emergent conversion to cardiopulmonary bypass. Several studies have shown that emergent conversion to cardiopulmonary bypass after attempting off-pump grafting is associated with significantly higher rates of mortality, stroke, renal failure, respiratory failure, and postoperative bleeding.[20,28]

Figure 23-7. Aortosaphenous vein anastomosis performed in a "clampless" fashion with an anastomotic connector.

One approach is to initiate cardiopulmonary bypass with standard aortic and venous cannulas and to perform the grafts with the heart beating but supported.[29,30] The patients are moderately cooled during the procedure, and perfusion pressures are maintained in the 60– to 80–mm Hg range. Grafting then proceeds in similar fashion to off-pump beating-heart surgery. This technique not only supplies hemodynamic stability but also avoids the global myocardial ischemia seen with cardioplegic arrest. In one small study, the use of extracorporeal circulation and beating-heart grafting was associated with significant elevation of inflammatory markers such as interleukin 6 (IL-6), IL-8, IL-10, and tumor necrosis factor alpha (TNF-α).[31] The clinical significance of the elevation of these biochemical markers is yet to be determined; theoretically, however, they may be associated with increased capillary leak, myocardial injury, increased risk of bleeding, and a predisposition to wound infection. Aortic clamping and manipulation also can be avoided by using sealing-type devices such as the HEARTSTRING to perform the proximal anastomoses while on bypass.

THORACOTOMY FOR BEATING-HEART BYPASS GRAFTING

A thoracotomy incision has long been used to provide access to the heart for isolated valvular procedures, repair of atrial septal defects, and aortic arch and descending aortic aneurysm repair. Coronary reoperations also represent a patient cohort in which this technique has been used effectively.[32,33] Patients undergoing reoperative CABG owing to progression of native-vessel disease or attrition of previous bypass grafts have an increased operative mortality and morbidity compared with patients undergoing primary revascularization. Various strategies have evolved to minimize the risks of reoperative revascularization. These include avoiding repeat sternotomy, where the potential exists to injure patent grafts; reducing manipulation of the aorta or previous grafts to decrease the potential for embolization; and changes in approach to myocardial protection. Furthermore, a median sternotomy can be complicated by poor wound healing, sternal dehiscence, mediastinitis, and prolonged pain that may delay return to normal activities. In addition to reoperations, some surgical groups advocate primary multivessel CABG by thoracotomy as an alternative technique to standard off-pump bypass grafting by median sternotomy.

After induction of general anesthesia and insertion of a double-lumen endotracheal tube, patients either are placed in a right lateral decubitus position or are positioned such that the left side is elevated approximately 45 degrees. In reoperative patients, harvesting of the bypass conduit (e.g., radial artery or saphenous vein) occurs prior to positioning. The left internal mammary artery (LIMA) also can be used if not harvested previously. A left posterolateral thoracotomy incision is performed in the fourth or fifth intercostal space depending on the target vessel selected for revascularization. The left lung is collapsed, and the inferior pulmonary ligament is divided. This allows mobilization of the lung superiorly to the level of the inferior pulmonary vein. Patients with previous LIMA grafts generally have adhesions between the lung and the mammary bed that must be taken down in order to fully mobilize the lung and expose the pericardium. The pericardium is opened longitudinally posterior to the phrenic nerve. Lysis of existing adhesions and target-vessel identification then are performed. A Silastic suture is placed proximally around the target vessel to achieve vascular control. A stabilizer is positioned straddling the anastomotic area, and a misted CO_2 blower is used to keep the anastomotic site clear of blood and the edges of the artery separated. Senile grafts can be used as markers to identify the target vessels. The anastomosis is performed in a continuous fashion with a 7-0 Prolene suture. The proximal anastomosis then is performed by means of a side-biting clamp on the descending aorta or the left subclavian artery with a running 6-0 polypropylene. Proximal anastomotic connectors can facilitate the conduct of the operation and reduce the technical obstacles associated with operating deep within the chest. The graft then is positioned inferiorly to the hilum of the lung in a gentle curve if the inflow is the descending aorta or anterior to the hilum if the inflow is the subclavian artery (Fig. 23-8). Several reports describing the reoperative revascularization of the circumflex distribution using off-pump techniques via left thoracotomy have been published.[34,35] These series demonstrated no mortality, minimal morbidity, and symptomatic improvement from angina.

In patients undergoing primary revascularization via a thoracotomy, the internal mammary arteries are the conduits of choice. Both the right and left internal mammary arteries can be harvested for use either under direct vision or using robotically assisted techniques.[36,37] When the saphenous vein is used for conduit, the proximal vein graft anastomoses are performed prior to the distal anastomoses by means of a partial occluding clamp on the ascending aorta. The systemic blood pressure is maintained at 70 to 90 mm Hg using vasodilators during the proximal anastomoses. The distal anastomoses then are performed by using a suction device to position the heart and expose the target vessels. Stabilization of the target artery is achieved using standard suction-type stabilizers. A recent series reported excellent operative outcomes with an average of 2.9 grafts per patient and bypass grafts to all regions of the heart.[38] Patients with morbid obesity, ventricular hypertrophy with reduced ejection fraction, or a severely dilated cardiomyopathy that require grafts to the RCA circulation are poor candidates for this approach. Patients with reduced cardiac function and/or ventricular enlargement who require only revascularization to the LAD and circumflex distributions still can be grafted using this technique. Beating-heart bypass via thoracotomy provides a safe and effective alternative approach to median sternotomy for patients requiring limited redo CABG or even selected first-time procedures.

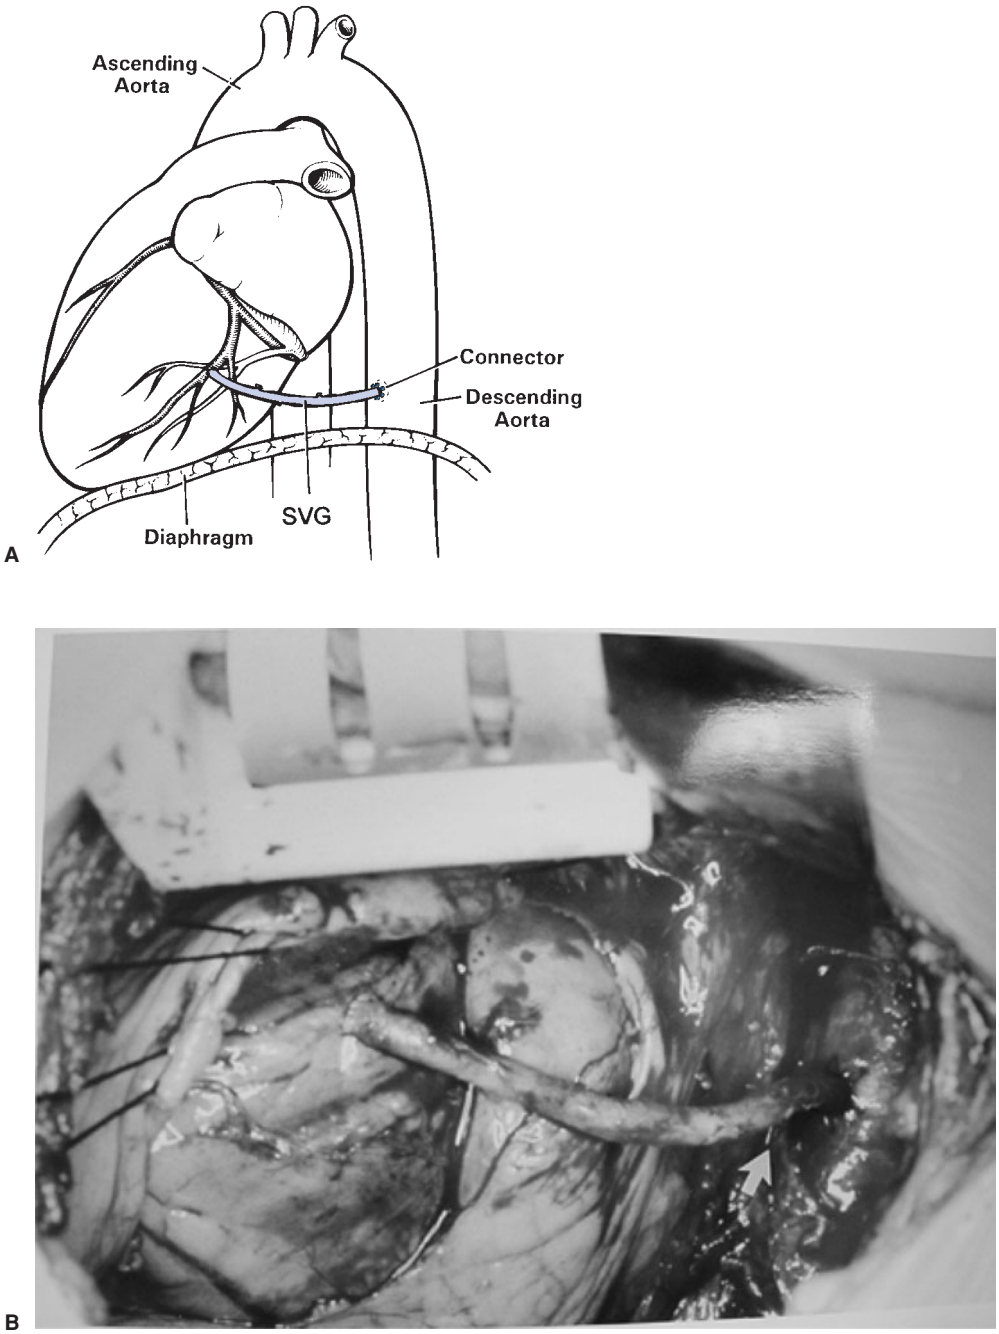

Figure 23-8. Saphenous vein graft (SVG) between descending aorta and an obtuse marginal branch of the circumflex coronary artery with a gentle curve beneath the inferior pulmonary vein.

RESULTS

Conventional CABG clearly has been demonstrated to prolong life and reduce symptoms. However, this comes at a price of significant risk, including mortality (2 to 5%), stroke (2%), transfusion (30 to 90%), atrial fibrillation (30%), and neurocognitive dysfunction (50 to 75%).[39–42] Although off-pump bypass surgery eliminates cardiopulmonary bypass and hypothermic cardiac arrest, manipulation of the ascending aorta by partial clamping is for the most part not eliminated. Whether elimination of bypass leads to superior outcomes is far from clear and may be somewhat mitigated by a small but real incidence of increased adverse outcomes associated with conversion from off-pump to on-pump bypass surgery.

Since the previous edition of this book, a large amount of new information has been published regarding the efficacy of OPCABG compared with conventional on-pump CABG. Even with data from the highest levels of evidenced-based medicine available, the question of the superiority of one surgical technique over the other has not been

answered clearly. Despite a significant number of randomized, controlled trials and seemingly almost as many meta-analyses of these trials, the issue is far from resolved. The debate continues to be a passionately argued one in the medical literature, at major meetings, and in the lay press. There have now been 37 randomized clinical trials published in 53 papers that have enrolled 3369 patients comparing OPCABG versus conventional CABG.[43–95] Three meta-analyses of not only these randomized trials but also major observational studies also have been published recently.[96–98] The American Heart Association has published a scientific statement, and the International Society for Minimally Invasive Cardiac Surgery (ISMICS) has published a consensus statement.[99,100]

Most of the early trials comparing OPCABG versus conventional CABG were nonrandomized comparisons of low-risk patients undergoing single- or double-vessel bypass with significant patient selection bias. More recently, nonrandomized comparisons of high-risk patients and randomized comparisons of mixed-risk patients have been published. Some trials focused on clinical endpoints, and some used surrogate endpoints such as inflammatory mediators and enzyme elevation. Because of the large number of patients required to adequately power important clinical outcomes such as death, stroke, and myocardial infarction, none of the randomized trials, even when analyzed by meta-analysis, are adequately powered to be able to define benefit. For these endpoints to be powered adequately to demonstrate a benefit in a randomized trial in the current clinical population would require approximately 85,000 patients to demonstrate a difference in death, 6000 patients to analyze any difference in stroke, and 12,000 patients to analyze any difference in myocardial infarction.[96] Thus, even though a large peer-reviewed published literature including randomized trials exists, all are underpowered to be able to adequately assess a potential benefit to off-pump techniques compared with on-pump surgery.

Operative Mortality

In randomized trials, there has been no difference in mortality at 30 days (Table 23-5). Pooled analyses of these randomized trials also has found no difference in 30-day mortality [odds ratio (OR) 1.02, 95% confidence interval (CI) 0.58–1.80, $p = .9$, $n = 3082$ patients in 29 randomized, controlled trials (RCTs)].[100] The pooled mortality risk was 1.2% for OPCABG and 1.0% for conventional CABG. Since the mortality in these studies is significantly lower than the Society of Thoracic Surgeons (STS) operative mortality in 2004 (2.4%), it is clear that these studies represent mostly low-risk patients. As mentioned earlier, to find a mortality difference of 0.2%, 85,000 patients would be required. Two meta-analyses of mixed-risk groups that included nonrandomized data did find that there was a reduced risk of mortality at 30 days with OPCABG of 36%. This analysis was in 39,647 patients in 43 combined studies. A second meta-analysis by Beattie found a 21% reduction in mortality in 159,845 patients in seven studies.[97]

Late Mortality

No difference has been found in mortality from 1 to 3 years in six randomized, controlled trials of 1135 patients. A meta-analysis of these trials also has found no difference in mortality at 1 to 3 years (OR 0.88, 95% CI 0.41–1.88, $p = .8$).[96]

Mortality in Patients Converted from Off-Pump to On-Pump CABG

Twenty randomized trials have reported conversion rates ranging from 0% to over 20% with an average rate of 8% of patients whose surgery was initiated off-pump.[96] There are five studies that quote a mortality specifically for converted patients ranging from 6 to 15%.[102–106] Criticisms of early OPCABG versus conventional CABG studies were that they were not analyzed on an intent-to-treat basis. Most studies now published report on an intent-to-treat basis, with converted patients being analyzed as off-pump patients. Suffice it to say that it has become clear that there is an increased incidence in mortality and morbidity when patients are converted *urgently* (i.e., owing to ventricular fibrillation or cardiopulmonary resuscitation) from off-pump to on-pump CABG. However, there does not appear to be an increased risk of complications in patients who are *electively* converted owing to an inability to access appropriate vessels.

Perioperative Morbidity

Most randomized trials have shown a significant reduction in the need for red blood cell transfusion, inotropic support, respiratory infections, and atrial fibrillation with OPCABG versus conventional CABG[98,107] (see Table 23-5). A meta-analysis of the randomized trials in mixed-risk populations shows a reduced incidence in the need for red blood cell transfusion (OR 0.43, 95% CI 0.29–0.65, $p < .0001$, $n = 2412$ patients in 17 RCTs), inotrope requirements (OR 0.48, 95% CI 0.32–0.73, $p < .0001$, $n = 1655$ in 16 RCTs), respiratory infection (OR 0.41, 95% CI 0.23–0.74, $p < .0001$, $n = 896$ patients in 7 RCTs), and atrial fibrillation (OR 0.58, 95% CI 0.44–077, $p = .0001$, $n = 2425$ patients in 17 RCTs).[100] No randomized trials have shown a significant reduction in stroke, myocardial infarction, acute renal failure, intra-aortic balloon pump (IABP) requirement, mediastinitis or wound infection, recurrence of angina, or need for reintervention within 30 days of OPCABG compared with conventional CABG.[97,98] Meta-analyses of these randomized trials also showed that OPCABG had a similar incidence of stroke, myocardial infarction, acute renal failure, IABP requirement, mediastinitis or wound infection, angina recurrence, and need for reintervention within 30 days. Similar results also were shown in these endpoints at 1 to 3 years. Retrospective studies and two meta-analyses of those retrospective studies have shown a reduced stroke risk of OPCABG versus conventional CABG.[97,98] The aforementioned studies also

LOS = Length of stay; NNT = number needed to treat; WMD = weighted mean difference.

showed a 40% and 45% reduction in the risk of stroke. The same two studies also showed a significant reduction in myocardial infarction (OR 0.58, 95% CI 0.44–076, $p = .00009$, $n = 24{,}322$ patients in 26 studies), atrial fibrillation (OR 0.69, 95% CI 0.58–081, $p = .00001$, $n = 22{,}092$ patients in 28 studies), renal failure (OR 0.62, 95% CI 0.58–0.78, $p = .00003$, $n = 20{,}845$ patients in 17 studies), reoperation for bleeding (OR 0.54, 95% CI 0.44–0.67, $p < .0001$, $n = 33{,}000$ patients in 24 studies), wound infection (OR 0.155, 95% CI 0.37–0.83, $p = .004$, $n = 16{,}039$ patients in 17 studies), and need for reintervention (OR 3.63, CI 1.91–6.78, $p = .0001$, $n = 2823$ patients in 7 studies).[97,98]

Neurocognitive Outcomes

One of the early reasons for the introduction of OPCABG was to attempt to improve neurocognitive outcomes after coronary bypass surgery or to avoid "pump head." Whether any improvement has been achieved continues to remain controversial. Two randomized trials showed a significant reduction in early cognitive decline, whereas one randomized trial did not show any difference at 1 month.[68,86,94] There are also three randomized trials that show improved cognitive outcomes with OPCABG at 2 to 6 months and one that shows no difference.[95] Pooled analysis of these trials shows a 46% reduction in the number of patients with cognitive dysfunction with OPCABG.[68,72,86,95] Four randomized trials have looked at neurocognitive outcomes at 1 year and found no difference in OPCABG versus conventional CABG. A meta-analysis of these trials again shows no difference at 1 year.

Resource Utilization

Various studies have shown a significant reduction in the duration of ventilation, ICU stay, hospital stay, and in-hospital costs with OPCABG. These results have been confirmed in a meta-analysis of randomized trials.[96] The reduction appears to be due to a reduction in the ICU length of stay, hospital length of stay, and need for blood transfusion, and a lower incidence of postoperative complications.

High-Risk Patients

Advocates of off-pump surgery feel that the greatest benefit is in high-risk patients who are most likely to have complications. In addition, because of the higher incidence of complications in these patients, studies would be more likely to demonstrate a benefit if present. There have been no randomized trials of only high-risk patients. However, 42 nonrandomized trials of high-risk patients have been identified that do demonstrate a significant reduction in mortality with OPCABG (Table 23-6). Specific patient subgroups that appear to benefit in different studies include a Euroscore of greater than 5, left ventricular dysfunction, and the presence of atheromata in the ascending aorta.[100] No benefit has been found in patients specifically with older age, left main disease, diabetes, renal dysfunction, and chronic obstructive pulmonary disease. Morbidity appears to be less in a meta-analysis of high-risk patients in specific subgroups in nonrandomized trials. Specific endpoints that appeared to be reduced include stroke, myocardial infarction, atrial fibrillation, renal dysfunction, transfusion, inotrope requirements, need for IABP placement, and reoperation for bleeding (Tables 23-7 through 23-9). No significant difference has been found in postoperative wound infection or pulmonary complications. Specific patient risk subgroups that appear to have lower morbidity with OPCABG include those who have a Euroscore of greater than 5, a recent acute myocardial infarction, age over 75 years, or a history of stroke, atrial fibrillation, diabetes, renal failure, left ventricular dysfunction, left main disease, redo CABG, and chronic obstructive pulmonary disease.[62]

Completeness of Revascularization and Graft Patency

Specific concern has been raised as to whether potential benefits of OPCABG have come at a cost of less complete revascularization and lower graft patency compared with conventional CABG. These concerns specifically were raised by one highly publicized study by Khan.[66] Although that study had significant shortcomings, it did raise the profile of this issue. A meta-analysis of randomized trials has consistently shown a lower number of grafts per patient in off-pump versus on-pump CABG (2.6 versus 2.8, $p < .0001$).[100] Even analysis of later trials in which surgeon experience is greater still shows less complete revascularization performed off-pump versus on-pump (2.7 versus 2.9 grafts). It still has not been clarified whether this represents patient selection or incompleteness of revascularization. Completeness of revascularization has been reported only in randomized trials, and two studies have demonstrated a decrease in completeness of revascularization,[53,56] whereas five other trials have shown no difference.[54,66,69,76,79] Nonrandomized trials suggest that completeness of revascularization may be similar or decreased with OPCABG. Graft patency has been evaluated in four randomized trials from in-hospital to 1 year postoperatively. Puskas demonstrated no difference in graft patency at discharge,[79] whereas Khan showed a decreased graft patency in the off-pump group at 3 months.[66] Two studies showed no difference in graft patency at 1 year.[76,79] A meta-analysis at 1 year confirmed that there is no significant difference between off-pump and on-pump revascularization.[100]

Despite the extensive peer-reviewed literature, the potential benefits of off-pump versus on-pump surgery are still not clear. For the most important clinical endpoints, even pooled analysis of randomized trials is severely underpowered to demonstrate a difference. Nonrandomized trials are subject to selection bias and therefore do not reach the level of evidence of randomized trials. Most retrospective nonrandomized trials do appear to show some benefit in specific outcomes other than mortality, as well as a benefit in specific high-risk subgroups. There is consistently a lower number of grafts performed off-pump, but it is still not clear whether this represents less complete revascularization or

patient selection. For the goal of OPCABG in seeking to improve patient outcomes by avoiding side effects attributable to cardiopulmonary bypass, there does appear to be some reduction in morbidity. The following conclusions were reached in the ISMICS consensus statement:

- OPCABG should be considered a safe alternative to conventional CABG with respect to mortality in patients undergoing surgical myocardial revascularization. With the appropriate use of modern stabilizers and heart positioning devices and adequate surgeon experience, similar completeness of revascularization and graft patency can be achieved with OPCABG.
- OPCABG can be recommended to reduce perioperative morbidity. It also can be recommended to minimize midterm neurocognitive dysfunction, although no long-term benefit has been demonstrated.
- OPCABG should be considered equivalent to conventional CABG for quality of life. There does appear to be a decrease in resource utilization with decreased duration of ventilation, ICU, and hospital stay with off-pump surgery.
- OPCABG should be considered specifically in high-risk patients undergoing surgical revascularization and in patients with specifically identified risk factors to reduce perioperative mortality, morbidity, and resource utilization.

The percentage of patients undergoing OPCABG continues to remain static at 20 to 25%. Advocates continue to feel

strongly that significant benefit is afforded patients. Other practitioners feel just as strongly about conventional CABG. The strongest evidence of benefit appears to be in patients at highest risk for complications. The data forthcoming in the foreseeable future are unlikely to shed further light on the extensive body of literature that has accumulated over the past decade.

CHAPTER 24

Myocardial Revascularization with Carotid Artery Disease

Cary W. Akins • Richard P. Cambria

Next to operative mortality, permanent stroke is the most dreaded complication of myocardial revascularization not only because of the devastating consequences to the patient but also because of the increased cost of hospitalization and posthospital care. Perioperative stroke following coronary bypass grafting (CBG) is of increasing concern because the average age of coronary bypass patients continues to rise and with it the risk of stroke. This chapter will investigate the relationship of carotid artery disease to perioperative neurologic complications following myocardial revascularization and evaluate treatment options for dealing with severe concomitant carotid and coronary artery disease (CAD).

PERIOPERATIVE STROKE

Incidence of Perioperative Stroke

The risk of stroke coincident with CBG is well defined. In 1986, Gardner and colleagues[1] found the risk of stroke to be a direct function of patient age. Patients younger than 45 years of age had a stroke rate of 0.2%, which rose to 3.0% for patients in their 60s and to 8.0% for patients older than age 75. Other risk factors associated with stroke were preexisting cerebrovascular disease, ascending aortic atherosclerosis, long cardiopulmonary bypass time, and perioperative hypotension.

Tuman and colleagues[2] in 1992 investigated the effect of age on cardiac performance and neurologic injury in coronary bypass patients. Whereas the rates of low cardiac output and myocardial infarction (MI) were constant as patient age increased, the incidence of neurologic damage rose exponentially after age 65. The stroke rate rose from 0.9% for patients younger than 65 years to 8.9% for patients older than age 75.

To place the problem of the increasing age of coronary bypass patients into a more contemporary context, at our institution the mean age of coronary artery bypass (CAB) patients rose from 56 years in 1980 to over 68 years in 2001. In addition, in 1980 only 6% of patients were age 70 or older, whereas by 2001 over 45% were age 70 or older, and 13% were age 80 or older.

In 1995, John and colleagues[3] reported a stroke rate of 1.4% for 19,224 coronary bypass patients from the New York State Cardiac Surgical Database. Multivariable predictors of stroke included aortic calcification, renal failure, prior stroke, smoking, carotid artery disease, age, peripheral vascular disease, and diabetes. In their review of 10,860 patients having primary myocardial revascularization, Puskas and colleagues[4] noted that stroke occurred in 2.2%. Multivariable predictors of stroke were age, previous transient ischemic attack, and carotid bruits.

Cost of Perioperative Stroke

Puskas and colleagues[4] also found that perioperative stroke was associated with significantly more in-hospital morbidity, longer length of stay, and almost twice the hospital cost. Patients who suffered a perioperative stroke had a 23% hospital mortality rate. Roach and colleagues[5] noted a 21% mortality rate for patients suffering a perioperative stroke following coronary artery bypass grafting (CABG) with a mean hospital stay of 25 days among survivors.

Causes of Perioperative Stroke

Possible causes of perioperative neurologic injury are listed in Table 24-1. The most common cause of perioperative stroke is atherosclerotic or thrombotic emboli from the heart or major vessels. Intracardiac emboli can arise from mural thrombus secondary to MI, left atrial thrombus associated with valvular disease or atrial fibrillation, or suture lines in the aorta or left side of the heart. Catheters in the left side of the heart also can be a source of perioperative emboli. Less

Table 24–1.

Potential Causes of Perioperative Neurologic Injury During Coronary Artery Bypass Grafting

Vascular occlusion, usually embolic
Heart
Aorta
Innominate, carotid, or vertebral arteries
Low-flow phenomenon
Insufficient perfusion pressure on cardiopulmonary bypass
Poor collateral circulation
Vascular spasm
Intracranial hemorrhage

commonly, entrapped air may cause neurologic events, although rarely focal deficits.

The aorta is also a possible source of emboli. Cannulation of the ascending aorta for bypass, aortic occlusion clamps, and intra-aortic cardioplegia delivery devices may dislodge existing atherosclerotic material from the aorta. Wareing and colleagues[6] found aortic atherosclerosis to be a risk factor for perioperative stroke. Intraoperative echocardiography of the ascending aorta to identify atherosclerosis and the subsequent alteration of operative techniques to address identified problems improved the stroke risk in their patients.

Embolism from atherosclerotic carotid bifurcation disease is a well-defined cause of perioperative neurologic injury. Carotid plaque morphology has an important impact on the stroke risk of patients with carotid stenosis. A companion study to the North American Symptomatic Carotid Endarterectomy Trial found that plaque ulceration was a significant incremental risk factor for stroke across all degrees of carotid stenosis.[7]

Many studies list flow-limiting carotid stenosis as a risk factor for perioperative stroke, but whether the carotid lesion is an etiologic factor or only a nonspecific marker of overall risk is unclear.[1,8–10] The Buffalo Cardiac Cerebral Study Group found that while carotid stenosis predicted increased risk of perioperative stroke and death, most strokes occurred over 24 hours after the myocardial revascularization, and the anatomic distribution of the strokes did not correlate well with the site of the carotid lesion.[10,11]

Neurologic injury can result from inadequate blood flow on cardiopulmonary bypass. Adequate perfusion pressure on bypass has been verified by Schwartz and colleagues,[12] who found that cerebral blood flow depends on arterial perfusion pressures, not on cardiopulmonary bypass flow rates. Low cerebral blood flow occurred with perfusion pressures of less than 60 mm Hg and was not influenced by the pump flow rate. Adequate perfusion pressure is very important in the presence of carotid stenosis, particularly with internal carotid occlusion.[8] When there is occlusion of carotid or intracerebral arteries, brain blood flow depends on collateral circulation, which, in turn, depends on perfusion pressure. Whether carotid or intracerebral vascular spasm can contribute to neurologic injury is unknown.

Finally, intracranial hemorrhage can lead to neurologic injury following cardiopulmonary bypass, but the fact that this is truly rare is surprising, given that patients are fully anticoagulated for cardiopulmonary bypass. In our institution, where computed tomographic (CT) scanning is routine to evaluate suspected perioperative stroke to guide the use of heparin, the finding of primary intracerebral bleeding is extraordinarily uncommon.

Of all the potential causes of perioperative neurologic injury listed in Table 24-1, carotid stenosis is the one situation about which the surgeon routinely can take action to remove the pathology. Because carotid stenosis is a significant risk factor for perioperative stroke, the need to define carotid disease prior to coronary artery grafting becomes obvious. The logical extension that surgical correction of carotid stenosis can decrease the risk of stroke has been the basis of our approach, and that of others, for many years. While level I evidence to support this approach does not exist, the safety of the combined operative approach has been verified, as will be discussed.

Relationship of Carotid Stenosis to Perioperative Stroke

Early studies relating the presence of carotid stenosis to perioperative stroke used auscultatory evidence of carotid disease as a surrogate for carotid stenosis. In 1988, Reed and colleagues[13] from our institution documented a 3.9-fold increase in the odds ratio for stroke in the presence of a carotid bruit.

Yet carotid bruits are reliable indicators of neither the presence nor degree of carotid stenosis. Sauve and colleagues[14] found poor correlation between carotid bruits and the degree of carotid stenosis. Indeed, as carotid lesions progress to high degrees of stenosis, carotid bruits may become inaudible. Despite these limitations, auscultation for carotid bruits remains a common mode of detecting carotid stenosis, particularly in asymptomatic patients.

Currently, Doppler ultrasound–based noninvasive studies are the initially applied and often definitive (and sufficient) diagnostic testing modality for carotid stenosis. While quality control is essential with noninvasive testing, verification of its accuracy has been demonstrated many times.[15,16]

Brener and colleagues[8] studied 4047 cardiac surgical patients and found a 9.2% rate of stroke or transient ischemic attack in patients with asymptomatic carotid stenosis, significantly greater than the 1.3% rate in patients with no carotid stenosis.

Faggioli and colleagues[17] in 1990 reported that routine carotid noninvasive testing in CAB patients with no ischemic

neurologic symptoms yielded an odds ratio for stroke of 9.9 with greater than 75% carotid stenosis. In patients over age 60 with greater than 75% carotid stenosis, the stroke rate was 15 versus 0.6% for patients of the same age with no carotid disease. Perioperative strokes occurred in 4 (14.3%) of 28 patients who had greater than 75% carotid stenosis who did not have concomitant carotid endarterectomy compared with no strokes in the 19 patients with greater than 75% carotid stenosis who had a prophylactic carotid endarterectomy with their CABG.

In 1992, Berens and colleagues,[18] using routine carotid duplex scanning for cardiac surgical patients 65 years of age or older, found that the risk of stroke was 2.5% for carotid stenoses greater than 50%, 7.6% for carotid stenoses greater than 50%, 10.9% for carotid stenoses greater than 80%, and 10.9% for unilateral carotid artery occlusion.

Thus, adequate evidence exists that significant carotid artery stenosis is an important incremental risk factor for the development of perioperative neurologic injury following CABG. In addition, the study by Faggioli and colleagues[17] suggests that carotid endarterectomy performed with CABG yields a lower stroke rate.

Mechanism of Perioperative Stroke with Carotid Stenosis

How carotid stenoses cause perioperative strokes is not well understood, especially since patients are fully anticoagulated on cardiopulmonary bypass. Perioperative strokes may result from emboli from the carotid plaque possibly due to dynamic plaque events. Loss of pulsatile perfusion or an inadequate perfusion pressure on bypass may lead to diminished flow distal to a significant stenosis, resulting in a watershed stroke. However, Reed and colleagues[13] and Ricotta and colleagues[10] found that over one-half of strokes occur after the immediate postoperative period. Such delayed strokes in patients with uncorrected carotid stenoses may be related to the prothrombotic milieu that occurs in the early days after cardiopulmonary bypass, potentially causing destabilization of a previously asymptomatic carotid lesion.

Relationship of Uncorrected Carotid Stenosis to Late Stroke

In 1985, Barnes and colleagues[19] assessed the late risk of untreated asymptomatic carotid stenosis in 65 patients who had cardiovascular operations, of whom 40 had CABG. At mean follow-up of only 22 months, 10% of coronary bypass patients had died, and 17.5% had suffered a stroke. Noninvasive testing revealed progression of the carotid artery disease in one-half the patients within 4 years. Contemporary randomized trials of surgery versus medical therapy for significant carotid stenosis have defined the late risk of carotid-related stroke in medically treated patients. In the landmark Asymptomatic Carotid Surgery Trial, actuarial risk of stroke at 5 years was 12% in medically treated patients.[20]

CAROTID STENOSIS IN CORONARY ARTERY BYPASS PATIENTS

Incidence of Carotid Stenosis in Coronary Artery Bypass Patients

In 1977, Mehigan and colleagues,[21] using noninvasive testing in 874 patients prior to coronary artery grafting, found a 6% incidence of significant extracranial cerebrovascular disease. Ivey and colleagues[22] reported that routine ultrasonic duplex scanning for a history of neurologic events or cervical bruits in 1035 patients having isolated CABG revealed significant carotid artery stenosis in 86 patients (8.3%). Faggioli and colleagues[17] evaluated 539 neurologically asymptomatic CAB patients using noninvasive methods and found that 8.7% had a carotid stenosis greater than 75%. The rate rose from 3.8% for patients younger than age 60 to 11.3% for patients over age 60. Berens and colleagues,[18] using routine carotid artery scanning in 1087 candidates for cardiac surgery who were 65 years of age or older (91% with coronary disease), found that 186 (17.0%) had a greater than 50% carotid stenosis and that 65 (5.9%) had a greater than 80% carotid stenosis. Predictors of carotid artery disease were female gender, peripheral vascular disease, history of transient ischemic attacks (TIAs) or stroke, smoking history, and left main CAD. D'Agostino and colleagues,[23] using noninvasive carotid artery testing in 1279 CABG candidates, found that 262 (20.5%) had greater than 50% stenosis in at least one carotid artery and that 23 (1.8%) had bilateral stenoses greater than 80%. Significant multivariable predictors of carotid artery disease were age, diabetes, female sex, left main CAD, prior stroke, peripheral vascular disease, and smoking.

Diagnosis of Carotid Artery Disease

Physical examination

Palpation of a carotid artery provides little information about carotid stenosis, except for the correlation of a weak common carotid pulse with a very proximal flow-limiting stenosis, and theoretically can dislodge thrombus or embolic debris. As noted earlier, auscultation of carotid bruits cannot reveal the degree of carotid stenosis.

Essentials of noninvasive testing

Ultrasound-based Doppler interrogation for carotid stenosis exploits the Doppler effect; namely, the reflected or altered frequency of an ultrasound wave is shifted in proportion to the velocities of the sampled, flowing blood, which are increased in regions of significant arterial stenosis.

Current carotid noninvasive studies use several modalities combined into what is called *triplex imaging*. These include B-mode imaging to localize the bifurcation and characterize plaque morphology. Sophisticated high-resolution scanning is available for detailed plaque characterization, but this is largely an investigational tool and not a component of routine testing. Pulsed, ranged-gated Doppler is used to interrogate the common, internal, and external carotid arteries and establish the direction of vertebral artery flow in its cervical portion. Vertebral artery origins generally are obscured by bony structures. Doppler interrogation produces two data sets—first is Doppler-shifted flow velocities in regions of interest, and second is spectral analysis of turbulent flow, which lends a qualitative determination of stenosis severity. Doppler samples must be obtained in the tightest portion of the stenosis for accuracy.

Derived Doppler velocities include peak systolic velocity (PSV), end-diastolic velocity (EDV), and the ratio between the PSV in the internal carotid artery and in the proximal common carotid artery (ICA/CCA ratio). The derived ratio corrects for baseline variations in hemodynamics, such as cardiac output and increased overall flows, that might be noted in contralateral internal carotid occlusion. PSV is the single most important criterion, followed by the ICA/CCA ratio. EDV is helpful in discriminating severe versus "very severe" lesions. An ICA/CCA ratio of more than 4.0 equates to a greater than 70% diameter stenosis, the general threshold for a flow-reducing lesion at basal conditions according to the physics of critical arterial stenosis.

Supplementing direct Doppler interrogation are a number of indirect testing methods that can add additional information concerning the hemodynamic significance of the lesion and/or the status of intracranial collateral blood flow. Periorbital directional Doppler insonation of ophthalmic arteries and transcranial Doppler (TCD) are the principal indirect testing modalities; neither is applied routinely. Selective use, in particular of TCD, can provide helpful information on such variables as tandem lesions in the carotid siphon or middle cerebral stem, direction and adequacy of collateral flow through the circle of Willis, and intraprocedural monitoring.

Some general comments about the efficacy of ultrasound-based carotid noninvasive tests are in order because many vascular surgeons proceed to carotid endarterectomy based solely on these preoperative studies.[16] Surgeons must be familiar with the specifics of noninvasive diagnostic criteria, and laboratories must have quality-control documentation of accuracy. Thorough knowledge of the translation of ultrasound-derived data to corresponding degrees of internal carotid artery stenosis is necessary. This is not a trivial consideration because the original Doppler velocity diagnostic criteria considered stenosis measurements at the carotid bulb (E method), whereas randomized trial data consider stenosis percentage referenced to the diameter of the normal distal internal carotid artery (N method).[24] While complete coverage of these important diagnostic caveats is beyond the scope of this chapter, comprehensive reviews are available.[25]

Indications for noninvasive testing

Current indications for screening patients for carotid artery disease prior to surgical myocardial revascularization include

1. An audible bruit in the neck
2. History of a prior stroke
3. History of transient ischemic attacks
4. Patients with severe peripheral vascular disease
5. Patients with a prior carotid endarterectomy
6. Elderly patients

All of these indications are self-explanatory except the last. Because the incidence of carotid stenosis rises dramatically in patients over age 65, there must be an age at which it becomes cost-effective to screen all patients for carotid disease. However, that age limit has not yet been determined. One would have to demonstrate the cost advantage of routine carotid endarterectomy versus that of strokes related to uncorrected carotid stenoses.

Role of carotid angiographic modalities

CATHETER-BASED CAROTID ANGIOGRAPHY: At our institution until the mid-1990s, symptomatic patients with an audible bruit or asymptomatic patients with a noninvasive test suggesting severe carotid stenosis had catheter-based carotid angiography. While catheter-based carotid angiography yields excellent detailed images of the carotid and intracranial vessels, angiography is expensive, requires potentially nephrotoxic contrast material, and is not without risks, including arterial dissection and stroke. Cholesterol embolization owing to catheter manipulation in a diseased aorta can cause emboli to other vascular distributions, especially renal and/or other visceral arteries. (Indeed, in the Asymptomatic Carotid Atherosclerosis Study, one-half of the 2.3% stroke risk with carotid endarterectomy was referable to mandated angiography.[26]) For these reasons, conventional carotid angiography had all but vanished from the practice of many vascular surgeons by the year 2000.[27] Ironically, current enthusiasm for carotid stenting has resurrected carotid angiography as a diagnostic and therapeutic tool.

MAGNETIC RESONANCE ANGIOGRAPHY: Great enthusiasm accompanied the introduction of magnetic resonance angiography (MRA) in the early 1990s to define carotid lesions because, compared with catheter-based angiography, it was noninvasive, lacked nephrotoxicity, and when used with diffusion-weighted brain imaging, yielded an extremely accurate map of the intracranial circulation. However, its limitations soon became obvious. These relate to the nature of the magnetic resonance vascular imaging, which relies on reflected magnetic pulses of flowing blood cells that vary as a function of flow turbulence. Since turbulent flow is characteristic of high-grade carotid stenoses, signal "dropout" in magnetic resonance imaging (MRI) is common. The literature verifies poor correlation of MRA with the precise degrees of stenosis. Indeed, MRA alone can overestimate carotid stenosis

severity. Thus, in a reversal of prior algorithms, we insist that stenosis severity information from MRA be verified by a duplex study.

COMPUTED TOMOGRAPHIC ANGIOGRAPHY: Computed tomographic angiography (CTA) is the noninvasive test of choice when supplemental information is required after duplex scanning. While CTA requires iodinated contrast material, it can provide excellent arterial mapping from the aortic arch to the intracranial vasculature, which can be important to both vascular and cardiac surgeons. Accurate assessment of residual lumen diameter within a carotid artery lesion is obtained from both axial and three-dimensional (3-D) reconstructed images, with the important limitation that such accuracy diminishes in highly calcified lesions.

Definition of Severe Carotid Artery Stenosis

The definition of severe carotid stenosis has changed as techniques used to investigate carotid artery disease have changed. Severe carotid stenosis by direct carotid angiography reduces the residual lumen diameter to less than 1.5 mm or by more than 70%. With MRA, severe stenosis causes signal dropout. The definition of severe stenosis with ultrasound-based scanning was presented earlier.

EFFICACY OF CAROTID ENDARTERECTOMY AS A TREATMENT FOR CAROTID STENOSIS

C. Miller Fisher's original description of the relationship of ipsilateral hemispheric stroke to internal carotid artery occlusion in 1951[28] was followed by Eastcott's description of surgical therapy for symptomatic carotid artery atherosclerosis in 1953.[29] Thereafter, carotid endarterectomy became popular for stroke prevention until publication of the negative results in the multinational EC/IC bypass trial[30] in the mid-1980s. A vocal segment of the neurology community decried the apparent lack of evidence verifying the efficacy of carotid endarterectomy in stroke prevention, which led to a series of large-scale, prospective, randomized trials comparing carotid endarterectomy with medical therapy. In summary, there is now Level I evidence verifying the efficacy of carotid endarterectomy for stroke prevention in both symptomatic and asymptomatic patients.

Carotid Endarterectomy for Symptomatic Carotid Stenosis

In 1986, Hertzer and colleagues[31] studied 211 patients with TIAs or strokes and a carotid stenosis greater than 50%, of whom 126 had medical treatment and 85 had carotid endarterectomy. Although there was no difference in survival between the two groups at a mean follow-up of 36 months, carotid endarterectomy yielded significantly better freedom from late stroke for patients with (1) a greater than 70% unilateral stenosis, (2) greater than 50% bilateral stenoses, and (3) a greater than 50% carotid stenosis in association with contralateral internal carotid artery occlusions. This study set the stage for several large-scale, randomized trials.

In 1991, the results of the randomized North American Symptomatic Carotid Endarterectomy Trial (NASCET) of medical treatment or carotid endarterectomy were reported.[24] All patients had either hemispheric retinal TIAs or nondisabling strokes within 120 days of entry into the trial and 70 to 99% stenosis in the symptomatic carotid artery. The actuarial risk of any ipsilateral stroke at 2 years was significantly lower at 9% in the 328 surgical patients versus 26% in the 331 medical patients. The data-safety monitoring committee halted further randomization given the widely disparate 18-month follow-up data. For major or fatal ipsilateral strokes, the risk was 2.5% for surgical patients versus 13.1% for medical patients ($p < .001$). When all strokes and deaths were included, carotid endarterectomy still was better than medical treatment. Subsequent follow-up studies from the NASCET investigators indicated that the benefit of carotid endarterectomy in symptomatic patients also extended to those with even moderate (50 to 69%) carotid artery lesions.[32]

Also in 1991, the Veterans Affairs Cooperative Study of symptomatic carotid stenosis reported its results of randomization of 189 men with stenoses greater than 50% to medical or surgical treatment.[33] After 1 year, there was a significant reduction in stroke or TIAs in the patients having carotid endarterectomy (7.7%) compared with medically treated patients (19.4%). The results were even more divergent for patients with a carotid stenosis greater than 70%.

The European Carotid Surgery Trial randomized 2518 patients with nondisabling stroke, TIA, or retinal infarction in conjunction with stenosis in the ipsilateral carotid artery to medical or surgical treatment.[34] For the 778 patients with severe stenoses of 70 to 99%, the cumulative risk of stroke at carotid endarterectomy of 7.5%, plus an additional late stroke rate at 3 years of 2.8%, was less than the 16.8% rate for medically treated patients. At 3 years, the cumulative risk of operative death, operative stroke, ipsilateral ischemic stroke, and any other stroke was 12.3% for the surgical cohort versus 21.9% for the medical group ($p < .01$). Finally, the risk of fatal or disabling ipsilateral stroke at 3 years was 6.0% for the carotid endarterectomy patients versus 11.0% for the medical control patients ($p < .05$).

Although the benefit of carotid endarterectomy in these studies was due in part to the high risk of stroke in medically treated patients, the results were significant even in an era when the 30-day combined stroke and death risk of carotid endarterectomy was about 7.5%. While the combined stroke and death risk with carotid endarterectomy is higher in symptomatic versus asymptomatic patients, the current combined risk is closer to 3 to 5%.[20,27,35,36]

Carotid Endarterectomy for Asymptomatic Carotid Stenosis

Hertzer's group studied operative and nonoperative treatment in 290 previously unoperated patients who had greater than 50% asymptomatic carotid stenoses.[37] During follow-up to 3 years, prophylactic carotid endarterectomy in 95 patients had a significantly reduced incidence of neurologic events compared with medical treatment in 195 patients ($p = .05$).

Data from Moneta and colleagues[38] indicate that carotid endarterectomy patients had a significantly lower stroke risk compared with the natural history of patients without intervention. This study also suggested that late coronary events were so frequent as to question the wisdom of intervention for the carotid artery lesion. Accordingly, a series of trials in asymptomatic patients were performed.

The Veterans Affairs Cooperative Study of asymptomatic carotid stenosis, defined as greater than 50% diameter reduction by angiography, randomized 444 men to medical or surgical treatment.[39] At a mean follow-up of 4 years, the combined incidence of ipsilateral neurologic events was 8.0% for the surgical patients versus 20.6% for the medical patients ($p < .001$). The difference in stroke alone between the two groups (8 versus 20%) did not achieve statistical significance because of the study's sample size, nor was there a significant difference when all strokes and deaths were analyzed. Excessive late mortality (about 40% at 4 years in both groups) was due largely to associated CAD. These mitigating factors limited definitive conclusions about the efficacy of carotid endarterectomy in asymptomatic patients in this trial.

In 1995, the results of the Asymptomatic Carotid Atherosclerosis Study of 1662 patients randomized to surgical or medical treatment were published.[26] At mean follow-up of 2.7 years, aggregate risk for ipsilateral stroke and any perioperative stroke or death for the surgical group was 5.1%, significantly lower than the rate of ipsilateral stroke of 11.0% for the medical group, a benefit limited to male patients. Critics suggested that the low combined stroke and death rate (2.3%) in the surgical patients was not representative of results across a broader spectrum of hospitals.

In 2004, the Asymptomatic Carotid Surgery Trial (ACST) contributed important data on the value of carotid endarterectomy for asymptomatic carotid stenosis.[20] Touted as the world's largest surgical trial from 126 hospitals in over 30 countries, the study randomized over 3000 patients to carotid endarterectomy or medical therapy, which included at least aspirin. Over 40% of randomized patients had over 3 years of follow-up. Risk of any stroke, any ipsilateral stroke, or any disabling stroke was halved in surgical patients, who had a perioperative combined stroke and death rate of about 3%. The time threshold to achieve statistical benefit, i.e., cancel perioperative morbidity, by actuarial analysis was 2 years, suggesting that patients selected for endarterectomy should have a life expectancy of greater than 2 years. Indeed, the only subgroup in which endarterectomy did not achieve statistical significance was in patients over 75 years of age.

In summary, Level I evidence supports the advantage of carotid endarterectomy over medical management for patients with severe asymptomatic carotid artery stenoses.

CAROTID STENTING

Following the success of percutaneous transluminal coronary angioplasty, particularly with adjunctive stenting, percutaneous interventionalists increasingly sought to treat carotid stenosis with angioplasty and stenting.[40–42] Technical aspects of the procedure to guard against procedure-related stroke dominated the first years of its evolution. Today, use of distal embolic protection devices potentially makes carotid stenting comparable with carotid endarterectomy in safety and efficacy.[43] Emerging reports (mostly from industry-sponsored trials) indicate that carotid stenting can produce equivalent outcomes to carotid endarterectomy.[44–47] In one large series, the 30-day combined stroke and death rate was 7.4%, and most strokes were minor.[48] Results improved with experience, and late stroke-free survival was comparable with that for carotid endarterectomy.

In 2004, the initial randomized trial of carotid endarterectomy versus stenting with routine embolic protection, designed as a "noninferiority" trial, i.e., insufficiently powered to detect superiority of one treatment, concluded that carotid stenting was not inferior to carotid endarterectomy in high-risk patients.[47] Study endpoints (composite death/stroke/MI at 30 days and 1 year) and the high 30-day combined stroke and death rate (5.7%) in asymptomatic patients limit the value of the data. While a number of trials of carotid stenting versus carotid endarterectomy in various patient subsets are underway, the recently published French carotid endarterectomy versus stenting study in patients with symptomatic, severe carotid stenosis indicated that stenting is associated with a 2.2-fold increased risk of stroke or death at 30 days compared with endarterectomy. The trial was halted by the data-safety monitoring committee after the randomization of 527 patients.[49] Furthermore, published evidence documents an increased periprocedural risk of stroke after carotid stenting in elderly patients.[50]

Scant data are available about carotid artery stenting versus endarterectomy in patients requiring CABG. Investigators from the Cleveland Clinic compared patients treated with either carotid artery stenting before or carotid endarterectomy with open-heart surgery. After propensity scoring, the authors found no significant differences in combined stroke/death/MI in the two approaches.[51]

MYOCARDIAL ISCHEMIC EVENTS IN PATIENTS AFTER CAROTID ENDARTERECTOMY

Although this chapter is focused primarily on managing CAB patients who have concomitant carotid artery disease,

some comment on the impact of CAD on short- and long-term risks of carotid endarterectomy patients is appropriate.

Incidence of Coronary Artery Disease in Carotid Endarterectomy Patients

Mackey and colleagues[52] found that 53% of carotid endarterectomy patients had evidence of CAD by clinical history or electrocardiographic studies. Using thallium exercise testing in 106 carotid endarterectomy patients, Urbinati and colleagues[53] found that 27 (25%) had significant defects on myocardial scanning. In 1985, the Cleveland Clinic reported the results of routine preoperative coronary angiography in 506 carotid endarterectomy patients.[54] Only 7% of patients had normal coronary arteries, and 28% had mild to moderate CAD. However, 30% had advanced but compensated disease, 28% had severe, correctable disease, and 7% had severe, inoperable CAD.

Risk of Myocardial Ischemic Events

Short-term risks

The impact of CAD on the short-term risks of carotid endarterectomy is well documented. In 1981, Hertzer and colleagues[55] reported that hospital mortality in 335 carotid endarterectomy patients was 1.8%, of which 60% of deaths were due to CAD. In the Mackey and colleagues study cited earlier, carotid endarterectomy patients with clinical CAD had an operative mortality of 1.5% and an MI rate of 4.3% compared with no mortality and an infarction rate of 0.5% for patients without CAD.[52] While the frequent coexistence of CAD with carotid artery disease is often invoked as the principal cause of short- and long-term morbidity in carotid endarterectomy patients, the risk of perioperative MI will vary with the risk profile of the cohort studied. For example, in the protected carotid artery stenting versus endarterectomy trial, 30-day non-Q-wave MI occurred in 6.6%.[47] In our cohort of over 2000 carotid endarterectomy patients, the perioperative MI rate was 1.2%.[27] A National Surgical Quality Improvement Program (NSQIP) database report of over 13,000 endarterectomy procedures had a perioperative MI rate of 1.4%,[56] similar to results from the ACST trial.[20] Clearly, improved care has lowered coronary ischemic risks during carotid endarterectomy.

Long-term risks

Mackey's study of carotid endarterectomy patients reported the 5- and 10-year survival rates of patients with CAD to be 68.6 and 44.9%, respectively, versus 86.4 and 72.3% for patients with no CAD.[52] When Urbinati and colleagues[53] followed their carotid endarterectomy patients, the 7-year freedom from all cardiac events was 51% for patients with silent myocardial ischemia compared with 98% for patients with normal thallium exercise testing.

In the Hertzer and colleagues study[55] of 209 patients with clinically suspected CAD, 5-year mortality rate for hospital survivors was 27%, and 37% of late deaths were due to MI. Actuarial survival at 11 years was significantly better for the patients with CAD who had bypass grafting. A later study from the same group of 329 carotid endarterectomy patients followed to 10 years confirmed that MI caused more late deaths (37%) than did stroke (15%).[57] Again, 10-year survival was significantly better for patients having CABG.

In our Massachusetts General Hospital cohort of over 2000 carotid endarterectomy patients treated between 1990 and 1999, 10-year actuarial survival was 45%. Among variables associated with increased late mortality, concomitant CAD [odds ratio (OR) 1.4; $p = .0002$] figured prominently.[27]

TIMING OF CAROTID AND CORONARY ARTERY SURGERY

If one accepts that (1) uncorrected carotid stenosis increases the risk of stroke for patients with severe carotid and CAD who have only isolated CABG, (2) carotid endarterectomy is the indicated treatment for severe symptomatic and asymptomatic carotid stenosis, (3) CAD increases the early and late risk of death for carotid endarterectomy patients, and (4) CABG is an indicated treatment for CAD, then the important question becomes not the indication for but the timing of the two operative procedures.

Staged Carotid and Coronary Artery Operations

One approach is to perform the carotid endarterectomy and CAB operations as staged procedures. By convention, doing the carotid endarterectomy before coronary bypass grafting is referred to as a *staged procedure,* whereas doing the CABG before the carotid artery operation is called a *reverse staged procedure.*

Most surgeons who advocate a sequential operative approach to patients with severe combined disease usually do the carotid endarterectomy first if the patient is not ischemic and is hemodynamically stable. Improvements in patient management, especially use of regional anesthesia, often can allow safe initial isolated carotid endarterectomy. Recent data from studies powered to detect an impact of regional anesthesia have verified that composite outcomes of stroke/death/ MI after carotid endarterectomy are reduced significantly with use of regional anesthesia.[56,58] However, other practical considerations, such as imminent need for the large doses of heparin required for cardiopulmonary bypass, airway and/or neck swelling, and the risk of perioperative coronary ischemic events, remain real issues.

For unstable cardiac patients, particularly those with asymptomatic carotid stenosis, some cardiac surgeons opt to

perform initial myocardial revascularization followed by an interval carotid endarterectomy. The principal risk with this approach is the potential for neurologic complications either during or shortly after the myocardial revascularization.

Currently, we advocate concomitant carotid and coronary artery operations for virtually all patients with severe combined disease. However, in patients with severe bilateral carotid stenosis, a staged approach may be appropriate, especially if the patient is stable cardiovascularly. We occasionally treat the more severe of the two carotid artery lesions with initial isolated endarterectomy, followed by combined CABG and endarterectomy of the other carotid artery within a few days. Use of a reversed staged approach, namely, doing one carotid endarterectomy with myocardial revascularization followed several days later by the other carotid endarterectomy, is rare because of an increased stroke risk with reversed staged procedures (to be discussed below).

Concomitant Carotid and Coronary Artery Operations

In 1972, Bernhard and colleagues[59] published the first report of successful combined carotid endarterectomy and CABG in 15 patients. Since then, numerous groups have published their results. The strategy of performing both operative procedures during one anesthetic is based on the premise that such an approach in patients with severe combined disease ought to minimize cardiac events that frequently complicate isolated carotid endarterectomy and neurologic events that complicate isolated CABG.

Daily and colleagues[60] reported that doing both operative procedures together is more cost-effective than a staged or reversed staged approach, which require two anesthetics and can incur the additional costs of two hospitalizations.

OPERATIVE TECHNIQUES FOR CONCOMITANT CAROTID AND CORONARY ARTERY OPERATIONS

Standard Approach

The usual operative technique for concomitant carotid endarterectomy and CABG has been to perform the carotid endarterectomy during harvesting of CAD conduits prior to cardiopulmonary bypass, the approach we use at our institution, where the carotid operation is performed by vascular surgeons as the cardiac surgical team harvests whatever saphenous vein or other conduits may be needed.

Technical components of carotid endarterectomy have evolved over time. Preoperative aspirin has been validated in large database studies.[61] We use routine electroencephalographic monitoring, selective shunting, and either eversion endarterectomy (presuming no need for a shunt) or patch closure. Simple primary closure is associated with a higher rate of restenosis.[62] After the carotid endarterectomy is completed, the neck incision is loosely approximated over a sponge. Final closure, usually over a plastic drain, is done after cardiopulmonary bypass is completed and heparinization is reversed.

Alternative Approaches

Minami and colleagues[63] reported using some perceived advantages of cardiopulmonary bypass, namely, heparinization, hypothermia, and hemodynamic control, to perform carotid endarterectomy in 116 patients while on bypass for CABG. Operative mortality was 1.7%, and total stroke risk was 4.3%. Weiss and colleagues[64] perform the carotid endarterectomy on bypass with systemic hypothermia to 20°C with the heart protected with cardioplegia. They had no neurologic events and one postoperative death in 23 patients. Theoretically, hypothermia on cardiopulmonary bypass provides an extra margin of ischemic protection for the brain during the carotid endarterectomy and avoids the need for intravascular shunting. The level of systemic hypothermia used has varied among surgical groups employing this approach.

Whether performing the carotid and coronary artery operations on cardiopulmonary bypass saves total operative time is not proven, but it prolongs aortic occlusion and cardiopulmonary bypass times, something most cardiac surgeons would prefer to avoid. A deeper level of hypothermia is not favored by most cardiac surgeons, particularly as the trend toward using lesser degrees of hypothermia has become more popular.

HIGHLIGHTS OF POSTOPERATIVE MANAGEMENT

In our institution, postoperative management of patients following concomitant carotid endarterectomy and CABG does not differ importantly from the management of patients having isolated myocardial revascularization. We believe that maintenance of a good coronary perfusion pressure and, by extension, good cerebral perfusion pressure in the early postoperative hours is beneficial. Early clearing of perioperative edema with diuresis seems to be efficacious.

The routine anticoagulation protocol for our myocardial revascularization patients, aspirin begun within 6 hours of completion of the operation, is adequate for patients who have either primary or saphenous vein patch closure of the carotid arterotomy. When a prosthetic patch is used, the patient has considerable residual disease higher in the carotid system, or contralateral carotid disease is uncorrected, especially if the plaque is ulcerated, some surgeons

prefer early anticoagulation with heparin, followed by long-term warfarin anticoagulation.

If a surgeon decides not to treat a severe carotid stenosis either with a staged approach or concomitant operation, the increased incidence of stroke in the early days after isolated myocardial revascularization seen with the reversed staged approach would seem to suggest that heparinization of the patient is appropriate once the acute bleeding risk of the CAB operation is past.

RESULTS OF STAGED AND CONCOMITANT CAROTID AND CORONARY ARTERY OPERATIONS

Early Results

Staged carotid and coronary artery operations

Several studies report the results of staged operations for concomitant carotid and CAD, but only one study randomized patients to concomitant or reversed staged operation. Hertzer and colleagues[65] published a study containing a randomized subgroup of patients with unstable coronary artery syndromes and incidental asymptomatic carotid stenosis. Over 5 years, these authors treated 275 patients with severe combined disease. Their criteria for carotid endarterectomy was symptomatic and/or severe (>70%) carotid artery disease. Only 24 (9%) of the patients had CAD that was stable enough to allow carotid endarterectomy prior to CABG. Of those 24 patients, 1 (4.2%) suffered a perioperative stroke after the carotid endarterectomy and died of an MI awaiting CABG. Symptomatic or severe bilateral carotid artery disease in 122 patients was treated with combined carotid and coronary artery operation with an operative mortality rate of 6.1% and a perioperative stroke rate of 7.1%.

The remaining 129 patients with unstable coronary artery symptoms and unilateral, asymptomatic, severe carotid stenoses were randomized to either a combined operation or a reversed staged operation. Patients having concomitant carotid and coronary artery operations had a mortality rate of 4.2% versus a combined rate of 5.3% for the two operations in the staged patients. The incidence of stroke in the concomitant operations was 2.8%, which was significantly lower than the 14% risk of the reversed staged operations (6.9% during the isolated CABG and 7.5% during the delayed isolated carotid endarterectomy). This randomized study emphasizes the advantage of concomitant operations over reversed staged procedures.

In 1999, Borger and colleagues[66] performed a meta-analysis of nonrandomized observational studies published from centers that documented results with both staged and concomitant operations. They identified a trend toward increased risk of stroke and death with combined operations. The results of this study need to be viewed with caution for several reasons. First, using meta-analysis to compare observational and nonrandomized studies limits its statistical power. Second, in most series, unstable patients had combined operations and stable patients had staged procedures. Third, the criteria for entry into these studies was operations completed, not intention to treat. One cannot be sure if some patients for whom a staged approach was planned were not studied because the second operation was never performed due to a poor result from the first procedure.

Concomitant carotid and coronary artery operations

Since the late 1970s, some surgeons in our group have had an aggressive approach to patients with combined carotid and CAD, using concomitant operative repair as the standard approach. Staged operations were reserved for the few patients with very stable CAD. Our first report in 1989 in a small group of patients suggested that combined operation was safe (2% stroke or death risk). That study was among the first to document the disparate cardiac risk among patients having combined operations versus patients having isolated CABG.[67]

In 1995 we published our results of combined operations between 1979 and 1993 in the first 200 consecutive patients.[68] Hospital mortality was 3.5%, MI 2.5%, and perioperative stroke 4.0%.

More recently, we published results of concomitant operation between 1979 and 2001 in 500 patients, with that approach being used in virtually all patients with combined disease since our second report.[69] Mean patient age was 69 years, about 6 years older than that for all CAB patients during that time period. Three-quarters of the patients had unstable angina pectoris, and 53% had prior MI. Although the distribution of single-, double-, and triple-vessel disease was as expected at 4%, 21%, and 75%, respectively, 42% of patients had significant left main CAD. Of the 500 patients, 329 (66%) were neurologically asymptomatic, 21% had transient ischemic attacks, and 13% had a prior stroke. Unilateral severe carotid stenosis was found in 336 patients (67%); 32% had disease in the contralateral carotid artery.

Urgent or emergency operations were required in 54% of patients; 3% were on the intra-aortic balloon preoperatively. The average number of grafts per patient was 3.7. While only 50% of the first 200 patients received at least one mammary artery graft, 90% of the last 300 patients received a mammary artery graft.

Hospital mortality was 3.6%, MI was 2.0%, and stroke occurred in 4.6%. Of the 23 strokes, 12 were ipsilateral to the carotid endarterectomy and 11 contralateral or bilateral, suggesting that, in our experience, concomitant carotid endarterectomy and CABG have neutralized the impact of carotid stenosis as a risk factor for stroke during surgical myocardial revascularization.

Significant multivariate predictors of hospital death were preoperative TIAs, preoperative MI, and nonelective

operation. Peripheral vascular disease predicted postoperative stroke. Significant predictors of prolonged postoperative hospital stay were failure to use a mammary artery graft, perioperative stroke, and advanced age.

Vermeulen and colleagues[70] found that the only significant multivariate predictor of hospital death in 230 combined operations was left main CAD. Postoperative neurologic events were predicted by severe left ventricular dysfunction and preoperative neurologic events, either stroke or TIAs.

Several series of concomitant carotid endarterectomy and CABG published since 1985 are noted in Table 24-2. Our results stand in contrast to some others, particularly reports using administrative data. Brown reported a 17.7% stroke risk for combined operations in Medicare patients in Midwestern states.[71] A Canadian study found that the combined risk of stroke and death for CABG alone was 4.9% versus 13% for combined carotid and coronary artery operations.[72] However, data available from the New York State Registry indicate that such results can be explained largely by the disparate cardiac risk profiles of the two patient groups. Ricotta and colleagues[9] used propensity scoring to match risk-factor profiling and found no difference in combined stroke and death risk for the two operations after case-control matching.

Late Results

Follow-up in our series of combined operations revealed the following 10-year actuarial freedoms from late events: death, 43%; MI, 87%; percutaneous transluminal coronary angioplasty, 92%; reoperative myocardial revascularization, 96%; total stroke, 85%; and ipsilateral stroke, 90%.[69]

Vermeulen and colleagues[70] found their 10-year actuarial freedom from cardiac events to be 50%, from neurologic events to be 81%, and from all events to be 41%. The only significant multivariate predictors of late cardiac mortality were advanced age and severe left ventricular dysfunction.

In a study of 127 combined carotid and coronary artery operations, Rizzo and colleagues[73] reported a 5-year survival rate of 70%, freedom from MI of 84%, and freedom from stroke of 88%. Survival was worse for patients with low ejection fractions. Late strokes were fewer in patients who were

Table 24–2.

Series of Combined Carotid and Coronary Operations with More than 100 Patients

Reference	Year	Patients (no.)	Mean age (y)	Deaths (%)	MI (%)	Stroke (%)
Dunn[74]	1986	130	60	6 (4.6)	—	13 (10.0)

Akins[69]	2005	500	69	18 (3.6)	10 (2.0)	23 (4.6)

neurologically asymptomatic preoperatively, more common in patients who were transiently symptomatic, and most frequent in patients with prior stroke.

CONCLUSION

The risk of perioperative stroke following myocardial revascularization rises with the increasing age of CABG patients, and increasing age is accompanied by an increased incidence of carotid artery disease. Several studies have defined severe, uncorrected carotid stenosis as a major risk factor for perioperative stroke. Therefore, in addition to patients with audible carotid bruits or a history of ischemic neurologic events, patients who are 65 years of age or older ought to have noninvasive carotid artery evaluation prior to CABG. Also, randomized trials have established the safety and efficacy of carotid endarterectomy as the most appropriate treatment for both symptomatic and asymptomatic severe carotid stenosis. Another randomized study has demonstrated the advantage of concomitant carotid endarterectomy and CABG over reversed staged operations. Thus, we advocate combined carotid and coronary artery operations for virtually all patients with severe concomitant coronary and carotid artery disease, which on its own merits would require treatment.

CHAPTER 25

Myocardial Revascularization after Acute Myocardial Infarction

Isaac George • Mehmet C. Oz

The ability of surgical interventions to minimize myocardial loss following myocardial infarction has advanced dramatically over the past two decades. Acute myocardial infarction still afflicts approximately 1.5 million individuals each year in the United States,[1] and 30% of these patients die before reaching the hospital, while 5% die during hospital admission.[1] Prompt medical attention, including transport to the hospital, diagnosis, and treatment of the myocardial infarction, is critical to patient survival. Since 1989, the death rate due to acute myocardial infarctions has declined 24%, while the actual number of deaths declined only 7%.[2] Over the last 40 years, especially during the 1980s, new pharmacologic agents, interventional cardiology procedures, and coronary artery bypass surgical techniques have advanced and have led to a decrease in the overall morbidity and mortality associated with acute myocardial infarction.[3,4] Despite this overall improvement, mechanical and electrical complications such as cardiogenic shock, rupture of the ventricular septum or free wall, acute mitral regurgitation, pericarditis, tamponade, and arrhythmias challenge the medical community caring for patients presenting with acute myocardial infarction on a daily basis.[3,4] Of these complications, cardiogenic shock complicating acute myocardial infarctions has the most significant impact on in-hospital mortality and long-term survival. The loss of more than 40% of functioning left ventricular mass and its accompanying systemic inflammatory response are major causes of cardiogenic shock and are determined by the degree of preinfarction ventricular dysfunction, the size of the infarcted vessel, and pathologic level of inflammatory mediators.[5–7] Restoration of blood flow to the threatened myocardium offers the best chance of survival following acute coronary occlusion, but the means and timing of revascularization continue to be a highly debated and studied topic. Thrombolytics, percutaneous transluminal coronary angioplasty (PTCA), intracoronary stenting, and coronary artery bypass graft (CABG) surgery have decreased the mortality associated with acute myocardial infarctions. Advances in myocardial preservation and mechanical support lead the surgical armamentarium in the treatment of acute myocardial infarctions.

PATHOGENESIS OF ACUTE OCCLUSION

Myocardial ischemia due to coronary occlusion for as little as 60 seconds causes ischemic zone changes from a state of active systolic shortening to one of passive systolic lengthening.[8] Occlusions for less than 20 minutes usually cause reversible cellular damage and depressed function with subsequent myocardial stunning. Furthermore, reperfusion of the infarct leads to variable amounts of salvageable myocardium. After 40 minutes of ischemia followed by reperfusion, 60 to 70% of the ultimate infarct is salvageable, but this decreases dramatically to 10% after 3 hours of ischemia.[9,10] Animal model evidence has also demonstrated that 6 hours of regional ischemia produces extensive transmural necrosis.[11] The exact timing in humans is even more difficult to analyze because of collateral flow, which is a major determinant of myocardial necrosis in the area at risk in humans.[10] The collateral blood supply is extremely variable, especially in patients with long-standing coronary disease. However, collateral flow is jeopardized with arrhythmias, hypotension, or the rise of left ventricular end-diastolic pressure above tissue capillary pressure.[9] Thus loss of collateral flow to the infarct area may lead to the cellular death of salvageable myocardium. Control of blood pressure and prevention of arrhythmias are vital during this immediate time after infarction.

Many clinical trials have shown the beneficial effects of early reperfusion within 24 hours after acute myocardial infarction.[12] Although benefits of late reperfusion beyond 36 hours, particularly in asymptomatic patients, have yet to be shown in large clinical studies, advocates for aggressive management believe that reperfusion is warranted to

preserve the border areas that may be underperfused during the early days after an infarction. While some of these patients may develop objective evidence of ischemia, the clinical assumption that a hypotensive patient with a suddenly dilated and pressure-overloaded ventricle is prone to losing more muscle mass in border zones of the infarct is reasonable. This is true even in patients who have had complete revascularization. Conservative measures, such as nitroglycerin and intra-aortic balloon pumps, have demonstrated their efficacy in this population of patients without clearly salvageable myocardium by improving coronary blood supply and reducing the work demand of the left ventricle. More radical approaches such as insertion of a left ventricular assist device (LVAD) have been advocated as well. At our center, placement of an LVAD into this group of patients, allowing complete pressure-volume unloading, has occasionally resulted in sufficient improved ventricular function to allow device explantation months later.[13,14]

Table 25-1 outlines the effects of anatomic, physiologic, and therapeutic variables on the evolution of final infarct size. Anatomically, the location of the coronary obstructive lesion, additional diseased vessels, and the presence of collateral flow will determine the extent of early injury, especially for borderline areas. However, ventricular remodeling of the infarct has important consequences influencing ventricular function after myocardial infarction.[15,16] Thus appropriate and aggressive invasive therapies such as PTCA, intra-aortic balloon pump use, CABG, controlled reperfusion, and LVAD insertion can mitigate myocardial injury and salvage borderline areas, even if the interventions occur many hours or days after the initial infarction, particularly in patients with ongoing ischemia.

Reperfusion injury also contributes to myocardial damage as free oxygen radicals are released and destroy endothelial cells and produce interstitial edema. The timing and management of reperfusion effects on myocardial damage may have an impact on both survival and functional recovery of individuals following acute myocardial infarction.[17] Some centers have argued convincingly that controlled reperfusion with specially designed perfusate and a decompressed, energy-conserving ventricle resting on cardiopulmonary bypass is the best means to preserve muscle mass.[18]

CARDIOGENIC SHOCK

Definition

Cardiogenic shock is defined clinically as a systolic blood pressure below 80 mm Hg in the absence of hypovolemia, peripheral vasoconstriction with cold extremities, changes in mental status, and urine output of less than 20 mL/h. Hemodynamic parameters for cardiogenic shock include cardiac index less than 1.8 L/min/m^2, stroke volume index less than 20 mL/m^2, mean pulmonary capillary wedge pressure greater than 18 mm Hg, tachycardia, and a systemic vascular resistance of over 2400 dyn(sec/cm^5). These patients are defined as type IV by the Killip classification, a widely used system to classify myocardial infarctions.[19]

Prevalence

Shock is the most common cause of in-hospital mortality following myocardial infarction.[20] The in-hospital mortality associated with cardiogenic shock has remained unchanged at approximately 80% despite the development of new treatment modalities.[20] Cardiogenic shock occurs in 2.4 to 12.0% of patients with acute myocardial infarction.[21] Since 1975, the incidence of cardiogenic shock complicating acute myocardial infarctions has remained constant at 7.5%, ranging between 5 and 15% (Fig. 25-1).[20] The progressive reduction in time delay from symptom onset to treatment may account for these constant figures. Previously, patients with excessive time delays would have died before reaching the hospital or soon thereafter, as it is known that treatment delays increase 1-year mortality incrementally (Fig. 25-2).[22] There was also a decrease in the incidence of out-of-hospital deaths due to coronary disease between 1975 and 1988.[20] The key to success in patients in shock is early intervention and revascularization. In a prospective randomized study, Hochman and

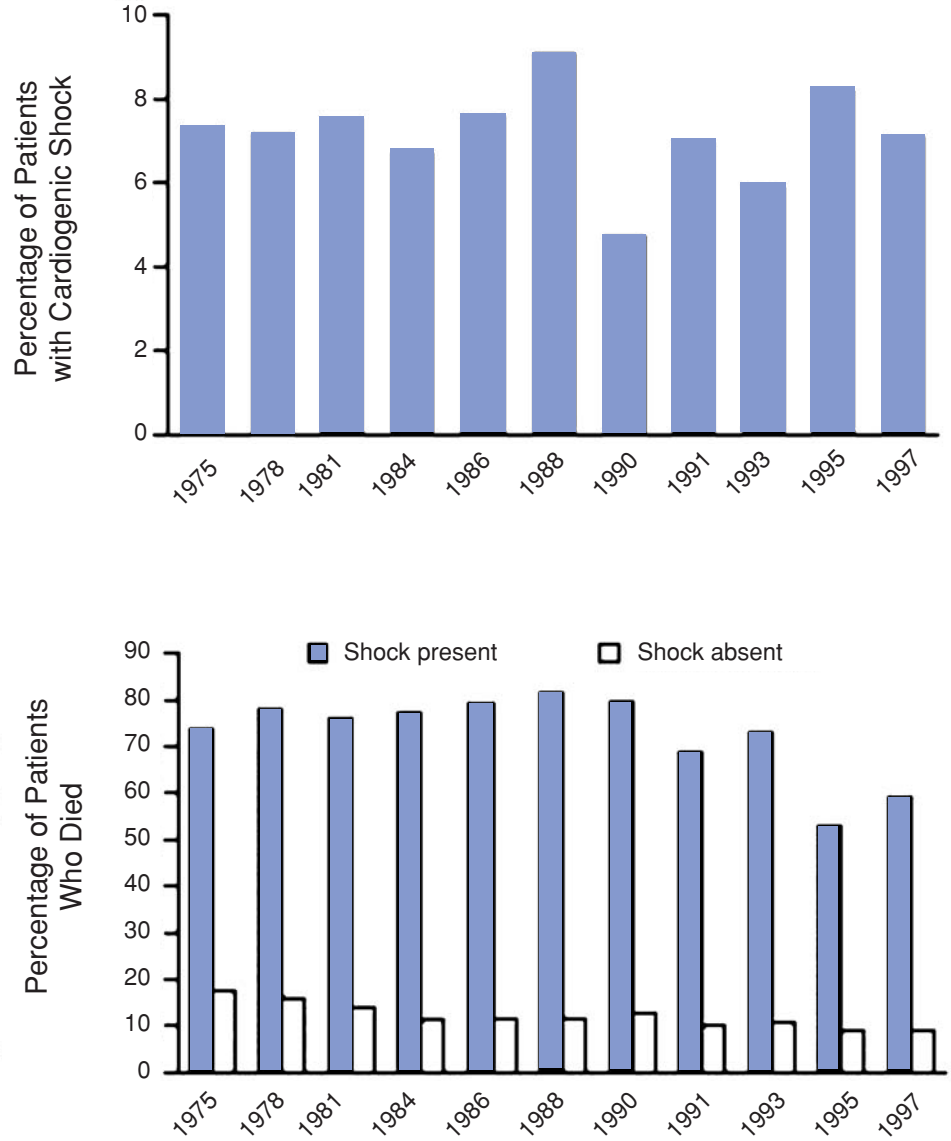

Figure 25-1. Trends in cardiogenic shock and survival based on presence or absence of shock. (*Reproduced with permission from Goldberg R, Samad N, Yarzebski J, et al: Temporal trends in cardiogenic shock complicating acute myocardial infarction. N Engl J Med 1999; 340:1162.*)

associates showed that revascularization within 6 hours of diagnosis of cardiogenic shock confers survival benefits, particularly in those patients under 75 years of age.[23,24] Use of mechanical circulatory support also may play a role by resting stunned myocardium to allow its recovery and to prevent the irreversible end-organ injury that may result from prolonged shock.[13,14]

Pathophysiology and Infarct Size

Shock is directly related to the extent of the myocardium involved, and infarctions resulting in loss of at least 40% of the left ventricle have been found on autopsy in patients with cardiogenic shock.[5,6,25] Autopsy findings also revealed marginal extension of the recent infarct and focal areas of necrosis in patients with cardiogenic shock.[5] Extensive three-vessel disease is usually found in individuals with cardiogenic shock, and extension of the infarct is an important determinant in those individuals.[5,6,25] Limiting the size of the infarct and its extension is one of the key therapeutic interventions in patients with myocardial infarction. By following creatine phosphokinase levels, Gutovitz and colleagues[26] showed that the progression/extension of myocardial damage results in cardiogenic shock. Patients who develop shock have higher peak values. New insights into the mechanisms underlying cardiogenic shock have been gained from recent clinical studies/registries (e.g., SHould we emergently revascularize Occluded Coronaries for cardiogenic Shock [SHOCK]) that also highlight the contribution of the pathologic systemic inflammatory response after myocardial

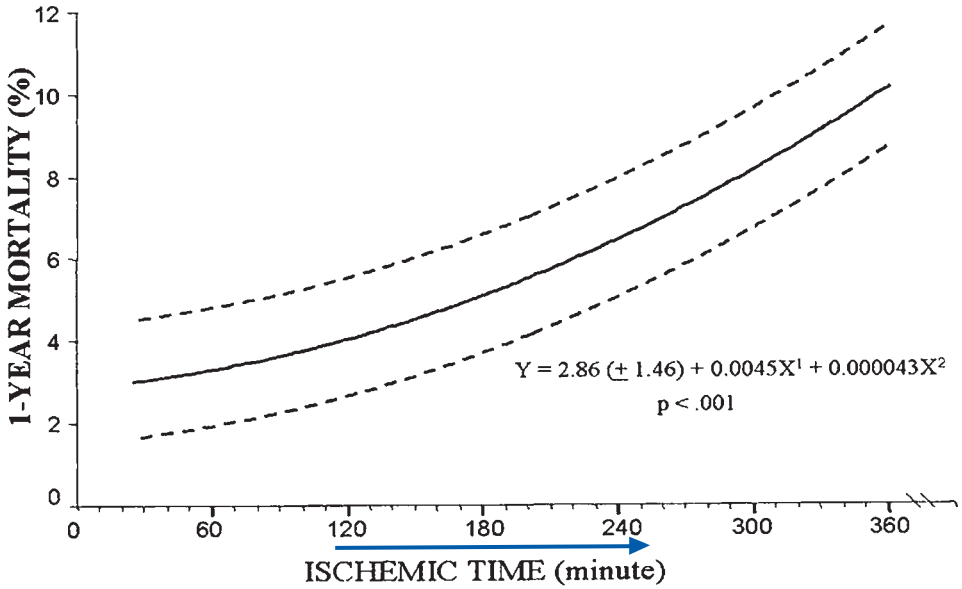

Figure 25-2. Relationship between time to treatment and 1-year mortality, as a continuous function, was assessed with a quadratic regression model. Circulation 2004; 109:1223.*)

infarction.[7] Noting that many patients in cardiogenic shock possessed only moderately depressed ejection fraction (30%) and systemic vascular resistance was within the normal range (on average), investigators in the SHOCK trial found evidence of an elevated inflammatory response in some patients (fever, leukocytosis, and decreased systemic vascular resistance), which may have contributed to the clinical syndrome of shock.[23,24] In addition, data are now emerging that link cytokine release, nitric oxide–dependent mechanisms, complement cascade activation, and other inflammatory mediators to cardiac injury.[27–34] The role of systemic inflammation in cardiogenic shock is still being clarified, and adjunctive anti-inflammatory therapy, including nitric oxide inhibitors and complement inhibitors, are currently being investigated.

MEDICAL MANAGEMENT OF MYOCARDIAL INFARCTION

The management of patients with acute myocardial infarctions demands expeditious treatment and decision making. With the ultimate goal of reperfusing the ischemic myocardium, treatment strategies should be directed toward reducing myocardial oxygen demand, maintaining circulatory support, and protecting the threatened myocardium before irreversible damage and expansion of the infarct occur.

Clinical assessment and risk stratification begins at triage during presentation, where electrocardiographic changes and cardiac biomarkers are used to identify patients suitable for revascularization versus medical management. At our center, clinical algorithms have been instituted to rapidly aid decision making.[35] Patients presenting with ongoing chest pain for more than 20 minutes *and* ST-segment elevation in two contiguous leads *or* new (or not known to be old) left bundle-branch block *or* anterolateral ST depression are classified as having ST-elevation myocardial infarction (STEMI). These patients are referred for primary percutaneous intervention in the cardiac catheterization suite 24 hours a day, 7 days a week, if no contraindications exist. The other group of patients, those with non-ST segment elevation myocardial infarction (NSTEMI), present with chest pain at rest for 10 minutes or more *and* ST-segment depression greater than 0.5 mm *or* ST-segment elevation 0.6 to 1 mm *or* T-wave inversions greater than 1 mm *or* positive troponin levels *or* a history of unstable angina in a patient with coronary artery disease risk factors. These patients are treated medically with a combination of antiplatelet therapy, intravenous heparin, and other traditional medications discussed below.

Both clinical and basic science research have demonstrated that reperfusion is the main treatment option for acute myocardial infarction. Unfortunately, the majority of patients with myocardial infarction receive only conservative medical management; only 40% of patients having an acute myocardial infarction receive thrombolytic therapy, the most common means of reperfusion.[36]

A major tenet of medical management is the provision of adequate arterial oxygenation, defined as >90% saturation. Supplemental oxygen and mechanical ventilation, including positive end-expiratory pressure and endotracheal intubation, aid in the management of pulmonary edema.

Nitroglycerin dilates epicardial arteries, increases collateral flow, and decreases ventricular preload. Although clearly beneficial in the treatment of myocardial infarction, nitrates may increase ventilation-perfusion mismatch and cause hypotension due to preload reduction.

Adequate analgesia is also beneficial. Morphine sulfate, the most commonly used analgesic, reduces preload and afterload, myocardial oxygen demand, anxiety, and circulating catecholamines. Side effects include hypotension and respiratory depression, each of which is treatable with basic resuscitative efforts.

Antiarrhythmic therapy, including lidocaine, is indicated under certain guidelines, along with atropine and countershock therapy when arrhythmias occur. Since arrhythmias are one of the most common complications after myocardial infarction, electrocardiographic (ECG) monitoring is recommended for the first 48 to 72 hours.

Arterial monitoring and the balloon flotation catheter aid in the management of patients who are hemodynamically unstable, developing congestive heart failure, or developing mechanical complications of a myocardial infarction. Long-term therapy for uncomplicated myocardial infarction includes the use of beta blockers, calcium channel blockers, and angiotensin-converting enzyme inhibitors.

Medical management includes the use of vasopressors and inotropic agents as first-line treatment strategies for cardiogenic shock. Optimizing filling pressure by balancing fluid management and diuretics is essential. Pulmonary capillary wedge pressures should be kept in the 16– to 22–mm Hg range.[3]

The use of dobutamine and dopamine is part of the pharmacologic armamentarium. These agents affect adrenergic receptors in different ways. Dopamine at doses of 5 to 8 μ/kg per minute stimulates beta-adrenergic receptors; at higher doses, alpha-adrenergic receptors are activated. At rates of more than 10 μ/kg per minute, left ventricular filling pressures rise and increase myocardial oxygen consumption. Dobutamine affects beta-adrenergic receptors and thus decreases afterload while stimulating the myocardium. Although vasopressors are necessary to maintain adequate perfusion pressures, they also increase afterload of the heart and increase myocardial oxygen demand, potentially worsening ischemia and extending the area of infarction. Neither of these drugs has been shown to provide a survival benefit in this setting.

While medical management of cardiogenic shock complicating acute myocardial infarctions is associated with high mortality, early revascularization will reduce mortality. As will be discussed later, early revascularization with PTCA or CABG has been shown to be the treatment of choice in this cohort.

In contrast to using inotropic agents to improve circulation, beta blockers have been used successfully to reduce death after infarction, probably due to their ability to reduce myocardial oxygen demand and arrhythmias. In hypotensive patients or individuals suffering bradycardia after infarctions involving the right coronary artery, beta blockade is contraindicated. Other mainstay therapies mentioned earlier—heparin, nitrates, and morphine—also comprise the traditional medical management of these critically ill patients.

STATES OF IMPAIRED MYOCARDIUM

Coronary insufficiency can result in three states of impaired myocardium: infarcted, hibernating, and stunned. Each state requires separate clinical interventions and carries different prognostic implications. Infarcted myocardium is irreversible myocardial cell death due to prolonged ischemia. Hibernating myocardium is a state of impaired myocardial and left ventricular function at rest due to reduced coronary blood flow and impaired coronary vasodilatory reserve that can be restored to normal if a normal myocardial oxygen supply-demand relationship is reestablished.[37–39] Hibernating myocardium is defined as contractility-depressed myocardial function secondary to severe chronic ischemia that improves clinically immediately following myocardial revascularization. Stunned myocardium is left ventricular dysfunction without cell death that occurs following restoration of blood flow after an ischemic episode. If a patient survives the insult resulting from a temporary period of ischemia followed by reperfusion, the previously ischemic areas of cardiac muscle eventually demonstrate improved contractility (Table 25-2).

Hibernating Myocardium

Hibernation may be acute or chronic. Carlson and associates[40] showed that hibernating myocardium was present in

Table 25–2.

States of Myocardial Cells after Periods of Ischemia

Condition	Viability of cells	Cause of injury	Return of function
Infarcted	Nonviable	Prolonged ischemia	No recovery
Stunned viable	Limited ischemia	Delayed with reperfusion	Recovery
Hibernating	Viable	Ongoing ischemia	Prompt, sometimes unpredictable recovery

up to 75% of patients with unstable angina and 28% with stable angina. The entity also occurs after myocardial infarction. Angina after myocardial infarction commonly occurs at a distance from the area of infarction.[41] In fact, mortality is significantly higher in patients with ischemia at a distance (72%) compared with ischemia adjacent to the infarct zone (33%).[41] It is the hibernating myocardium that may be in jeopardy and salvageable, although its presence is usually incidental to the occurrence of the acute infarction. By distinguishing between hibernating myocardium and irreversibly injured myocardium, a more aggressive approach to restoring or improving blood flow to the area at risk is reasonable. Function often improves immediately after revascularization of appropriately selected regions.

Stunned Myocardium

In the 1970s it was observed that after brief episodes of severe ischemia, prolonged dysfunction upon reperfusion with gradual return of contractile activity occurred. In 1982 Braunwald and Kloner[42] coined the phrase "stunned myocardium." Stunning is a fully reversible process despite the severity and duration of the insult if the cells remain viable. However, myocardial dysfunction, biochemical alterations, and ultrastructural abnormalities continue to persist after return of blood flow. Within 60 seconds of coronary occlusion, the ischemic zone changes from a state of active shortening to one of passive shortening.[6] Coronary occlusion lasting less than 20 minutes is the classic model reproducing the stunning phenomenon.[42–44]

The most likely mechanisms of myocardial stunning are calcium overload, generation of oxygen-derived free radicals, excitation-contraction uncoupling due to sarcoplasmic reticulum dysfunction, or a combination thereof. Other mechanisms that may contribute to the stunning phenomenon include insufficient energy production, impaired energy use by myofibrils, impaired sympathetic neural responsiveness, impaired myocardial perfusion, damaged extracellular collagen matrix, and decreased sensitivity of myofilaments to calcium (Table 25-3).[43,45,46]

Stunned myocardium can occur adjacent to necrotic tissue after prolonged coronary occlusion and can be associated with demand-induced ischemia, coronary spasm, and cardioplegia-induced cardiac arrest during cardiopulmonary bypass. Clinically these regions are edematous, and even hemorrhagic, and can lead to both systolic and diastolic dysfunction.[47] They also have a propensity for arrhythmias, which can lead to more extensive ventricular stunning and hypotension with subsequent infarction of these regions.

In summary, infarcted myocardium is nonviable myocardium, while hibernating myocardium is viable myocardium that is chronically dysfunctional due to impaired blood supply. Stunned myocardium is viable myocardium that is acutely dysfunctional after adequate blood supply has been restored.

Table 25–3.

Mechanisms of Contractile Dysfunction after Myocardial Stunning

Generation of oxygen-derived free radicals*
Excitation-contraction uncoupling due to sarcoplasmic reticulum dysfunction
Calcium overload
Insufficient energy production by mitochondria
Impaired energy use by myofibrils
Impairment of sympathetic neural responsiveness
Impairment of myocardial perfusion
Damage to the extracellular collagen matrix
Decreased sensitivity of myofilaments to calcium

Diagnosis of Viable Myocardium

Mechanisms to identify patients with myocardial stunning and hibernation include ECG findings, radionuclide imaging, positron emission tomography (PET), dobutamine echocardiography, and more recently magnetic resonance imaging (MRI). Thallium identifies perfusion-related defects of the myocardium and can distinguish between viable and scarred myocardium as well. However, early redistribution of thallium does not distinguish between hibernating and scarred myocardium since many segments with irreversible defects by thallium improve after reperfusion.[48] Redistribution imaging and reinjection imaging improve the predictive value of thallium imaging in distinguishing hibernating myocardium.

PET measures the metabolic activity of myocardial cells. It has high positive and negative predictive values.[49] It is now regarded as the best method to determine myocardial viability, particularly in patients with severe left ventricular dysfunction in whom other modalities are less accurate.[39,50,51]

Dobutamine echocardiography identifies hibernating and stunned myocardium by monitoring changes in segmental wall motion while the heart is stressed inotropically and chronotropically by dobutamine infusion. It has high specificity, sensitivity, and more importantly, positive predictive value.[52]

MRI has also been established as an effective method to assess hibernating myocardium.[53] It has been proven to accurately diagnose the degree of both acute and chronic myocardial infarction and predict functional recovery.[54–56]

Figure 25-3. Short-axis MRI images of anterior myocardial infarction. (*Reproduced with permission from Stuart Clarkson, GE Healthcare, and Luigi Natale, MD, Universita Cattolica, Rome, Italy.*)

A number of advantages exist with cardiac MRI, such as superior image resolution allowing accurate identification of transmural infarction (Fig. 25-3). By providing morphologic, functional, and metabolic information, it may ultimately supplant other modalities for the diagnosis of cardiac injury and recovery.

Finally, multislice computed tomography has been used to measure hibernating myocardium, and early data suggest it may be a reliable and sensitive method compared to MRI, although its use in clinical practice is limited.[57]

Treatment of Stunned Myocardium

Several approaches to management of this critically ill group should be taken. Blocking the production of oxygen free radicals will reduce both additional cell death and edema in stunned myocardium. By reducing inflammation, the prothrombotic effects on injured endothelial cells also can be reduced and thus enhance ventricular recovery. Several techniques attack the production or effects of these oxygen free radicals. Allopurinol blocks the xanthine oxidase-hypoxanthine pathway and decreases superoxide anion radicals; however, clinical trials have yielded conflicting results.[58–60]

Iloprost, an analogue of prostacyclin, has demonstrated some effectiveness in reducing stunning in animals. The proposed mechanism is inhibition of neutrophil and platelet function and reduction in the production of oxygen free radicals. In the Thrombolysis and Angioplasty in Myocardial Infarction (TAMI) trial, iloprost did not show improved ventricular function after reperfusion with tissue plasminogen activator (t-PA).[61]

Recombinant superoxide dismutase (SOD), an oxygen free radical scavenger, is a hydrophilic enzyme that does not cross the cell membrane. Additionally, SOD works most effectively if it is in tissue prior to reperfusion injury and oxygen free radical production.[62,63] Perhaps because of these

two limitations, the use of SOD has not yet shown clinical effectiveness.[64]

Adenosine, a naturally occurring nucleoside and arrhythmic agent, was given to patients after thrombolysis or mechanical reperfusion in a double-blind, randomized trial (Acute Myocardial Infarction Study of Adenosine [AMISTAD II]). A significant reduction in infarct size was seen with infusion 15 minutes before fibrinolysis or coronary intervention, although no differences were seen in clinical outcomes after 6 months.[65]

Treatment after coronary artery bypass has been investigated with mixed results. In the GUARDIAN trial, cariporide, a sodium-hydrogen exchanger, was administered to high-risk patients undergoing percutaneous or surgical revascularization. Patients in the surgical arm demonstrated a significantly lower rate of death and/or myocardial infarction after 36 days.[66] A lower rate of myocardial infarction was reconfirmed in the larger EXPEDITION trial; however, a high rate of neurologic complications has prevented widespread clinical use.[67]

Other pharmacologic agents, including calcium antagonists, nitrates, beta-blocking agents, and angiotensin-converting enzyme inhibitors, also have been studied with some beneficial results.[68–72] Recent clinical studies have shown that patients receiving calcium channel blockers had improved recovery from stunning over nitrate therapy.[73,74] Intracellular adhesion molecule blockers and P-selectin blockers also may prove beneficial in the coming years.

The use of inotropic agents can overcome stunning in both animal experiments and human observation. It is recognized that contractility of reversibly injured myocardium can be enhanced by catecholamines. Thus inotropic agents may have a role in supporting the patient with borderline function until the stunned myocardium can recover.[63]

Hemodynamic stability must be maintained while stunned myocardium is recovering or being treated by one of the above-mentioned means. Short-term mechanical circulatory devices can aid in the support of patients until the myocardium has sufficiently recovered.

Summary

Differentiation between infarcted, hibernating, and stunned myocardium guides therapeutic options in patients with poor ventricular function. If adequate regions of hibernating myocardium are present as documented by PET, thallium scanning, or dobutamine echocardiography, revascularization may allow ventricular recovery. In patients without evidence of hibernating or stunned myocardium, medical management or transplantation is a better option.

Further distinction is required between stunned and hibernating myocardium. Hibernating myocardium requires revascularization to restore blood supply to the area. Stunned myocardium requires only support, which may take the form of pharmacologic manipulations, including addition of epinephrine, dobutamine, and/or amrinone. If conservative measures fail, an intra-aortic balloon pump (IABP) or short-term LVAD support becomes necessary.

RATIONALE FOR AGGRESSIVE MANAGEMENT OF MYOCARDIAL INFARCTION

Randomized trials have shown beneficial effects of early reperfusion within 12 hours and possibly up to 24 hours after acute myocardial infarction.[12,23,24] Early reperfusion clearly reduces infarct size in the major areas at risk. Controlled reperfusion may even be superior. The arguments are more difficult to make for patients outside the 24-hour window; however, patients with ongoing ischemia often have ischemic border regions that are prone to arrhythmias and necrosis. In addition, these patients are at risk for prolonged periods of hypotension with resulting end-organ injury and further left ventricular dysfunction. Even if revascularization does not appear critical, ventricular unloading with IABP or LVAD may provide the bridge to recovery needed in patients dying after myocardial infarction. The major limiting factors to aggressive surgical management are major comorbidities, which make continuation of life undesirable or unlikely, and an unclear neurologic status, especially after a period of cardiopulmonary arrest.

REPERFUSION

Although restoration of blood flow to ischemic regions is essential, the accompanying reperfusion injury initially can worsen rather than improve myocardial dysfunction. The area at risk is affected not only by reperfusion, but also by the conditions of reperfusion and the composition of the reperfusate.[17] Thus controlling reperfusion itself may aid in reducing myocardial infarct size and ventricular injury.

At the cellular level, myocardial ischemia results in a change in energy production from aerobic to anaerobic metabolism. The consequences of ischemia vary from decreased adenosine triphosphate production and increased intracellular calcium to decreased amino acid precursors such as aspartate and glutamate. These changes can be reversed only by reperfusion.

However, as oxygen is reintroduced into a region, oxygen free radical generation ensues with resulting cellular damage. Cellular swelling and/or contracture leads to a "no-reflow phenomenon" that limits the recovery of some myocytes and possibly adds to irreversible injury of others. The production of oxygen free radicals during ischemia and at the time of reperfusion is the leading mechanism proposed to explain cellular injury. Four basic types of reperfusion injury have been described: lethal cell death,

Table 25–4.

Potential Types of Reperfusion Injury

Lethal	Cell death secondary to reperfusion
Vascular	Progressive damage causes an expanding zone of "no reflow" and deterioration of coronary flow reserve during the phase of reperfusion
Reperfusion arrhythmias	Arrhythmias, mainly ventricular, that occur shortly after reperfusion
Stunned myocardium	Postischemic ventricular dysfunction

Source: Modified with permission from Kloner RA: Does reperfusion injury exist in humans? J Am Coll Cardiol 1993; 21:537.

microvascular injury, stunned myocardium, and reperfusion arrhythmias (Table 25-4).

Buckberg and coworkers[17,18,75–91] conducted studies of controlled reperfusion after ischemia and produced a clinical application for controlled reperfusion. The conditions of reperfusion and the composition of the reperfusate allowed more muscle salvage, less post-ischemic edema, and greater immediate recovery of systolic shortening than uncontrolled reperfusion.[75] The composition of the reperfusate was designed to provide oxygen, reduce calcium influx, reverse acidosis, mobilize edema, and replenish substrates. To accomplish this, the cardioplegic solution was hyperosmolar and basic and contained blood, a chelating agent, aspartate, and glutamate.[76] The duration of reperfusion, 20 minutes, as well as the dose, was critical.[83]

The surgical strategy of controlled reperfusion, especially as espoused by Buckberg and associates, includes several elements. First, extracorporeal circulation is established as expeditiously as possible with venting of the left ventricle as required. Initially, antegrade cardioplegia is delivered using either a warm Buckberg solution to rebuild adenosine triphosphate stores, or cold high-potassium cardioplegia to achieve rapid diastolic arrest. We routinely add retrograde cardioplegia to ensure global cooling, even in areas of active ischemia. The temperatures of the anterior and inferior walls of the ventricle are measured to ensure adequate cooling. After each distal anastomosis, cold cardioplegia is infused into each graft and the aorta at 200 mL/min over 1 minute. This is followed by retrograde infusion through the coronary sinus for 1 minute. After completion of the final distal anastomosis, warm substrate-enriched blood cardioplegia is given at 150 mL/min for 2 minutes into each anastomosis and the aorta. After removal of the aortic cross-clamp, regional blood cardioplegia is given at 50 mL/min into the graft supplying the region at risk for 18 minutes. This controlled rate of reperfusion minimizes cellular edema and myocyte damage. The proximal vein grafts are then completed, followed by re-establishment of normal blood flow. To decrease oxygen demand, the heart is allowed to beat in the empty state for 30 minutes. After this time, the patient is weaned off bypass.

Application of the Buckberg solution and technique has been shown to be effective in improving mortality rates and myocardial function after acute coronary occlusion. With ischemic times averaging 6 hours, a prevalence of multivessel disease, and cardiogenic shock, the overall mortality in patients with acute coronary arterial occlusions who underwent surgical revascularization applying this method of reperfusion was 3.9%. Postoperative ejection fractions averaged 50%.[18] Surgical revascularization in this series using controlled reperfusion compared favorably with PTCA in several large series.[18] The superior results of this method for the treatment of cardiogenic shock, a 9% mortality, have brought this method to the forefront in the treatment of cardiogenic shock.[18]

Methods of Reperfusion

Role of thrombolytic therapy

Since myocardial salvage depends on reperfusion of occluded coronary arteries, rapid dissolution of an occluding thrombus with thrombolytic therapy is an appealing intervention. Intracoronary streptokinase in patients with acute myocardial infarction demonstrates that thrombolytic therapy is a safe and efficient way to achieve the desired early reperfusion.[92] Following this study, a number of multi-institutional mega-trials showed the effectiveness of thrombolytic therapy in treating acute myocardial infarctions.

The trial of the Italian Group for the Study of Streptokinase in Myocardial Infarction (Gruppo Italiano per lo Studio della Streptokinasi nell'Infarto Miocardio [GISSI])[93] and the Second International Study of Infarct Survival (ISIS-2)[94] found a reduced hospital mortality in patients treated with streptokinase. The effectiveness of tissue-type t-PA also has been evaluated in randomized studies. The Thrombolysis in Myocardial Infarction (TIMI) study[95] and the European Cooperative Study Group (ECSG)[96] demonstrated the effectiveness of t-PA for the treatment of acute myocardial infarction.

When streptokinase and t-PA were compared, two studies failed to demonstrate any difference in mortality.[97,98] A third study, however, the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial, supported the use of t-PA by demonstrating a more rapid and complete restoration of coronary flow that resulted in improved ventricular performance and reduced mortality.[99,100] After 90 minutes, 54% of the group receiving t-PA and heparin had normal flow, compared with less than 40% in the other groups. While patency rates were similar

after 3 hours, 30-day mortality was lowest in patients whose flow was normal at 90 minutes (4.4%).[99,100] This supports the importance of rapid restoration of flow. Although the actual difference in patient survival between the two groups was small (6 versus 7% mortality), the number of lives saved each year may justify the added expense of t-PA.[99,100] The mode of delivery of t-PA has been credited for the differences in the outcomes in these trials. Differences in methods of delivery between t-PA and streptokinase and adjuvant therapy with aspirin and heparin, along with cost factors of each agent, have stimulated a continuing debate over these two drugs.[36]

The addition of new antithrombotic agents has failed to provide added survival benefit. The Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT-3 PLUS) and GUSTO V found no difference in outcomes with thrombolysis plus glycoprotein IIb/IIIa inhibitors or low-molecular-weight heparin, and actually increased the rate of overall bleeding in patients over the age of 75.[101–103]

While thrombolysis improves survival and ventricular function, the patency of infarct-related arteries is reported to be between 50 and 85%.[93–100] Normal flow should be achieved in 60% of patients by today's standards. Thrombolytic therapy works well but is not without complications, including bleeding and intracranial hemorrhage.[104] Bleeding is usually minor and occurs mostly at the sites of vascular puncture. Intracranial hemorrhage and stroke rates are around 1% and are an "acceptable" risk. The relative benefits of thrombolytic therapy appear to decrease as patient age increases, and a higher risk of intracranial hemorrhage in the elderly may partially account for these findings.[99,105,106] Careful selection of patients suitable for fibrinolytic therapy is warranted, especially in an increasingly older population.

Cardiogenic shock

Thrombolytic therapy for patients presenting in cardiogenic shock or heart failure does not appear to improve survival in this population, but may decrease the incidence of patients developing heart failure after myocardial infarction.[107] However, a recent randomized SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock) trial found clear survival benefits for early revascularization by PTCA or CABG over initial medical stabilization by thrombolytic therapy.[21,23]

Summary

Thrombolytic agents for the treatment of myocardial infarction have demonstrated several important points. Survival is improved by decreasing time to reperfusion. The GUSTO trial showed that patients treated within the first hour had the greatest improvement in survival, with a 1% reduction in mortality for each hour of time saved.[99,100] Thrombolytic therapy is easy to administer in the community by trained personnel, although a significant risk of bleeding exists in certain patients. Since the time to reperfusion is a critical element in preserving myocardium, thrombolytic therapy is ideal for most communities without percutaneous interventional capabilities.[108] In this setting, thrombolytics may be used for treatment of patients with acute myocardial infarction.

Role of Percutaneous Transluminal Coronary Angioplasty

Since the first reported use of PTCA by Gruntzig and associates[109] in 1979, the efficacy of this procedure in the treatment of coronary artery disease has been well recognized. A number of studies have evaluated the efficacy of primary PTCA in the treatment of acute myocardial infarction. Overall, PTCA hospital mortality rates range from 6 to 9%.[110–115]

Several different strategies employing PTCA for acute myocardial infarction have been developed and examined through clinical trials. Primary, rescue, immediate, delayed, and elective PTCA are options for the treatment of acute myocardial infarction. Primary PTCA uses angioplasty as the method of reperfusion in patients presenting with acute myocardial infarction. Rescue, immediate, delayed, and elective PTCA all are done in conjunction with or following thrombolytic therapy. Rescue PTCA is done following recurrent angina or hemodynamic instability following thrombolytic therapy. Immediate PTCA is performed in conjunction with thrombolytic therapy, and delayed PTCA occurs during the intervening hospitalization. Finally, elective PTCA is done following thrombolytic therapy and medical management when a positive stress test is obtained during the same hospitalization or soon thereafter.

Primary PTCA functions in several roles for the treatment of acute myocardial infarctions. Since there are some absolute and relative contraindications to thrombolytics, PTCA is the one of best methods of reperfusion in patients with acute myocardial infarction, according to studies that evaluated PTCA as first-line therapy. Several studies evaluated the role of PTCA compared with thrombolytic therapy. The first study, the Primary Angioplasty in Myocardial Infarction Study Group trial in 1993, concluded that immediate PTCA without thrombolytics reduced occurrence of reinfarction and death and was associated with a lower rate of intracranial hemorrhage.[111] Since then, more than 20 studies have compared PTCA to thrombolysis. The results from these studies have consistently and conclusively demonstrated the superiority of PTCA to thrombolysis, regardless of the thrombolytic agent used. The findings include a lower short-term mortality rate, lower rates of reinfarction, reduced stroke and intracranial hemorrhage rates, and a decreased composite endpoint of death, reinfarction, and stroke.[116] These findings have been reconfirmed on long-term follow-up. A higher overall rate of bleeding was observed, likely due to vascular access complications. Myocardial salvage is similar for PTCA and thrombolytic therapy. However, primary PTCA may be slightly less costly than thrombolytic therapy.[112,113]

There are limits to the use of primary PTCA. Logistic and economic constraints apply to invasive modes of therapy. Catheterization laboratories and personnel must be ready at all times. This is not practical in most communities, and transportation to tertiary care centers raises costs considerably.

Immediate PTCA following thrombolytic therapy initially did not improve clinical outcome and was associated with increased complication rates. The ECSG,[96] the TAMI trial,[114] and the TIMI-IIA trial[115] demonstrated that immediate angioplasty does not improve clinical outcome or left ventricular function compared with delayed angioplasty.[96,114,115] Immediate angioplasty was also associated with a higher risk of bleeding and emergent bypass. The ECSG trial demonstrated a lower incidence of bleeding, hypotension, and ventricular fibrillation, as well as lower mortality with delayed PTCA.[96] The TAMI trial, which compared immediate versus delayed PTCA after thrombolysis, showed no difference in global ventricular function at 1 week between the two groups in patients with angiographically patent infarct arteries.[114] Finally, TIMI-IIA concluded that immediate PTCA after thrombolytic therapy for acute myocardial infarction does not improve survival or ventricular function,[115] and is associated with increased bleeding, reinfarction, and emergency CABG. However, alternative dosing strategies have helped improve outcomes of immediate PTCA after thrombolysis. The Plasminogen-Activator Angioplasty Compatibility Trial (PACT) examined the use of reduced-dose alteplase followed by PTCA in acute myocardial infarction.[117] A higher vessel patency and TIMI coronary flow grade were found in patients who underwent thrombolysis plus PTCA compared to PTCA alone, without increased bleeding complications. Further study of long-term outcomes will be necessary before definitive conclusions regarding its efficacy can be made.

Delayed PTCA does not improve clinical outcome. The Treatment of Post-Thrombolytic Stenoses (TOPS) study group concluded that there is no functional or clinical benefit from routine late PTCA after acute myocardial infarction treated with thrombolytic therapy in patients who did not have ischemia on stress testing before hospital discharge.[118] However, the TIMI-IIB trial indicated that thrombolytic therapy followed by angioplasty in individuals with symptomatic or provokable ischemia is appropriate.[115]

Intracoronary stents

The use of intracoronary stents after myocardial infarction has expanded as PTCA has become more prevalent. Benefits of stenting include lowered rates of restenosis and abrupt closure, and a reduced need for target revascularization after PTCA. Although the STENT-PAMI trial in 1999 using first-generation stents showed lower restenosis rates compared to thrombolysis, a trend toward higher mortality was seen, and its effectiveness as first-line therapy was questioned.[119] Composite endpoints of death, reinfarction, and urgent target vessel revascularization at 30 days have now been shown to be lower in subsequent studies, such as the CADILLAC, ISAR-2, and ADMIRAL trials, which employed newer-generation stents.[120–122] In these trials, abciximab, a glycoprotein IIb/IIIa inhibitor, was added to primary stenting. A striking reduction in restenosis rates with stenting plus abciximab versus PTCA alone was evident at 12-month follow-up in the CADILLAC study (41 versus 22%).[120] Current data suggest that stenting combined with antiplatelet therapy provides superior benefit to PTCA alone. Drug-eluting stents offer the potential to lower restenosis even further through the use of anti-inflammatory medication delivered via the stent. Most recently, patients in the STRATEGY trial treated with drug-eluting stents after acute ST-elevation myocardial infarction (STEMI) had a significantly lower composite endpoint of death, reinfarction, stroke, and angiographic evidence of restenosis at 8-month follow-up compared to stenting plus abciximab (50 versus 19%).[123,124] Concerns regarding increased thrombogenicity with drug-eluting stents are present, but have not been reported in a large trial to date; further research is warranted. Intracoronary stenting with adjunctive antiplatlelet medications has been embraced by the medical community for off-label use after acute myocardial infarction since its recent introduction.

Cardiogenic shock

Primary PTCA may play a greater role in patients presenting in cardiogenic shock, and percutaneous interventions have become more common over the past 10 years (Fig. 25-4). The GISSI-1 and GISSI-2 trials demonstrated no benefit from intravenous thrombolysis, with mortality rates of 70%.[93,97] In patients presenting in or developing cardiogenic shock after acute myocardial infarction, PTCA improved survival to 40 and 60%.[125,126] This improvement was even greater when angioplasty was successful; in-hospital survival rates increased to 70%. In most of these series an IABP was used in conjunction with PTCA. The SHOCK trial showed that revascularization by PTCA or CABG within 6 hours of the onset of cardiogenic shock results in improved 1-year survival (46.7 versus 33.6% for initial medical stabilization followed by revascularization) in this high-risk group, particularly for those under the age of 75 years (Fig. 25-5).[23,24] Subgroup analysis in patients undergoing successful PTCA or with TIMI grade 3 coronary flow after PTCA in the SHOCK trial revealed that 1-year survival was even higher, at 61%.[127] Independent predictors of mortality include age, hypotension, lower TIMI flow, and multivessel PTCA.

Summary

Primary PTCA or intracoronary stenting should be performed in patients with acute myocardial infarction and contraindications to thrombolytic therapy. Patients with established or developing cardiogenic shock should be revascularized early by PTCA or stenting rather than initial medical stabilization by thrombolytic therapy. Specialized centers

JAMA 2005; 294:448.*)

that have 24-hour catheterization facilities can provide primary PTCA or stenting as a first-line therapy. Rescue PTCA after failed thrombolytic therapy for patients with ongoing ischemia or clinical compromise is also recommended. Finally, elective PTCA should be performed on patients who have recurrent or provokable angina prior to hospital discharge.

Role of Coronary Artery Bypass Grafting

The role of surgical revascularization in the treatment of acute myocardial infarction has changed considerably over the past 30 years. Improvements in intraoperative management and myocardial preservation techniques have strengthened the surgeon's armamentarium. However, the development and use of thrombolytic therapy and PTCA offer effective alternatives to surgery.

Early studies reported increased morbidity and mortality for patients undergoing surgical revascularization within 30 days of the infarct.[128] A concern arose over a high risk of extension and hemorrhage into infarction after surgical revascularization of acute myocardial infarction.[129] Medical management was believed to be the more prudent therapy. The only absolute indications for emergent operative intervention treatment of acute myocardial infarctions during this era were papillary muscle rupture, ventricular septal defect, and left ventricular rupture. For these entities, surgery was the only hopeful option.

During the 1980s, reports appeared recommending surgical revascularization in preference to medical therapy for acute myocardial infarction.[94–100] Mortality rates under 5% were reported. Critics argued that these studies lacked randomization or consecutive entry of patients, that preoperative stratification was absent, and that enzyme levels were not included. Inherent bias that favored surgery in low-risk patients was believed to be the reason for the excellent outcomes.[137]

At the time these reports surfaced, thrombolytic therapy and interventional cardiology were emerging as alternative options for acute infarction. With the availability of thrombolytics and PTCA, large multicenter trials began looking at the efficacy and usefulness of these two techniques. Randomized trials using CABG were not done, and thus this option was never established as an option for acute myocardial infarction.

However, several centers continued to use surgical revascularization to treat acute myocardial infarction. Excellent results were achieved by coordinated community and hospital systems. However, practical, logistic, and economic constraints relegate surgical revascularization to a third option behind thrombolytics and PTCA for the primary treatment of acute myocardial infarction.

There continue to be several scenarios that require emergent or urgent surgical revascularization. Failure of thrombolytics, PTCA, or intracoronary stenting with acute occlusion may require surgical intervention. Additionally, CABG for postinfarction angina has become a critical step in the pathway of treating acute myocardial infarction. Finally, surgical revascularization may be indicated in patients with multivessel disease or left main coronary artery disease developing cardiogenic shock after myocardial infarction.

Table 25–5.

Comparison of Hospital Mortality with Respect to Time of Surgery—Transmural Versus Nontransmural Myocardial Infarction

	Mortality	
Time between CABG and MI	**Transmural MI (%)**	**Nontransmural MI (%)**
<6 hours	14	13
6–23 hours	14*	6*
1–7 days	5	4
>7 days	3	3

**p <.01 nontransmural versus transmural.*
CABG = coronary artery bypass graft; MI = myocardial infarction.
Source: Data compiled from the New York State Cardiac Surgery Registry, which included every patient undergoing a cardiac operation in the last decade in the state of New York.

Timing after infarction

If surgical revascularization within 6 hours after the onset of symptoms is feasible, the mortality rate is improved over that of medically treated, nonrevascularized patients.[130–137] While these early studies were not controlled and were criticized for selection bias, they did demonstrate that surgical revascularization may be performed with an acceptable mortality in the presence of acute myocardial infarction with improved myocardial protection, anesthesia, and surgical techniques. However, with the advent of thrombolytic therapy, PTCA, and an aging population, the surgical patient we encounter today bears little resemblance to the patient population represented in these early data.

Recent analyses of the New York State Cardiac Surgery Registry, which included every patient undergoing a cardiac operation in the last decade in the state of New York, resulted in valuable information regarding the optimal timing of CABG in acute myocardial infarction. In this large and contemporary patient population, there is a significant correlation between hospital mortality and time interval from acute myocardial infarction to time of operation, particularly if CABG was performed within 1 week of acute myocardial infarction. In addition, patients with transmural and nontransmural acute myocardial infarction have different trends in mortality when the time course is taken into consideration. Mortality for the nontransmural group peaked if the operation was performed within 6 hours of acute myocardial infarction, then decreased precipitously (Table 25-5).[138] On the other hand, mortality for the transmural group remained high during the first 3 days before returning to baseline.[139] Multivariate analyses confirmed that CABG within 6 hours for the nontransmural group and 3 days for the transmural group were independently associated with in-hospital mortality.[138,139] Optimal timing of CABG in patients with acute myocardial infarction is a controversial subject. Early surgical intervention has the advantage of limiting the infarct expansion and ventricular remodeling that may result in possible ventricular aneurysm and rupture.[140] However, there is the theoretical risk of reperfusion injury, which may lead to hemorrhagic infarction resulting in extension of infarct size, poor infarct healing, and scar development.[141] The data from these studies caution against early revascularization, particularly among patients with transmural acute myocardial infarction within 3 days of onset. Some have advocated the use of mechanical support to stabilize and allow elective rather than emergent surgery.[142] Utilizing mechanical support "prophylactically" instead of CABG to improve outcome, however, would require placement of such support in many unnecessary cases. If revascularization cannot be delayed, aggressive mechanical support such as a LVAD must be available since mortality is most likely due to pump failure. Furthermore, mechanical circulatory support has been shown to be efficacious as a bridge to ventricular recovery or transplantation for this patient cohort.[14] While emergent cases such as structural complications and ongoing ischemia clearly cannot be delayed, nonemergent cases, particularly patients with transmural acute myocardial infarction, may benefit from delay of surgery. Early surgery after transmural acute myocardial infarction has a significantly higher risk and surgeons should be prepared to provide aggressive cardiac support including LVADs in this ailing population. Waiting in some cases may be warranted.

Risk factors

In addition to timing of surgery as discussed above, risk factors include urgency of the operation, increasing patient age, renal insufficiency, number of previous myocardial infarctions, hypertension,[143] reoperation cardiogenic shock, depressed left ventricular function and the need for cardiopulmonary resuscitation,[144] left main disease, female gender, left ventricular wall motion score,[145] IABP, and transmural infarction.[146] Characteristics associated with better outcome early after myocardial infarction include preservation of left ventricular ejection fraction, male gender, younger patients, and subendocardial versus transmural myocardial infarction.

Cardiogenic shock

Surgical revascularization in acute myocardial infarction complicated by cardiogenic shock has been shown to improve survival. Cardiogenic shock, as discussed earlier, is accompanied by 80 to 90% mortality rates; various mechanisms of cardiogenic shock are shown in Fig. 25-6. DeWood and colleagues[147] were the first to demonstrate improved results with revascularization in patients with cardiogenic shock complicating acute myocardial infarction. Patients who were stabilized with an IABP and underwent emergent surgical revascularization had survival rates of 75%. Early surgical revascularization is associated with survival rates of 40 to 88% in patients in cardiogenic shock due to nonmechanical causes. Guyton and coworkers[148] reported an 88% in-hospital survival and a 3-year survival of 88%, with no late deaths reported. Furthermore, the SHOCK trial demonstrated survival benefit in early revascularization by CABG or PTCA within 6 hours of the diagnosis of cardiogenic shock for those under 75 years of age.[23,24] Patients comprising the CABG cohort in the SHOCK trial had more severe disease, with higher rates of three-vessel disease, left main coronary artery disease, diabetes, and elevated mean coronary jeopardy scores than the PTCA cohort.[149] Despite this, 87.2% of these patients achieved successful *and* complete revascularization with CABG, compared with successful revascularization in 77.2% with PTCA, and only 23.1% with complete revascularization with PTCA. Overall, mortality was no different between groups at 1 year (Fig. 25-7). On subgroup analysis, patients older than age 75, with left main coronary disease or three-vessel disease, or with diabetes had trends toward better survival at 30 days and 1 year after CABG compared to PTCA. Thus for patients in cardiogenic shock, surgical revascularization has become an established and viable option for select patient groups.

Advantages of coronary artery bypass grafting

Reported survival rates are similar for CABG and PTCA in the treatment of acute myocardial infarction. To date there have been no large randomized clinical trials comparing CABG with PTCA and thrombolytics after myocardial infarction. For patients with stable angina and elective revascularization for ischemic heart disease, a number of trials have been conducted comparing CABG to stenting.[150–153] In these studies, trends favoring CABG for multivessel disease were seen after 2 years in composite cardiac event endpoints, rate of reinfarction, and mortality; revascularization rates were five times higher in the stenting groups.[154] Most notably, survival after CABG for two or more diseased vessels was significantly higher than stenting with 2-year follow-up in a retrospective study of the New York State Cardiac Surgery Reporting System and Percutaneous Coronary Intervention Reporting System.[155] These results must be interpreted with caution, however, as patients with acute infarctions less than 24 hours pretreatment were excluded. Due to the lack of prospective, randomized trials, recommendations must be based on retrospective and observational studies. CABG offers several potential advantages. First, surgical revascularization is the most definitive form of treatment of the occlusion. CABG offers the longest patency of revascularized stenotic and occluded arteries in elective cases; 90% of internal mammary artery grafts are patent at 10 years. Second, CABG also offers more complete revascularization, since all the vessels are treated. This concept becomes especially important in patients with multivesssel disease or patients in cardiogenic shock, in whom remote myocardium may continue to be comprised with only "culprit vessel" revascularization and inadequate restoration of collateral flow.[156,157] A complete revascularization returns global myocardial perfusion to normal levels and offers the best chance for myocardial salvage. Third, difficult distal

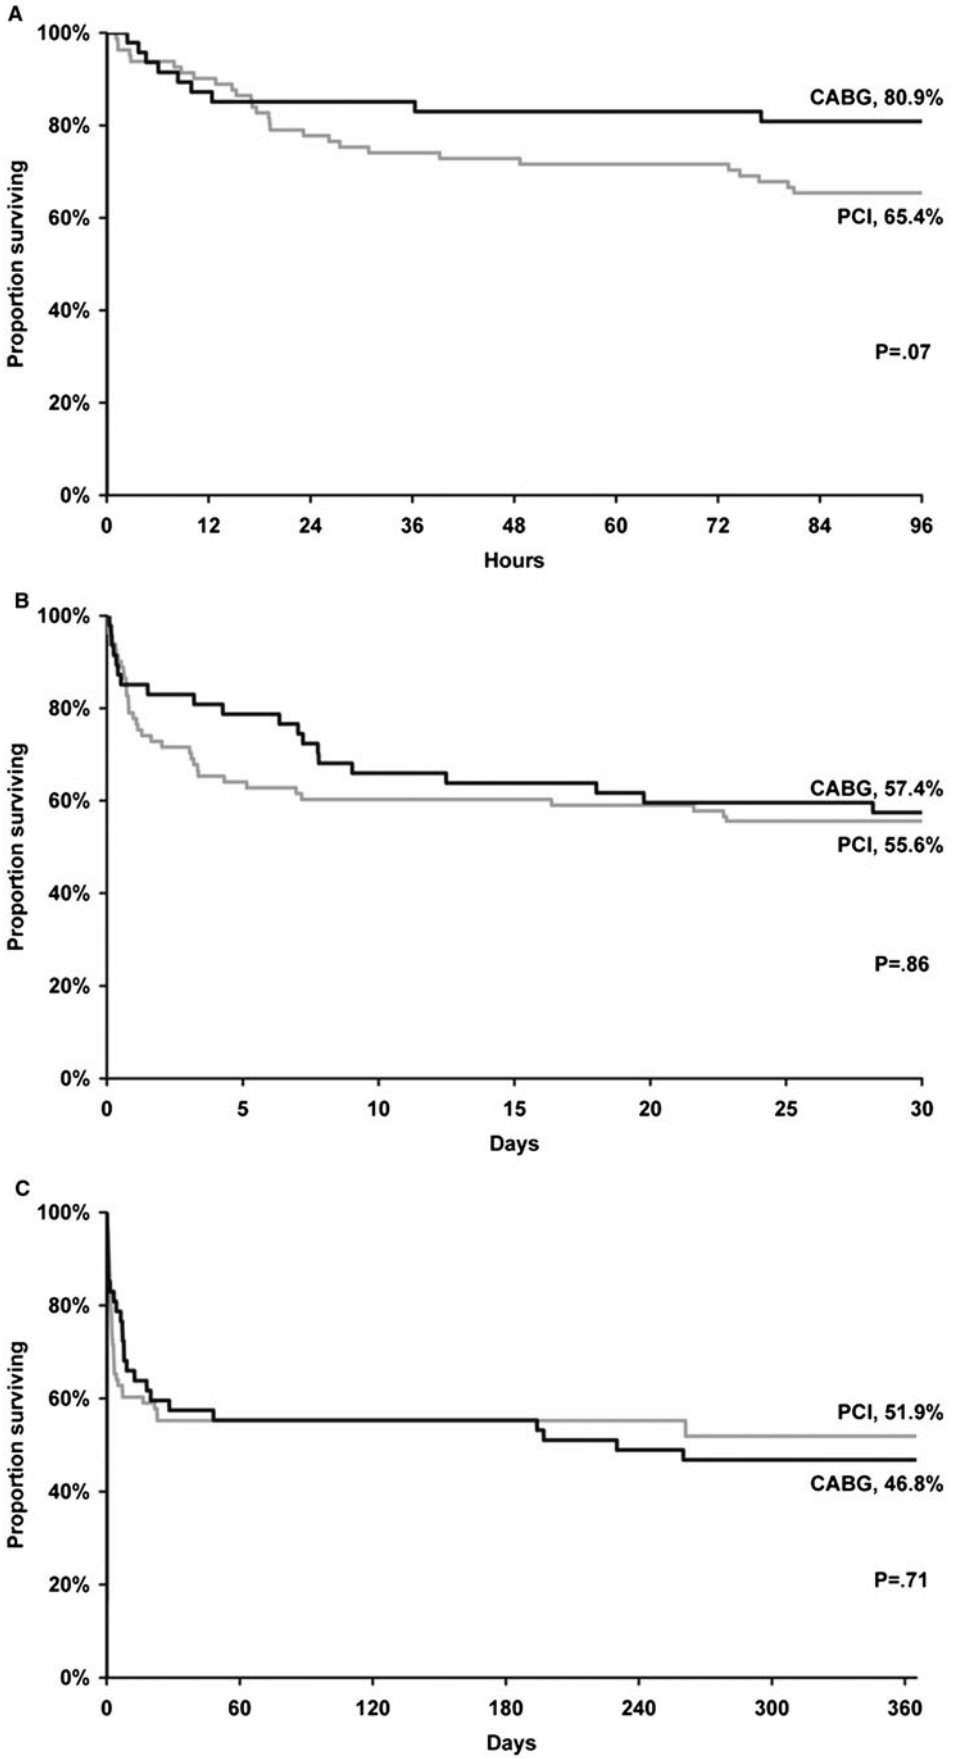

Figure 25-7. Kaplan-Meier survival estimates at 96 hours (A), 30 days (B), and 1 year (C) in patients treated with emergency percutaneous coronary intervention (PCI) versus emergency coronary artery bypass graft (CABG) in the SHOCK trial. *(Reproduced with permission from White et al.[149])*

obstructions can be reached. Fourth, there is controlled reperfusion to reverse ischemic injury and reduce reperfusion injury. Fifth, as with other forms of reperfusion, CABG interrupts the progression of ischemia and necrosis and limits infarct size.

Disadvantages of coronary artery bypass grafting

Disadvantages of immediate surgical revascularization include the high mortality associated with early CABG. Off-pump procedures may reduce perioperative complications in high-risk patients, but are not yet widely practiced and have limitations.[158] Rapid availability of catheterization and operating room personnel for emergency procedures imposes logistic and economic constraints. Thus CABG is not readily applicable to the vast majority of patients in the community, and to provide this would strain health care resources. Second, it is difficult to analyze published results of CABG for acute myocardial infarction because randomized trials have not been done. Comparisons thus far have used medically treated patients as controls. Patients in the surgical group may be at lower risk; this might explain their progression to operation rather than continuing medical treatment. Crossover of patients from medical to surgical treatment also may have skewed the data.

Summary

Surgical revascularization following acute myocardial infarction can be performed with excellent results when the timing and patient cohort are appropriate. Most patients do not need such measures and would not benefit from this aggressive form of therapy. However, patients with mechanical complications, those in cardiogenic shock, and those with postinfarction angina are likely to benefit from early CABG.

USE OF THE INTRA-AORTIC BALLOON PUMP

The early use of aortic counterpulsation with an intra-aortic balloon pump (IABP) demonstrated the safety but not efficacy of this device for patients in cardiogenic shock following acute myocardial infarction.[159] While survival was not improved, aortic counterpulsation did improve the myocardial oxygen requirements and myocardial energetics were reduced in patients in shock.[113] The use of IABP is also effective for temporary hemodynamic stabilization in complications of acute myocardial infarction, such as ventricular septal rupture, acute mitral valve insufficiency,[160,161] postinfarct angina,[162] ventricular arrythmias,[163] and acute heart failure following infarction.[164,165] As revascularization techniques for the repair of occluded coronary arteries of patients in cardiogenic shock have improved, use of aortic counterpulsation has found a role as an adjuvant to treatment protocols.

IABP counterpulsation in combination with early reperfusion is effective in the treatment of acute myocardial infarction complicated by cardiogenic shock.[147,166] While the major improvement in survival is due to early reperfusion, patients who had combined reperfusion and IABP additionally have improved long-term survival. IABP improves circulatory physiology and decreases end-organ damage in the early shock period before the myocardium is reperfused and recovers function.

Aortic counterpulsation decreases the reocclusion rate, recurrent ischemia, and need for emergency PTCA in patients who have coronary artery patency established by emergency cardiac catheterization following acute myocardial infarction.[167] Prophylactic counterpulsation for 48 hours sustains patency in coronary arteries after patency is re-established following myocardial infarction. No increase in vascular or hemorrhagic complications is observed as compared with controls.[167]

Weaning from the IABP should take place only after there is clear evidence of myocardial and end-organ recovery. In general, inotropic requirements should be reduced first in order to minimize myocardial stress. The one exception is the development of limb ischemia due to the IABP catheter.

ROLE OF CIRCULATORY ASSIST

Circulatory support devices are reserved for patients who are hemodynamically unstable; however, intervention should not be delayed until after irreversible end-organ injury occurs. This group of shock patients has a mortality rate of 80%, and survival data with the use of assist devices reflect the critical condition of patients treated. Mortality rates have changed very little in the last 20 years despite improvements in medical and surgical therapy.

Patients in cardiogenic shock who are candidates for circulatory assist devices may be divided into two groups: individuals who have stunned myocardium and need a bridge to recovery, and those who have irreversible myocardial damage and need a bridge to cardiac transplantation. For example, if a patient with a previously normal ventricle develops a large myocardial infarction, we prefer short-term support, since enough recovery may occur to allow a fruitful existence with the native heart. However, if a patient with preexisting heart failure has another infarction, the need to definitively bridge the patient to transplant with a long-term implantable device is apparent. This approach is supported by results from a multicenter study, in which overall survival at 6 and 12 months was higher in patients who underwent direct LVAD implantation rather than revascularization followed by LVAD, in patients suffering cardiogenic shock (Fig. 25-8).[168] Difficulty arises in assessing the results of mechanical assistance for patients following acute myocardial infarction and cardiogenic shock because of these different objectives.

Mechanical assist devices augment systemic perfusion and prevent end-organ damage while resting the stunned

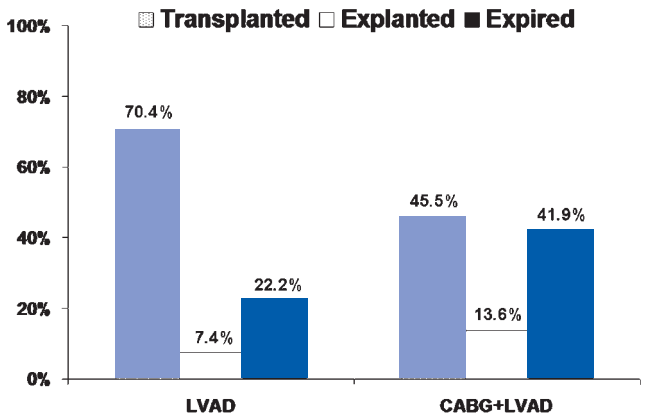

Figure 25-8. Outcomes of direct left ventricular assist device (LVAD) implantation versus coronary artery bypass graft (CABG) followed by LVAD implantation for cardiogenic shock. *(Reproduced with permission from Dang et al.[168])*

ventricle with complete or partial pressure-volume unloading.[169] Early studies of implantable LVADs have shown that end-organ function is an early predictor of mortality. Treatment of patients prior to end-organ deterioration is essential to improving the odds for long-term survival. In addition to affecting end-organ function, assist devices promote "reverse remodeling" by improving myocardial contractility and calcium handling, altering the extracellular matrix, and decreasing myocardial fibrosis.[168,170–173] Recent studies have shown that circulatory support early after myocardial infarction improved survival and offered a feasible bridge to recovery or transplantation.[13,14]

Decisions regarding specific device use depend on the degree of circulatory support needed and many other factors. Selection criteria for device placement include:

1. Potential reversibility of cardiac dysfunction
2. Cause of the cardiac dysfunction
3. Degree of right and left ventricular dysfunction
4. Amount of circulatory support needed
5. Importance of the device for myocardial functional recovery
6. Patient size
7. Anatomic location of collapse or deterioration
8. Whether the patient is a candidate for cardiac transplantation
9. Whether the patient can be anticoagulated
10. Expected duration of support
11. The patient's age and severity of comorbid conditions[174]

At New York Presbyterian Hospital (Columbia Center), several circulatory assist devices are available to aid treatment of each group. Short-term devices that can be placed percutaneously include the IABP, extracorporeal membrane oxygenation, and percutaneous assist devices. Devices that require sternotomy and are beneficial for short-term use include the ABIOMED and Thoratec pumps. Both these devices primarily treat stunned myocardium, but they are capable of bridging to transplant. These devices are easy to insert, do not require excision of ventricular muscle, and do not compromise ventricular function following device removal. These devices can be removed without the need to reinstitute cardiopulmonary bypass. These devices are effective in patients who require emergency support secondary to cardiogenic shock.

The Heartmate (Thoratec, Pleasanton, Calif) and Novacor (Ottawa Heart, Ottawa, Canada) LVADs are long-term pulsatile implantable assist devices that we use for bridging to transplantation. Initial reports of increased mortality in this high-risk patient population have been refuted by studies reporting higher-than-usual survival in acute myocardial infarction patients who received ventricular assist device support. At our facility, over 80% of this patient cohort have survived until transplantation, a result threefold better than that seen in databases of extracorporeal systems.

Second-generation assist devices employ axial flow rotors that can generate up to 6 L of flow (partial unloading of the left ventricle). These devices are driven by an electromagnetically actuated impeller drive shaft, contain fewer moving parts, and are smaller than pulsatile devices, thus making them less prone to mechanical failure and driveline infections, at least in theory.[175] The major disadvantages to axial flow pumps are the need for systemic anticoagulation, the lack of pulsatile flow, and incomplete pressure-volume unloading of the left ventricle; these concerns have limited its use in the post–myocardial infarction setting and further research is needed to clarify its therapeutic potential for these patients. A full discussion of mechanical circulatory support is reported in Chapter 67.

Weaning of Circulatory Support

Cardiac enzyme levels at the time of infarction, ECG changes, and the preinfarction condition of the ventricle help determine the likelihood of left ventricular recovery. If the ventricle is considered to be unlikely to recover, early use of a long-term device is rational. On the other hand, if recovery is possible, the heart should be rested for 3 to 5 days, loaded with the institution's choice of inotropic support including a phosphodiesterase inhibitor, and allowed to beat and eject. If a transesophageal echocardiogram or transthoracic echocardiogram on reduced support demonstrates recovery, the short-term support device should be removed in the operating room and kept available for 1 hour while the patient is observed for signs of decompensation. If the device cannot be removed within a week, the heart is not likely to recover. In this event, either a longer-term device is placed or patient support is discontinued.

We have reported a baseline left ventricular recovery in more than half of patients supported for a prolonged period with implantable devices. Upon removal of the device, most of these patients have redeveloped congestive heart failure in our experience[14] although other centers have reported high success rates.[176,177] As our understanding of the underlying

causes of left ventricular failure improve, we will be able to design targeted therapies that can be used with temporary device support to facilitate sustainable recovery.

Ethical Considerations

Programs that aggressively pursue surgical approaches to high-risk patients also must aggressively seek termination of care in futile cases. A liaison should be developed with a medical ethics individual or group to provide support for primary caregivers; however, the burden of medical decisions must rest with the attending physician. The family should not be forced to sign declarations withdrawing care unless significant controversy and/or the potential of legal action encumbers the decision. In the case of mechanical circulatory support, each pump of the device can be interpreted as a new intervention and therefore can be terminated if necessary. A precedent for this course of action has been set with mechanical ventilation. If significant neurologic or other end-organ dysfunction has developed and cardiac function has not returned, termination of support is reasonable and appropriate.

The Ethics Committee of the Columbia Presbyterian Center of The New York Presbyterian Hospital has drafted a statement that patients and physicians must review together prior to placement of a ventricular assist device (VAD), or when circumstances do not permit, immediately thereafter. The statement asserts that VAD restoration of hemodynamic stability in a patient with critical myocardial dysfunction may, for various reasons, not reach the goal of enabling the patient to receive a heart transplant or achieve adequate stability to be discharged home on the device.

The statement reads as follows:

> Every effort will be made to help our patients on ventricular assist devices (VADs) to improve to the point where they meet the criteria to receive a heart transplant, or stabilize enough to be discharged from the hospital on the VAD. However, if despite all our efforts, a patient has no reasonable chance of achieving either of these goals, we will discontinue the VAD, as it will, under these circumstances, no longer be serving the purpose for which it was originally used. When this occurs, the VAD will be discontinued only after the physicians caring for the patient are in agreement that the goals for VAD use cannot be met, and have consulted with the patient, or, when the patient is too ill, with the family or friends of the patient.

We believe that such a document is needed at the beginning of the patient's care to make clear to the family the goals of VAD use. Specifically, a VAD should not be used solely to prolong a patient's dying. Once a medical determination has been made by both the attending cardiac surgeon and the attending cardiologist that the patient cannot survive to leave the hospital, continued use of the VAD is inappropriate.

If the patient or his or her health care proxy or surrogates disagree with the decision to discontinue the VAD, the case is submitted to the ethics committee for arbitration.

SURGICAL MANAGEMENT

New York Presbyterian (Columbia Center) Approach

Patients who are potential transplant candidates and those who are dying of cardiogenic shock after myocardial infarction are all candidates for placement of a long-term implantable left ventricular assist device (LVAD) (Fig. 25-9). If at all possible, a coronary angiogram is obtained to allow revascularization with or without LVAD insertion. Surgery is delayed if the culprit vessel can be opened with angioplasty and the patient stabilized in the catheterization laboratory. If hemodynamics continue to deteriorate, the patient is taken directly to the operating suite, even if infarction occurred earlier than 6 hours before the planned procedure. Hemodynamic observations that favor early CABG are pulmonary artery pressures <60/30 mm Hg and cardiac output of more than 3 L/min. If the hemodynamics are worse, early implantation of a long-term implantable LVAD may be needed, especially if the mixed venous oxygen saturation is <50%. The decision to place a long-term LVAD is influenced by the patient score on a screening scale designed for this purpose (Table 25-6). These scores were selected to identify end-organ dysfunction (lung, liver, or kidney) and operative constraints (right-sided heart failure and bleeding). We have nearly a 90% survival if the summed scores are less than 5 points, versus 30% survival with summed scores greater than 5 points.[178] For this reason, if the total score is greater than 5 points, an attempt is made to stabilize the patient prior to beginning long-term LVAD insertion. Patients with lower scores are offered temporary LVAD.

If a patient is not a potential transplant candidate, our approach is more conservative, since we do not have a safety net if coronary revascularization fails and a temporary support device is inserted. An angiogram must be obtained; if hemodynamics are not favorable and no acute ischemia is present, we delay surgery until pulmonary arterial pressures fall. If the patient is ischemic, we proceed with CABG as described below. If the patient cannot be separated from bypass without high-dose inotropic support including alpha agonists, if the cardiac index is less than 2 L/min per meter squared, and if left-sided filling pressures remain high with mixed venous oxygen saturations of less than 50%, short-term LVAD support with the ABIOMED system is instituted. IABP alone in this patient population often does not prevent death and almost always results in significant renal, hepatic, and pulmonary dysfunction that significantly complicates patient recovery even if adequate cardiac function returns. Most important, stressing the

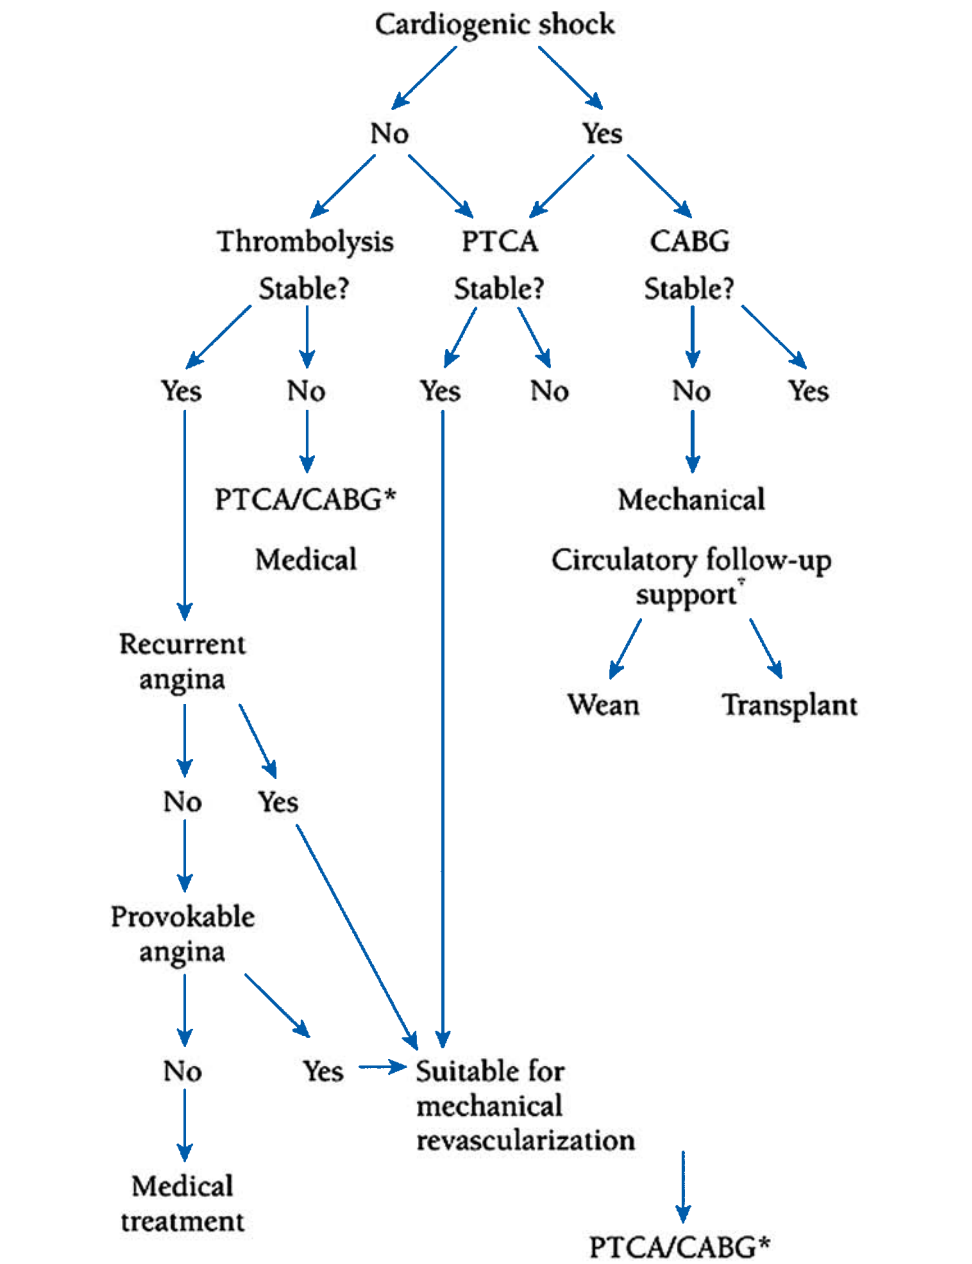

Figure 25-9. Acute myocardial infarction algorithm.

heart with high-dose inotropic agents and high filling pressures when it is weakest during the early reperfusion period after acute infarction may compromise border zone regions. This concern is especially true of patients with older infarctions (more than 6 hours). We err on the side of implanting this short-term device early, since the survival rate is only 7% if the device is inserted after a cardiac arrest in the recovery room.

Operative Techniques for Acute Myocardial Infarction

Anesthesia

Anesthesia is provided by a rapid narcotics-based regimen with perfusion and surgical teams prepared to respond to catastrophic hypotension or cardiac arrest. Transesophageal probes are always placed in these patients if possible. As the

Table 25–6.

Preoperative Risk Scale for Left Ventricular Assist Device Placement*

Criteria	Points
Urine output <30 mL/h	3
Intubated	2
Prothrombin time >16 seconds	2
Central venous pressure > 16 mm Hg	2
Reoperation	1

A combined score of >5 is associated with a 70% mortality risk.

patient is prepped, a test dose followed by a loading dose of aprotinin is given.

Bleeding

Bleeding is a significant complication of emergency CABG and often results in further myocardial depression and pulmonary hypertension. Cytokine release induced by infusion of blood products and thromboxane A_2 released by cardiopulmonary bypass stimulate pulmonary hypertension, which can be catastrophic in the setting of right ventricular ischemia. Use of aprotinin decreases bleeding during CABG[179,180] and reduces right-sided heart failure and death after LVAD insertion.[181] There are reported cases of aprotinin use following thrombolytic therapy for acute myocardial infarction.[182] Successful use of aprotinin for reoperative, emergency, or high-risk CABG is common in many institutions.

The use of clopidogrel deserves special mention, and its expanding administration can pose unique problems for the cardiac surgeon. Clopidogrel, an oral irreversible antagonist of the 5′-adenosine diphosphate that inhibits platelet activation and aggregation, is used extensively in patients with acute coronary syndromes and has been shown to lower cardiovascular risk by up to 20%, and reduce reinfarction and stroke rates;[183,184] in addition, it is commonly given prior to percutaneous interventions and after intracoronary stenting to prevent thrombosis. However, patients frequently require surgical revascularization after medical therapy or cardiac catheterization while taking clopidogrel. The risk of bleeding after clopidogrel and cardiac surgery can be substantial. In multiple reports, the risk of reoperation for hemorrhage in patients receiving clopidogrel within 7 days of cardiac surgery was six times higher, and patients required more blood, platelet, and fresh frozen plasma transfusions.[185–187] Due to these complication rates and the inability to reverse clopidogrel's effect on platelets, surgery is often delayed until platelet function is restored, which may take 7 to 10 days, or the life of the platelets. Emergent surgery while taking clopidogrel necessitates frequent blood product transfusions and confers significant morbidity, and possibly mortality. Further study is underway to determine if current dosing regimens after acute myocardial infarction can be reduced to lessen bleeding complications.

Choice of conduits

For emergency cases, the choice of conduit should not differ from elective cases in most circumstances. The internal mammary artery is not associated with a higher number of complications compared with saphenous vein grafting in emergent situations and can be used in most circumstances.[188,189] There is one reported case of successful use of polytetrafluoroethylene for coronary revascularization in a patient in shock.[190]

Intraoperative considerations

Decompression of the ventricle during revascularization after acute coronary occlusion decreases muscle damage and improves functional outcome by decreasing wall tension and reducing oxygen consumption (Figs. 25-10 and 25-11).[85] Indeed, ventricular decompression reduces metabolic energy consumption by 60%. Diastolic basal arrest, by avoiding the energy of contraction, is the second most important means of minimizing oxygen consumption and further reduces metabolic energy consumption by 30%. Cooling of the patient and heart has an impact only on the final 10% of basal energy requirements.

Reduction of myocardial energy consumption is best achieved by early institution of cardiopulmonary bypass to maintain a high perfusion pressure. If a coronary salvage catheter has been placed across a tight coronary lesion, the catheter is left in place until just before cross-clamping.

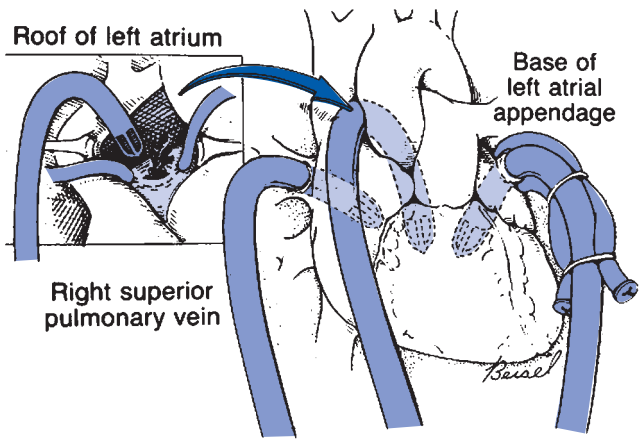

Figure 25-10. The inflow cannula for short-term left ventricular assist device support can be placed through the right superior pulmonary vein, the dome of the left atrium, or the left atrial appendage. Lighthouse tip cannulas allow improved venous return.

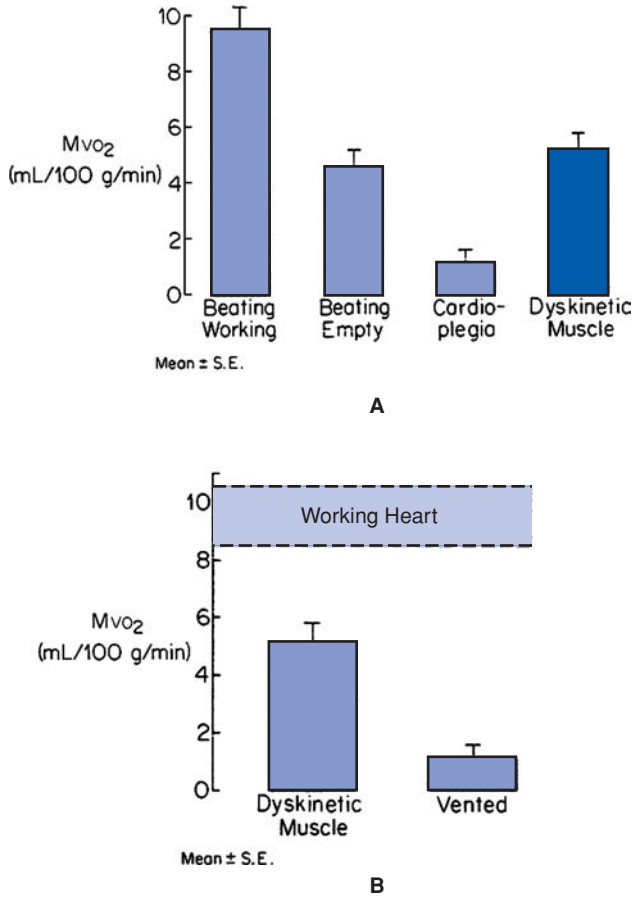

Figure 25-11. (A) Myocardial oxygen uptake (MVO_2), measured in milliliters per 100 grams per minute, in beating and working, beating and empty, and arrested hearts. Values after cardioplegia were determined both during cardiopulmonary bypass (cardioplegia) and during regional cardioplegic reperfusion in the working heart (dyskinetic muscle). Note (1) marked fall in MVO_2 with cardioplegia in the decompressed heart and (2) oxygen requirements of dyskinetic muscle increase fivefold over cardioplegia alone, and equal almost 55% of beating, working needs. (B) Regional oxygen uptake during selective cardioplegic reperfusion in dyskinetic and vented cardiac muscle. Stippled areas show requirements in working heart (8.5 to 10.5 mL/100 g/min). Note (1) high oxygen demands of dykinetic muscle and (2) marked reduction in demands when noncontracting muscle is decompressed by venting. *(Reproduced with permission from Allen et al.[85])*

Antegrade and retrograde catheters are placed prior to cross-clamping to allow quick instillation of retrograde cardioplegia and protection of the territory supplied by the occluded or compromised vessel. The standard Buckberg protocol is followed, including warm induction to allow regeneration of depleted adenosine triphosphate stores.

If the territory at risk is grafted by saphenous vein, this anastomosis is performed first to allow direct instillation of cardioplegia into the territory at risk. The proximal anastomoses should be performed prior to removal of the cross-clamp to allow complete perfusion of the entire heart upon removal of the cross-clamp. The role of off-pump CABG in this setting is appealing, but remains unproven.

While large ventricular aneurysms are treated by resection and patch, debate surrounds smaller aneurysms. Our group does not resect small aneurysms, but some groups are more aggressive. If an aneurysm is resected, the defect is repaired with a patch of bovine pericardium sewn to the fibrotic rim of the endoaneurysm surface. The native left ventricular wall is closed over the patch.

Utilization of the Dor procedure (endoventricular circular patch plasty repair) in the post–myocardial infarction setting is a controversial subject. Recent data have shown that surgical remodeling improves systolic function, ejection fraction, and intraventricular dyssynchrony.[191–193] However, a large clinical trial is needed to definitively answer this question.

Postoperative care

A higher incidence of complications in shock patients compared with nonshock emergencies has been reported. Guyton and associates[148] report a 47% complication rate associated with cardiogenic shock, compared with 13% for patients with nonshock emergencies. This increase in complications probably reflects the preoperative condition of the patients rather than the treatment itself. Long-term follow-up in patients following emergency surgical revascularization shows that survival rates are closely correlated with postoperative ejection fraction and left ventricular size.[194,195]

FUTURE THERAPIES AND TRENDS

Improving outcomes in patients suffering acute myocardial infarction can occur through pharmacologic advances, optimization of existing practices, and application of new technology. Various medications have been described that reduce ischemic-reperfusion injury and limit infarct size in animal models, such as oxygen-derived free radical scavengers, folic acid, nitric oxide inhibitors, and others;[196] clinical study of these promising drugs will determine their efficacy. Sudden death after myocardial infarction may be reduced with administration of omega-3 fatty acids.[197] Reducing transport time to the hospital after the onset of symptoms and implementation of clinical guidelines have been initiatives of many hospitals and emergency services. The increased number of local hospitals able to perform primary percutaneous interventions has meant quicker revascularization, and thus improved outcomes.[22] This trend should continue in the future. Mechanical circulatory support has advanced greatly over the past 10 years, and pumps have become smaller, safer, less invasive, easier to use, and easier to implant. The indications for LVAD use are expanding in this population, and they may allow myocardial recovery to occur in select patients requiring hemodynamic support after acute infarction. The option of living long-term with these devices has also become a reality. Finally, the rapidly emerging field of cellular therapy holds great promise for repair of damaged

myocardium. A number of cell types, such as endothelial progenitor cells, mesenchymal stem cells, skeletal myoblasts, resident cardiac stem cells, and embryonic stem cells, are being investigated;[198] the optimal cell type, mode of delivery (intracoronary artery infusion, intravenous infusion, transendocardial injection, and transepicardial injection), and timing of administration have yet to be determined. Nevertheless, early clinical trials suggest that cellular therapy may offer benefits. One-year follow-up of 59 patients suffering acute myocardial infarction in the TOPCARE-AMI trial who received either circulating progenitor cells or bone marrow–derived progenitor cells demonstrated increased cardiac function and reduced ventricular dimensions, without adverse events.[199] Numerous other clinical trials are underway to address questions regarding mechanisms of benefit, cell viability, and dosing. Future randomized clinical trials will be required to establish outcome benefit.

CONCLUSION

The treatment of acute myocardial infarction should be divided into two approaches. Uncomplicated acute myocardial infarction can be treated in most community hospitals. In most areas of the country, these patients are treated effectively with thrombolytic therapy and medical management. For communities and facilities that have catheterization laboratories, primary angioplasty may be more cost-effective and produces improved results. At this time, emergency coronary artery bypass surgery is not the most cost-effective approach; randomized controlled studies to demonstrate advantages of emergency CABG have not yet been performed.

The approach to acute myocardial infarctions complicated by cardiogenic shock presents a more difficult problem. Mortality rates are high with medical management. Reperfusion therapy is the only real hope for improved survival in this group of patients. Thrombolytic therapy is associated with poor outcomes. Early PTCA and CABG are the primary options in patients under the age of 75. Mechanical circulatory assistance has an important role for supporting patients until the myocardium recovers. Use of pharmacologic agents and means to control reperfusion are important areas of current research and development. Assist devices and artificial heart programs offer indispensable options and must be considered in this patient population, especially since all therapies offer suboptimal results.

CHAPTER 26

Minimally Invasive Myocardial Revascularization

Volkmar Falk • Friedrich W. Mohr

The term *minimally invasive coronary artery bypass grafting* is not well defined. According to one definition, avoidance of cardiopulmonary bypass (CPB) is considered essential in decreasing the morbidity associated with conventional coronary artery bypass grafting (CABG).[1] Other authors consider the median sternotomy as a potential source for morbidity, referring to the risk of mediastinitis and the associated delayed return to daily life activities.[2] Accordingly, a number of surgical strategies have evolved to avoid the need for extracorporeal circulation and to minimize surgical access. At the same time, it was widely recognized that open harvesting techniques for bypass grafts often are associated with wound-healing problems, especially in diabetic patients. As a consequence, endoscopic harvesting techniques for both venous and radial artery grafts have been developed.

OFF-PUMP CORONARY ARTERY BYPASS GRAFTING (OPCAB)

For decades, CABG was performed with cardioplegic arrest and on CPB. A decompressed, nonbeating heart, a bloodless surgical field, and easy exposure were regarded essential for success of the procedure. Results were excellent, mortality declined constantly, and standard CABG became the "bread and butter" of our profession.

Anecdotal reports on the deleterious effects of CPB and systematic reports examining the pathophysiology of extracorporeal circulation started to question the dogma of "the pump is your friend." CPB is associated with (1) a systemic inflammatory response, (2) release of cytokines, (3) activation of the clotting cascade, (4) metabolic changes, (5) microembolization, and numerous other adverse effects. Although tolerated in most cases, these effects alone or in combination may cause substantial morbidity and thus affect the results of the procedure. With an ever-aging population and increasing comorbidity, surgeons all over the world sought to further minimize the risk of CABG, and it seemed logical to question the role of CPB in CABG.

The evolution of *off-pump coronary artery bypass grafting* (OPCAB) is closely linked to the development of stabilizers that became available in the early 1990s. Initially, pure pressure stabilizers were engineered, but it soon became obvious that exposure of the back wall of the heart would require additional means of support. With the introduction of vacuum-assisted stabilizers by the Utrecht group, local myocardial immobilization was greatly facilitated and independent of the area of revascularization and OPCAB gained popularity. Despite better stabilizers, it was recognized that OPCAB requires a team approach and awareness of the sudden hemodynamic changes that may occur during the procedure.

Anesthesia Requirements

In most centers, general anesthesia is applied, and the patient is intubated. Incidental reports indicate that the operation is also possible on the awake, spontaneously breathing patient under high epidural anesthesia.[3] Standard monitoring is applied. In addition, some centers prefer online cardiac output measurement using the PICCO or similar methods.[4] A Swan-Ganz catheter is usually not helpful and potentially can cause arrhythmia when the heart is positioned during the procedure. It is of utmost importance that the patient is kept warm at all times during the procedure. Temperature management includes placing the patient on a warming blanket, using warm infusions, and keeping the room temperature high. Volume management is essential because it is the preferred means for counterbalancing hemodynamic changes. Exposure of the back wall of the heart usually causes some degree of right ventricular outflow obstruction that can be treated adequately by increasing venous return by tilting the operating room table to the right with the head low. Since no

CPB is used and filtering is not possible, intravenous volume overload must be avoided, especially in end-stage renal failure (ESRF) patients. The use of inotropes should be reserved for those with severe hemodynamic alterations only because they invariably increase the heart rate and thus complicate the procedure. In a recent review of human factors associated with manual control and tracking, it was pointed out that the human operator can at his or her best track a three-dimensional motion (such as the beating heart) only up to a frequency of 1 Hz, which happens to equal a heart rate of 60 beats per minute.[5] Higher frequencies cannot be tracked, and thus the preferred heart rate should be kept in the range of 50 to 70 beats per minute to simplify suturing. In case of atrial fibrillation, pharmacologic slowing of the heart rate and temporary ventricular pacing using an epicardial pacing wire may facilitate the procedure. The use of a Cell Saver is recommended to minimize the risk for blood transfusion, which is rarely necessary. If less than 500 mL is collected, the blood usually is discarded.

Surgical Technique

After standard median sternotomy, single or bilateral internal thoracic artery (ITA) harvesting is performed. The patient is heparinized (150 units/kg), keeping the activated clotting time (ACT) at a level above 300 seconds. If an arterial T-graft is to be performed, the radial artery should be anastomosed to the left internal thoracic artery (LITA) with the pericardium still closed because there is less motion and immediate blood supply is warranted after the distal anastomosis. In order to facilitate exposure of the heart, it is recommended to divide the pericardial and mediastinal attachments. Opening of the right pleura may become necessary in severely dilated hearts. After the pericardium is opened, pericardial stay sutures are placed to aid in exposure of the heart. Numerous methods have been proposed for placing these sutures. Ideally, three or more sutures are placed beginning at the level of the right upper pulmonary vein all the way down distally to the lowest point of the epicardial sac (Fig. 26-1). To avoid damage to the myocardium, the sutures should be covered by plastic tubing; sponges may be used alternatively. Placement of the stay sutures should be done slowly because abrupt changes in positioning of the heart may cause undesired hemodynamic alterations. The sequence for the grafts depends largely on the individual needs of the patient. In general, the left anterior descending (LAD) artery is the most important target vessel and the easiest to bypass. Therefore, revascularization should start with a LITA graft to the LAD. By lifting the stay sutures, the LAD comes easily into view. The stabilizer is placed at the site of the anastomosis, and dissection of the surrounding tissue is begun. If the vessel is covered by excessive fat or muscle, low-energy cautery and clipping of epicardial veins may help to ensure minimal bleeding from the surrounding tissue. Once the site for the anastomosis is identified, the stabilizer is placed so as to ensure enough space for suturing and equal distance to the stabilizer feet. Vacuum stabilizers should be locked only after vacuum is applied and the stabilizer sucks to the surface. Only a small amount of pressure then will be required to immobilize the heart. This not only minimizes the hemodynamic impact of the stabilizer but also decreases the amount of residual motion. Excess pressure from the stabilizer will cause increasing motion as the heart works with more force against its compression. Temporary occlusion of the target vessel can be achieved in many ways. Surrounding 4-0 felt-pledgeted sutures or Silastic tapes are used widely. The occlusion tapes ought to be placed at a distance from the anastomosis to avoid compression of the target vessel at the level of the anastomosis and thus allow for easy suturing. The suture needs to be placed deep enough in the tissue to avoid damage of the target vessel. Distal occlusion should be avoided in general and is rarely necessary even in occluded vessels. Care must be taken to stay outside stented areas because the occlusion tapes may bend or kink an implanted stent. The incision usually is made before the occlusion suture is tightened to ensure complete filing of the vessel, which will minimize the risk of back wall injury. The suture then is tightened gently until bleeding stops. If there is only minimal coronary blood flow, occlusion may not at all be necessary. A CO_2 blower-mister is used to control residual bleeding from septal branches or the distal coronary at a rate not exceeding 5 L/min. Excessive blowing can cause dissection of both the graft and the coronary artery or cause air embolism. The use of coronary artery shunts is controversial because they also may cause endothelial damage. If shunts are used, care must be taken to ensure atraumatic placement. The anastomosis is performed in a running fashion in the usual way. The circumflex artery and its branches are grafted next in a sequence that is dictated mainly by the individual anatomy and the preference of grafts. The distal circumflex artery is regarded as the most challenging vessel to graft during OPCAB because exposure may be difficult. In large hearts, it may be necessary to open the right pleura and divide the right-sided pericardium low to the level of the phrenic nerve. This will allow displacement of the heart underneath the

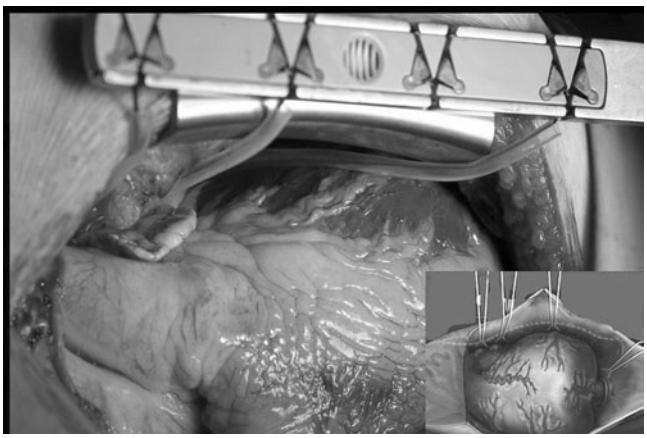

Figure 26-1. Setup for off-pump coronary artery bypass grafting. Placement of pericardial stay sutures.

sternum into the right pleural cavity. This maneuver minimizes right outflow tract obstruction and exposes all posterior vessels. After the circumflex artery, the right coronary artery (RCA) and its branches are grafted. If the RCA is the dominant vessel and the stenosis is less than 80%, it may be necessary to use a shunt because ischemia of the atrioventricular (AV) nodal artery on occlusion of the RCA can cause acute AV block. It is therefore advisable to place and connect a temporary pacing wire before occluding the vessel.

To maximize both the short- and long-term benefit of an OPCAB procedure, arterial grafting is preferred. This will obviate the need for aortic clamping, another source for emboli and independent predictor of stroke.[6] If vein grafts are used, the proximal or distal anastomosis can be performed first. It is of utmost importance to partially clamp the aorta under low pressure. This can be achieved via a brief period of inflow occlusion by manually compressing the inferior vena cava. This maneuver also should be repeated for declamping. Intraoperative graft patency control using transient-time Doppler or other means is recommended. If the operative field is dry, heparin usually is not completely antagonized. Postoperatively, aspirin is begun on the day of operation.

Special Situations

In patients with unstable angina, in low-output states, or with ejection fraction (EF) below 20%, the preoperative implantation of an intra-aortic counterpulsation pump (IACP) may be useful. Patients with atrial fibrillation (AF) show an irregular contraction pattern that may distract during suturing (regular-motion patterns allow the development of coping strategies such as the "wait and see" strategy that are less effective when motion is unpredictable[4]). It therefore may be helpful to slow the heart rate pharmacologically and temporary pace the patient in a VVI mode. If AF is paroxysmal, epicardial ablation of the pulmonary veins on the beating heart may be applied.

Results

The number of OPCABs performed has reached 30% of all coronary revascularizations worldwide, in some countries exceeding 80%. In some units, OPCAB is used almost exclusively with no patient selection.

When discussing outcomes, it is important to keep in mind that despite the fact that propensity scoring was applied for most analyses, some selection bias cannot be excluded. As pointed out by Sergeant and colleagues, clinically relevant reductions of mortality, stroke, and renal failure with the OPCAB approach mandate large cohorts of patients to reach statistical significance in the presence of above-standard on-pump performance.[7] When the first reports on OPCAB were published, concerns were raised regarding (1) incomplete revascularization[8–11] and (2) impaired graft patency due to a more challenging technique.[12] These concerns are no longer justified. In contemporary series, completeness of revascularization is achieved on a routine basis. In the SMART study, 200 unselected and randomized patients received an average of 3.4 grafts in both on- and off-pump CABG.[13] The few studies that provide angiographic data on graft patency reveal equal patency rates for on- and off-pump bypass surgery.[13,14]

Regarding operative and short-term mortality, most studies are in favor of OPCAB. In a retrospective analysis of the Society of Thoracic Surgeons database for the years 1999 and 2000, including 17,969 OPCAB patients (8.8% of total), a significant survival advantage with OPCAB compared with on-pump CABG was demonstrated by risk-adjusted multivariate logistic regression analysis [odd ratio (OR) 0.76, 95% confidence interval (CI) 0.68–0.84] and conditional logistic regression of propensity-matched groups (OR 0.83, 95% CI 0.73–0.96).[15] Similar results have been reported from another multicenter analysis consisting of some 7283 patients by Mack and colleagues. Following propensity score matching and multivariate regression analysis, the use of CPB was identified as an independent predictor of mortality (OR 2.08, 95% CI 1.52–2.83, $p < .001$).[16] Especially in high-risk populations (e.g., the elderly, those with EFs below 30%, and obese patients), OPCAB seems to offer a survival benefit.[17–20] There are only sparse data on the midterm outcome. After 2 and 4 years, similar survival has been reported.[8,21]

There is growing evidence that neurocognitive outcome is better and stroke rate is reduced after OPCAB.[23–25] According to a number of studies, CPB is an independent predictor of adverse neurologic outcome.[26] The embolic load measured by transit-time Doppler of the medial cerebral artery is reduced significantly during OPCAB.[27–29] Within the OPCAB group, partial clamping remains an independent predictor of stroke, and a no-touch technique using all arterial grafting therefore is advocated by some.[6] The risk of renal failure is decreased in off-pump surgery,[30–32] especially in high-risk groups with preoperative renal insufficiency.[33,34]

The incidence of postoperative atrial fibrillation is reduced after OPCAB,[34,35] and biochemical markers for myocardial injury (e.g., creatinine kinase and troponin) are reduced after OPCAB.[36–38] Blood loss is less, and transfusion rate is reduced.[20] Overall, OPCAB reduces hospital costs by 15 to 35%[19,39] possibly owing to decreases in length of stay and resource utilization.[19]

In a thorough meta-analysis, the International Society for Minimally Invasive Cardiac Surgery Consensus Group recently has published the current evidence for OPCAB.[20] Accordingly, OPCAB reduces mortality and length of stay and the incidence of postoperative myocardial infarction (MI), renal failure, AF, and transfusion rate in mixed-risk and high-risk patients (Fig. 26-2).

MINIMALLY INVASIVE DIRECT CORONARY ARTERY BYPASS (MIDCAB)

One goal of minimally invasive cardiac surgery has been to avoid sternotomy to reduce the amount of surgical trauma and avoid wound complications. Therefore, techniques for

Figure 26-2. MR on the beating heart without sternotomy were developed. The operation was termed *minimally invasive direct coronary artery bypass* (MIDCAB), and since its introduction in the mid-1990s,[40–44] it has found a widespread application. In some centers, MIDCAB is the preferred method of surgical revascularization for isolated coronary artery disease (CAD) of the LAD coronary artery. In addition, MIDCAB is a valuable alternative to standard CABG or OPCAB in selected high-risk patients with multivessel disease and extensive comorbidity, who are at a high risk for sternotomy-related complications.

Anesthesia

Standard monitoring is applied, and temperature management as for OPCAB is applied. Since single-lung ventilation is used, a double-lumen tube or bronchus blocker is applied to provide selective right lung ventilation. To allow for fast extubation, short-acting anesthetics are used.

Surgical Technique

Standard MIDCAB usually is performed through a muscle-sparing minithoracotomy. After making a 5 to 6 cm anterolateral incision in the fifth iintercostal space or the inframammary fold, the pectoralis muscle is displaced bluntly with minimal division following the muscle fiber orientation (muscle-sparing approach). This will decrease the likelihood of lung herniation that has been reported infrequently with this approach. The chest then usually is entered one intercostal space higher than the actual incision. Excessive rib spreading must be avoided at all times to prevent dislocation or fracture of ribs. Removal of a rib is almost never necessary. Takedown of the LITA usually is performed under direct vision, but endoscopic ITA takedowns using a harmonic scalpel or telemanipulation systems have been reported.[44–46] For dissection of the LITA under direct vision, the left lung is deflated. The intrathoracic fascia is divided to facilitate takedown of the LITA, which usually is done in a pedicled manner. Takedown is performed from the fifth intercostal space to the origin of the subclavian artery. Additional length can be gained by dividing the mammary vein at its junction with the subclavian vein. Side branches are clipped or cauterized based on the preference of the surgeon. Heparin is administered prior to distal transsection of the graft. The ACT is kept at a level of 300 seconds. After opening the pericardium above the course of the LAD, the target vessel is identified. The pericardium should be opened 3 cm above and parallel to the phrenic nerve all the way to the aorta to allow visualization of the left atrial appendage and the groove between the aorta and the pulmonary artery. This will facilitate location of the target vessel if excess epicardial fat or an intramuscular course is present. To enhance exposure, one or two pericardial stay sutures may be used to rotate the heart. Standard reusable pressure stabilizers are used to immobilize the target region (Fig. 26-3). Vacuum stabilizers in general are too bulky and not required for a single anastomosis to the LAD. Proximal LAD occlusion is performed using

Figure 26-3. Minimally invasive direct coronary artery bypass. Through a muscle-sparing incision, the left anterior descending artery is easily exposed; standard pressure stabilizers are used.

a 4-0 felt-pledgeted suture or vessel loops. Preconditioning is not helpful, and the use of shunts is rarely necessary, but they may be applied based on the preference of the surgeon. Distal occlusion is avoided whenever possible (99% of patients). A blower-mister is used in all cases to achieve a bloodless field. The anastomosis then is performed in a standard fashion. Graft patency assessment is performed using transit-time Doppler. A single chest tube is inserted into the left pleural space, and intercostal nerve blockade is applied using local anesthetics. Patients are started on antiplatelet therapy on the day of operation. Extubation usually is performed on the table or a few hours postoperatively.

Results

A number of papers have reported excellent results with this approach. Immediate angiographic patency rates are in the range of 94 to 98% and thus similar to those reported for conventional CABG.[43,47] At 6 months, patency rates of 94% have been reported.[48] Reported in-hospital mortality for MIDCAB is less than 1% and compares favorably with the off-pump single-bypass mortality of 1.4% and with the mortality of single bypass with CPB of 3.6% that was been reported in the registry of the German Society for Thoracic and Cardiovascular Surgery in 2004.[49] The rates of perioperative major complications such as stroke, MI, and the need for target-vessel reintervention are low as compared with standard CABG.

In our own series of 1461 patients who underwent MIDCAB from 1996 to 2005, in-hospital mortality was 0.8% (predicted mortality by Euroscore 3.6%), and stroke rate was 0.4%. Conversion to sternotomy was necessary in 1.8%. A total of 709 patients received routine postoperative angiogram demonstrating a 95.6% early patency rate. At 6 month follow-up, graft patency was 94.3% ($n = 350$). Five-year survival is 91.5% (95% CI 89.51–93.5%) (Fig. 26-4*A*). The freedom from MACCE and angina after 5 and 7 years was 88.6% (95% CI 86.4–90.9%) (see Fig. 26-4*B*). These results are in accordance with the findings of other groups.[48,50,51]

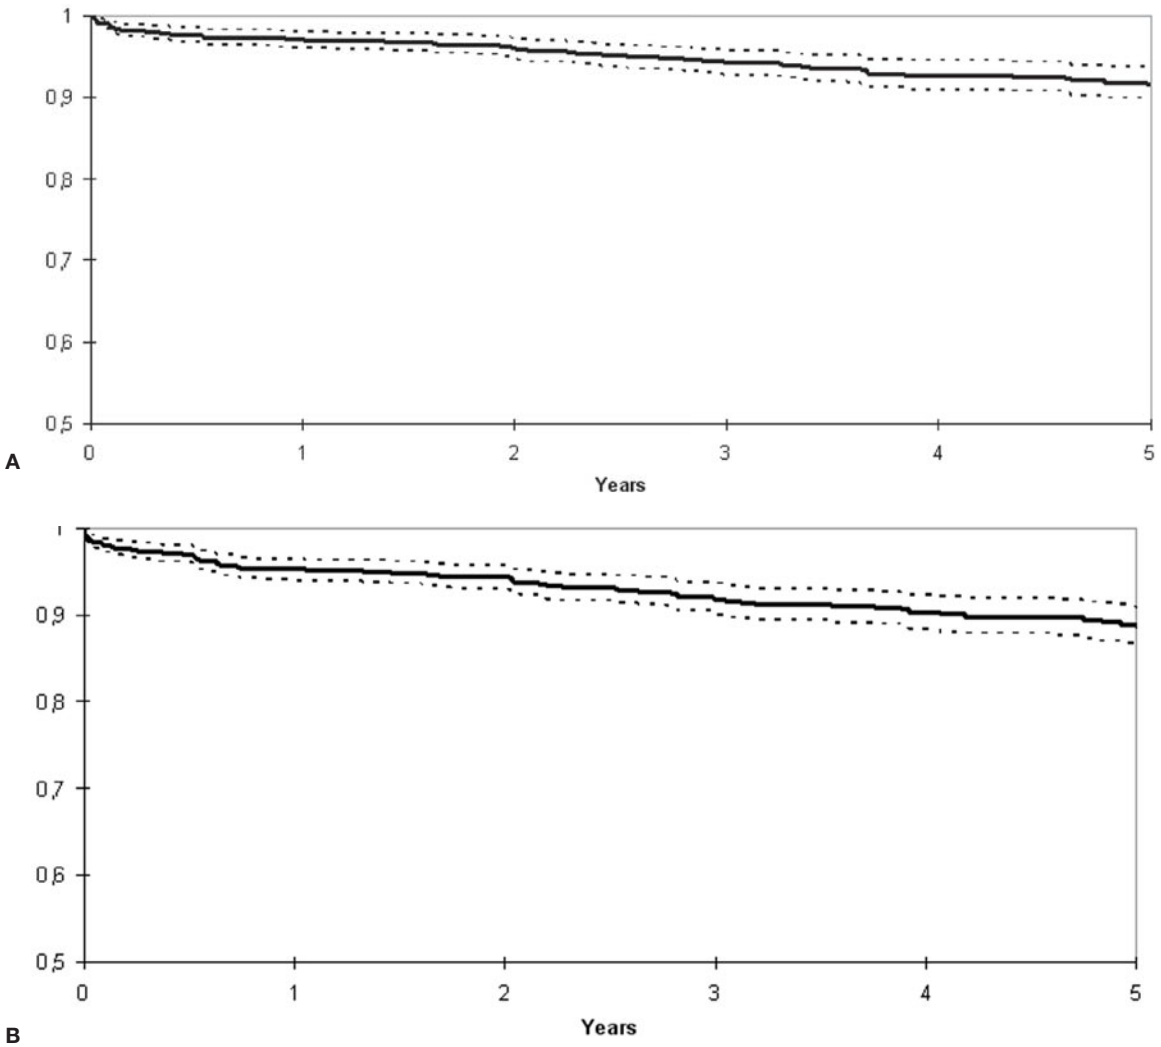

Figure 26-4. Five-year survival curve (*A*) and event-free survival curve (freedom from death, myocardial infarction, stroke, freedom from angina, freedom from reintervention) (*B*) after minimally invasive direct coronary artery bypass. Data from 1461 patients undergoing MIDCAB at the Heartcenter Leipzig.

A few randomized trials comparing MICAB versus bare metal stenting have demonstrated better early patency and superior freedom from target-vessel reintervention and angina for the surgical group up to 5 years of follow-up.[52–56]

Operating through limited access and on the beating heart remains challenging, however, and efforts to facilitate the graft-to-coronary-artery anastomosis under the constraints of a limited working field led to the development of a number of anastomotic devices,[57,58] some of which were used in MIDCAB and endoscopic bypass grafting.[59,60] Given the mixed results, most of these devices are of historic interest only.

Some studies have pointed out that the lateral approach is associated with higher pain levels than sternotomy mainly owing to the excessive rib spreading required for visualizing the LITA during takedown.[44] Rib dislocation or fracture has been reported infrequently with this approach. Direct harvesting of the LITA is regarded as technically challenging and has been one of the arguments for many surgeons to disregard MIDCAB as the primary operation for patients who require surgical revascularization of the LAD. Limited working space and incomplete vision are blamed for insufficient graft length, incomplete mobilization, and the occasional reports of LITA injury or injury of the subclavian vein.

Techniques for endoscopic LITA takedown therefore were introduced to facilitate graft takedown in MIDCAB and to avoid excessive rib spreading. A number of papers have been published on the subject, demonstrating the potential advantages of an endoscopic inferior mammary artery (IMA) harvest: less pain, better visualization, and better access to the proximal and distal portions of the graft.[45,46] Despite these advantages, endoscopic IMA harvest using standard endoscopic tools has not found widespread application. Most cardiac surgeons were not familiar with endoscopic surgical techniques and not willing to accept their limitations: monocular vision, limited dexterity, impaired hand-eye alignment, working with fulcrums, impaired tactile feedback, and increased difficulties in the handling of complications such as bleeding and injury of the graft.

With the introduction of computer-enhanced telemanipulators into the field of cardiac surgery, some of these limitations were overcome, as outlined below. The surgical skills required for a safe takedown of the ITA therefore are easily transferable into a closed-chest environment.

The technique of "robot-assisted" takedown is relatively straightforward and requires only minimal conceptual changes. The ITA is easily visualized, and takedown can be performed as a pedicle or skeletonized process based on the preference of the surgeon.[61] As compared with direct takedown through a lateral thoracotomy such as in MIDCAB, the conduit usually is longer with an endoscopic harvesting technique because distal takedown is greatly facilitated. The learning curve, which is long for a standard endoscopic technique and a source of great frustration, is relatively short for the robot-assisted endoscopic technique. Most surgeons will master the technique in 30 to 40 minutes after a step learning curve including some 20 patients.[62] While with standard endoscopic techniques any further manipulation of the graft, the pericardium, or the heart is extremely difficult, if not almost impossible, in situ preparation of the distal end for the anastomosis is accomplished easily using a telemanipulation system. In patients with a suitable anatomy and coronary morphology, the revascularization procedure can be continued and completed endoscopically on the beating heart. Bilateral endoscopic harvest, which is helpful for multivessel small-thoracotomy approaches, is greatly facilitated.

Even with improved outcomes of interventional procedures and less in-stent restenosis with the use of drug-eluting stents, MIDCAB, given its good long-term results, will remain a true alternative for patients with single-vessel disease, especially for complex ostial lesions, chronic occlusions, and repeated in-stent restenosis.

TOTAL ENDOSCOPIC CORONARY ARTERY BYPASS GRAFTING (TECAB)

The possibly least invasive approach for surgical revascularization is *total endoscopic coronary artery bypass grafting* (TECAB) on the beating heart. Although desirable, the closed-chest approach imposes a number of anatomic and technical challenges that have to be met. The closed chest can be described as a confined space that presents the human operator with the challenge of a remote work environment requiring microsurgical precision. Working through ports has long been known for limiting the available space to perform motions, for substantially decreasing the dexterity of the operator, and for altering the hand-eye coordination.[63] Active assistance, an indispensable component of open surgery, is difficult in thoracoscopic procedures. The transition from limited-access cardiac surgery to endoscopic cardiac surgery therefore complicates the procedure substantially and has rendered previous attempts at endoscopic CABG using conventional endoscopic instruments impossible. To overcome some of the instrument-related limitations, computer-enhanced instrumentation systems have been developed.

Principles of Telemanipulation Technology

The field of telemanipulation surrounds the science and technology involved in enhancing or enabling human interaction with a potentially hazardous environment or performance in confined spaces. The operator involved in the interaction is physically removed but not necessarily remote from the environment in which he or she wishes to perform work. This separation between the operator and the object is bridged by a computer-controlled electromechanical system that serves to transmit the human's actuation commands to the environment and conversely feed back sensory information from the environment to the operator. Three key components comprise a telemanipulator system. The first two components, a master and slave manipulator pair, provide kinesthetic coupling between the human operator and the remote object. This coupling implies that force commands

from the human are replicated at the environment site and that forces generated by the interaction at the environment site are reflected back to the human. This force coupling is essential to enable the human to perform physical work in the environment in a manner that is intuitive and productive. The *input manipulator* (surgical console) refers to an electromechanical system that the human operator interfaces with and serves to interpret the position of the hand and its manual actions and to transmit this information electronically to the executing manipulators. Forces that are generated in the environment are displayed haptically to some degree at the input device. The other half of the kinesthetic coupling, the *executing manipulator,* is also an electromechanical system that performs the inverse task of the input manipulator except in the remote environment. That is, it displays position commands received from the master and interprets forces generated by the environment for transmission back to the master and hence the human operator. The third key component of a telemanipulator system is the technology that provides visual feedback from the environment to the human operator. The kinesthetic coupling is of limited use if the human cannot observe the results of his or her actions in the environment. Together, both haptic and visual feedback enable a human operator to perform useful work in a remote environment while he or she is immersed in a local virtual environment.

Application of telemanipulation technology to endoscopic surgery is particularly well suited because it addresses the key performance limitations of minimally invasive surgery, namely, reduced articulation, monocular vision, and loss of hand-eye coordination.[64]

The traditional design of endoscopic instruments presents significant limitations with respect to intuitive manipulation. Motions of the tool inside the body are reversed from the intended motion outside the body because of the fulcrum effect. Since the instruments pivot around a fixed entry point in the body, scale largely depends on the ratio of internal and external shaft length.[65] Standard endoscopic instruments provide only four degrees of freedom of motion at the tip of the instrument, impairing the surgeon's ability to perform multidimensional tip motion, and do not allow for free orientation of the instrument tip relative to the tissue. Shear stress generated at the pivot point leads to a nonlinear force relationship between the handle and the tip of the instrument, increasing operator fatigue and imposing on any force feedback.[66] Another major limitation of standard endoscopic surgery is the loss of hand-eye coordination because the endoscope enters a port in the body that is not collinear with the surgeon's eyesight, thus forcing the operator to operate the tools from a perspective different from his or her own eyes.[67] By inserting a telemanipulator between the surgeon and the patient, these limitations can be resolved. Nonintuitive directional motion of the tool tip caused by the fulcrum effect can be resolved by matching the surgeon's input motions to the working tip of the tool instead of the tool handle, avoiding reversed motion and unwanted scaling artifacts. Additional degrees of freedom can be added into computer-controlled endoscopic instruments, and finally, hand-eye coordination can be restored to a surgeon using a telemanipulator because the system has full information regarding the orientation and position of the endoscope and tools on both the input and effector sides.

Surgical Technique

Standard monitoring for cardiac surgery is applied. Defibrillator pads are placed on the back and to the right side of the chest. Single-lung ventilation of the right lung is applied using a double-lumen endotracheal tube or a bronchus blocker. Temperature management follows the principles of OPCAB surgery. After draping the instrument arms and camera arm, camera and scope calibration are performed, and the endostabilizer is prepared. A holding arm for the endostabilizer is mounted to the operating table rail on the patient's right side, and the operating table is rotated 10 to 15 degrees to raise the patient's left side.

After single right-lung ventilation is initiated, the camera port is placed in the fifth intercostal space 2 cm medial to the anterior axillary line. CO_2 insufflation is begun for adequate visualization and to create working space as tolerated hemodynamically (usually 10 to 12 mm Hg of insuflation pressure). A 30-degree scope angled up is used for takedown of the LITA. The right instrument port is placed in the third intercostal space medial to the anterior axillary line, and the left instrument port is placed in the seventh intercostal space medial to the anterior axillary line. The instrument arms are centered for optimal range of motion by adjusting the respective setup joints, and the instruments are inserted. LITA takedown starts by dividing the intrathoracic fascia covering the LITA with low-power monopolar cautery. The LITA is dissected bluntly off the chest wall moving from the lateral to the medial aspect as a pedicle, keeping the lateral veins. Side branches are cauterized or clipped. Dissection is performed from the first intercostal space to the level of the bifurcation. The pedicle is not detached from the chest wall until the anastomosis is finally performed to avoid torsion of the graft. The distal end of the graft is skeletonized to facilitate suturing the anastomosis. Epicardial fat is removed, and the mediastinal and diaphragmatic attachments to the pericardium are dissected bluntly to widen the available space. The pericardiotomy is performed with a longitudinal incision in the pericardium over the suspected course of the LAD. The ideal site for the anastomosis is determined by absence of visible atheromatous plaques and avoiding proximity to bifurcations. At this point, changing the angle of the endoscope from 30 degrees, angled up to 30 degrees, angled down may enhance visualization. After heparinization (an ACT of 300 seconds is recommended), a vascular clamp is placed approximately 2 cm proximal to the transsection site. The LITA is clipped distally, cut, and spatulated in preparation for the anastomosis in situ. Graft patency is confirmed by briefly releasing the vascular clamp. The LITA pedicle is still left attached to the chest wall in order to keep orientation of the graft until the anastomosis is performed. A 12 mm

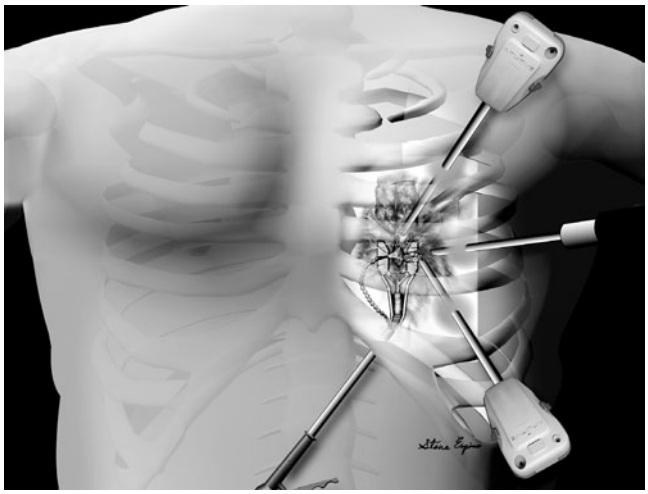

Figure 26-5. Setup for total endoscopic coronary artery bypass grafting. Two instrument ports, one central camera port, and a subxyphoidal port for the endostabilizer are required.

subxyphoid cannula is inserted under endoscopic vision. Before introduction of the endostabilizer, temporary Silastic occlusion tapes and a 7 cm 7-0 double-armed Prolene suture are introduced through this port and stored in the mediastinum. Some surgeons prefer Gore-Tex sutures to avoid the memory effect. Alternatively, nitinol clips (U-clips) may be used. The endostabilizer then is introduced under endoscopic vision by the patient-side surgeon (Fig. 26-5). Vacuum lines and irrigating saline line are connected, and the multilink irrigator is advanced into the field of view. The console surgeon then positions the stabilizer feet parallel to the LAD target site. After suction is applied, the feet are locked into position. After blunt dissection of the anastomotic target site, the Silastic tapes are placed proximal and distal to the anastomotic site, and temporary occlusion is applied. After a 5 to 6 mm arteriotomy is performed, transsection of the LITA is completed, and the graft is brought in close proximity of the target site. The anastomosis is best performed by beginning at the middle of the medial wall (12 o'clock position), suturing inside-out on the LITA and outside-in on the LAD toward and around the heel. Care has to be taken to tension the suture continuously. After the needles are broken off, an instrument knot is tied. The occlusion tapes and vascular clamp are released and evacuated through an instrument port. The pedicle may be fixed to the epicardium by stay sutures. For graft patency, control transient-time Doppler flow measurements can be performed endoscopically if a probe without a handle is available. This probe can be advanced through the stabilizer port. Alternatively, intraoperative angiography has been performed using a mobile angiography unit. The quality of these angiograms, however, may vary. After pleural effusion is drained under vision, the stabilizer and instruments are withdrawn, and the left lung is ventilated. A chest tube is inserted through one of the port holes. In case a four-arm system is used, the fourth arm is introduced after harvesting of the LITA in the third intercostal space in the anterior axillary line. It may be used to provide countertraction during epicardial fat removal and pericardiotomy and to present the pedicle during the anastomosis. The new version of the da Vinci system also will allow the use of a remotely controlled stabilizer that is placed on the fourth arm and thus can be adjusted from the console.

Results

Despite the use of advanced telemanipulator technology, the TECAB procedure remains technically demanding and is performed infrequently. Initially, TECAB was performed on the arrested heart using the Port-Access platform with femorofemoral artery bypass, endoaortic balloon clamping, and cardioplegic arrest. CPB time and cross-clamp times were in the range of 80 to 120 and 40 to 60 minutes, respectively. The reported patency rate for the TECAB procedure on the arrested heart ranged from 95 to 100% prior to discharge and 96% at 3 month follow-up angiography.[62,68–70] It was demonstrated in these initial series that equal patency rates as compared with standard bypass procedures could be achieved endoscopically in selected patients. However, operating times were in the range from 4 to 6 hours for a single bypass graft. In a more recent multicenter analysis, angiographic patency rate was 98.2%. However, the conversion rate was 23%, mostly related to problems with the Port-Access system or peripheral cannulation.[71]

Endoscopic CABG on the beating heart is even more challenging.[72–74] Based on intention to treat, the conversion rate (elective conversion to a MIDCAB procedure) in a five-center registry was 33% (37 of 117). Conversions were mostly due to calcified target vessels or the inability to locate or dissect the LAD and rarely other conditions such as arrhythmia or hemodynamic instability. In most centers, takedown of the LITA is now a routine procedure that can be performed in 30 to 40 minutes and is comparable with the times required in MIDCAB procedures. A time-consuming step is the setup of the stabilizer and preparation for the anastomosis. Time for LAD occlusion is in the range of 25 to 40 minutes and thus markedly longer than for MIDCAB or OPCAB. Operating times for a beating-heart TECAB procedure thus range from 2.5 to 3.5 hours in most centers. The patency rates for completed beating-heart TECAB procedures are in the range of 92 to 94%.[71]

TECAB can be performed safely but is currently restricted to few indications (e.g., single-vessel bypass grafting of the LAD and occasionally double-vessel grafting) but clearly has the potential for endoscopic multivessel procedures.[75,76] Exposure of the posterior and inferior wall vessels, however, will require rotation and displacement of the heart to various degrees. Endoscopic suction devices such as the Endostarfish may help exposure in a closed-chest environment and are being investigated currently for a small-thoracotomy multivessel approach (MVST). For this operation, one or both IMAs are harvested endoscopically. A small anterolateral thoracotomy is performed. Through this thoracotomy, a T-graft is performed. With the help of the Enodstarfish,

sequential grafting of obtuse marginal branches or the posterior descending artery is possible.[76]

Operating times for TECAB are still long, and conversions to MIDCAB or open surgery frequently are necessary. A number of steps that occur between ITA takedown and performing the anastomosis are challenging owing to the lack of assistance, limited space, the lack of fine tactile feedback, and a limited number of instruments. Among the difficulties are the handling of excessive epicardial fat, determination of the optimal site for an anastomosis, target-vessel calcification, and backbleeding from septal branches. In addition, difficulties with positioning of the stabilizer or incomplete immobilization render beating-heart closed-chest bypass grafting difficult.

As with all new technologies, a learning curve has to be overcome, and a structured training is considered essential for procedural success. This includes a principal understanding of the system architecture of telemanipulation systems and the underlying human-machine interface technology. Port placement is paramount to reducing the degree of difficulty and ensuring success of the procedure. Knowledge about the range of motion and kinetics of the slave arms is essential. The assessment of potential collisions among the slave arms or the slave arms and the patient's body is important to determine the optimal placement of ports. Since inside the chest a large range of motion with a number of different trajectories is required to perform the proximal-to-distal ITA dissection, the pericardiotomy, and the anastomosis, the ideal port triangle will vary according to the target.

A team approach is crucial for success, and it is important that the table-side surgeon understands the basic mechanisms of joint motion of the manipulators in order to provide a setup that allows an unrestricted range of motion. Takedown of the ITA should be accomplished routinely, before aiming at a complete TECAB procedure.

With recent refinements in telemanipulator technology, providing more range of motion and direct control of the stabilizer, endoscopic bypass grafting will evolve further and may prove beneficial for selected patients. New methods for preoperative planning and simulation, intraoperative navigation, and image guidance, as well as augmented reality techniques, are currently under investigation.[78,79] A new endoscopic stabilizer that can be operated by the surgeon from the surgeon's console (Fig. 26-6), as well as endoscopic anastomotic connectors, may help to facilitate the procedure further.[60]

ENDOSCOPIC CONDUIT HARVEST

To minimize the overall trauma of a bypass procedure, conduit harvest should be performed through limited incisions or endoscopically. There is a body of evidence indicating that while the quality of the conduit is not impaired by an endoscopic harvest, wound infections and other complications of the harvesting procedure are decreased substantially. The cosmetic advantage is obvious.

Figure 26-6. Endoscopic coronary artery bypass grafting. New endoscopic vacuum stabilizer including irrigating channel. The stabilizer is mounted to the fourth arm of the new da Vinci system and can be operated remotely by the surgeon at the console.

Endoscopic Saphenous Vein Harvesting

Despite the fact that arterial grafting yields better long-term results than venous grafting, and despite increased use of the IMA and other arterial grafts, the greater saphenous vein is still used frequently for CABG. The standard longitudinal open harvesting technique of the greater saphenous vein is associated with a 2 to 25% rate of wound complications (e.g., dehiscence, delayed healing, infection, cellulitis, sepsis, and occasionally, limb amputation), complicating ambulation of the patient, prolonging hospitalization, and causing an economic burden.[80–83] In addition, open saphenous vein harvest is associated with postoperative pain, neuropathy, and long-term pain and scarring impairing patient satisfaction.

Various techniques for endoscopic vein harvest exist that require one or two 2 cm incisions. For a single-incision technique, the greater saphenous vein is identified through a 2 cm longitudinal incision at the crease of the knee posterior to the medial femoral condyle. A space anterior and posterior at the surface of the vein is dissected, and a subcutaneous retractor or dissection cannula is introduced. An endoscope is inserted into the subcutaneous tissue. Exposure can be enhanced by insufflating CO_2. The vein is mobilized circumferentially, and side branches are either clipped, coagulated using bipolar endoscopic bipolar cautery scissors, or vaporized using a harmonic scalpel. Whenever bipolar cautery is applied, a distance of at least 2 mm between the scissors and the vein should be kept in order to avoid thermal damage. Proximal and distal control of the greater saphenous vein is accomplished with endoscopic application of a Prolene suture, clips, or ligation loops. With this technique, the entire length of the vein can be harvested from the saphenous-femoral junction to the medial malleolus through a single incision. The wound is closed in a standard fashion, and the leg is wrapped circumferentially with bandages. In

experienced hands, the procedure takes between 30 and 50 minutes.[84] As with all endoscopic techniques, a learning curve is associated with endoscopic vein harvesting, with training involving approximately 30 patients and a conversion rate ranging from 0 to 22%. This is also illustrated by the finding that endoscopically harvested veins require a significantly greater number of repairs as compared with the open technique.[84,85]

Results

The ISMICS Consensus Group recently reviewed the results of 1319 randomized and 8023 nonrandomized patients. In this meta-analysis, the risk of wound complications was reduced significantly by 69% with endoscopic vein harvesting compared with the open technique (OR 0.31, 95% CI 0.23–0.43; $p < .0001$).[85] The need for surgical intervention for wound infection also was reduced significantly (OR 0.29, 95% CI 0.12–0.70; $p = .007$). With regard to the incidence of moderate to severe postoperative pain, a reduction of 74% was found with endoscopic vein harvesting compared with the open technique (OR 0.26, 95% CI 0.12–0.55; $p < .0001$), and this reduction was 90% at 4 to 6 weeks follow-up (OR 0.10, 95% CI 0.03–0.37; $p < .0001$). The incidence of mobility disturbance at discharge was reduced by 69% (OR 0.31, 95% CI 0.15–0.65; $p = .002$). No difference was found for MI, rethoracotomy, angina recurrence or reintervention, and death over the short term.[85] However, the number of trials looking at cardiac outcomes and providing angiographic data on patency rates are too limited to allow any meaningful conclusion. The few trials that looked at vascular integrity and vessel wall trauma did not find a difference for the endoscopic versus open technique.[86,87]

Harvesting times were increased for the endoscopic technique in most trials. Although closure time was reduced significantly, this resulted in a net increase in total harvesting time. Total blood loss was reduced with endoscopic vein harvest ($p = .04$). ICU length of stay and time to ambulation were not reduced, but total hospital length of stay was reduced.[85]

Endoscopic Radial Artery Harvest

Use of the radial artery for CABG has regained popularity over the last decade. In conventional radial artery harvest, the incision runs from below the antecubital fossa to the wrist, along the medial border of the brachioradialis muscle. While wound complications are reported infrequently, delayed healing of the forearm can cause severe discomfort.[88] Objective sensory loss in 10% of patients and forearm scar discomfort in 33% undergoing open radial artery harvest have been reported.[89,90] Endoscopic techniques for graft harvest have been developed subsequently.[91]

Surgical technique

Collateral circulation from the ulnar artery to the palmar arch has to be verified pre- or intraoperatively using either the standard Allen test or modification of the test by applying Doppler or measuring oxygen saturation in patients in whom the signs of visual reperfusion are in doubt. In order to prevent brachial plexus injury, the arm should not be overextended above 90 degrees. One centimeter superior to the radial styloid prominence, a 2 to 3 cm incision is made, and the radial artery is identified and dissected. A subcutaneous retractor and a 5 mm, 30 degree endoscope are placed into the incision. By bluntly advancing the retractor through the subcutaneous tissue, the radial artery is visualized (Fig. 26-7). Side branches and surrounding tissue are divided using an ultrasonic harmonic scalpel that is placed underneath the retractor. The fascia between the brachioradialis and flexor carpi radialis muscles is divided anterior to the radial artery with the harmonic scalpel to increase the space for insertion of the subcutaneous retractor.[92] After division of all side branches, a vessel retractor is advanced from the distal incision to verify complete isolation of the conduit. The proximal radial artery is clipped distal to the origin of the ulnar artery branch and transsected with endoscopic scissors. The graft is recovered through the distal incision, and the distal end is ligated. The incision is closed in a standard fashion.

Figure 26-7. Endoscopic radial artery harvest. Endoscopic view.

Results

The reported incidences of neurologic complications after standard open harvesting technique of the radial artery vary in the literature from 2.4 to 30% and can be related to injury of the superficial radial nerve or the lateral antebrachial cutaneous nerve. With endoscopic technique, the latter usually is not encountered because the dissection is performed underneath the brachioradialis muscle. Superficial radial nerve injury, however, still may occur during distal dissection.[92] With regard to wound infections, endoscopic radial artery harvest is associated with a lower rate of infection (0 to 2.7%) compared with the open technique.[84,93] Regarding the quality of the graft, patency rates, and impact on long-term

survival, there is currently no evidence in favor of either technique. The indication for endoscopic radial harvest therefore can be based on improved wound healing, better patient comfort, and improved cosmesis.

CONCLUSION

In summary, minimally invasive bypass surgery continues to play an increasing role in surgical revascularization. There is growing evidence in favor of OPCAB, which is already the preferred method of bypass grafting in many centers. MIDCAB is still limited to patients with single-vessel disease, but excellent long-term data confirm the efficacy of the approach. Endoscopic bypass grafting using robotic assistance is still an evolving procedure that is applied only to selected patients, and its continued application will depend heavily on technological improvements. As for endoscopic vein graft harvesting, there is a body of evidence suggesting superior results compared with an open harvesting technique, which also may be true for the technique of endoscopic radial artery harvest in the future.

CHAPTER 27

Coronary Artery Reoperations

G. V. Gonzalez-Stawinski • Bruce W. Lytle

Coronary artery reoperations are more complicated than primary operations. Patients undergoing reoperations have distinct, more dangerous pathologies; reoperations are technically more difficult to perform; and the risks are greater.[1–12] Vein graft atherosclerosis, present in most reoperative candidates, is a unique and dangerous lesion. Reoperative candidates commonly have severe and diffuse native-vessel distal coronary artery disease (CAD), a problem that has had the time to develop only because these patients did not die from their original proximal coronary artery lesions. Aortic and noncardiac atherosclerosis are also often far advanced in many reoperative candidates. Some technical hazards, including the presence of patent arterial grafts and sternal reentry, are unique to reoperations, and others, such as lack of bypass conduits and difficult coronary artery exposure, are common.

INCIDENCE OF REOPERATION

After a primary bypass operation, the likelihood of a patient undergoing a reoperation depends on patient-related variables, primary operation-related variables, adherence to strict medical control of risk factors for disease progression following bypass surgery, the possibility of alternative treatments, physician opinion about the feasibility of reoperation, and time. Studies from our institution noted a cumulative incidence of reoperation of 3% by 5 years, 10% by 10 years, and 25% by 20 postoperative years[13] (Fig. 27-1). Factors associated statistically with an increased likelihood of reoperation have been variables predicting a favorable long-term survival [e.g., young age, normal left ventricular function (LVF), and single- or double-vessel disease], variables designating an imperfect primary operation [e.g., no internal thoracic artery (ITA) graft and incomplete revascularization], and symptom status (e.g., class III or IV symptoms at primary operation). Young age at primary operation and incomplete revascularization are also markers of a severe atherogenic diathesis.

More recently, however, the proportion of isolated coronary artery operations that are reoperations has decreased. This decrease is related in part to the more aggressive use of coronary artery interventions for patients with previous bypass surgery and possibly to more effective risk factor control. In 1990 about 37% of coronary artery revascularization operations were reoperative interventions, whereas in 2002 this figure decreased to 30%[14] (Fig. 27-2). Also, surgery has changed in directions that will decrease the rate of reoperation. Use of the left internal thoracic artery (LITA) to graft the left anterior descending (LAD) coronary artery decreases the risk of reoperation compared with the strategy of using only vein grafts, and the LITA-LAD graft has become a standard part of operations for coronary artery revascularization.[15] Furthermore, it now appears that use of bilateral ITA grafts decreases the likelihood of death and reoperation when compared with the single LITA-LAD strategy[16] (Fig. 27-3). The use of other arterial conduits such as the radial artery and the gastroepiploic artery in the context of total arterial revascularization may decrease the risk of reoperation further, but as yet the long-term data are insufficient to answer this question.

The patient population of reoperative candidates has evolved. Cleveland Clinic Foundation studies have shown that in the early years of bypass surgery (1967–1978), only 28% of patients underwent reoperation solely because of graft failure, and that graft failure often occurred early after the primary operation (mean postoperative interval of 28 months after primary operation). Reoperation because of the progression of atherosclerosis in nongrafted coronary arteries was common in the 1967–1978 time period (55% of patients).[1,2] Between 1988 and 1991, almost all patients had graft failure as at least part of the indication for reoperation (92%), but that graft failure occurred late after the primary operation at a mean interval of 116 months.[3] Today, patients

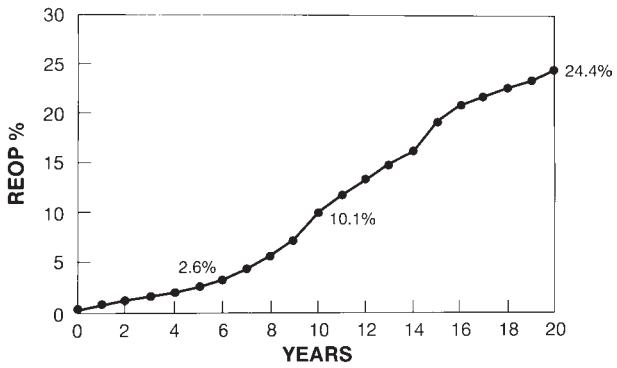

Figure 27-1. Study of 4000 patients who underwent bypass surgery from 1971 to 1974 showed that 25% of patients had undergone a reoperation within a period of 20 years after primary operation. undergoing reoperation usually had a successful primary operation at least 10 years previously for the treatment of multivessel CAD, and the angiographic indications for reoperation are progression of native-vessel distal CAD in combination with late graft failure caused by vein graft atherosclerosis.

GRAFT FAILURE

An understanding of the pathology and causes of saphenous vein graft failure is important not only for an understanding of the causes of the need for reoperation but also for understanding the dangers inherent in either the interventional or the conservative treatment of patients with previous bypass surgery. Saphenous vein to coronary artery grafts exhibit different pathologies at different intervals after operation.[17–20] Within a few months, they often have diffuse endothelial disruptions with associated mural thrombus. The mural thrombus usually is not obstructing, and when grafts do become occluded early after operation owing to thrombosis, it may not be a result of these intimal changes but rather may be related to hemodynamic factors. Most saphenous vein grafts examined more than 2 to 3 months after operation have developed a proliferative intimal fibroplasia. This is a concentric cellular process, and it is diffuse, extending the entire length of the graft (Fig. 27-4). It evolves with time to a more fibrous lesion. It is not friable, and although intimal fibroplasia involves most vein grafts, it causes stenoses or occlusions of only a few.

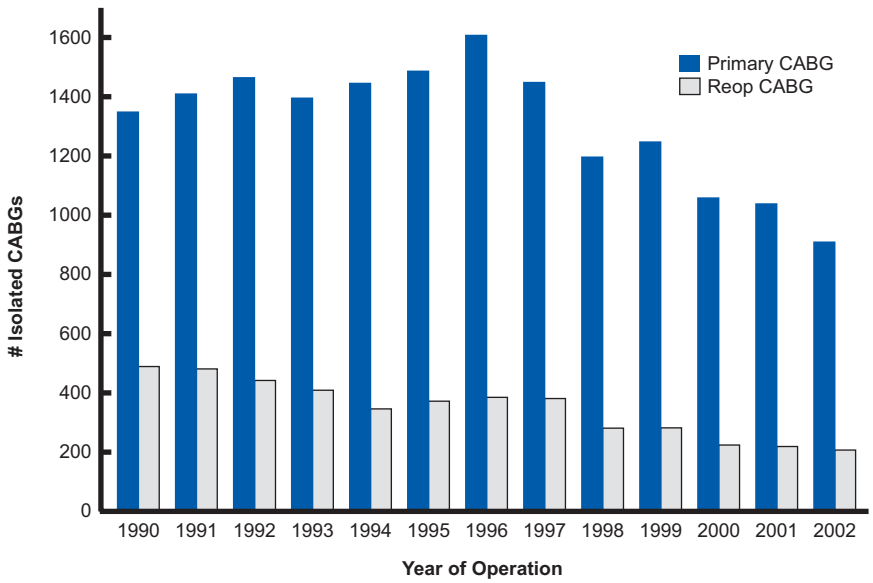

Figure 27-2. Study of 21,568 patients who underwent bypass surgery from 1990 to 2003 showed a steady decrease in the number of patients undergoing redo coronary artery operations. (*Data from Sabik JF, Blacksotne EH, Houghtaling PL, et al: Is reopration still a risk factor in coronary artery bypass surgery? Ann Thorac Surg 2005; 80:1719.*)

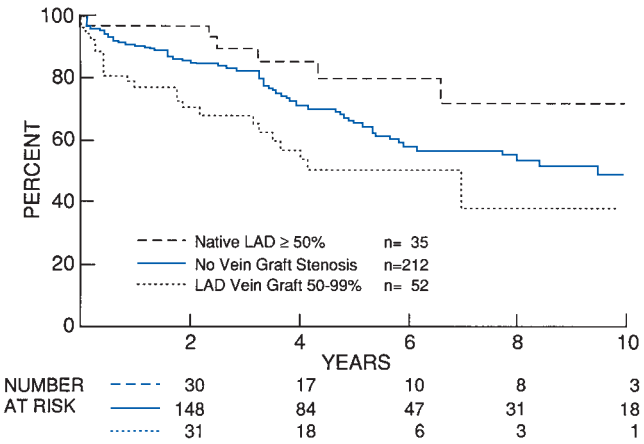

Figure 27-5. Patients with late stenoses in vein grafts to the LAD coronary artery had worse survival when compared with either patients with native coronary LAD stenoses or patients with no stenotic vein grafts. (*Reproduced with permission from Lytle BW, Loop FD, Taylor PC, et al: Vein graft disease: The clinical impact of stenoses in saphenous vein bypass grafts to coronary arteries. J Thorac Cardiovasc Surg 1992; 103:831.*)

Vein graft atherosclerosis is a distinct pathologic process that often is recognized as early as 3 to 4 years after operation and is characterized by lipid infiltration of areas of intimal fibroplasia (Fig. 27-5). The distribution of vein graft atherosclerosis mimics that of intimal fibroplasia in that it is concentric and diffuse, although as vein graft atherosclerosis progresses, stenotic lesions may become eccentric. In addition, vein graft atherosclerosis is a superficial lesion, it is very friable, and it is often associated with overlying mural thrombus. These characteristics make it different from native-vessel coronary atherosclerosis, a process that is segmental and proximal, eccentric, encapsulated, usually not friable, and usually not associated with overlying mural thrombus. Vein graft atherosclerosis is seen in a majority of grafts explanted more than 10 years after surgery whether or not those grafts are stenotic, and atherosclerotic lesions appear to account for almost all late saphenous vein graft (SVG) stenoses. The extreme friability of vein graft atherosclerosis creates a substantial risk of distal coronary artery embolization during percutaneous interventions to treat stenotic lesions and during reoperations for patients with atherosclerotic vein grafts. It is also probable that spontaneous coronary artery embolization may occur from atherosclerotic grafts. In addition, atherosclerotic stenoses in vein grafts appear to predispose to graft thrombosis. Vein graft atherosclerosis appears to be an "active" event-producing lesion.

The exact incidence of late SVG stenoses and occlusions is difficult to determine even with prospective studies because death and reoperation are nonrandom events that remove patients from prospective populations available for late coronary artery angiography. However, it appears that by 10 years after operation, approximately 30% of vein grafts are totally occluded, and 30% of patent grafts exhibit some degree of stenosis or intimal irregularities characteristic of vein graft atherosclerosis.[21,22] Although vein graft atherosclerosis is not the only factor related to late SVG occlusion, it is an important one. Native-vessel stenoses distal to the insertion site of vein grafts may decrease SVG graft outflow and contribute to graft failure, but late graft occlusion usually occurs in the presence of vein graft atherosclerosis. Furthermore, when stenotic vein grafts are replaced at reoperation, the late patency rate of the new vein grafts is good.[2]

Progress has been made toward decreasing the rate of vein graft failure. The early patency rates of SVGs have been improved by the use of perioperative and long-term platelet inhibitors,[23–25] but the best data involving patients receiving platelet inhibitors indicate that the 10-year vein graft failure rate is approximately 35%. Some studies have shown that lipid-lowering regimens decrease late vein graft disease and the risk of late cardiac events. However, the overall level of improvement has been small.[26,27] So far, the only way known to avoid vein graft atherosclerosis is to avoid using vein grafts.

ITA grafts rarely develop late atherosclerosis, and the late attrition rate of patent ITA grafts is extremely low. Left ITA to LAD grafts have a very high late (20 years) patency rate, and for most patients, the LAD is a profoundly important coronary artery.[21,28] These factors account for the impact of the LITA-LAD graft not only in decreasing the rate of late death after primary bypass surgery but also in decreasing the rate of reoperation.[15] Multiple ITA grafts provide incremental benefit in decreasing the risk of reoperation.[16] It is also important that ITA grafts do not develop graft atherosclerosis and, therefore, do not create the risk of coronary artery embolization during reoperation. The presence of patent arterial grafts may create other technical problems during repeat surgery, but embolization is not among them.

INDICATIONS FOR REOPERATION

The randomized trials of bypass surgery versus medical management that were initiated in the 1970s provided a framework of information concerning the indications for bypass surgery, and subsequent observational studies have added substance to that framework. However, no randomized trials of medical versus surgical management pertain to patients with prior surgery. The coronary pathology of patients with previous bypass surgery is different from that of patients with only native-vessel stenoses, and we cannot assume that the natural history of, for example, triple-vessel disease based on atherosclerotic vein grafts is equivalent to that of triple-native-vessel disease.

There are two nonrandomized, retrospective studies of patients who had angiograms after bypass surgery that addressed the issue of late survival.[29,30] One study showed that patients with early (fewer than 5 years after operation) stenoses in vein grafts and patients with no stenotic vein grafts had approximately the same outcomes and that these outcomes were relatively good.[29] *However, the presence of late (5 years or more after operation) stenoses in vein grafts predicted poor long-term outcomes, particularly if a stenotic vein graft supplied the LAD coronary artery. When late stenoses in LAD vein grafts were combined with other high-risk characteristics, the late survival rate was particularly dismal.* For example, patients with a 50 to 99% stenosis in a LAD vein graft combined with abnormal LVF and triple-vessel or left main stenoses had only a 46% 2-year survival without reoperation. Patients with late stenoses in an LAD vein graft had significantly worse long-term outcomes than did patients with the LAD jeopardized by a native lesion (see Fig. 27-5). This study showed that the difference in the pathology of early (intimal fibroplasia) and late (vein graft atherosclerosis) vein graft stenoses is associated with a difference in clinical outcome and that late stenoses in vein grafts are dangerous lesions.

A second study compared the outcomes of patients with stenotic vein grafts treated with reoperation (REOP group) versus those treated with medical treatment (MED group).[30] Again, this was a nonrandomized, retrospective study, and the patients in the REOP group were older and more symptomatic, had worse LVF, and had fewer patent grafts than the patients in the MED group.

The survival of patients with early (fewer than 5 years) SVG stenoses was not different in the two groups. The operative risk for the REOP group was low (no deaths among the 59 patients) and the long-term survival was good, but late survival was just as good for the patients treated medically (Fig. 27-6). It is important to note that the patients in the REOP group were more symptomatic to start with, and at late follow-up, they were less symptomatic than the patients in the MED group. Thus, reoperation for patients with early vein graft stenosis was an effective way of relieving symptoms of angina, but it appears that patients without symptoms can be treated medically with safety, at least over the short term.

However, the overall outcomes were worse for patients with late stenoses in vein grafts, and many subgroups had improved survival rates with reoperation. By multivariate testing (Table 27-1), a stenotic (20 to 99%) LAD vein graft predicted late death, and performing a reoperation increased late survival for these patients. Multivariate testing of smaller subgroups showed that the survival advantage for the REOP

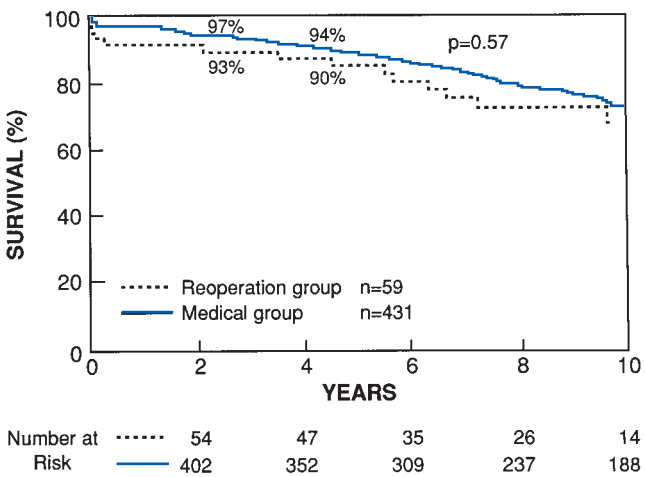

Figure 27-6. The survival of patients with early (<5 years after operation) stenoses in vein grafts was favorable with and without reoperation (p = NS). *(Reproduced with permission from Lytle BW, Loop FD, Taylor AC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein to coronary bypass grafts. group was true even for patients with only class I or class II symptoms and that reoperation still improved survival for the remaining patients when patients with stenoses in LAD vein grafts were excluded from the analysis.

Univariate comparisons for the REOP and MED subgroups of patients with stenotic LAD grafts are shown in Fig. 27-7, demonstrating the improved survival for the REOP group. When patients with stenotic LAD vein grafts were subgrouped on the basis of severity of the stenotic lesions (Fig. 27-8), the patients with severely stenotic (50 to 99%) vein grafts obviously benefited from surgery, exhibiting a decreased risk of death even early in the follow-up period. For patients with moderate stenoses (20 to 49%) in LAD vein grafts, the survivals of the MED and REOP groups were equivalent for about 2 years, but after that point, survival of the patients in the MED group became rapidly worse so that by 3 to 4 years of follow-up, the survival benefit of reoperation became apparent. Although the patients in these studies did not have consistent functional testing, there is evidence that myocardial perfusion and functional studies can help to identify patients likely to benefit from reoperation. Lauer and colleagues studied 873 symptom-free postoperative patients with symptom-limited exercise thallium-201 studies and found that patients with reversible perfusion defects were more likely to die or experience major cardiac events

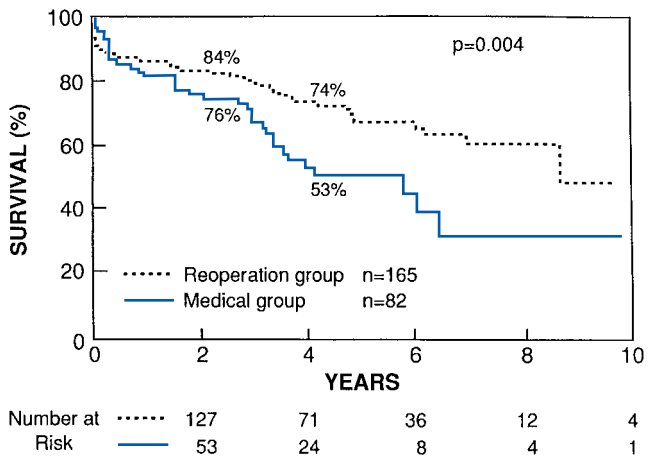

Figure 27-7. If patients had late (≥5 years after operation) stenoses in LAD vein grafts, they had a better survival rate (p = .004) with immediate reoperation than if they received initial nonoperative treatment. (*Reproduced with permission from Lytle BW, Loop FD, Taylor AC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein to coronary bypass grafts. J Thorac Cardiovasc Surg 1993; 105:605.*)

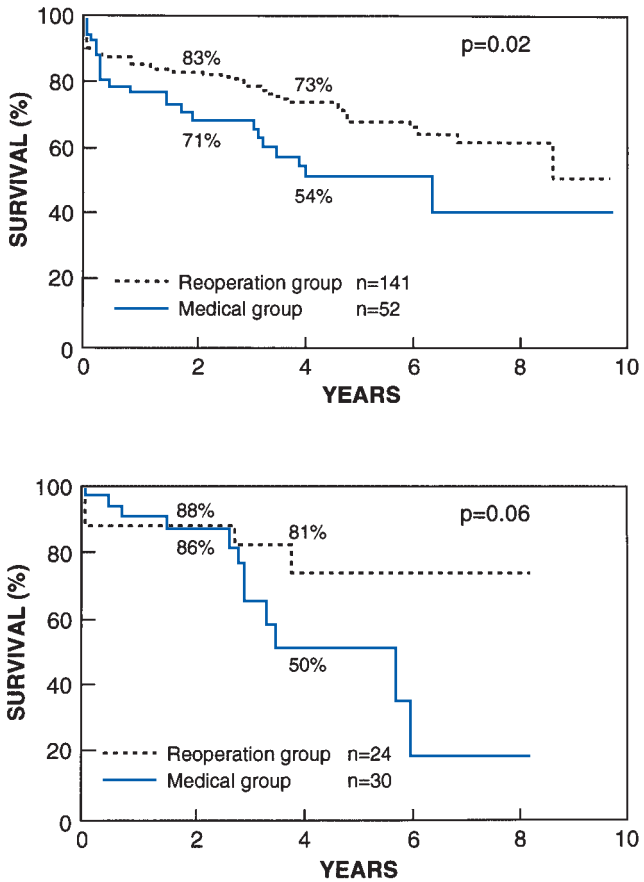

Figure 27-8. Patients with late stenoses in LAD vein grafts (*top*) had immediate improvement in their survival rate. Patients with moderate (20 to 49%) stenoses in LAD vein grafts had equivalent survival with or without reoperation for approximately 2 years, but after that point, the patients who did not have reoperation did poorly. (*Reproduced with permission from Lytle BW, Loop FD, Taylor PC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein to coronary bypass grafts. J Thorac Cardiovasc Surg 1993; 105:605.*)

during a 3-year follow-up.[31] Impaired exercise capacity also was strongly predictive of unfavorable outcomes.

Anatomic indications for reoperation to improve survival prognosis include (1) atherosclerotic (late) stenoses in vein grafts that supply the LAD artery, (2) multiple stenotic vein grafts that supply large areas of myocardium, and (3) multivessel disease with a proximal LAD lesion and/or abnormal LVF based on either native-vessel lesions or stenotic vein grafts or a combination of the two pathologies. Reoperation is also effective in other anatomic situations in which severe symptoms are the indication for invasive treatment, including patients with a patent ITA to LAD graft combined with other ischemia-producing pathology and multiple early vein graft stenoses. The combination of the anatomic characteristics just noted and reversible ischemia and/or worsening LVF during stress constitutes a particularly strong indication for reoperation.

PERCUTANEOUS TREATMENT OF POSTOPERATIVE PATIENTS

Percutaneous treatments (PCTs) represent alternative anatomic treatments for postoperative patients and often are useful. The effectiveness of PCTs is related to the vascular pathology to be treated and the clinical implications of treatment failure. Today, native coronary artery stenoses often can be treated with a low restenosis rate as long as those vessels are large enough to allow intracoronary stenting. Unfortunately, many postoperative patients have very diffuse native coronary atherosclerosis that makes PCT difficult or ineffective. Also, PCT has not been as effective in the treatment of diabetic native CAD.

The rate of technologic change in interventional cardiology has been rapid, and multiple percutaneous technologies have been used to treat stenotic vein grafts. Balloon angioplasty, first-generation PCT, was relatively dangerous to perform and produced ineffective long-term revascularization, particularly when used to treat older (atherosclerotic) vein grafts.[32] Direct coronary atherectomy (DCA) increased the risk of coronary embolization at the time of the procedure without improving the restenosis rate.[33] It has been hoped that the use of intracoronary stents, particularly covered stents and drug-eluting stents (DESs), in stenotic vein grafts might provide better outcomes, and stenting does represent an improvement over balloon angioplasty.[32] The Randomized Evaluation of Polytetrafluoroethylene Covered Stent in Saphenous Vein Grafts (RECOVERS) trial, a randomized study designed to compare rates of SVG restenosis between CABG patients treated with covered stents and with bare stents, showed identical restenosis rates at 6 months of follow-up (24.2% versus 24.8%; $p = .24$).[34] Finally, in a nonrandomized retrospective study comparing the effects of DESs with those of bare metal stents in treating SVG stenosis, Ge and colleagues reported significant differences in in-stent stenosis between groups at 6 months of follow-up (10 versus 26%; $p = .03$).[35]

However, the kinetics of treatment failure after PCT for vein grafts are different from those for native coronary vessels. Restenosis and new stenotic lesions in vein grafts continue to appear with time, and the shoulder on the adverse outcome curve that appears at 6 months to 1 year after PCT for native vessels does not appear for vein grafts. Thus, there is still some uncertainty about the clinical impact of PCTs of stenotic vein grafts. Patients with previous bypass surgery are an extremely heterogeneous group; some subgroups are at low risk without any anatomic treatment at all, and some subgroups are at high risk without effective therapy. To date, the reported studies of PCT of SVG lesions have not included clinical risk stratifications that would allow comparison of patient survival rates.

Despite persistently high restenosis rates following percutaneous interventions, there are still many indications for their use in the treatment of patients with previous bypass surgery. Realistically, the ideal uses of PCTs are in situations in which failure of the anatomic treatment is not likely to be catastrophic. These situations include symptomatic patients with (1) early vein graft stenoses, (2) native coronary stenoses, or (3) focal late SVG stenoses in vein grafts not supplying the LAD artery. There are many patients with previous surgery who will fall into a middle ground where it is not clear whether percutaneous transluminal coronary angioplasty (PTCA) or reoperation is likely to yield the best outcome, and judgments must be made on the specific advantages and disadvantages of the treatments for those particular patients. Factors making PTCA more attractive than reoperation are listed in Table 27-2.

Table 27–2.

Reoperation versus PTCA for Patients with Stenotic Vein Grafts

Factors favoring reoperation	Factors favoring PTCA
Late (≥5 years) stenoses	Early (<5 years) stenoses
Multiple stenotic vein grafts	Single stenotic vein graft
Diffusely atherosclerotic vein grafts	Other patent vein grafts
Stenotic LAD vein graft	Focal graft lesions
No patent ITA graft	Patent ITA-LAD graft
Abnormal left ventricular function	Normal left ventricular function

TECHNICAL ASPECTS OF CORONARY REOPERATIONS

Reoperations are more complicated than primary operations. The specific technical challenges that surgeons must recognize and solve that are unique to or more common during coronary reoperation are

1. Sternal reentry
2. Stenotic or patent vein or arterial bypass grafts
3. Aortic atherosclerosis
4. Diffuse native-vessel coronary artery disease
5. Coronary arteries located amid old grafts and epicardial scarring
6. Lack of bypass conduits

The overall problem of myocardial protection is more difficult during reoperations, with perioperative myocardial infarction still being the most common cause of in-hospital death.[3,6] The metabolic concepts of myocardial protection in use today are valid, but the reasons that myocardial protection sometimes fails during reoperation are related to anatomic causes of myocardial infarction. These anatomic causes of perioperative myocardial infarction include injury to bypass grafts, atherosclerotic embolization from vein grafts or the aorta to distal coronary arteries, myocardial devascularization secondary to graft removal, hypoperfusion through new grafts, failure to deliver cardioplegic solution, early vein graft thrombosis, incomplete revascularization, diffuse air embolization, and technical error.[3,36–40] To be consistently successful, coronary reoperations must be designed to avoid these causes of myocardial infarction.

Preoperative Assessment

A complete understanding of the patient's native coronary and bypass graft anatomy is essential. Achieving this goal is sometimes not as easy as it sounds, particularly if the patient has had multiple previous coronary operations. If bypass grafts, venous or arterial, are not demonstrated by a preoperative coronary angiogram, it usually means that they are occluded, but it is also possible that the angiogram simply has failed to demonstrate their location. Examination of old angiograms performed prior to previous operations and review of previous operative records often help to illustrate the patient's coronary anatomy.

It is also important to know that graftable stenotic coronary arteries supply viable myocardium. Myocardial scar and viability can be differentiated by thallium scanning, positron-emission tomography, and stress (exercise or dobutamine) echocardiography. The intricacies of establishing myocardial viability are beyond this discussion, but it is an important issue. Before embarking on a reoperation, it makes sense to be reasonably sure that there is a matchup between the patient's graftable arteries and some viable myocardium such that grafting those arteries will provide some long-term benefits.

It is also wise to have a preoperative plan for bypass conduit selection and to document that potential bypass conduits are available. ITA angiography often is helpful. Venous Doppler studies can be used to assess the presence of greater and lesser saphenous vein segments, and arterial Doppler studies can assess the radial and inferior epigastric arteries and establish the adequacy of flow to the digits during radial artery occlusion.

Median Sternotomy Incision, Conduit Preparation, and Cannulation

Most coronary reoperations are performed through a median sternotomy. Situations associated with increased risk during a repeat median sternotomy include right ventricular or aortic enlargement, a patent vein graft to the right coronary artery, an in situ right ITA graft patent to a left coronary artery branch, an in situ left ITA graft that curls under the sternum, multiple previous operations, and difficulty reopening the sternum during a previous reoperation. In such situations, vessels for arterial (via the femoral or axillary artery) and venous access for cardiopulmonary bypass are dissected out prior to sternal reentry. All bypass grafts except for the internal thoracic arteries may be prepared prior to sternal reentry. Preparation of radial artery and greater and lesser saphenous vein segments can be carried out simultaneously.

When reopening a median sternotomy, the incision is made to the level of the sternal wires; the wires are cut anteriorly and bent back but are not removed (Fig. 27-9). An oscillating saw is used to divide the anterior table of the sternum. When the anterior table has been divided, ventilation is stopped, and the assistants elevate each side of the sternum with rake retractors while the posterior table of the sternum is divided in a caudal-cranial direction. The sternal wires that have been left in place posterior to the sternum help to protect underlying structures. Once the posterior table of the sternum has been divided with the saw, the wires are removed, and sharp dissection with scissors is used to separate each side of the sternum from underlying structures. Once the sternum has been divided, it is important that the assistants retract in an upward direction, not laterally. The right ventricle is injured more often by lateral retraction while it is still adherent to the underside of the sternum than it is by a direct saw injury.

In high-risk situations, it can be helpful to perform a small anterolateral right thoracotomy (Fig. 27-10) prior to the repeat median sternotomy. Underlying structures, such as the aorta, patent bypass grafts, and the right atrium and ventricle, can be dissected away from the sternum via this approach, and thus, with the surgeon's hand placed behind the sternum, reentry is safe. This small additional incision contributes little morbidity.

Another technique for sternal reentry in high-risk patients is to heparinize, cannulate, and initiate cardiopulmonary bypass prior to median sternotomy. The advantages of this strategy are that the heart can be emptied and allowed to fall away from the sternum, and cardiopulmonary bypass already has been initiated for protection if an injury does occur. The disadvantages of this approach are that extensive mediastinal

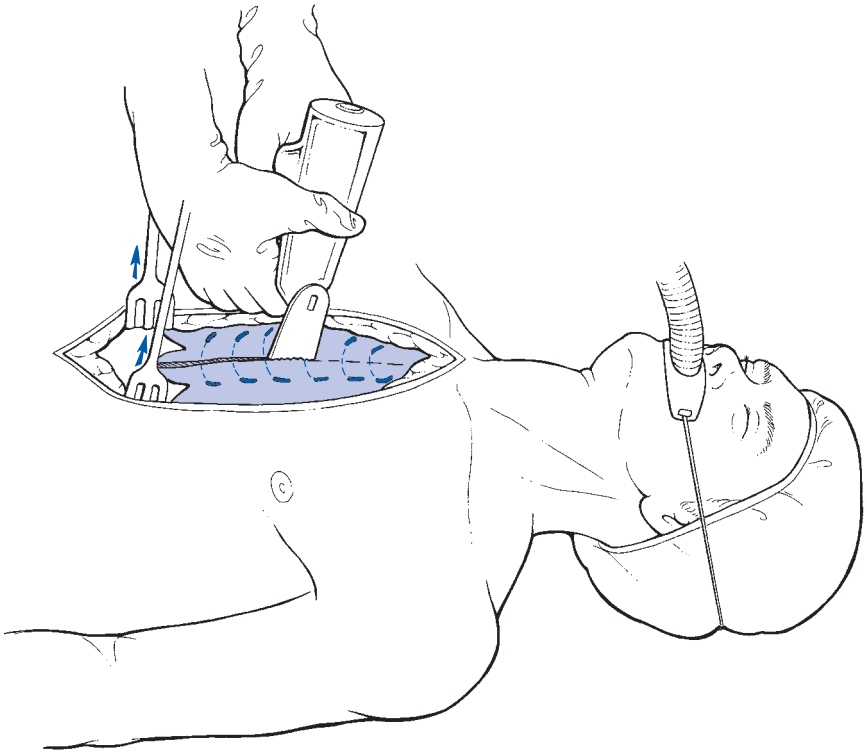

Figure 27-9. Leaving the sternal wires in place posteriorly helps to protect underlying structures while the posterior table of the sternum is divided with an oscillating saw. The direction of retraction with rake retractors should be anterior, not lateral.

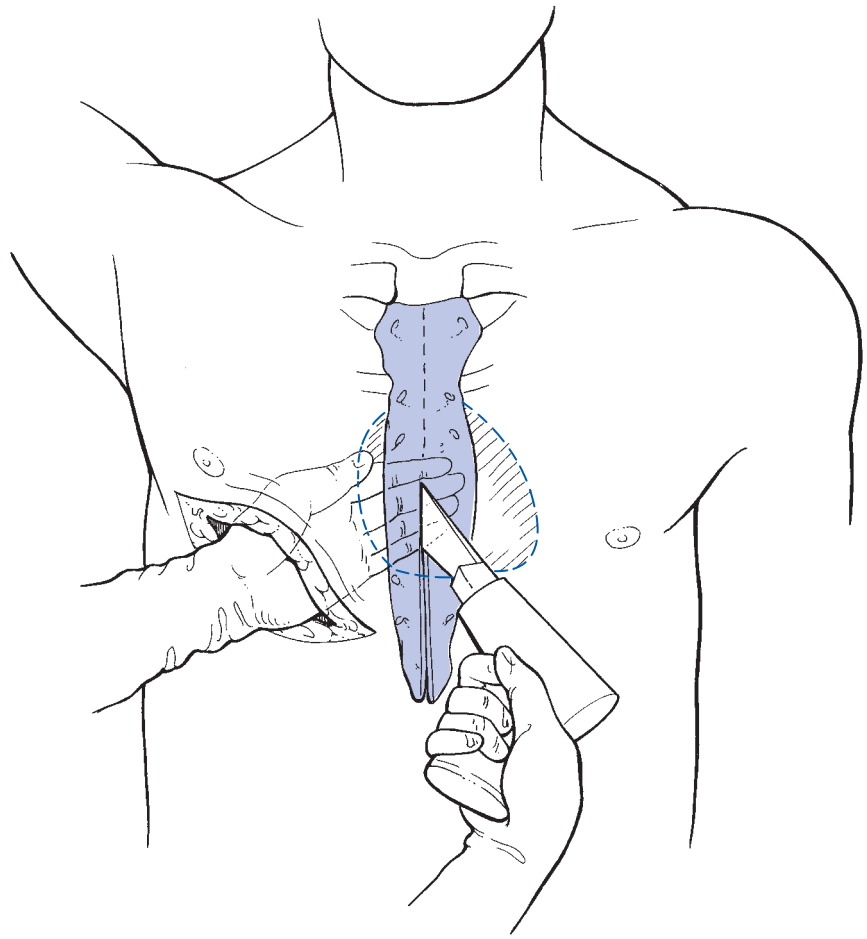

Figure 27-10. A small anterolateral right thoracotomy allows dissection of substernal structures such as patent grafts and the right ventricle or aorta away from the sternum under direct vision. While the sternum is being divided, the surgeon may place a hand behind the sternum for further safety.

dissection must be carried out in a heparinized patient, including dissection of the right internal thoracic artery if that is to be used. We rarely employ this approach except in situations in which adherence of an aortic aneurysm to the sternum or a patent right ITA-to-LAD graft creates a specific danger.

Once the sternum has been divided, the pleural cavities are entered. A general principle of dissection during reoperation is that starting at the level of the diaphragm and proceeding in a cranial direction is usually the safest approach. At the level of the diaphragm, few critical structures are injured if the wrong plane is entered. Therefore, at this point in the operation we usually dissect along the level of the diaphragm to the patient's right side until we enter the pleural cavity and then detach the pleural reflection from the chest wall in a cranial direction to the level of the innominate vein. The innominate vein is dissected away from both sides of the sternum with scissors, a maneuver that prevents a "stretch" injury to that vein.

Once the right side of the sternum is separated from the cardiac structures, it is usually possible to prepare a right ITA graft. Because of parietal pleural thickening, it is often more difficult to obtain length on ITA grafts during reoperation than it is during primary procedures, and the right ITA frequently is used as a "free" graft. Once the right ITA dissection is completed to the superior border of the first rib, an incision is made in the parietal pleura to separate the proximal ITA from the area of the phrenic nerve. Thus, if the right ITA needs to be converted to a "free" graft during aortic cross-clamping, it makes division at that point easier because the proximal ITA is clearly identifiable. Although intrapericardial dissection of the left side of the heart is left until later, freeing the left side of the anterior chest wall from the underlying structures (which may include a patent ITA graft) is undertaken now. This is difficult only if there is a patent ITA graft that is densely adherent to the chest wall. Again, it is best to enter the left pleural cavity at the level of the diaphragm and proceed in a cranial direction.

The most difficult point of dissection is usually at the level of the sternal angle, where a patent ITA graft may approach the midline and be adherent to the sternum or to the aorta. There are no tricks for dissecting out a patent ITA graft except for being careful. The danger to a patent left ITA graft during sternal reentry and mediastinal dissection is entirely related to the location of the graft at the time of the primary operation. Ideally, the pericardium should be divided at a primary operation, and the left ITA graft should be allowed to run posterior to the lung through the incision in the pericardium and to the LAD or circumflex artery (Fig. 27-11). When this is

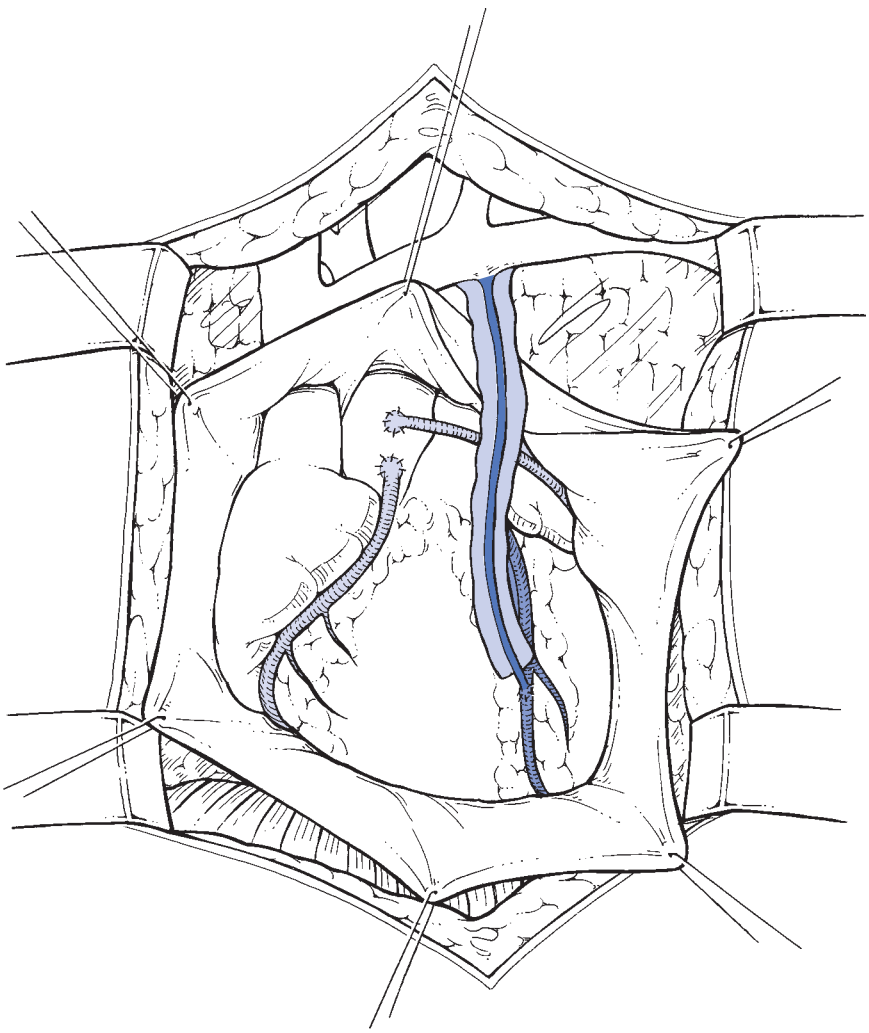

Figure 27-11. A patent left ITA-to-LAD graft should not pose a threat during reoperation. At a primary operation, the pericardium should be divided in a posterior direction, and the ITA graft should be placed in that incision. The ITA graft then will lie posterior to the lung and will not be pushed toward the midline by the lung or become adherent to the sternum.

done, the lung will lie anterior to the left ITA, and that graft will not become adherent to the aorta or to the chest wall.

Once the left side of the chest wall is free, the left IMA is prepared (if it has not been used at a previous operation), the sternal spreader is inserted, and the intrapericardial dissection of the aorta and right atrium is accomplished. Again, in most cases it is safest to find the correct dissection plane at the level of the diaphragm and then to continue around the right atrium to the aorta. The one situation in which this strategy may be dangerous is if an atherosclerotic vein graft to the right coronary artery lies over the right atrium. Manipulation of atherosclerotic vein grafts can cause embolization of atherosclerotic debris into coronary arteries, and it is best to employ a "no touch" technique with such grafts. If a vein graft to the right coronary artery lies in an awkward position over the right atrium, it is best to leave the right atrium alone and to use femoral vein and superior vena cava cannulation to establish venous drainage (Fig. 27-12). Once cardiopulmonary bypass has been established, the aorta has been cross-clamped, and cardioplegia has been given, the atherosclerotic vein graft then can be disconnected.

The goal of dissection of the ascending aorta is to obtain enough length for cannulation and cross-clamping and to avoid the most common error, aortic subadventitial dissection. The correct level of dissection on the aorta usually is found either by following the right atrium to the aorta in a caudal-to-cranial direction or by identifying the innominate vein and leaving all the tissue beneath the innominate vein on the aorta. At the level of the innominate vein, the pericardial reflection on each side of the aorta will be identifiable. Division of the pericardial reflection on the left side in a posterior direction will lead to the plane between the aorta and the pulmonary artery. Once the left side of the aorta is identified, the surgeon then may dissect posteriorly on the medial aspect of the left lung toward the hilum. The segment of tissue between these two dissection planes usually will include a patent left ITA graft, if present, and clamping that tissue will produce occlusion of the ITA graft.

When the aorta has been dissected out, heparin is given, and cannulation is undertaken. Cannulation of an atherosclerotic ascending aorta may cause atherosclerotic embolization leading to stroke, myocardial infarction, or multiorgan failure, so the ascending aorta should be studied with palpation and echocardiography to detect atherosclerosis before cannulation.[41,42] Although the most widely used alternative arterial cannulation site is the femoral artery, arteriopathic patients often have severe femoral artery atherosclerosis. The axillary artery is an alternative arterial cannulation site that we have used with increasing frequency because atherosclerotic disease is usually not present in that vessel, and its cannulation allows antegrade perfusion[43] (Fig. 27-13). If atherosclerotic disease or calcification of the aorta makes any aortic occlusion hazardous, the options are off-pump bypass surgery (see "Other Options" below) or replacement of the aorta with axillary artery cannulation,

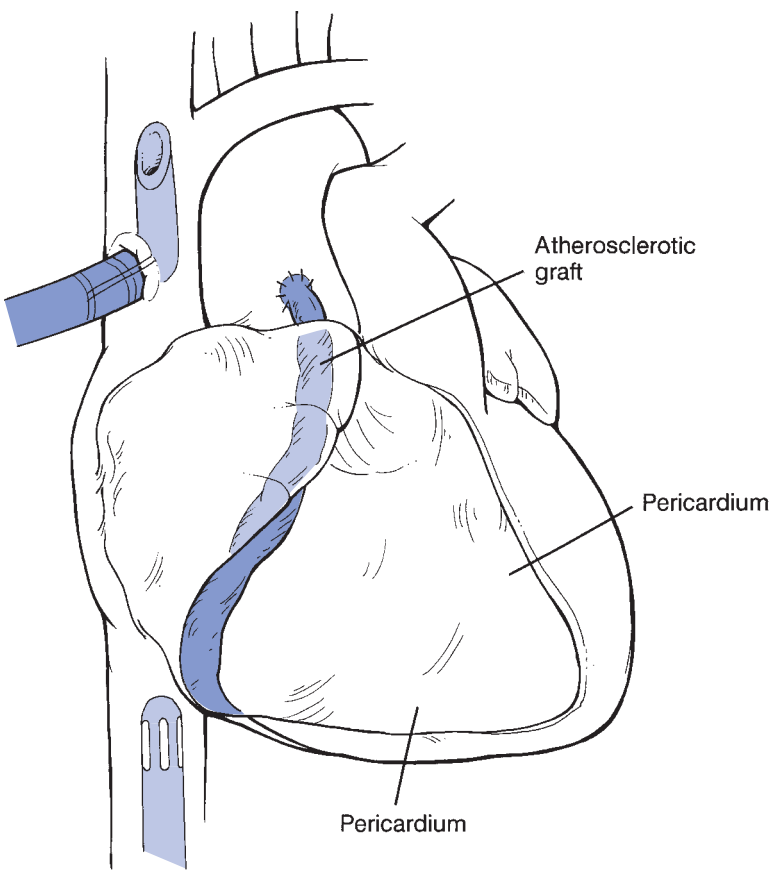

Figure 27-12. Manipulation of patent but atherosclerotic vein grafts should be avoided. If an atherosclerotic right coronary vein graft blocks access to the right atrium, femoral vein and direct superior vena cava cannulation are safer than mobilizing the vein graft in order to achieve right atrial cannulation.

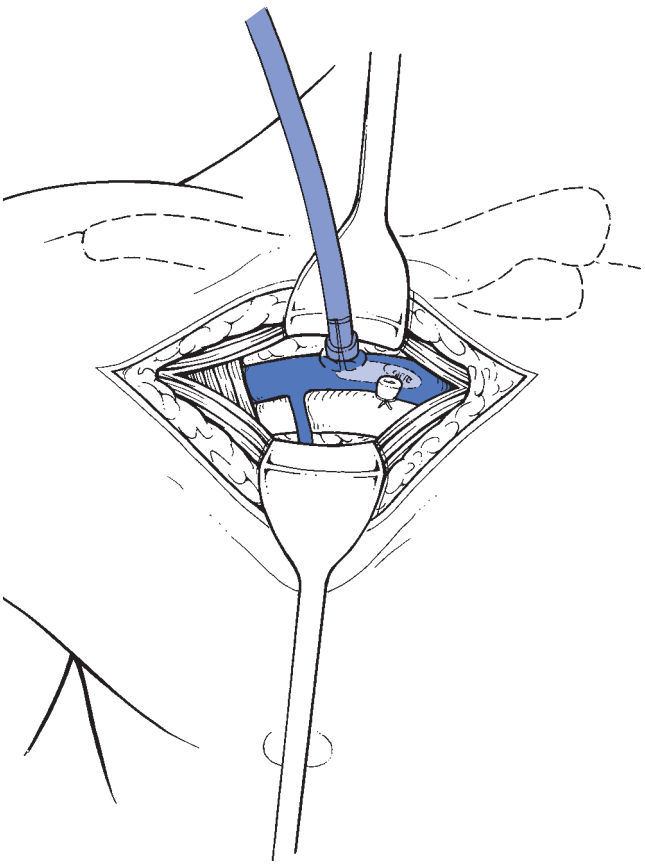

Figure 27-13. The axillary artery is an important alternative arterial cannulation site for patients with aortic and femoral artery atherosclerosis. A 21-gauge cannula will fit the axillary artery in most patients.

hypothermia, and circulatory arrest. Venous cannulation usually is accomplished with a single two-stage right atrial cannula. A transatrial coronary sinus cardioplegia cannula is inserted via a right atrial purse string with the aid of a stylet, and a needle is placed in the ascending aorta for delivery of antegrade cardioplegia and for use as a vent (Fig. 27-14).

Myocardial Protection

The myocardial protection strategy used by us during most coronary artery reoperations is a combination of antegrade and retrograde delivery of intermittent cold blood cardioplegia combined with a dose of warm reperfusion cardioplegia ("hot shot") given prior to aortic unclamping, principles developed by Buckberg and colleagues.[44,45] Multiple types of cardioplegic solutions have been described, and most appear to provide a metabolic environment that effectively protects the myocardium. Because of the potential anatomic challenges to cardioplegic myocardial protection during reoperations, the details of how the cardioplegic solution is delivered are very important. In most primary bypass operations, antegrade cardioplegia works well by itself. During reoperations, however, antegrade cardioplegia may not be effective for areas of myocardium that are supplied by patent in situ arterial grafts and may be dangerous because of the risk of embolization of atherosclerotic debris into the coronary arteries from old vein grafts. The delivery of cardioplegia through the coronary sinus and through the cardiac venous system to the myocardium (retrograde cardioplegia) has been a step forward in myocardial protection during reoperations.[46,47] Retrograde cardioplegia delivery avoids atheroembolism from vein grafts, can be helpful in removing atherosclerotic debris and air from the coronary artery system, and can deliver cardioplegia to areas supplied by in situ arterial grafts. The biggest disadvantage of retrograde cardioplegia is that it is not always possible to place a catheter in the coronary sinuses that will deliver cardioplegia consistently. It is important to monitor the adequacy of cardioplegia delivery by measuring the pressure in the coronary sinus, noting the distention of cardiac veins with arterial blood, the cooling of the myocardium, and the return of desaturated blood from open coronary arteries.

Cardiopulmonary bypass is begun, the perfusionist empties the heart and produces mild systemic hypothermia (34°C), and the aorta is cross-clamped. We usually initiate cardioplegia induction with aortic root cardioplegia. To induce and maintain cardioplegic protection, it is helpful to be able to occlude patent arterial grafts. If it has not yet been possible to dissect out a patent arterial graft so that it can be clamped, the systemic perfusion temperature is decreased to 25°C until control of the graft is achieved. After antegrade cardioplegia has been given for 2 to 3 minutes, we shift to retrograde induction for another 2 to 3 minutes. Giving any antegrade cardioplegia does risk embolization from atherosclerotic vein grafts, but if these grafts have not yet been manipulated, that danger is relatively small. Once the adequacy of retrograde cardioplegia delivery has been established, it is often possible to use that route predominantly for maintenance doses.

Intrapericardial Dissection

When the heart has been arrested completely, intrapericardial dissection of the left ventricle is undertaken, starting at the diaphragm and extending out to the left of the apex of the heart. After the apex is identified, the surgeon divides the pericardium in a cranial direction on the left side of the LAD artery (Fig. 27-15). A patent LITA-to-LAD graft will be contained within the strip of pericardium that lies over the LAD artery. Dissection of this pedicle from the anterior aspect of the pulmonary artery will allow an atraumatic clamp to be placed across the patent ITA graft and also will allow the passage of new bypass grafts from the aorta underneath the patent ITA graft to left-sided coronary arteries. The advantages of waiting until after aortic clamping and arrest to dissect out the left ventricle are that dissection is more accurate, there is less damage to the epicardium and less bleeding, manipulation of atherosclerotic vein grafts is less likely to cause coronary embolization, and the dissection of patent ITA grafts is safer.

After the heart is dissected out completely, the coronary arteries to be grafted can be identified, the lengths that

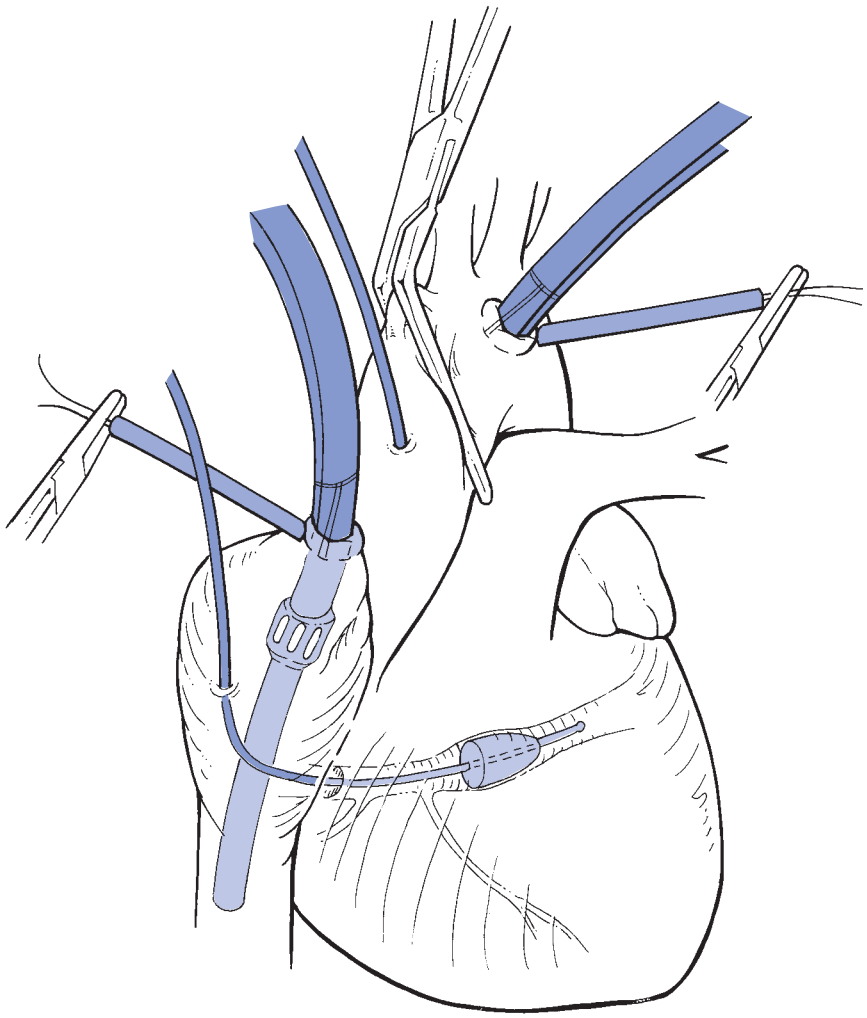

Figure 27-14. Standard cannulation for coronary artery reoperation includes aortic arterial cannulation, an aortic needle for antegrade delivery of cardioplegia and aortic root venting, a single two-stage venous cannula, and a transatrial coronary sinus catheter with a self-inflating balloon for delivery of retrograde cardioplegia. Cannulation is accomplished prior to dissection of the left ventricle.

bypass conduits need to reach those vessels may be assessed, and the final operative plan can be established. The old grafts and epicardial scarring that are present during reoperations make the preoperative prediction of the lengths of conduits needed for bypass grafts quite difficult, particularly the lengths of arterial grafts, and it is wise to have some flexibility in the operative plan. Prior to the construction of the anastomoses, those patent but atherosclerotic vein grafts that are going to be disconnected are identified and are disconnected with a scalpel. The order of anastomosis construction that is used by the authors is (1) distal vein graft anastomoses, (2) distal free arterial graft anastomoses, (3) distal in situ arterial graft anastomoses, and (4) proximal (aortic) anastomoses.

Stenotic Vein Grafts

When should patent or stenotic vein grafts be replaced, and what should they be replaced with? Atherosclerosis in vein grafts is common if those grafts are more than 5 years old, and leaving them in place risks embolization of atherosclerotic debris at the time of reoperation and subsequent development of premature graft stenoses or occlusions after reoperation. On the other hand, replacement of all vein grafts extends the operation and may use up available bypass conduits.

In the past, our general rule has been to replace all vein grafts that are more than 5 years old at the time of reoperation, even if those grafts are not diseased angiographically. However, this strategy assumes that conduits are available that can replace these old grafts. Today, many patients have very limited conduits at reoperation because of the large numbers of vein grafts used at primary surgery or because of multiple previous operations. Thus, graft replacement must be individualized. Inspection of vein grafts at reoperation occasionally will identify a graft that looks normal angiographically and does not appear to have any thickening or atherosclerosis on visual inspection. Often such vein grafts will be left alone.

Replacing old vein grafts with new vein grafts is best accomplished by creating the new vein-to-coronary-artery anastomosis at the site of the previous distal anastomosis, leaving only 1 mm or so of the old vein in place (Fig. 27-16). If significant native-vessel stenoses have developed distal to the old vein graft, it is often best to place a new graft to the distal vessel in addition to replacing the vein graft. Many reoperative candidates have proximal occlusions of

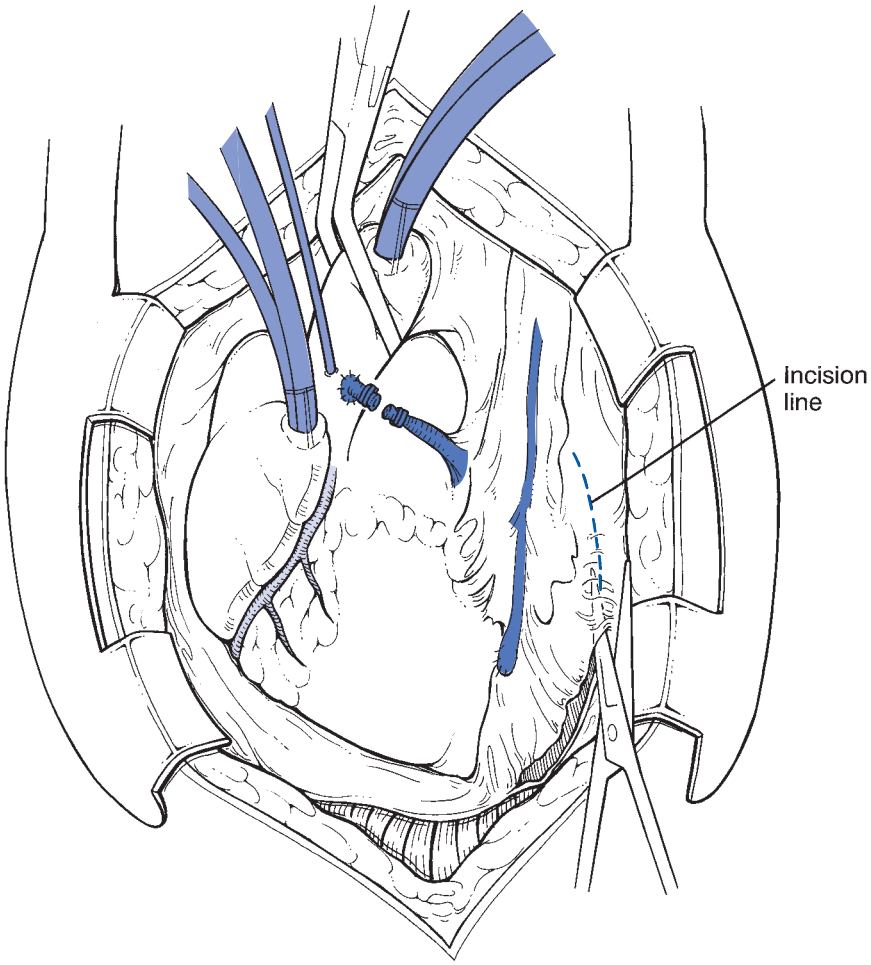

Figure 27-15. Division of the pericardium along the diaphragm allows the surgeon to reach a point to the left of the cardiac apex. From that point, the pericardium can be divided in a cranial direction to the left of the LAD artery, leaving a patent ITA graft in the strip of tissue overlying the LAD artery. Atherosclerotic vein grafts that are going to be replaced may be divided once a dose of antegrade cardioplegia is given.

the native coronary artery system and multiple stenoses throughout the vessel, and if only new distal grafts are constructed, the proximal segments of coronary arteries and their branches that are supplied by atherosclerotic vein grafts may be jeopardized. More than one graft to a major coronary artery may be desirable during reoperation (Fig. 27-17).

Sequential vein grafts often are very helpful during reoperation because they allow more distal anastomoses and fewer proximal anastomoses. Sites for proximal anastomoses are often at a premium in the scarred reoperative aorta.

Artery-to-coronary-artery bypass grafts have many advantages during reoperations. First, they are often available. Second, the tendency of arteries to remain patent even

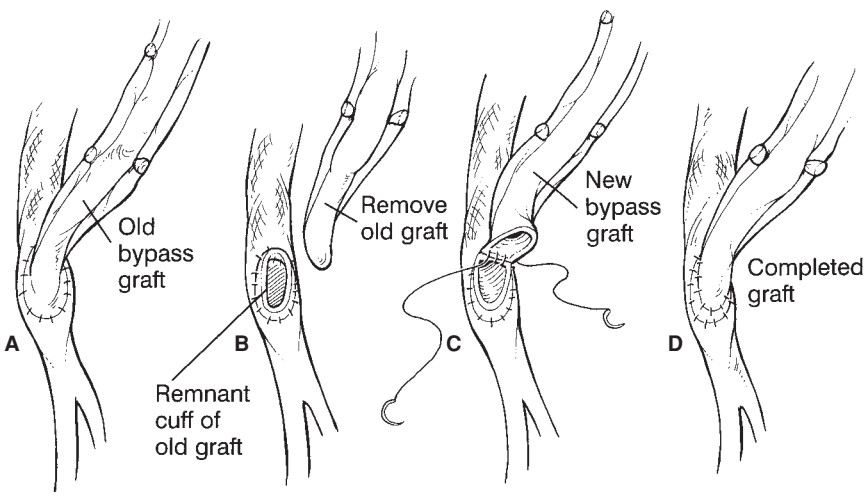

Figure 27-16. For patients with extensive native coronary atherosclerosis, the distal anastomotic site of an old vein graft is often the best spot for the distal anastomosis of a new graft. Only a small rim of the old graft should be left in place.

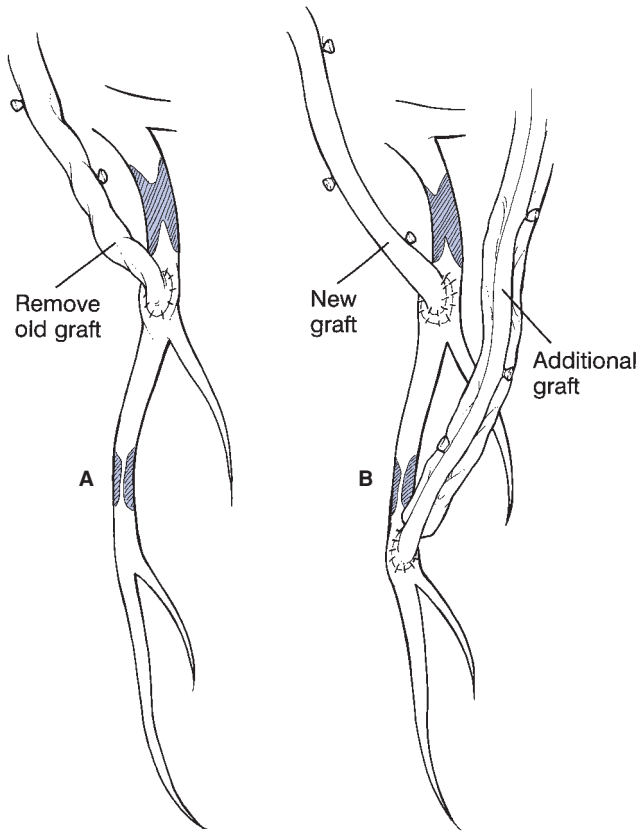

Figure 27-17. Extension of native-vessel coronary artery disease may indicate the placement of new distal grafts as well as replacement of diseased vein grafts supplying proximal coronary artery segments.

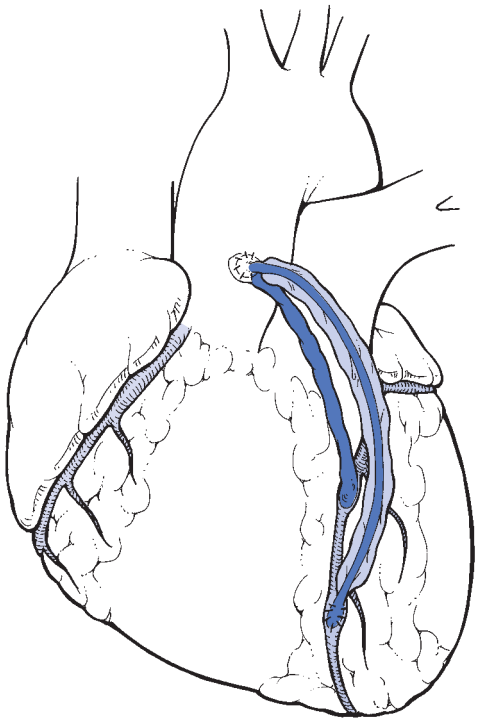

Figure 27-18. The hood of new or old vein grafts is often the best spot for the aortic anastomosis of free arterial grafts. Atherosclerosis rarely occurs in that "bubble" of vein.

when used as grafts to diffusely diseased coronary arteries makes them particularly applicable to reoperative candidates. Third, in situ arterial grafts do not require a proximal anastomosis. If the left ITA has not been used as a graft at a previous operation, a strong attempt should be made to use it as an in situ graft to the LAD artery. During primary operations, the right ITA usually can be crossed over as an in situ graft to left-sided vessels, but such a plan is more difficult during repeat surgery, so the right ITA is often used as a free graft.

Arterial graft proximal anastomoses are a problem at reoperation because the scarring and thickening of the reoperative aorta often make direct anastomoses of arterial grafts to the aorta unsatisfactory. However, when old vein grafts become occluded, there is usually a "bubble" of the hood of the old vein graft that is not atherosclerotic and that often is a good spot for construction of a free (aorta-to-coronary-artery) arterial graft anastomosis (Fig. 27-18). In addition, if new vein grafts are performed, the hood of that new vein graft represents a favorable location for an arterial graft anastomosis. Late angiographic data regarding this strategy are not available, but the relative freedom of the hood of vein grafts from the development of atherosclerosis means these grafts are likely to be successful.

Another effective strategy is to use either an old arterial graft or a newly constructed arterial graft for the proximal anastomosis of a free arterial graft (Fig. 27-19). Composite arterial grafts, usually using a new in situ left ITA graft at the proximal anastomotic site for a free right ITA graft, have been employed with increasing frequency, and early outcomes have been favorable.[48,49] This method is particularly useful during reoperations because it may avoid an aortic anastomosis, and less right ITA graft length is needed to reach distal circumflex arteries. Other advantages of using a previously performed patent ITA graft for the proximal anastomosis of a new arterial graft are that the old left ITA graft often has increased in size, and the preoperative angiogram has demonstrated its integrity. In situations where the effectiveness of an LITA-to-LAD graft has been jeopardized by a distal LAD lesion, a short segment of a new arterial graft can be used to bridge that stenosis from the old arterial graft to the distal LAD artery (see Fig. 27-18).

Can an ITA graft be used to replace a vein graft during reoperation? When faced with replacing a stenotic or patent vein graft during reoperation, the surgeon has a number of options, all of which have some potential disadvantages:

1. The surgeon may leave the old vein graft in place and add an arterial graft to the same coronary vessel. The dangers of this approach are that atherosclerotic embolization from the old vein may occur during the reoperation, and competitive flow

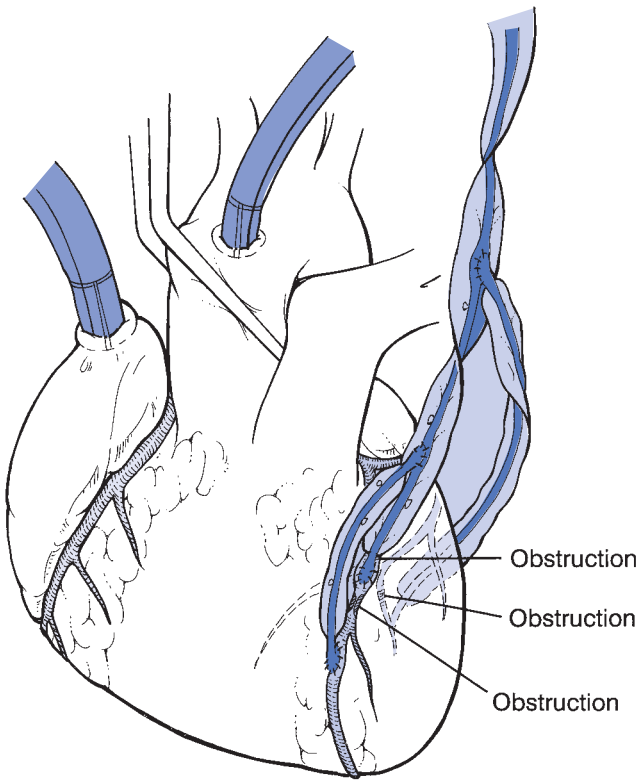

Figure 27-19. Composite arterial grafts can be constructed using a new or old left ITA graft as the inflow source. With its proximal anastomosis to the left ITA, a right ITA graft will easily reach the circumflex branches. Furthermore, a shorter segment of inferior epigastric artery or radial artery can be used to reach the distal LAD artery if intervening native LAD stenoses have limited the effectiveness of an old ITA graft.

between the vein graft and the arterial graft may jeopardize the ITA graft after reoperation.

2. The surgeon may remove the old vein graft and replace it with an ITA graft. This decreases the likelihood of atherosclerotic embolization and competitive flow but risks hypoperfusion during reoperation if the arterial graft cannot supply all the flow that had been generated previously by the vein graft.
3. The surgeon may replace the old vein graft with a new vein graft. The disadvantage of this approach is a long-term one: The coronary vessel is left dependent on a vein graft.

When we examined these choices in a retrospective study of operations for patients with atherosclerotic vein grafts supplying the LAD artery, we found that the worst outcomes resulted from removing a patent (although stenotic) vein graft and replacing it with only an ITA graft.[39] This strategy was associated with a significant incidence of hypoperfusion and severe hemodynamic difficulties during reoperation that were treated effectively only by adding a vein graft to the same coronary artery. The incidence of myocardial infarction associated with leaving a stenotic vein graft in place was low. Thus, atherosclerotic embolization from an atherosclerotic vein graft is a danger, but it appears that with the use of retrograde cardioplegia, it is not commonly a major catastrophe.

Another potential disadvantage of the strategy of adding an ITA graft to a stenotic vein graft is that competition in flow from the stenotic vein graft may lead to failure of the new ITA graft. However, this is unlikely to occur as long as the stenosis in the SVG is severe.[50] Our usual approach, therefore, is to remove atherosclerotic vein grafts when replacing them with a new vein graft but leave stenotic vein grafts in place when grafting the same vessel with an arterial graft (Fig. 27-20).

Alternative arterial grafts often are very useful during reoperation. The radial artery has particular advantages during repeat surgery because it is larger and longer than other free arterial grafts. These qualities increase the range of coronary arteries that can be grafted. Early studies of radial artery grafts have shown favorable patency rates, but few long-term data currently exist. If the high patency rates that have been documented by early studies are confirmed by the tests of time, the radial artery will be used extensively during reoperations. The inferior epigastric artery often is too short to function as a separate aorta-to-coronary-artery graft during

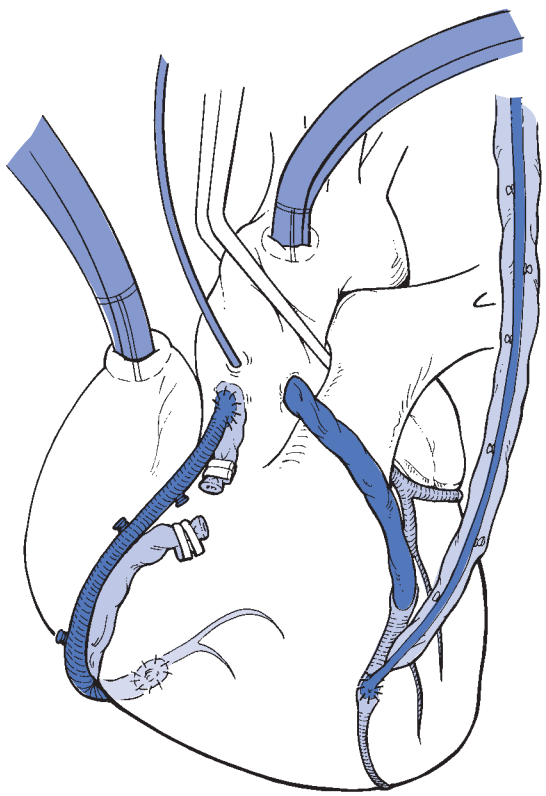

Figure 27-20. In this example, an atherosclerotic right coronary artery vein graft is disconnected and is replaced with a new vein graft. However, the stenotic vein graft to the LAD artery is left in place to avoid hypoperfusion, and a new ITA graft is added to the LAD artery.

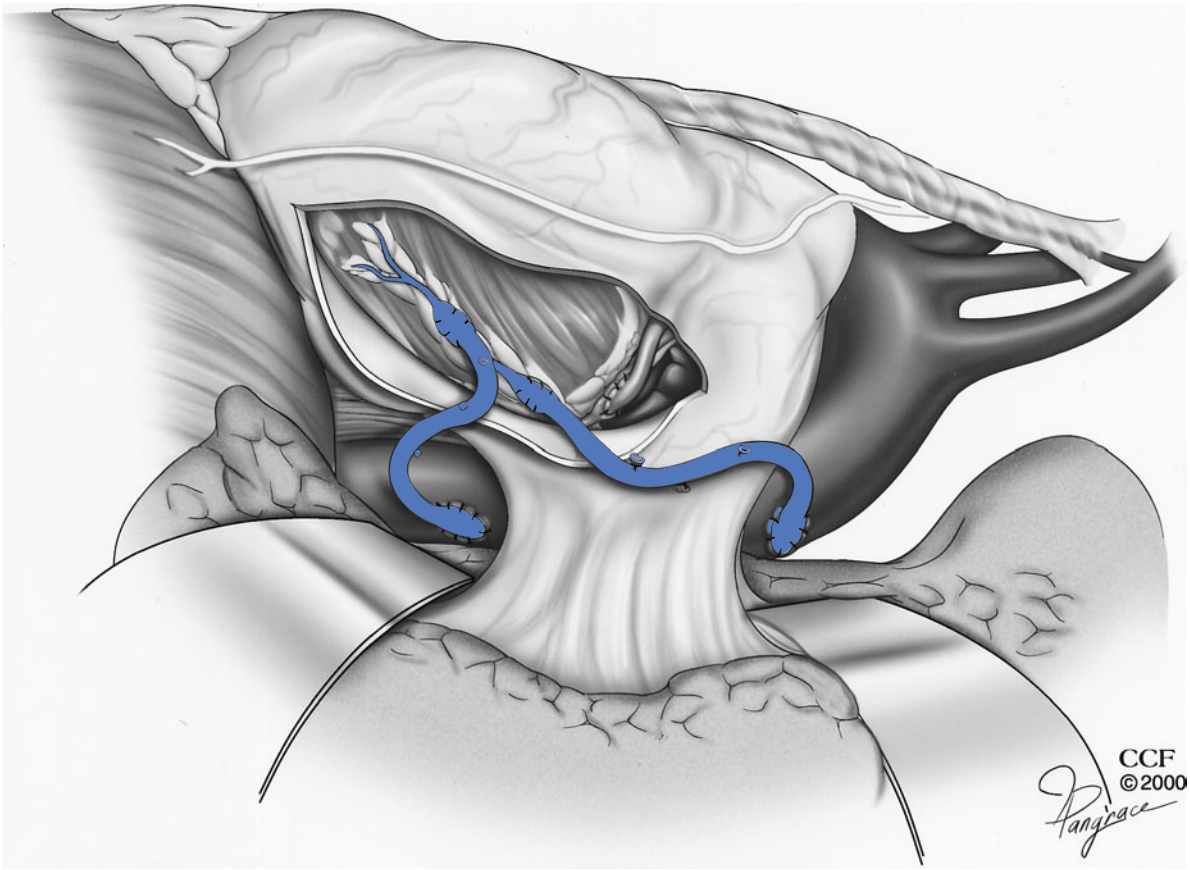

Figure 27-21. Circumflex vessels may be grafted through a left thoracotomy incision without cardiopulmonary bypass.

reoperation but can be extremely useful as a short composite arterial graft, as illustrated in Fig. 27-19.

The right gastroepiploic artery (RGEA) has established a good midterm graft patency rate record and often is useful during reoperation because it is an in situ graft.[51] Furthermore, it can be prepared prior to the median sternotomy. It is effective most often as an in situ graft to the posterior descending branch of the right coronary artery or to the distal LAD artery (Fig. 27-21).

The aortic anastomoses of the vein and arterial grafts are performed last during the single period of aortic cross-clamping. Sites for aortic anastomoses are often at a premium owing to previous scarring, atherosclerotic disease, or the use of Teflon felt during the primary operation, and often the locations of the previous vein graft proximal anastomoses are the best locations for the new ones. The advantages of constructing aortic anastomoses during a single period of aortic cross-clamping are that it minimizes aortic trauma and allows excellent visualization of the proximal anastomoses. In addition, if patent or stenotic vein grafts have been removed and replaced, reperfusion is not accomplished by aortic declamping until the aortic anastomoses have been completed.

The disadvantage of this approach is that it prolongs the period of aortic cross-clamping. However, our strategies for reoperation are not based on trying to minimize myocardial ischemic time. If cardioplegia can be delivered effectively, its metabolic concepts are valid, and myocardial protection is secure. Failure of myocardial protection usually is caused by anatomic events, not by metabolic failure. Once the proximal anastomosis has been constructed, a "hot shot" of substrate-enhanced blood cardioplegia is given, and the aortic cross-clamp is removed.

Other Options

Although most reoperations are performed through a median sternotomy with the use of cardiopulmonary bypass, the strategies of small-incision surgery and off-pump surgery that have been gaining increasing use for primary coronary artery operations also can be helpful during reoperations. Reoperations in situations in which a limited area of myocardium needs revascularization often can be accomplished through a limited incision and without the use of cardiopulmonary bypass [known as the *minimally invasive direct coronary artery bypass* (MIDCAB) *operation*]. The distal LAD artery may be exposed with a small anterior thoracotomy, and the LAD or diagonal artery may be grafted with a left ITA graft. A stabilizing device usually is employed for anastomotic construction, although the intrapericardial

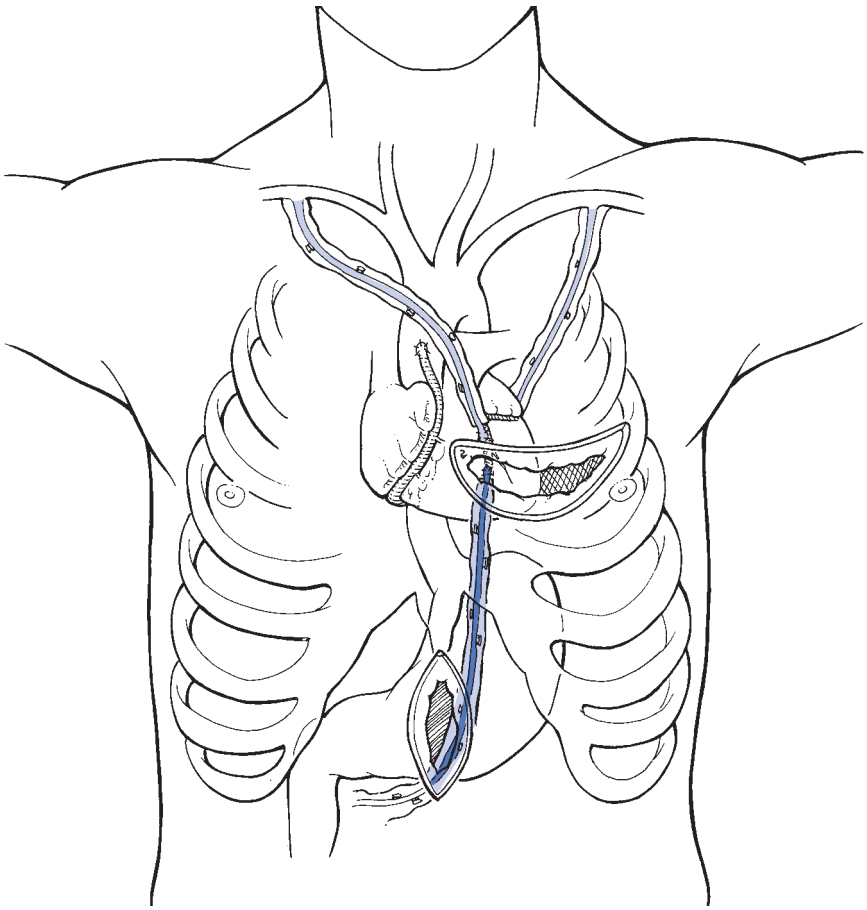

Figure 27-22. An in situ gastroepiploic artery (GEA) graft may be used for an on- or off-pump anastomosis to the distal LAD artery.

adhesions provide some stability during reoperations. If the left ITA is not available, a segment of saphenous vein can be anastomosed to the subclavian artery and routed in a transthoracic path to the LAD artery. If the right ITA is to be used as an in situ graft to the LAD artery, a median sternotomy is indicated, but if this is the only graft, off-pump surgery usually is possible.

The lateral wall of the heart can be exposed through a left lateral thoracotomy (Fig. 27-22), and the circumflex and distal right coronary artery branches can be grafted with this approach. Often the LITA already has been used for a graft, but the descending thoracic aorta may be used as a site for the proximal anastomosis of a vein graft or a radial artery graft using a partial occluding clamp. The disadvantages of this approach are that the right ITA is difficult to use as an in situ graft, and if the circumflex vessels are deeply intramyocardial, they may be difficult to expose and isolate with the off-pump strategy.

In addition to avoiding potential complications of cardiopulmonary bypass, the "limited-area, off-pump" approach also avoids extensive dissection of the heart and possible manipulation of atherosclerotic vein grafts. The disadvantage of this approach is that most patients who are candidates for reoperation need grafts to multiple vessels in multiple myocardial areas.

Use of a median sternotomy and the off-pump strategy to graft multiple myocardial areas is now a standard approach to primary coronary revascularization and also can be used during reoperation. However, because of the need to access all areas, extensive dissection sometimes is necessary for lysis of adhesions to be able to mobilize the heart. If patients have atherosclerotic vein grafts, dissection and manipulation create the dangers of embolization of atherosclerotic debris and myocardial infarction. This problem was encountered during the early years of bypass surgery when the risks of atherosclerotic embolization were less recognized. Another disadvantage of off-pump reoperative strategies is that reoperative candidates often have very distal and diffuse CAD, which leaves intramyocardial segments as the best areas for grafting. These characteristics stress off-pump isolation and immobilization techniques. In addition, the aortic anastomoses of vein or free arterial grafts may be difficult because of aortic atherosclerosis, adhesions, or previous aortic anastomoses that may limit the application of a partial occluding clamp. On the other hand, the use of off-pump techniques may minimize aortic trauma, particularly if in situ arterial grafts can be employed to provide inflow to new grafts.

In an individual case, the disadvantages of off-pump surgery may be important or irrelevant. Surgeons who perform

reoperative coronary artery surgery in a wide spectrum of situations will find both on- and off-pump strategies helpful.

RESULTS OF CORONARY ARTERY REOPERATIONS

Coronary artery reoperations are riskier than primary operations. A study from the Society of Thoracic Surgeons (STS) database reported an in-hospital mortality rate of 6.95% associated with reoperations for the years 1991–1993, and in a multivariate analysis of all isolated coronary artery bypass surgery, "previous operation" was identified as a factor that increased the mortality rate.[12] At the Cleveland Clinic Foundation, the in-hospital mortality rate of a first reoperation ranged between 3 and 4% from 1967 through 1991, and the rate was 3.7% for 1663 patients having repeat surgery from 1988 through 1991.[1–3] Progress during the last decade has continued to lower this risk. In a recent report by Sabik and colleagues, the hospital mortality rate for patients undergoing reoperative CABG was reduced to 2.5% in 2002, and risk adjustment identified the comorbidity burden carried by reoperative patients as a factor that increased risk, not reoperative status itself.[14]

Recent mortality rates from other large series range from 4.2 to 11.4%, most being around 7%.[4–9,52] All these figures are two to five times higher than the rates we would expect for the risk of primary CABG.

Coronary artery reoperations have been associated with a higher in-hospital mortality mostly because of an increased risk of perioperative myocardial infarction. In the Cleveland Clinic Foundation series, the cause of perioperative death was cardiovascular in 85% of cases in the most recent cohort of patients undergoing reoperation, a figure that contrasts with recent studies of primary operations, in which noncardiac causes of death have been increasingly important.[3,15] Furthermore, in the reoperative series, in-hospital mortality was associated with new perioperative myocardial infarction in 67% of cases. Multiple causes of myocardial infarction have been identified, including incomplete revascularization owing to distal CAD, vein graft thrombosis, ITA graft failure, atherosclerotic embolization from vein grafts, injury to bypass grafts, hypoperfusion from arterial grafts, preoperative myocardial infarction, and complications of PTCA.

Multiple studies of patients undergoing reoperation have identified increased age, female gender, and emergency operation as clinical variables that have a high association with in-hospital mortality. Emergency operation is a particularly strong factor. Although there is not a standard definition of *emergency,* mortality rates after emergency reoperations that have been reported range from 13 to 40%.[3,5–8] Data from the STS for the year 1997 documented a risk of 5.2% for elective reoperations, 7.4% for urgent reoperations, 13.5% for emergency reoperations, and 40.7% for "salvage" reoperations. There is clearly a major increment in risk associated with emergency reoperations, a larger increment than has existed for patients undergoing primary surgery.

Advanced age, by itself, does not increase the risk of reoperation substantially but does so when combined with other variables. In a review of 739 patients aged 70 years or older undergoing reoperation, we noted an overall in-hospital mortality rate of 7.6% and identified emergency operation, female gender, left ventricular (LV) dysfunction, creatinine concentration greater than 1.6 μg/dL, and left main coronary artery stenosis as specific factors increasing risk. For patients with none of these characteristics, the in-hospital mortality rate was only 1.5%.[53]

Specific anatomic situations, in particular, the presence of patent ITA grafts and atherosclerotic vein grafts, can increase the risk of reoperation, but with experience, these technical factors largely have been neutralized. We have never documented an increased mortality rate for patients with patent ITA grafts but have noted that the risk of ITA damage has dropped from 8% in our early experience to 3.7% more recently, an improvement almost entirely related to increased surgical experience. With proper positioning of an ITA graft at primary operation, a patent LITA-to-LAD-artery or LITA-to-circumflex-artery graft should not represent an impediment to reoperation. Situations in which a patent in situ right ITA graft crosses the midline to supply the LAD or circumflex system are more difficult and require extreme care in reoperating using a median sternotomy incision. Although these situations are uncommon and provide difficult technical challenges, the risks for these patients have not been increased.

Studies from the past noted that the presence of atherosclerotic vein grafts did increase perioperative risk. Perrault and colleagues documented mortality rates of 7, 17, and 29% for patients with one, two, or three stenotic vein grafts, respectively, and in a previous study of patients with atherosclerotic vein grafts, we noted that the presence of an atherosclerotic vein graft to the LAD artery increased in-hospital risk.[30,36] However, in our more recent study we found that atherosclerotic vein grafts did not increase mortality, although there was a nonsignificant trend toward increased risk for patients with multiple stenotic grafts.[3] The favorable results for these patients have been based on a combination of improved technology, the use of retrograde cardioplegia delivery, and increased surgeon experience.

Although arterial grafts may offer advantages at reoperation, their use may prolong an already complex operation, and the influence of arterial grafting on perioperative risk has been a concern. However, we have specifically studied this issue and found that the use of single or double ITA grafts at reoperation does not increase perioperative risk, and in fact, not having an ITA graft at either the first or second operation appeared to be a factor associated with increased in-hospital mortality.[3] Graft selection in that study was not randomized, and it is certainly possible that the increased risk for patients receiving only vein grafts was related to patient-related variables rather than surgical strategy. It does appear, however, that the use of arterial grafts does not increase risk. Except for an increased incidence

of perioperative myocardial infarction, in-hospital morbidity does not seem to be increased for patients undergoing reoperation. One important observation relates to wound complications. Multiple groups, including ours, have noted an increased risk of wound complications when diabetic patients have received bilateral (simultaneous) ITA grafts. However, there does not appear to be an increased risk of wound complications for diabetic patients who receive staged ITA grafts, one at the first and another at a second operation.

It is important to note that only the variables that can be identified and quantified are included in studies consistent enough to be identified as risk factors. For example, experience and logic dictate that severe atherosclerosis of the ascending aorta is a major risk factor, but this is rarely identified in large studies because patients do not routinely undergo echocardiography to identify the presence of aortic atherosclerosis.

Late Results

Patients who are undergoing reoperation are at a later stage in the progression of their native coronary atherosclerosis compared with the point when they underwent primary surgery, and the anatomic corrections achieved at reoperation are less perfect. Although the definition of *complete revascularization* varies widely, few reoperative candidates undergo an operation in which all diseased segments of all arteries receive bypass grafts. It is not surprising that the long-term results of reoperation have not been as favorable as the long-term results of primary operations.

The likelihood of recurrent angina after any bypass operation is related to time, but angina symptoms are more common after repeat surgery than they are after primary operation. Follow-up of our reoperative patients at a mean interval of 72 months after reoperation showed that 64% of patients were in New York Heart Association (NYHA) functional class I, although only 10% of patients had class III or class IV symptoms.[2] Weintraub and colleagues also noted at a 4-year follow-up that 41% of reoperative patients had experienced some angina.[6]

Late survival rates after reoperation are also inferior to those after primary surgery. Weintraub and colleagues noted 76% 5-year and 55% 10-year survival rates, and our most recent follow-up study found a 10-year survival rate of 69% for in-hospital survivors[2,6] (Fig. 27-23). The predictors of late survival have varied among studies, but LV dysfunction, advanced age, and diabetes consistently have been associated with a decreased late survival rate. The variables identified by multivariate testing as decreasing the late survival for 2429 hospital survivors of a first reoperation are listed in Table 27-3. The influence of ITA grafts on late survival has been difficult to determine for reoperations. We found a positive influence of a single ITA graft on late survival, as have others,[54] but the effect was not as dramatic as has been noted after primary operations. Weintraub and colleagues did not document an improved survival associated with ITA grafting.[6]

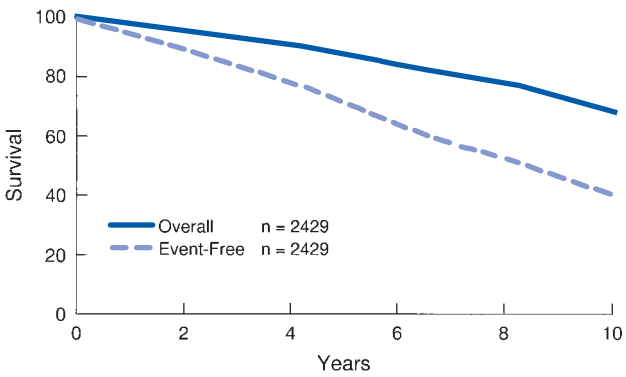

Figure 27-23. For 2429 hospital survivors who underwent reoperation between 1967 and 1987, the 10-year survival was 69%, and event-free survival was 41%. Multiple Coronary Artery Reoperations

Patients who have had more than one previous coronary artery operation are like patients undergoing first reoperations, only more so. Many patients undergoing multiple reoperations had their first procedure more than 15 years ago, and severe native-vessel disease and lack of bypass conduits are a common combination of problems. Selection

Table 27–3.

Factors Decreasing Late Survival After Reoperation: 1967–1987[2]

Factor	*p*-Value	Relative risk
LV dysfunction	.0001	1.9
Age	.0001	1.04
Current cigarette smoking	.0001	1.6
Hypertension	.0002	1.4
Left main ≥50%	.0001	2.0
Triple-vessel disease	.0001	1.6
NYHA III/IV symptoms	.003	1.4
Peripheral vascular disease	.001	1.5
Interval >60 months	.006	1.003
No ITA at first operation	0.03	1.5

criteria vary widely among institutions, but in-hospital mortality rates are increased relative to first reoperations.[10,11] Through 1993, we reoperated on 392 patients who had more than one previous bypass operation, with an in-hospital mortality rate of 8%. Over the next 10 years, this mortality rate has decreased to 5.8%.[14] Follow-up of the in-hospital survivors in the former group found late survival rates of 84% at 5 and 66% at 10 postoperative years. Thus, although the in-hospital risks were increased for these patients, the long-term outcome has been relatively favorable. Age was a major determinant of outcome. Recently, in-hospital mortality for patients younger than 70 years of age has decreased to 1 to 2%, but for patients over age 70, it has remained higher than 10%. Furthermore, patients over age 70 who did survive operation in our series had only a 50% 5-year late survival.

CONCLUSION

Coronary artery reoperations continue to present adult cardiac surgeons with their most difficult challenges in part because of the many technical pitfalls that exist but also because coronary artery reoperations are so common. The population of patients who have had previous bypass surgery is huge, and patients who develop recurrent ischemic syndromes expect that they will be treated effectively. Although we now understand the long-term implications of using vein grafts, technical and operative time considerations make it unlikely that a wave of total arterial revascularization will engulf primary coronary artery surgery. Thus, the numbers of reoperations are likely to continue to increase, and improvement over the principles outlined in this chapter will continue to be an important goal.

CHAPTER 28

Transmyocardial Laser Revascularization and Extravascular Angiogenetic Techniques to Increase Myocardial Blood Flow

Keith A. Horvath • Yifu Zhou

TRANSMYOCARDIAL LASER REVASCULARIZATION (TMR) HISTORY

Despite the success of medical therapy, percutaneous coronary interventions (PCIs), and coronary artery bypass grafting (CABG) in the treatment of coronary artery disease (CAD), there are a significant number of patients with refractory angina owing to diffuse CAD that is not amenable to PCI or CABG. This severe CAD can lead to incomplete revascularization following CABG and is noted to occur in up to 25% of CABG surgery.[1] This incomplete revascularization is a powerful independent predictor of operative mortality and perioperative adverse events.[1–3] Additionally, the presence of diseased but nongrafted arteries carries a poor prognosis and poses a significant negative influence leading to an increased incidence of death, recurrent angina, myocardial infarction (MI), and the need for repeat CABG.[4–6]

Strategies to treat patients with end-stage coronary disease have sought to create or enhance myocardial angiogenesis. Such techniques include TMR as well as protein-, gene-, and cell-based therapies. TMR was founded, in part, on previous methods of providing direct perfusion to the myocardium. Prior attempts at direct perfusion were based on Wearn's description of sinusoids that allowed blood to flow directly from the ventricle into the myocardium.[7] These arterioluminal connections provide perfusion in more primitive vertebrate hearts and occur clinically in children with pulmonary atresia, an intact ventricular septum, and proximal obstruction of the coronary arteries. Sen and colleagues[8] used myocardial acupuncture to establish direct perfusion and theoretically to recreate a coronary microcirculation similar to that of the reptilian heart. Additional methods of attempting to improve myocardial blood flow include Beck's creation of a form of superficial angiogenesis as a response to epicardial and pericardial inflammation.[9] Combining the acupuncture, implantation, and inflammation techniques, Boffi[10] and Borst[11] used hollow tubes implanted in the myocardium to establish direct perfusion. Results from all these procedures yielded limited success. The angina relief obtained was not long-lasting, was difficult to replicate, and most important, eventually was overshadowed by the ability to perform CABG. The mechanical trauma that resulted in poor long-term patency of myocardial acupuncture was overcome in theory by using a laser to create the channels. Although Mirhoseini and colleagues[12,13] and Okada and colleagues[14,15] pioneered the use of a laser to perform this type of revascularization in conjunction with CABG in the early 1980s, the use of a laser as sole therapy to establish its efficacy required advancements in the technology. The carbon dioxide (CO_2) laser used by Mirhoseini had a peak output of 80 W and therefore required a significant amount of time to complete a transmural channel. As a result, to perform TMR optimally, the heart had to be chilled and still. Increasing the output of the laser to 800 W allowed TMR to be performed on a beating heart. This breakthrough led to the widespread clinical application of TMR. Since then, over 25,000 patients have been treated with TMR around the world, and results from individual institutions, multicenter studies, and prospective, randomized, controlled trials have been reported.[16–29]

CLINICAL TRIALS

The early nonrandomized trials demonstrated that sole-therapy TMR could be performed safely on patients with

severe CAD who previously had no options. The significant angina relief seen in such patients led to prospective, randomized, controlled studies to further demonstrate the efficacy of TMR. In these pivotal trials, over 1100 patients were enrolled and randomized to receive either TMR or medical management as treatment for their severe angina.[23–28] The trials employed a 1:1 randomization in which half the patients were treated with laser and patients in the control group continued on maximal medical therapy. All patients were followed for 12 months.

TMR AS SOLE THERAPY

Patients

The entry criteria for these studies and for sole-therapy TMR in general are as follows: Patients had refractory angina that was not amenable to standard methods of revascularization, as verified by a recent angiogram. They had evidence of reversible ischemia based on myocardial perfusion scanning, and their left ventricular ejection fractions were greater than 25%.

The typical patient profiles of TMR patients in the randomized, controlled trials are listed in Table 28-1. Because the patients were equally randomized to the medical management group, there were no significant demographic differences between the TMR and control groups for any of these trials. Two different wavelengths of laser light were used. Three studies[23–25] employed a holmium:yttrium-aluminum-garnett (Ho:YAG) laser, and three[20–28] used a carbon dioxide (CO_2) laser. The average patient age was 62 years, and most were male (86%). While there were significant differences in the baseline distribution of patients according to Canadian Cardiovascular Society (CCS) angina class, the majority of the patients were in angina class IV (61%). The ejection fractions for all the patients were mildly diminished at 48 ± 10%. Many of the patients had suffered at least one previous MI, and most had some prior revascularization, CABG and/or PCI. Two of the trials[23,26] permitted a crossover from the medical management group to laser treatment for the presence of unstable angina that necessitated intravenous antianginal therapy for which they were unweanable over a period of at least 48 hours. By definition, these crossover patients were less stable than and significantly different from those who had been randomized initially to TMR or medical management alone.

Operative Technique

For sole-therapy TMR, the patient is placed in a supine position with his or her left side slightly elevated. General

Table 28–1.

Patient Characteristics in RCTS of Sole-Therapy TMR

Characteristic	Allen	Frazier	Burkhoff	Schofield	Aaberge
Patients (*N*)	275	192	182	188	100
Age (years)	60	61	63	60	61
Male gender (%)	74	81	89	88	92
EF (%)	47	50	50	48	49
CCS class III/IV (%)	0/100	31/69	37/63	73/27	66/34
CHF (%)	17	34	NR	9	NR
Diabetes (%)	46	40	36	19	22
Hyperlipidemia (%)	79	57	77	NR	76
Hypertension (%)	70	65	74	NR	28
Prior MI (%)	64	82	70	73	70
Prior CABG (%)	86	92	90	95	80
Prior PCI (%)	48	47	53	29	38

Baseline patient demographics from prospective, randomized, controlled trials of TMR.
CABG = coronary artery bypass grafting; CCS = Canadian Cardiovascular System angina class; CHF = congestive heart failure; EF = ejection fraction; MI = myocardial infarction; NR = not reported; PCI = percutaneous coronary intervention.

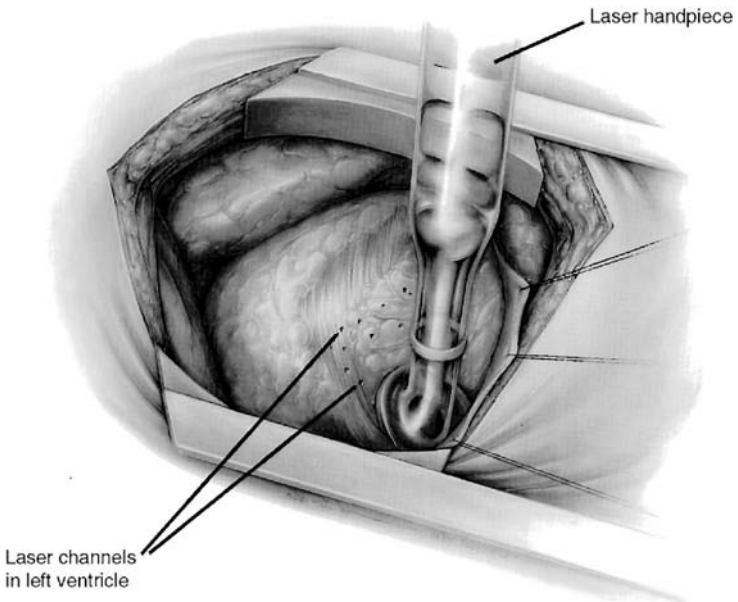

Figure 28-1. For TMR, channels of 1 mm diameter are created in a distribution of one per square centimeter starting inferiorly and then working superiorly to the anterior surface of the heart. The number of channels created depends on the size of the heart and on the size of the ischemic area.

anesthesia is established using a double-lumen endotracheal tube or a bronchial blocker to isolate the left lung. While not mandatory, this facilitates the operation, particularly because most of the patients have pleural and mediastinal adhesions from previous bypass surgery. Additionally, a thoracic epidural catheter can be employed to provide postoperative pain control.

A left anterior thoracotomy in the fifth intercostal space is the usual incision site. Once the ribs are spread by a retractor, the pericardium is opened to expose the epicardial surface of the heart (Fig. 28-1). Care must be taken to avoid previous bypass grafts. The left anterior descending (LAD) artery is identified and used as a landmark for the location of the septum. The inferior and posterolateral portions of the heart can be reached through this incision with a combination of manual traction, placement of packing behind the heart, and as illustrated, with the use of a right-angled laser handpiece. Channels are created starting near the base of the heart and then serially in a line approximately 1-cm apart toward the apex, starting inferiorly and working superiorly to the anterior surface of the heart. Since there is some bleeding from the channels, commencement of the TMR inferiorly keeps the anterior area clear and expedites the procedure. The number of channels created depends on the size of the heart and the size of the ischemic area. Myocardium that is thinned by scar, particularly when the scar is transmural, should be avoided because TMR will be of no benefit in these regions, and bleeding from channels in these areas may be problematic. The thoracotomy then is closed after placement of a chest tube, and in the majority of the cases, the patient is extubated in the operating room.

The handpiece in Fig. 28-2 is from a CO_2 laser and illustrates one of the differences between the two lasers employed for TMR. The CO_2 laser energy is delivered via hollow tubes and is reflected by mirrors to reach the epicardial surface. One-millimeter channels are made with a 15- to 20-J pulse. Firing of the laser is synchronized to occur on the R wave of the electrocardiogram (ECG) to avoid arrhythmias. The transmural channel is created by a signal pulse in 40 milliseconds and can be confirmed by transesophageal echocardiography (TEE). The vaporization of blood by the laser energy as the laser beam enters the ventricle creates an obvious and characteristic acoustic effect on TEE. The Ho:YAG laser achieves a 1-mm channel by manually advancing a fiber

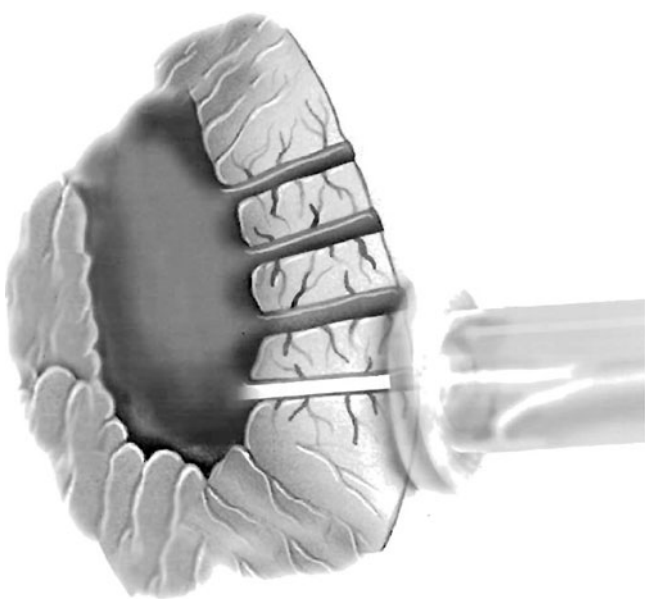

Figure 28-2. The CO_2 laser creates a transmural channel in a single 20-J pulse. Conceptually, direct perfusion may occur via the channel. Evidence indicates the laser stimulates angiogenesis in and around the channel that leads to improved perfusion.

bundle through the myocardium while the laser fires. Typical pulse energies are 2 J for this laser at a rate of 5 pulses per second; 10 to 20 pulses are required to traverse the myocardium. Detection of transmural penetration is done primarily by tactile and auditory feedback.

Endpoints

The principal subjective endpoint for all the trials was a change in angina symptoms. This was assessed by the investigator and/or a blinded independent observer. In addition to assigning an angina class, standardized questionnaires such as the Seattle Angina Questionnaire, the Short Form Questionnaire 36 (SF-36), and the Duke Activity Status Index were employed. These tests were used to detect changes in symptoms and quality of life. Objective measurements consisted of repeat exercise tolerance testing as well as repeat myocardial perfusion scans. Patients were reassessed at 3, 6, and 12 months after randomization.

RESULTS

Mortality

Prior to the randomized studies, mortality rates in the 10 to 20% range[16–22] were reported for TMR patients. In the randomized trials, lower perioperative mortality rates were reported ranging from 1 to 5%.[23–28] One of the important lessons learned from these controlled trials that differs from the earlier studies was a decrease in the mortality when patients taken to the operating room were stable, specifically not on intravenous (IV) heparin or nitroglycerin. When patients were allowed to recover from their most recent episode of unstable angina and were able to be weaned from intravenous medications such that their operation could be performed 2 weeks later, the mortality dropped to 1%.[26] The 1-year survival for TMR patients was 84 to 95% and for medical management patients was 79 to 96%. Meta-analysis of the 1-year survival demonstrated no statistically significant difference between the patients treated with a laser and those who continued with their medical therapy.[30] Long-term survival of the randomized patients from two of these studies has been reported. Four-year follow-up from Aaberge and colleagues, in which both the TMR and medical management groups were kept intact, demonstrated a 78% survival for TMR versus 76% for medical management (p = ns).[31] In a 5-year follow-up using an intent-to-treat analysis, Allen reported a survival for TMR patients at 65% versus 52% for medical management patients ($p = .05$).[32]

Morbidity

Unlike mortality, the exact definition of various complications varied from one study protocol to the next, and therefore, morbidity data are difficult to pool. Nevertheless, the typical TMR patient's postoperative course had a lower incidence of MI, heart failure, and arrhythmias than what has been documented in a similar cohort of patients, those who have reoperative CABG.[23–28]

Angina Class

The principal reason for performing TMR is to reduce the patient's anginal symptoms. This can be quantified by assessing the angina class before and after the procedure. Angina class assessment was performed by a blinded independent observer in all studies. This was done as the only angina assessment or as comparison with the investigators' assessment. Significant symptomatic improvement was seen in all studies for patients treated with the laser. Using a definition of success as a decrease of two or more angina classes, all the studies demonstrated a significant success rate after TMR, with success rates ranging from 25 to 76% (Fig. 28-3). A meta-analysis of this angina reduction yielded a summary odds ratio of 9.3 [95% confidence interval (CI) 4.6–18.5; $p < .000001$]. Significantly fewer patients in the medical management group experienced symptomatic improvement, and the success rate for these patients ranged from 0 to 32%. The seemingly broad range of success is due to differences between the baseline characteristics of the studies. It is more difficult to achieve a two-angina-class improvement if the baseline angina class is III. Studies that started with most of their patients in angina class III, not surprisingly, showed the lowest success rate. In contrast, the largest success rate for TMR was seen in the trial in which all the patients were in CCS class IV at enrollment. Of note, the medical management group in this study also showed the largest success rate.[23] This underscores some of the baseline differences between the studies.

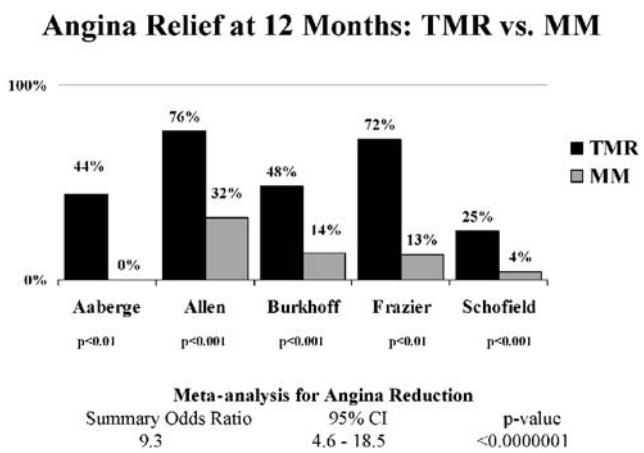

Figure 28-3. Summary of the angina relief results from five prospective, randomized, controlled trials comparing transmyocardial laser revascularization (TMR) and medical management (MM). Graph illustrates success rate for TMR or MM as measured by the percentage of patients that had a decrease of two or more angina classes. Meta-analysis of these results documents the significant advantage seen with TMR over MM.

Quality of Life and Myocardial Function

Quality-of-life indices as assessed by the Seattle Angina Questionnaire, the SF-36, and the Duke Activity Status Index demonstrated significant improvement for TMR-treated patients versus medical management in every study. Global assessment of myocardial function by ejection fraction using echocardiography or radionuclide multigated acquisition scans showed no significant change in overall ejection fraction for any of the patients regardless of group assignment or study.

Hospital Admission

Another indicator of the efficacy of TMR was demonstrated in a reduction in hospital admissions for unstable angina or cardiac-related events postprocedure. A meta-analysis of the data provided indicates that the 1-year hospitalization rate of patients in the laser-treated group was statistically significantly less than for those treated medically. Medical management patients were admitted four times more frequently than TMR patients over the year of follow-up.[30]

Exercise Tolerance

Additional functional test assessment using exercise tolerance also was performed in three of the trials.[24,27,28] While the method of treadmill testing differed between the trials, the results demonstrate an improvement in exercise tolerance for TMR-treated patients. Two studies showed an average of 65 to 70 second improvement in the TMR group at 12 months compared with their baseline, whereas the medical management group had either an average of 5 second improvement or a 46 second decrease in exercise time over the same interval.[27,28] One additional trial demonstrated that the time to chest pain during exercise increased significantly, and fewer patients were limited by chest pain in the TMR group, whereas the medical management group showed no improvement.[28]

Medical Treatment

All the studies employed protocols that continued all the patients on maximal medical therapy. For each study, the frequencies and dosages of antianginal and cardiovascular drugs were similar between the two groups at baseline. TMR patients, as a result of their symptomatic improvement, had a reduction in their medication use over the year of follow-up. Since many of these patients used a combination of short- and long-acting nitrates preoperatively, the trials demonstrated a significant decrease in the use of nitrates in TMR-treated patients, whereas the medical management patients showed a slight increase in their nitrate usage. At 1 year, the overall medication use decreased or remained unchanged in 83% of the TMR patients, and conversely, the use of medications increased or remained unchanged in 86% of the medical management patients.[26] The significant angina relief seen following TMR was not due to medication changes or increases for the TMR-treated patients.

Myocardial Perfusion

As stated previously, myocardial perfusion scans were obtained preoperatively to verify the extent and severity of reversible ischemia. The four largest randomized trials included follow-up scans as part of the study.[23,24,26,27] These results reflect over 800 of the patients randomized. The methodology of recording and analyzing these results differed in each study, so it is difficult to pool the data. Nevertheless, review of the results demonstrated an improvement in perfusion for CO_2 TMR-treated patients. Fixed (scar) and reversible (ischemic) defects were tallied for both the TMR-treated patients and the medical management groups. One study demonstrated a significant decrease in the number of reversible defects for both the TMR and the medical management patients.[27] This improvement in the reversible defects in the TMR group was seen without a significant increase in the fixed defects at the end of the study. However, the number of fixed defects in the medical management group had nearly doubled over the same 12-month interval. Similarly, there was a 20% improvement in the perfusion of previously ischemic areas in the CO_2 TMR group of another trial, and in that same trial there was a 27% worsening of the perfusion of the ischemic areas in the medical management group at 12 months.[26] There was no difference in the number of fixed defects between the groups at 12 months, nor was there a significant change in the number of fixed defects for each patient compared with his or her baseline scan. The remaining two Ho:YAG studies that obtained follow-up scans showed no significant difference between the TMR and medical management groups at 12 months and no significant improvement in perfusion in the TMR-treated patients over the same interval.[23,24]

Nonrandomized data previously had demonstrated an improvement in perfusion using dual isotope scanning at 1 and 2 years after CO_2 TMR.[33] Additionally, using N-13 ammonia position-emission tomographic (PET) assessment, subendocardial perfusion improved significantly compared with subepicardial perfusion after CO_2 TMR treatment.[34,35]

Long-Term Results

Two reports of long-term follow-up of prospectively randomized patients are available. Similar to the 1-year results, intention-to-treat analyses determined that significantly more TMR than medical management patients continued to experience at least two-class angina improvement from baseline (88% versus 44%; $p < .001$) or were free from angina symptoms altogether (33% verssu 11%; $p = .02$) at a mean of 5 years.[32] In long-term follow-up of the randomized trial that kept both the TMR and medical management groups intact (i.e., no crossover), it was shown that angina symptoms still were improved significantly (24% versus 3%, TMR versus medical management; $p = .001$), and unstable angina hospitalizations were reduced significantly ($p < .05$) at a mean follow-up of 43 months.[31] Follow-up of a series of nonrandomized patients who received TMR and survived

long term support these findings.[36] At a mean of 5 years and up to 7 years postprocedure, 81% of these patients improved to class II or better, 68% were found to have improved at least two angina classes from baseline, 17% were angina-free, and quality of life remained significantly improved. These last two reports reflect the sustained angina relief seen with CO_2 TMR because these patients had no additional procedures to account for their symptom improvement over the long term.

Based on an assessment of the cumulative results from these multiple randomized trials, the recently updated American College of Cardiology/American Heart Association (ACC/AHA) practice guidelines[37] and the Society of Thoracic Surgeons (STS) practice guidelines[38] have determined that the weight of the evidence favors the use of TMR in the treatment of stable, medically refractory angina patients.

TMR AS AN ADJUNCT TO CABG

Clinical Trials

Owing to its success as sole therapy, TMR has been evaluated in conjunction with CABG in patients with diffuse CAD who would be incompletely revascularized by CABG alone. The safety and effectiveness of adjunctive TMR have been somewhat difficult to assess owing to the influence of coronary bypass grafts and the lack of randomized control arms in some studies.[39–41]

Two prospective, randomized, controlled multicentered trials have been performed using TMR adjunctively with CABG in patients. In these studies, patients with one or more viable myocardial target areas served by coronary vessels that were not amenable to bypass grafting received either CABG plus TMR or CABG alone.[42,43] Baseline and operative characteristics were similar between groups, including the location and number of bypass grafts placed (3.1 ± 1.2, CABG + TMR; 3.4 ± 1.2, CABG alone; $p = .07$). Patients were blinded to their treatment group through 1-year follow-up.

RESULTS

Mortality

Improved outcomes following TMR + CABG versus CABG alone in terms of a reduced operative mortality rate (1.5% versus 7.6%; $p = .02$), reduced postoperative inotropic support requirements (30% versus 55%; $p = .001$), increased 30-day freedom from major adverse cardiac events (97% versus 91%; $p = .04$), and improved 1-year Kaplan-Meier survival (95% versus 89%; $p = .05$) have been reported.[42] Multivariable predictors of operative mortality were CABG alone [odds ratio (OR) 5.3; $p = 0.04$] and increased age (OR 1.1; $p = .03$).[42] A similar trend in operative mortality following TMR + CABG versus CABG alone (9% versus 33%; $p = .09$) was reported in a study of high-risk patients.[43]

Efficacy

The use of TMR adjunctively with CABG has been shown to decrease intensive-care-unit (ICU) times and length of hospitalization stay.[41] In a long-term follow-up of the randomized, controlled trial, the effectiveness of TMR + CABG versus CABG alone has been reported.[44] At a mean of 5 years, both groups experienced significant angina improvement from baseline; however, the TMR + CABG group had a lower mean number of angina-free patients (78% versus 63%; $p = .08$) compared with the CABG-alone group. Long-term survival was similar between randomized groups.

Observational data on the practice of TMR + CABG have been collected in the STS National Cardiac Database.[45,46] From 1998 to 2003, 5618 patients underwent TMR + CABG. These were compared with 932,715 patients who underwent CABG-only operations. The TMR + CABG patients therefore account for 0.6% of the surgical revascularization practice in the database. Table 28-2 outlines the significant baseline differences between the CABG-only patients and the TMR + CABG patients. The TMR + CABG patients have an increased incidence of every surrogate marker of diffuse arterial disease, and therefore, it is not surprising that their observed mortality was higher at 3.8% (versus 2.7% for CABG-only patients; $p < .001$). When unstable angina patients were removed, the observed mortality for TMR + CABG was decreased to 2.7%, and the observed:expected (O/E) ratio was 0.87. Comparison of use and outcomes from sites that have a TMR laser versus those that showed no evidence of overuse of TMR or difference in outcomes.[46]

MECHANISMS

Laser-Tissue Interactions

Understanding the mechanism of TMR starts with understanding the laser-tissue interaction. While numerous devices,[47,48] including ultrasound,[49] cryogenic ablation,[50] radiofrequency revascularization,[51,52] heated needles,[53,54] and the aforementioned hollow and solid needles have been used; none has engendered the same response that is seen with a laser. Additionally, numerous wavelengths of laser light also have been employed. These include xenon-chloride (XCl),[55,56] neodymium:YAG (Nd:YAG),[57] erbium:YAG (Er:YAG),[58] and thulium-holmium-chromium:YAG lasers (THC:YAG).[59] All these devices have been explored experimentally but have not been pursued on a significant scale clinically. Only CO_2 and Ho:YAG lasers are used for TMR. The result of any laser-tissue interaction depends on both laser and tissue variables.[33,58–60] A CO_2 laser has a wavelength of 10,600 nanometers, whereas a Ho:YAG laser has a wavelength of 2120 nanometers. These infrared wavelengths are absorbed primarily in water and therefore rely on thermal energy to ablate tissue. One significant difference, however, is that the Ho:YAG laser is pulsed, and the arrival of two successive pulses must be separated by time to allow for thermal dissipation. Otherwise, the accumulated heat will cause the

Table 28–2.

Comparison of CABG Only versus TMR + CABG Patients, STS Adult Cardiac Database 1998–2003

Characteristic	CABG only	TMR + CABG	*p*-Value
N	932, 715	5, 618	
Body surface area, m^2 (SD)	1.96 (0.24)	1.99 (0.23)	<.001
Diabetes (all types)	34%	50%	<.001
Insulin-dependent diabetes	10%	19%	<.001
Renal failure	5%	7%	<.001
Dialysis	1%	2%	<.001
CVA	7%	9%	<.001
Chronic lung disease	14%	17%	<.001
Peripheral vascular disease	16%	20%	<.001
Cerebral vascular disease	12%	17%	<.001
MI	46%	49%	<.001
Reoperation	9%	26%	<.001
Three-vessel CAD	71%	80%	<.001
Hypercholesterolemia	62%	73%	<.001
Hypertension	72%	80%	<.001

tissue to explode under pressure. Such explosions create acoustic waves that travel along the planes of lower resistance between muscle fibers and cause structural trauma as well as thermocoagulation.[60] The standard operating parameters for the Ho:YAG laser are pulse energies of 1 to 2 J and 6 to 8 W/pulse. The energy is delivered at a rate of 5 pulses per second through a flexible 1 millimeter optical fiber bundle. Despite the low energy level and short pulse duration, very high levels of peak power are delivered to the tissue so that with each pulse there is an explosion (Fig. 28-4). Additionally, the fiber is advanced manually through the myocardium, and it is therefore impossible to know whether the channel is being created by the kinetic energy delivered via the mechanical effects of the fiber or whether there has been enough time for thermal dissipation prior to the next pulse.

In contrast, the CO_2 laser was used at an energy level of 15 to 20 J/pulse with a pulse duration of 25 to 40 milliseconds. At this level, the laser photons do not cause explosive ablation, and the extent of structural damage is limited. Additionally, a transmural channel can be created with a single pulse (see Fig. 28-4). Confirmation of this transmurality is obtained by observing the vaporization of blood within the ventricle using TEE.

Finally, the CO_2 laser is synchronized to fire on the R wave, and with its short pulse duration, arrhythmic complications are minimized. The Ho:YAG device is unsynchronized and, owing to the motion of the fiber through the myocardium over several cardiac cycles, is more prone to produce ventricular arrhythmias.

Patent Channels

As noted earlier, the original concept of TMR was to create perfusion via channels connecting the ventricle with the myocardium. Clinical work has demonstrated some evidence of long-term patency.[61,62] Additional experimental work showed some evidence of patency as well.[63–66] There are also significant reports from autopsy series and laboratories that indicate that the channels do not remain patent.[67–71] The consensus is that while channels occasionally may remain patent, this is not the principal mechanism of TMR.

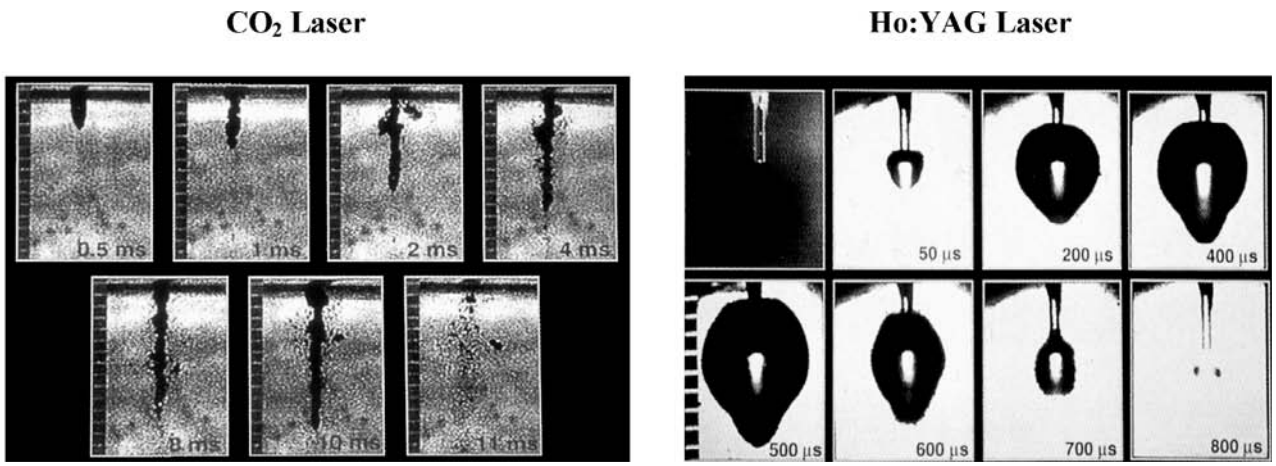

Figure 28-4. Sequential photography of the firing of a single pulse from a CO_2 laser and a HO:YAG laser into water. The pulse duration and energy levels are the same as those employed clinically.

Denervation

In contrast to the open-channel mechanism, damage to the sympathetic nerve fibers may explain the angina relief noted in clinical trials. The nervous system of the heart can function independent of inputs from extracardiac neurons to regulate regional cardiac function by reflex action. This intrinsic system contains afferent neurons, sympathetic efferent postganglionic neurons, and parasympathetic efferent postganglionic neurons. Because of this complex system, it is difficult to demonstrate true denervation. However, several experimental studies have demonstrated that denervation indeed may play a role in Ho:YAG TMR.[72–74] Experimental evidence to the contrary was performed in a nonischemic animal model.[75] Although the studies were carried out carefully, it is difficult to isolate the sympathetic afferent nerve fibers, and the experiments were in the acute setting and only address short-term effects. Regardless of the methodology employed in the laboratory, there is significant evidence of sympathetic denervation following PET scanning of Ho:YAG TMR–treated patients.[76]

Angiogenesis

The likely underlying mechanism for the clinical efficacy of TMR is the stimulation of angiogenesis. This mechanism fits the clinical picture of significant improvement in symptoms over time, as well as a concomitant improvement in perfusion, as seen with the CO_2 laser. Numerous reports have demonstrated a histologic increase in neovascularization as a result of TMR channels.[68,70,77–83] More molecular evidence of this angiogenic phenomenon was derived from work that demonstrated an upregulation of vascular endothelial growth factor (VEGF) messenger RNA, expression of fibroblast growth factor 2 (FGF2), and matrix metalloproteinases following TMR.[84–86] Histologically, similar degrees of neovascularization have been noted after mechanical injury of various types. Needle injury has been demonstrated by immunohistochemistry to also stimulate growth factor expression and angiogenesis. The conclusion is that TMR-induced angiogenesis is a nonspecific response to injury.[87–89] Investigation of this using hot and cold needles, radiofrequency energy, and laser energy to perform TMR clearly demonstrates a spectrum of tissue response to the injury.[53] The results in a model of chronic myocardial ischemia to mimic the clinical scenario indicate that indeed neovascularization can occur after mechanical TMR, but if these new blood vessels grow in the midst of a scar, there will be little functional contribution from blood flow through these new vessels. The recovery of function with laser TMR was due to a minimization of scar formation and a maximization of angiogenesis.

This then becomes a critical question: If TMR induces angiogenesis, is there an ensuing improvement in function? Clinically, this has been demonstrated subjectively with quality-of-life assessments, but more important, it has been demonstrated objectively with multiple techniques, including dobutamine stress echocardiography,[90] PET scanning,[34] and cardiac magnetic resonance imaging (MRI).[91,92] As further evidence of the angiogenic response, experimental data have mirrored the clinical perfusion results noted, with improvements in perfusion in porcine models of chronic ischemia where the ischemic zone was treated with CO_2 TMR.[93–96] This improved perfusion did lead to an improvement in myocardial function as well.

PERCUTANEOUS MYOCARDIAL LASER REVASCULARIZATION

Myocardial laser revascularization has been performed percutaneously,[97–99] thoracoscopically,[100] via thoracotomy,[23–29] and via sternotomy.[39–42] Aside from the PMR approach, any of the other surgical approaches have yielded similar

symptomatic improvement. Several percutaneous trials have attempted to demonstrate a symptomatic improvement with the creation of 2 to 3 millimeter-deep subendocardial divots achieved with a laser fiber fed via a peripheral artery into the left ventricle.[97–99] Even with the use of electromechanical mapping to verify the position of the fiber and creation of the channel, the results from PMR have been less favorable than those seen with TMR. A double-blinded, randomized, controlled trial showed no benefit to the laser-treated patients compared with the untreated control group.[99] Since the patients were blinded to their treatment, the possibility of a significant placebo effect for PMR has been raised. Of note, the morbidity and mortality of PMR reportedly are similar to those seen with TMR. As a result, the U.S. Food and Drug Administration (FDA) rendered PMR unapprovable.

The failure of PMR to achieve the same clinical results that have been seen with TMR may be due to several significant limitations, the first of which is the partial-thickness treatment of the left ventricle. Even at the maximal estimated depth of 6 millimeters that has been reported with PMR, this is significantly less than the full-thickness treatment of the myocardium that is achieved with an open TMR approach. Furthermore, typically fewer of these partial-thickness channels are created with PMR. The exact location of the channel and the establishment of a wide distribution of the channels from inside a moving ventricle are also problematic. Finally, the limitations of Ho:YAG TMR are also applicable to PMR because that is the wavelength of light that has been employed.

FUTURE USES OF TMR

Other potential applications include the use of TMR in the treatment of cardiac transplant graft atherosclerosis. While the procedure has been performed on a small number of patients, the results have indicated a benefit.[101,102] Finally, the combination of TMR plus other methods of angiogenesis may provide an even more robust response. Experimental work investigating these combinations has verified a synergistic effect with regard to histologic evidence of significant angiogenesis and, perhaps more important, an improvement in myocardial function with a combination of TMR and gene therapy versus either therapy alone.[103–107]

Cardiothoracic surgeons increasingly are faced with a more complex patient who has developed a pattern of diffuse CAD and has exhausted nonsurgical options. Results replicated in multiple randomized, controlled trials augmented by recently available long-term results have validated the safety, effectiveness, and substantially improved health outcomes achieved through application of TMR for the treatment of selected patients with severe angina owing to diffuse disease when used alone and as adjunctive therapy to achieve a more complete revascularization.

EXTRAVASCULAR ANGIOGENETIC TECHNIQUES

Prior to TMR, investigators have been trying different mechanical strategies to increase blood flow in ischemic hearts since the 1930s by obliterating the pericardial sac with mechanical abrasion and the addition of asbestos powder,[108] tacking omentum to ischemic hearts,[109,110] removing the epicardium,[111] or combining several of these with the addition of implanting the internal mammary artery into the myocardium.[112] Subsequently, pharmacologic strategies were employed in both experimental and clinical studies in an attempt to revascularize ischemic hearts by using heparin[113–115] and growth factors such as VEGF in the late 1970s and 1980s[116–120] and basic fibroblast growth factor (bFGF, or FGF2) and acidic FGF (aFGF, or FGF1) in the 1980s.[121–125] The angiogenic growth factors were first applied via direct delivery of specific proteins, and subsequently, owing to the development of DNA technology and gene delivery techniques, gene therapy studies were performed in both experimental and clinical studies. In the late 1990s, cell-based therapy was introduced in therapeutic angiogenesis for ischemic heart diseases and has been the most rapidly progressing and hot research field over the past 5 years. In this section we will discuss the topic of protein-, gene-, and cell-based therapeutic angiogenesis for the treatment of ischemic cardiovascular diseases.

Proteins

Experimental studies

Several early studies were published demonstrating that VEGF, aFGF (FGF1), and bFGF (FGF2) proteins produced in vitro changes compatible with their having angiogenesis potential.[126–131] These studies were followed by in vivo work showing that these factors actually do stimulate the growth of new vessels.[126,132,133] The more recent elegant genetic studies of vasculogenesis occurring during embryogenesis in the mouse add to the now unequivocal evidence documenting the critical importance of many molecules, including major contributions of VEGF and angiopoietin-1, to the development of mature, branching blood vessels.[134–136]

That bFGF and VEGF proteins actually could stimulate the development of collaterals to tissues supplied by an obstructed artery and in the process augment tissue blood flow was first demonstrated in the early 1990s. In experiments on myocardial ischemia, a portion of the left ventricle of dogs was made ischemic by gradual occlusion of the circumflex coronary artery. The intracoronary or left atrial administration of bFGF or intracoronary administration of VEGF proteins daily for 28 days significantly increased collateral flow.[137–139] Likewise, studies in the rabbit ischemic hind limb model demonstrated that intramuscular administration of bFGF protein daily for 2 weeks improved limb perfusion significantly.[140]

Although such studies demonstrated proof of concept, additional studies also raised issues that still have not been resolved. For example, in attempts to determine a clinically feasible strategy for delivery of protein to enhance collateral flow, different durations of intra-arterial protein administration were studied in the canine myocardial ischemia model. While 28 days of administering boluses of VEGF into the left atrium improved collateral flow, 7 days of administration did not,[141] and while 7 and as few as 2 days of intracoronary administration of bFGF improved collateral flow, a single bolus injection did not.[142] These results demonstrated, at least in this model of myocardial ischemia, that the duration of exposure of the vessels supplying the ischemic tissue to angiogenesis factors is critical for a therapeutically relevant effect.

Additional studies employing ^{125}I-labeled bFGF demonstrated that route of administration is another critical factor in determining local tissue uptake[143] and, potentially, therapeutic response. Thus, whereas 3 to 5% of an intracoronary dose of bFGF was recovered in the myocardium, only 0.5% of an intravenous dose was. The most plausible explanation of these findings derives from the fact that myocardial uptake depends on peak serum concentration; because bFGF has a heparin-binding domain, considerable first-pass uptake in the lungs will occur following intravenous administration (the lungs contain large amounts of heparin sulfates), resulting in a blunted peak serum concentration presented to the myocardium when compared with the very high concentrations presented to the myocardium with bolus injection directly into the coronary artery.

The biologic consequences of these differences were demonstrated in angiogenesis studies of the same canine ischemia model. Collateral flow improved with intracoronary administration of bFGF but did not increase when the drug was given intravenously, despite its being given for 1 week.[142] Although similar uptake studies have not been performed with VEGF, its 165 isoform ($VEGF_{165}$) also has a heparin-binding domain (whereas $VEGF_{121}$ does not), suggesting that similar results would be seen.

Animal studies that appear to be at variance with these results also have been reported. Thus, Lopez and colleagues[144] delivered $VEGF_{165}$ to a porcine model of myocardial ischemia (ameroid occlusion of the circumflex coronary artery) by three different local intracoronary delivery systems (via an InfusaSleeve catheter, via intracoronary bolus infusion, and via epicardial implantation of an osmotic delivery system). VEGF was administered 3 weeks after ameroid placement, and indices of collateral function were assessed at that time (baseline) and 3 weeks later. Whereas there was no significant improvement in circumflex territory perfusion in control pigs, improved circumflex perfusion was demonstrable within each VEGF-treated group using paired *t*-tests to compare pre- and posttreatment perfusion values. Although these data are suggestive of a VEGF treatment effect, they are not convincing. First, ongoing collateral development has been observed in pigs throughout the 6-week period following circumflex ameroid placement.[145] In the Lopez study, however, the control group did not exhibit the expected increase in circumflex territory perfusion during that interval. Second, direct comparisons between individual VEGF treatment groups and the control group were not statistically significant. Only when all three VEGF treatment groups were combined in a post hoc analysis was a statistically significant difference demonstrable between VEGF groups and the control group. Third, there were three deaths in VEGF-treated animals during the investigation. Elimination of three animals in a small study such as this could have an important effect on the results through selection bias. Thus, while suggestive, the data from this experiment do not demonstrate unequivocally that a *single* bolus intracoronary injection of VEGF is capable of increasing collateral flow to a greater extent than that which occurs in the absence of therapy.

Hariawala and colleagues[146] also reported improved flow in a similar model. However, this study is flawed by the fact that intracoronary bolus administration of VEGF (2 mg) caused severe hypotension that led to the acute death of 4 of 8 animals in the treated group; hence the surviving animals, which were found to have greater collateral flow than the untreated controls, may have survived only *because* they had greater intrinsic collateral flow. These investigators also demonstrated in the rabbit hind limb model of ischemia that a single dose of intrafemoral bFGF or $VEGF_{165}$ improves collateral flow and, surprisingly, that a single intravenous dose of $VEGF_{165}$ also improves flow.[147,148] Thus conflicting results are reported in the literature relating to whether a *single* intra-arterial bolus injection of VEGF or bFGF protein improves collateral flow and whether improvement occurs following intravenous administration, at least for heparin-binding agents.

Clinical trials

The clinical trials of protein-based angiogenesis have been reported by using growth factors like FGF and VEGF families. The effect of FGF-1 on the ischemic myocardium was first performed by Schumacher and colleagues[149] in a series of 20 patients. In the study, 0.01 mg/kg of FGF-1 protein was injected directly into the ischemic myocardium along LAD while patients were undergoing bypass surgery. Three months later, neoangiogenesis, together with the development of a normal vascular appearance, was demonstrated angiographically. The first randomized, double-blind, placebo-controlled clinical trial for basic FGF was reported by the Simons' group.[150] Twenty-four patients undergoing CABG were randomized to three groups, receiving either 10 μg or 100 μg of bFGF, or placebo through delivery of microcapsules capable of sustained-release which were implanted in ischemic myocardium. During 16 months of follow-up, all patients in the 100 μg bFGF remained angina-free and a stress nuclear perfusion imaging test at baseline and 3 months showed significant improvement. The efficacy of single intracoronary infusion of FGF-2 (0, 0.3, 3, or 30 μg/kg; n=337 patients) was tested by a multicenter FIRST trial.[151] At 90 days, in all FGF-2 treated groups angina symptoms were significantly reduced compared with placebo, but not in 180 days due to the continued improvement in the

placebo. The effect of intracoronary injection of recombinant human VEGF on myocardial perfusion was first performed on 14 severe CAD patients[152], and followed by a multicenter VIVA trial on a total of 178 patients.[153] In the small patients group study, seven patients who received high-dose VEGF (0.05–0.167 μg/kg) showed improvement in resting myocardial perfusion and collateral count density at 60 days follow-up.[152] In the VIVA trial, patients were randomized to receive a 20-minute intracoronary infusion of placebo, low-dose (17 ng/kg/min)or high-dose (50 ng/kg/min) rhVEGF and followed by 4-hour intravenous infusion on days 3, 6, and 9. However, the study showed no significant differences in primary end point of the trial and ETT time compared with placebo at 60 days follow-up. At day 120, high-dose patients showed improvement in angina class and favorable trends in exercise treadmill test time and quality of life.[153]

Genes

Experimental studies

Gene therapy presents one of the solutions to the possible dosing conundrum because gene therapy can be considered a sophisticated form of a sustained delivery system. Once transfected, the target cell expresses gene product for days, weeks, or longer depending on the specific tissue transfected and the specific vector used.

Proof of concept that gene therapy can improve collateral function was demonstrated by Giordano and colleagues.[154] They found in a porcine model of myocardial ischemia (ameroid occlusion of the circumflex coronary artery) that a single-dose intracoronary administration of an adenoviral vector carrying the FGF5 transgene into the nonoccluded right coronary artery increased myocardial flow and function. Surprisingly, they found that about 95% first-pass myocardial uptake was achieved with intracoronary administration. Hammond and colleagues have since demonstrated that FGF4 produces similar effects in restoring myocardial flow and function.[155] Improvement of myocardial contractility in a porcine model of chronic ischemia has been reported recently by using a combined TMR and FGF-2 gene therapy approach.[156] In this study, adenoviral vector encoded FGF-2 was formulated in a collagen-based matrix and directly injected into ischemic myocardium. Other investigators also have performed studies employing the rabbit hind limb model of ischemia and have reported that injection into the femoral artery of the $VEGF_{165}$ transgene carried in a plasmid vector improves collateral flow.[157]

Direct intramyocardial injection

No matter how efficient first-pass uptake is, a considerable proportion of an angiogenesis factor *injected into an artery* supplying the target tissue will enter the systemic circulation and thereby expose nontarget tissues to its biologic effects.[158] While there is no definitive evidence yet that such systemic spillover will produce serious side effects, there is always that possibility (see below). It therefore would appear that if *direct intramuscular injection* of the angiogenesis factor, either by the transepicardial or transendocardial route, does result in enhanced collateral flow, such an approach might be preferable.

A protein injected once intramuscularly would be unlikely to persist in the tissue long enough to exert an important biologic effect.[158] Although multiple injections of protein might well improve collateral flow,[140] such a strategy has practical limitations. Therefore, once it was demonstrated that an adenoviral vector carrying a reporter transgene efficiently expresses its gene product after intramyocardial injection,[159] this approach to gene delivery was explored as an approach for gene therapy.

Proof of concept that intramyocardial injection could enhance collateral flow and improve impaired myocardial function was demonstrated in a porcine model of myocardial ischemia. This was achieved by the transepicardial injection of an adenoviral vector carrying the $VEGF_{121}$ transgene performed following thoracotomy.[160] The feasibility of catheter-based transendocardial delivery of angiogenesis genes has been shown recently,[161,162] demonstrating that the direct injection of angiogenesis factors into the myocardium can be accomplished without the need for thoracotomy.

However, because VEGF induces marked increases in vascular permeability and tissue edema, excessive VEGF administration could develop deleterious effects. Recent reports showed that in a chronic ischemic rabbit ear model, both adenoviral encoded VEGF and Angiopoietin-1 (Ang-1) increased flow at one week after injection. However, Ang-1-induced flow was localized to larger vessels, with no visible inflammatory response, but VEGF produced a diffuse increase in flow that was associated with pronounced swelling, vessel leakage, and inflammatory cell infiltration. At 4 weeks, the flow in the VEGF treated group decreased from pretreatment values. In contrast, the Ang-1-induced improvement was maintained.[163] Similar deleterious effects of VEGF were also reported by Masaki et al in their mouse hind limb ischemia model.[164]

Clinical trials

The first clinical trial on gene-based therapy using adenoviral vector was reported by Rosengart and colleagues.[165] In this phase I trial, 15 patients received adenoVEGF121 by direct intramyocardial injection as an adjunct to conventional CABG and six patients received gene-therapy only. Thirty days after the treatment, all patients showed improvement of wall motion in the area of vector administration by coronary angiography and stress ^{99m}Tc-sestamibi perfusion scan, as well as improvement in angina class after therapy. There was no evidence of systemic or cardiac-related adverse events related to vector administration. The effect of plasmid encoded VEGF2 on chronic myocardial ischemia was studied in 19 patients using catheter-based delivery.[166] In this small phase 1/2 study, Losordo and colleagues used an injecting catheter device guided by NOGA mapping technique and administered 200–800 μg of phVEGF2 plasmid directly into the endomyocardium. The end point analysis at

3 months disclosed improvement in angina class and strong trends favoring efficacy of phVEGF2 versus placebo in exercise duration, functional improvement, and Seattle Angina Questionnaire data. The adenoviral encoded FGF4 was studied by AGENT trial by Grines et al in a group of 79 patients with chronic stable angina pectoris.[167] In this trial, patients received one time intracoronary injection of five different doses of adenoviral encoded FGF4 (from $3.3 \times 10^8 - 10^{11}$ viral particles in half-log increments). In this first report of a randomized, double-blind and placebo-controlled trial, ad5-FGF4 showed a trend to have greater improvements in exercise time versus placebo at 4 weeks' follow-up. The same group also reported an AGENT-2 study of 52 patients with chronic stable angina using a single dose of 10^{10} viral particle of ad5FGF4 intracoronary infusion. At 8 weeks after treatment, ischemic defect size was significantly decreased in ad5FGF4 injected patients compared with placebo-treated patients and the viral vector was well tolerated and did not result in any permanent adverse sequelae.[168] Hedman et al. conducted a phase II Kuopio Angiogenesis Trial (KAT) to study the effects of VEGF on restenosis and chronic myocardial ischemia by intracoronary injection of either adenoviral or plasmid encoded VEGF165 on 103 patients who underwent PTCA and stenting.[169] At 6 months' follow-up, no difference was found in restenosis rate or minimal lumen diameter between all study groups. However, myocardial perfusion showed a significant improvement in the adenoVEGF treated group. Recently, the Euroinject One Trial was reported by Kastrup and colleagues[170] on direct intramyocardial plasmid VEGF-A_{165} gene therapy in patients with stable severe angina pectoris. In this study, 80 "no option" patients with severe stable ischemic heart disease were randomly assigned to receive either 0.5 mg of phVEGF-A_{165} or placebo plasmid in the myocardial region showing stress-induced perfusion defects under the guidance of the NOGA-MyoStar system. At three months' follow-up, the VEGF gene transfer did not significantly improve stress-induced myocardial perfusion defect compared with placebo. However, improved regional wall motion indicated a favorable anti-ischemic effect.

In summary, single protein or gene-based therapy so far has not achieved significant convincing beneficial results in improving myocardial perfusion both experimentally and clinically. More clinical studies are needed in order to determine how to achieve optimal myocardial angiogenesis. Many aspects of gene transfer, including the appropriate vector dose, formulation, and administration route, are still to be tested.

Cell-Based Therapy

Two classical concepts have been challenged in recent years by cell-based therapy using either embryonic or adult stem cells: First, vasculogenesis, which previously referred to a process that occurred only in the embryo, in which the vascular system develops from mesodermal precursor cells called *angioblasts* that invade the different embryonic organs and assemble in situ to form the primary capillary plexus. However, many investigators now believe that in adults, bone marrow–derived stem cells or endothelial progenitor cells can be recruited to and incorporated into tissues undergoing neovascularization. Second, cardiac myocytes originally were considered to be terminally differentiated cells that cannot be regenerated in adulthood. However, recent studies have shown that a limited number of cardiomyocytes may be regenerated by locally sited or recruited circulating stem cells. Therefore, stem cells, which include hematopoietic stem cells (HSCs), endothelial progenitor cells (EPCs), mesenchymal stem cells/stromal stem cells (MSCs), myoblasts, and undifferentiated side population cells, have been used as an alternative therapeutic strategy for ischemic cardiovascular diseases that cannot be treated by routine interventional approaches. Theoretically, embryonic stem cells have more potential to differentiate into cardiomyocytes; however, clinical trials are now only limited to adult stem cells owing to the fact that they are relatively easier to handle, and autologous transplantation can be performed in clinical patients. Several centers around the world, specifically in Germany and Korea, had reported an improved functional status in experimental animals and clinical patients after such therapy; however, it is still unclear how bone marrow–derived stem/progenitor cells are mobilized and recruited into ischemic tissues, if the injected cells in clinical trial patients differentiated into functional cardiomyocytes, and what particular cell type is better to use compared with others. This section will focus on the progress status of clinical trials, mechanisms of involving functional improvements by stem cell therapy, limitations for applications, and potential risks.

Clinical trials

TOPCARE-AMI: Assmus and colleagues first reported cell-based therapy for 20 acute myocardial infarction (AMI) patients in 2002.[171] In this study, the authors performed intracoronary infusion of autologous bone marrow–derived mononuclear cells ($n = 9$) or circulating blood-derived progenitor cells ($n = 11$) 4 to 5 days after AMI. The circulating blood-derived progenitor cells were expanded ex vivo for 3 days before injection. The bone marrow–derived cells were extracted on the same day as injection without expansion. At 4 months following cell injection, patients' cardiac function was improved compared with 11 matched controls. The authors also reported postinfarction remodeling outcome using serial contrast-enhanced MRI.[172] A total of 28 patients with reperfused AMI who received bone marrow-derived cells or circulating blood progenitor cells were analyzed. They found that intracoronary infusion of adult progenitor cells in patients with AMI beneficially affects postinfarction remodeling processes. The migratory capacity of the infused cells is a major determinant of infarct remodeling, suggesting a causal effect of progenitor cell therapy on regeneration enhancement.[172] In 2004, the same group reported final 1-year results of 59 patients that showed similar functional improvements.[173]

Strauer and colleagues conducted a study to test the effect of autologous bone marrow-derived mononuclear cells (BMCs) on myocardial repair or regeneration. The authors first reported the data with 10 AMI patients who received BMCs by intracoronary injection and compared with 10 compatible patients treated with standard therapy alone. At 3 months following cell therapy, they found that the infarct region had decreased significantly and wall motion also significantly improved.[174] More recently, the same group reported another study using same cell therapy technique on 18 patients with chronic MI (5 months to 8.5 years old) for their effects on myocardial regeneration.[175] At 3 months, the patients with cell therapy showed that the infarct size was reduced by 30% and global left ventricular ejection fraction and infarction wall movement velocity increased significantly, whereas in the control group no significant changes were observed. The authors also found that following BMC transplantation there were improvements in maximum oxygen uptake and regional ^{18}F-fluor-desoxy-glucose uptake into infarct tissue suggesting a regeneration of myocardium after infarction.

Perin and colleagues[176] reported their results using a NOGA catheter technique to transendocardially inject autologous bone marrow stem cells for severe chronic ischemic heart failure patients. Fourteen patients who received cell injection showed significant functional improvement compared with seven controls. Similar methods also were reported by Fuchs and colleagues in Washington Hospital Center in 10 no-option patients with advanced CAD. The authors first initiated a porcine ischemic model to test the effect of freshly extracted autologous bone marrow on myocardial blood perfusion. Improved collateral flow and contractility in a treated group of animals was found.[177] Subsequently, in a pilot clinical study, the 10 no-option patients with advanced CAD autologous bone marrow direct myocardial injection induced a significant improved Canadian Cardiovascular Society angina score and stress-induced ischemia occurring within the injected territories.[177,178]

Chen and colleagues[179] were the first group to use autologous ex vivo expanded bone marrow–derived mesenchymal stem cells in patients with AMI. In their study, a total of 69 patients who received PCI 12 hours after AMI were chosen randomly for either cell injection ($n = 34$) or control ($n = 35$). The bone marrow–derived mononuclear cells were cultured in vitro for 10 days, and then patients underwent intracoronary injection of the fibroblast-like mesenchymal stem cells. Patients who received mononuclear stem cell injection showed significant improvement in left ventricular (LV) function at 3 to 6 months of follow-up.

Magic Cell

Kang and colleagues[180] reported a mobilized peripheral blood mononuclear cell study for AMI patients after coronary stenting. A total of 27 patients with AMI who underwent PCI 48 hours later were studied. Ten patients received intracoronary injection of mobilized [granulocyte colony-stimulation factor (G-CSF) 10 μg/kg for 4 days] PBMC, and 10 patients received injection of G-CSF alone, 7 as control. At 6 months, the cell infusion group showed improvement in LV function compared with the other two groups.

DIRECT MYOCARDIAL STEM CELL TRANSPLANTATION: Patel and colleagues[181] recently reported direct myocardial injection of autologous bone marrow–derived stem cells in 10 patients who underwent bypass surgery. Six months later, the cell injection patients showed improvement in LV function compared with 10 patients who received bypass surgery alone. No side effects were found with this direct stem cell injection.

Safety and Efficacy

Potential for deleterious effects

For most potent therapeutic interventions, therapeutic efficacy is rarely free of the potential for harmful effects to occur. The biologic activities of most of the angiogenesis agents currently being tested clinically are very potent, and it is likely that the same activities that lead to a therapeutic effect also could cause unwanted side effects. It is therefore probable that some side effects consequent to the cellular effects of these agents inevitably will occur. If this concept is true, then the critical question we will have to address in large clinical trials is whether the incidence of these risks is sufficiently low that they will be outweighed by the therapeutic benefits.

Among the side effects that might occur as a result of the biologic effects of these agents is the development of new blood vessels in nontargeted tissues, a complication that would be particularly devastating if it were to occur, for example, in the retina. It is possible that this particular complication may not develop unless a tissue is "primed" to respond with an angiogenesis response. That is, quiescent cells have low constitutive expression of receptors for the VEGF and FGF family of agents—thus, unless the tissue is exposed to very high doses of the ligands for prolonged periods, it is possible that normal tissue is resistant to the neovascularization effects of angiogenesis factors, a result suggested by the study by Banai and colleagues.[182] In this regard, a patient with diabetic retinopathy does have vascular cells that are "primed," insofar as it has been demonstrated that there are increased levels of one of the receptors for VEGF.[183–185]

Other VEGF-specific complications could develop as a result of the potent activity of VEGF as an inducer of vascular permeability.[117–121,186,187] Although angiogenesis and vascular permeability might be considered two separate biologic activities, it is also possible that the vascular permeability properties of VEGF are essential for angiogenesis to occur.

Whatever the interrelation between these two actions, if vascular permeability increases in tissues other than the tissue targeted for angiogenesis, serious consequences could accrue. That this could occur was demonstrated in a recent study in which the effects of overexpression of VEGF (achieved by injecting an adenovirus carrying the VEGF transgene) in adult mice was investigated.[188] The mice, as expected, developed elevated circulating levels of VEGF

following injection of the adenoviral vector. However, a high percentage died within days, developing increased vascular permeability and severe multiple-organ edema.

Other potential complications based on biologic activities are the expansion and induction of instability of atherogenic plaque and the growth of tumors. For example, Flugelman and colleagues demonstrated an association between unstable angina and the intraplaque presence of aFGF and bFGF.[189] They suggested that these agents might play a role in plaque instability. In addition, the broad range of cells on which the FGF family of agents exerts mitogenic effects could result in the growth of cells resident within plaques or of malignant cells.

Although the direct mitogenic effects of VEGF are limited largely to endothelial cells, it is of note that VEGF and its receptors, VEGFR1 and VEGFR2 (flt-1 and Flk-1), are overexpressed in atherosclerotic lesions.[190] Moreover, a number of nonendothelial tumor cells have been found to possess low levels of functional VEGFR1 and VEGFR2.[191] Also of possible relevance is the fact that the uterus possesses functional VEGF receptor tyrosine kinases[192] and that VEGF is mitogenic for uterine smooth muscle. These observations raise the possibility that the atherosclerotic lesion, certain tumors, and the common leiomyoma (fibroid) could at least theoretically respond to direct exogenous stimulation by VEGF.

There is also increasing evidence suggesting that growth of microvessels into plaque or tumors, through angiogenesis processes, is critical to growth of both tumor and plaque.[193–198] Thus, microvascular angiogenesis per se, an activity inherent in most angiogenesis factors, could predispose to plaque or tumor growth. In addition, the potent vascular permeability effect of VEGF could result in exposing a plaque or tumor to many cytokines and growth factors that normally are confined to the plasma and through this indirect mechanism stimulate their growth.

It must be emphasized that there have been *no* conclusive reports in clinical studies demonstrating that angiogenesis agents actually induce new tumor development, increase growth of in situ tumors, or increase plaque size. However, several experimental studies have demonstrated that prolonged exposure of skeletal muscle or myocardium to high local levels of VEGF or FGF family peptides can cause hemangioma-like tumors and vascular malformations[182,190,199–204] and can increase neointimal development.[205–207]

A phase I randomized, dose-escalation trial also demonstrated that high doses of bFGF can lead to the development of thrombocytopenia and renal toxicity.[208] In addition, the immune surveillance system is not normally exposed to large amounts of these proteins. It is therefore possible that antibodies can develop to these cytokines and that these could either impair the efficacy of repeated administration of the agents or even possibly lead to immunopathogenic processes. It also should be noted that one of the clinical trials in progress employs FGF2 of porcine origin[150,151]; although the high homology between the FGFs in different species makes it unlikely that recognition of nonself protein will occur, this certainly is not beyond the realm of possibility.

FGF and VEGF proteins, administered acutely, can produce hypotension through, at least in part, a nitric oxide–mediated pathway[209–211] and, in the case of FGF2, through a potassium channel–mediated mechanism.[212] The hypotensive effect has resulted in the death of pigs that had chronic myocardial ischemia and that were treated with the intracoronary injection of $VEGF_{165}$ protein[146] and in a prolonged hypotensive episode of a patient entered into a phase I study testing the safety of intracoronary administration of bFGF.[208] This complication appears to occur only when high systemic levels of bFGF and VEGF develop rapidly. Thus, it would appear to be of little or no concern if bFGF and VEGF proteins are not administered rapidly and of no concern when the factors are given as genes—which express the proteins they encode slowly.

We also need to consider, in the case of gene therapy employing viral vectors, the potential for the vectors themselves to cause deleterious effects. The administration of large amounts of virus can lead to massive immune responses that could cause serious, even fatal immunopathology. Such responses are unlikely given the amount of adenovirus administered in current clinical cardiovascular protocols. However, the foreign proteins presented by the virus, even when administered in relatively small amounts, probably will induce immune responses that conceivably could decrease subsequent sensitivity to the beneficial effects of the transgene delivered by the virus if administered repeatedly or could possibly lead to immune-mediated tissue damage.

In cell-based therapy, most of the clinical trials so far are using no ex vivo expanded or short time expanded (4 to 5 days) cells. In animal studies, stem cells potentially can transform in in vitro expansion. These transformed cells can create tumors in nude mice.[213] Similar incidents occurred occasionally in adult bone marrow–derived mesenchymal stem cells. It is still not clear which cell type is best for clinical myocardial ischemic patients; however, if it is decided to use ex vivo expanded cells, you have to be sure that they are not tumorigenic. It is absolutely necessary to test these cells for tumorigenic potential in nude mice and to perform a karyotyping test before injecting them into patients.

CHAPTER 29

Surgical Treatment of Complications of Acute Myocardial Infarction: Postinfarction Ventricular Septal Defect and Free Wall Rupture

Arvind K. Agnihotri • Joren C. Madsen • Willard M. Daggett, Jr.

Rupture of the ventricular chamber (septum or free wall) following myocardial infarction is a relatively infrequent condition with high mortality. These conditions, resulting from transmural infarction, may cause early death precluding surgical repair. Free wall rupture can result in tamponade and sudden cardiovascular collapse. In septal rupture, there is a variable amount of left-to-right shunting and it often leads to symptoms of heart failure. The clinical presentation ranges from an asymptomatic murmur to cardiogenic shock.

The first step in the evolution of surgical techniques to repair an acute postinfarction ventricular septal rupture involved differentiating the surgical treatment of these acquired lesions from the surgical approaches used to repair congenital ventricular septal defects (VSDs), which are for the most part not applicable. Next, understanding the significance of differing anatomic locations of postinfarction VSDs led to innovations in terms of the location of the cardiotomy and the type of repair necessary to achieve a successful result in any given patient. Then, the gradual appreciation of different clinical courses pursued by patients after postinfarction ventricular septal rupture, both in terms of location of the defect and the degree of right ventricular functional impairment, led to an increased urgency relative to the timing of surgical repair. More recently, improved results have been reported using the technique of endocardial patching with infarct exclusion, which may signify progress in the evolution of the surgical management of postinfarction VSDs. The incorporation of specific anatomic concepts of surgical repair and a better understanding of the physiologic basis of the disease has led to an integrated approach to the patient that has improved salvage of patients suffering this catastrophic complication of acute myocardial infarction (AMI).[1]

An *acute* postinfarction VSD is a perforation of the muscular ventricular septum occurring in an area of acutely infarcted myocardium. A ventricular septal rupture may be termed *chronic* when it has been present for more than 4 to 6 weeks. A *postinfarction ventricular rupture* is a perforation of the ventricular free wall occurring in an area of acutely infarcted myocardium.

POSTINFARCTION VENTRICULAR SEPTAL DEFECT

History

In 1845 Latham[2] described a postinfarction ventricular septal rupture at autopsy, but it was not until 1923 that Brunn[3] first made the diagnosis antemortem. Sager[4] in 1934 added the 18th case to the world literature and established specific clinical criteria for diagnosis, stressing the association of postinfarction septal rupture with coronary artery disease (CAD).

The treatment of this entity was medical and strictly palliative until 1956, when Cooley and associates[5] performed the first successful surgical repair in a patient 9 weeks after the diagnosis of septal rupture. These first patients who underwent similar repairs in the early 1960s usually presented with congestive heart failure (CHF), having survived for more than a month after acute septal perforation.[6,7] The success of operation in these patients and the precipitous, acute course of other patients with this complication[8] gave rise to the belief that operative repair should be limited to patients surviving for 1 month or longer.[6,9] This purportedly allowed for scarring at the edges of the defect, which was thought to be crucial to the secure and long-lasting closure of the septal rupture.[10,11]

In the late 1960s, more rapid recognition of septal rupture following infarction led to the recommendation that operation be attempted earlier in patients who were hemodynamically deteriorating.[1,3,12] The use of improved prosthetic materials accompanied the successful surgical repair of defects from 1 to 11 days old, as reported by Allen and Woodwark[12] in 1966, Heimbecker and colleagues[13] in 1968, and Iben and coworkers[14] in 1969. Notable among these was a superb early study by Heimbecker and associates of infarctectomy and its clinical application to patients with postinfarction VSDs. The surgical management of these patients was further refined by the inclusion of infarctectomy[13,15,16] and aneurysmectomy[17,18] and the development of techniques to repair perforations in different areas of the septum.[19–21] Over the last 15 years, it has become increasingly clear that in the majority of cases postinfarction ventricular septal rupture constitutes a surgical emergency. More recently, improved surgical techniques, newer prosthetic materials, enhanced myocardial protection, and improved perioperative mechanical and pharmacologic support have led to more favorable results in the surgical management of patients with postinfarction septal rupture.[22,23]

Incidence

Postinfarction ventricular septal defects complicate approximately 1 to 2% of cases of AMIs and account for about 5% of early deaths after MI.[24,25] The average time from infarction to rupture has been reported to be between 2 and 4 days, but it may be as short as a few hours or as long as 2 weeks.[25–28] These observations correlate well with the pathologic findings, which demonstrate that necrotic tissue is most abundant and ingrowth of blood vessels and connective tissue is only beginning 4 to 21 days following an MI.[29,30] Postinfarction ventricular septal defects occur in men more often than women (3 to 2), but more women experience rupture than what would be expected from the incidence of CAD in women.[8] The age of patients with this complication ranges from 44 to 81 years, with a mean of 62.5 years. However, there is some evidence that the average age is increasing.[23,25,31,32] The vast majority of patients who experience ventricular septal rupture do so after their initial infarction.[25,32] The overall incidence of postinfarction ventricular septal rupture may have decreased slightly during the past decade as a result of aggressive pharmacologic treatment of ischemia and thrombolytic and interventional therapy in patients with evolving MI, as well as the prompt control of hypertension in these patients.[32]

Angiographic evaluation of patients with postinfarction ventricular rupture indicates that septal rupture is usually associated with complete occlusion rather than severe stenosis of a coronary artery.[33] On average, these patients have slightly less extensive CAD, as well as less developed septal collaterals than do other patients with CAD.[34] The lack of collateral flow noted acutely may be secondary to anatomic configuration, edema, or associated arterial disease. Hill and associates,[35] in reviewing 19 cases of postinfarction ventricular septal rupture, found single-vessel disease in 64%, double-vessel disease in 7%, and triple-vessel disease in 29%. However, the frequency of single-, double-, and triple-vessel CAD is more evenly distributed in other series.[28,36]

Postinfarction ventricular septal defects are most commonly located in the anteroapical septum as the result of a full-thickness anterior infarction (in approximately 60% of cases). These anterior septal ruptures are caused by anteroseptal MI following occlusion of the left anterior descending (LAD) artery. In about 20 to 40% of patients, the rupture occurs in the posterior septum following an inferoseptal infarction, which is usually due to occlusion of a dominant right coronary artery, or less frequently, a dominant circumflex artery.[37] Thus, ventricular septal perforations occur most frequently in 65-year-old men with single-vessel coronary disease and poor collateral flow who present 2 to 4 days following their first anterior MI.

Pathogenesis

The infarct associated with septal rupture is transmural and generally quite extensive, involving, on average, 26% of the left ventricular wall in hearts with septal rupture, compared with only 15% in other acute infarctions.[25] In an autopsy study, Cummings and colleagues[38] found that in patients with acute anterior or inferior infarctions, the amount of right ventricular infarction was much greater in the hearts with septal ruptures as compared to those without septal defects. Likewise, hearts with posterior septal rupture had more extensive left ventricular necrosis than did hearts with inferior infarctions and no septal defects.

Why certain hearts rupture and others do not is not fully understood. Slippage of myocytes during infarct expansion[39] may allow blood to dissect through the necrotic myocardium and enter either the right ventricle or pericardial space.[40] Hyaline degeneration of cardiomyocytes with subsequent fragmentation and enzymatic digestion may allow fissures to form, predisposing to rupture.[41]

There are two types of rupture: simple, consisting of a direct through-and-through defect usually located anteriorly; and complex, consisting of a serpiginous dissection tract remote from the primary septal defect, which is usually located inferiorly.[42] Multiple defects, which may develop within several days of each other, occur in 5 to 11% of cases and are probably due to infarct extension. Since a successful surgical outcome is related to adequacy of closure of septal defects, multiple defects must be sought preoperatively if possible, and certainly at the time of operative repair.

Of the small number of patients who survive the early period of ventricular septal rupture, 35 to 68% go on to develop ventricular aneurysms[26,35] through the process of ventricular remodeling.[43] This compares with a 12% incidence of aneurysm formation in patients suffering an infarction but no septal rupture,[44] and probably relates to the size

and transmural nature of the infarction associated with septal rupture. Postinfarction septal rupture, especially in the posterior septum, may be accompanied by mitral valve regurgitation due to papillary muscle infarction or dysfunction. In approximately one-third of cases of septal rupture, there is a degree of mitral insufficiency, usually functional in nature, secondary to left ventricular (LV)dysfunction with mitral annular dilation, which usually resolves with repair of the defect.[34]

Pathophysiology

The most important determinant of early outcome following postinfarction ventricular septal rupture is the development of heart failure (left, right, or both). The associated cardiogenic shock leads to end-organ malperfusion, which may be irreversible. The degree to which heart failure develops depends on the size of the ventricular infarction and the magnitude of the left-to-right shunt. Left ventricular dysfunction due to extensive necrosis of the left ventricle is the primary determinant of CHF and cardiogenic shock in patients with anterior septal rupture, while right ventricular dysfunction secondary to extensive infarction of the right ventricle is the principal determinant of heart failure and cardiogenic shock in patients with posterior septal rupture.[36,45,46] However, the development of CHF and cardiogenic shock in a patient with postinfarction VSDs is not explained solely by the degree of damage sustained by the ventricle.[47]

The magnitude of the left-to-right shunt is the other key variable in the development of hemodynamic compromise. With the opening of a VSD, the heart is challenged by an increase in pulmonary blood flow, and a decrease in systemic blood flow, as a portion of each stroke volume is diverted to the pulmonary circuit. As a consequence of the sudden increase in hemodynamic load imposed upon a heart already compromised by acute infarction, and possibly by a ventricular aneurysm, mitral valve dysfunction, or a combination of these problems, a severe low cardiac output state results. The normally compliant right ventricle is especially susceptible to failure in this circumstance.[48,49] Patients with posterior ventricular septal rupture and right ventricular dysfunction may display shunt reversal during diastole because the end-diastolic pressure in the right ventricle can be higher than in the left.[40,50] Ultimately, persistence of a low cardiac output state results in peripheral organ failure.

Diagnosis

The typical presentation of a ventricular septal rupture is that of a patient who has suffered an AMI, and who after convalescing for a few days develops a new systolic murmur, recurrent chest pain, and an abrupt deterioration in hemodynamics. The development of a loud systolic murmur, usually within the first week following an AMI, is the most consistent physical finding of postinfarction ventricular septal rupture (present in over 90% of cases). The murmur is usually harsh, pansystolic, and best heard at the left lower sternal border. The murmur is often associated with a palpable thrill. Depending on the location of the septal defect, the murmur may radiate to the left axilla, thereby mimicking mitral regurgitation.[27] Up to one-half of these patients experience postinfarction chest pain in association with the appearance of the murmur.[25] Coincident with the onset of the murmur, there is usually an abrupt decline in the patient's clinical course, with the onset of congestive failure and often cardiogenic shock. The findings of cardiac failure that occur acutely in these patients are primarily the result of right-sided heart failure, with pulmonary edema being less prominent than that occurring in patients with acute mitral regurgitation due to ruptured papillary muscle.[51]

The electrocardiographic (ECG) findings in patients with acute septal rupture relate to the changes associated with antecedent anterior, inferior, posterior, or septal infarction. The localization of infarction by ECG correlates highly with the location of the associated septal perforation. In our review[32] of 55 patients with postinfarction septal rupture, the location of the defect corresponded to the territory of transmural infarction as determined by ECG in all but three patients. Up to one-third of patients develop some degree of atrioventricular conduction block (usually transient) that may precede rupture,[52] but there is no pathognomonic prognostic indicator of impending perforation. The chest radiograph usually shows increased pulmonary vascularity consistent with pulmonary venous hypertension.

It is important to realize that the sudden appearance of a systolic murmur and hemodynamic deterioration following infarction may also result from acute mitral regurgitation due to ruptured papillary muscle. Distinguishing these two lesions clinically is difficult, but a number of points may help. First, the systolic murmur associated with a septal rupture is more prominent at the left sternal border, whereas the murmur resulting from a ruptured papillary muscle is best heard at the apex. Second, the murmur associated with septal perforation is loud and associated with a thrill (in over 50% of patients), whereas the murmur of acute mitral regurgitation is softer and has no associated thrill.[8] Third, septal rupture is often associated with anterior infarctions and conduction abnormalities, whereas papillary muscle rupture is commonly associated with an inferior infarction and no conduction defects.[53] Finally, it should be noted that septal rupture and papillary muscle rupture may coexist following infarction.[20,54,55]

Until recently, the mainstay of differentiating septal rupture from mitral valve dysfunction has been right heart catheterization using the Swan-Ganz catheter.[56] With septal rupture, there is an oxygen saturation step-up between the right atrium and pulmonary artery. Step-up in oxygen saturation greater than 9% between the right atrium and pulmonary artery confirms the presence of a shunt.[57] The pulmonary-to-systemic flow ratios (Qp:Qs) obtained from oxygen saturation samples range from 1.4:1 to greater than 8:1 and roughly correlate with the size of the defect.[58] In contrast, with acute mitral regurgitation secondary to papillary muscle rupture,

there are classic giant V waves in the pulmonary artery wedge pressure trace. It should be noted, however, that up to one-third of patients with septal rupture also have mild mitral regurgitation secondary to LV dysfunction.[59]

Advances in transthoracic and transesophageal echocardiography, especially color flow Doppler mapping, have revolutionized the diagnosis of both the presence and site of septal rupture.[59–62] Echocardiography can detect the defect, localize its site and size, determine right and left ventricular function, assess pulmonary artery and right ventricular pressures, and exclude coexisting mitral regurgitation or free wall rupture. Smyllie and associates[61] reported a 100% specificity and 100% sensitivity when color flow Doppler mapping was used to differentiate ventricular septal rupture from acute severe mitral regurgitation following AMI. It also correctly demonstrated the site of septal rupture in 41 of 42 patients. Widespread use of this technology has, for the most part, replaced thermodilution catheter insertion, which in outlying hospitals, where patients are often seen first, may be time consuming and difficult to accomplish. Indeed, the trend toward early surgical referral and prompt operative repair is at least partially explained by the more widespread use of color Doppler echocardiography for diagnosis in peripheral centers.[23]

The necessity of preoperative left heart catheterization with coronary angiography has been a matter of debate. On one hand, left heart catheterization provides important information concerning associated CAD, left ventricular wall motion, and specifics of valvular dysfunction, which are all important in planning operative correction of postinfarction septal rupture. In most series[63] over 60% of patients with septal rupture have significant involvement of at least one vessel other than the one supplying the infarcted area. Bypassing associated CAD may increase long-term survival when compared with patients with unbypassed CAD.[63] However, left heart catheterization has disadvantages—it is time consuming and can contribute to both the mortality and morbidity of these already compromised patients.[23] Thus, some centers do not carry out preoperative left heart catheterization.[64,65] Others use it selectively, avoiding invasive studies in patients with septal rupture caused by anterior wall infarction, which is associated with a much lower incidence of multiple-vessel disease than septal defects resulting from posterior infarctions.[23] The issue of concomitant coronary bypassing is discussed in greater detail below.

Natural History

Reviews by Oyamada and Queen,[66] Sanders and colleagues,[8] and Kirklin and coworkers[67] reveal that nearly 25% of patients with postinfarction septal rupture and no surgical intervention died within the first 24 hours, 50% died within 1 week, 65% within 2 weeks, and 80% within 4 weeks; only 7% lived longer than 1 year. Lemery and associates[68] reported that of 25 patients with postinfarction VSDs treated medically, 19 died within 1 month. Thus, the risk of death following postinfarction VSD is highest immediately after infarction and septal rupture, and then gradually declines. Interestingly, there are reports of spontaneous closure of small defects, though this is so rare that it would be unreasonable to manage a patient with the expectation of closure.

Despite the many advances in the nonoperative treatment of CHF and cardiogenic shock, including the intra-aortic balloon pump and a multitude of new inotropic agents and vasodilators, these do not supplant the need for operative intervention in these critically ill patients.

Management

It has become clear that the early practice of waiting for several weeks after ventricular septal rupture before proceeding with surgery only selects out the small minority of patients in whom the hemodynamic insult is less severe and is better tolerated.[19,36,69] Likewise, it has also become clear that to manage most patients supportively, in hopes of deferring operation, is to deprive the great majority of those with postinfarction ventricular septal rupture of the benefits of definitive surgery before irreversible damage due to peripheral organ ischemia has occurred.[63,70]

While we[22] as well as others[69] have advocated early surgery since the middle of the 1970s, some continue to prefer to defer operation in patients who are easily supported and exhibit no further hemodynamic deterioration.[71,72] Persistence of CHF or marginal stabilization with rising blood urea nitrogen and borderline urine output necessitate aggressive therapy and prompt operation. The routine use of the intra-aortic balloon pump (IABP), whenever technically feasible, frequently results in *transient* reversal of the hemodynamic deterioration. This period of stability often makes it possible to complete left heart catheterization before proceeding to operation but should not significantly delay definitive surgical treatment. Patients with septal rupture rarely die of cardiac failure per se, but rather of end-organ failure as a consequence of shock. Shortening the duration of shock by operating early is the only therapeutic solution for this group of patients and can yield dramatic results.[32,73]

Our experience and the experience of others suggest that patients in cardiogenic shock represent a true surgical emergency requiring immediate operative repair. Because deaths in these patients result from multisystem failure secondary to organ hypoperfusion, delay in operative repair for patients in cardiogenic shock represents a failed therapeutic strategy. Those few patients who are completely stable, with no clinical deterioration, and who require no hemodynamic support, can undergo operative repair when convenient during that hospitalization. The large group of patients who are in an intermediate position between those with shock and those in stable condition should be operated on early (usually within 12 to 24 hours) after appropriate preoperative evaluation. Since the group of patients in stable condition constitutes 5% or less of the total population of patients with postinfarction ventricular septal rupture, the overwhelming majority of patients require prompt surgical treatment.

Rarely, because of a delayed referral, a patient will be seen for surgical therapy who is already in a state of multisystem failure or has developed septic complications. Such a patient is unlikely to survive an emergency operation and thus may benefit from prolonged support with an IABP before an attempted operative repair. We have found it necessary to treat a small number of patients (3 of 92) in this fashion. Baillot and colleagues[72] have reported individual successes with such an approach, which we consider the exception rather than the rule.

Preoperative Management

Because the natural course of the disease in unoperated patients is so dismal, the diagnosis of postinfarction ventricular septal rupture can be regarded as its own indication for operation.[70] Preoperative management is directed toward stabilization of the hemodynamic condition so that peripheral organ perfusion can be best maintained while any further diagnostic studies are obtained and while deciding on the optimal time for surgical intervention. Although the early clinical course of patients with postinfarction ventricular septal rupture can be quite variable, 50 to 60% present with severe CHF and a low cardiac output state requiring intensive therapy.[74]

The goals of preoperative management are to: (1) reduce the systemic vascular resistance, and thus the left-to-right shunt; (2) maintain cardiac output and arterial pressure to ensure peripheral organ perfusion; and (3) maintain or improve coronary artery blood flow. This is best accomplished by the IABP. Counterpulsation reduces left ventricular afterload, thereby increasing cardiac output and decreasing the left-to-right shunt, as reported by Gold and associates in 1973.[75] In addition, IABP support is associated with decreased myocardial oxygen consumption, as well as improved myocardial and peripheral organ perfusion. Although counterpulsation produces an overall improvement in the patient's condition, a complete correction of the hemodynamic picture cannot be obtained.[76] Peak improvement occurs within 24 hours and no further benefit has been observed with prolonged balloon pumping.[77] Pharmacologic therapy with inotropic agents and diuretics should be instituted promptly. The addition of vasodilators (i.e., sodium nitroprusside or intravenous nitroglycerine) makes good theoretical sense, because it can decrease the left-to-right shunting associated with the mechanical defect, and thus increase cardiac output. However, these effects are often associated with a marked fall in mean arterial blood pressure and reduced coronary perfusion, both poorly tolerated in these critically ill patients. It must be stressed that pharmacologic therapy is intended primarily to support the patient in preparation for operation and should not in any way delay urgent operation in the critically ill patient. We now admit patients with postinfarction septal rupture directly to the surgical intensive care unit rather than to the coronary care or medical intensive care unit.

Other techniques that have been tried in an effort to improve the hemodynamics of patients with interventricular septal rupture include venoarterial extracorporeal membrane oxygenation,[78] and inflation of a balloon in the right ventricular outflow tract to decrease the left-to-right shunt.[79] Neither has been proven reliable in clinical application. There are anecdotal reports of successful use of a left ventricular support device to reverse multiorgan failure prior to operation.[80] To avoid shunting across the lesion (right to left at the ventricular level), atrial cannulation is necessary. Use of a catheter-mounted axial flow pump (Hemopump) in stabilizing these patients is controversial because of the risk of acute pump failure due to catheter blockage from pieces of necrotic tissue.[81]

Operative Techniques

The first repair by Cooley and colleagues[5] of an acquired VSD was accomplished using an approach through the right ventricle with incision of the right ventricular outflow tract. This approach, which was adapted from surgical techniques for closure of congenital VSDs, proved to be disadvantageous for many reasons. Exposure of the defect was frequently less than optimal, particularly for defects located in the apical septum. It involved unnecessary injury to normal right ventricular muscle and interruption of collaterals from the right coronary artery. Finally, it failed to eliminate the paradoxical bulging segment of infarcted left ventricular wall. Subsequently, Heimbecker and associates[13] introduced, and others adopted,[16,26,82] a left-sided approach (left ventriculotomy) with incision through the area of infarction. Such an approach frequently incorporates infarctectomy and aneurysmectomy, together with repair of septal rupture.

Experience with a variety of techniques for closure of postinfarction ventricular septal rupture has led us to the evolution of eight basic principles (Table 29-1). Adherence to these principles in the closure of septal defects in different locations has led to the evolution of individualized approaches to apical, anterior, and inferoposterior septal defects.

General techniques

Patients are anesthetized using a fentanyl-based regimen. Pancuronium is selected as the muscle relaxant so as to prevent bradycardia. Pulmonary bed vasodilators such as dobutamine are avoided to minimize the left-to-right shunt fraction. Preoperative antibiotics include both cefazolin and vancomycin, given the fact that prosthetic material may be left in the patient.

Cardiopulmonary bypass is accomplished with bicaval venous drainage. Systemic cooling to 25°C is employed. Cardiac standstill is achieved with cold, oxygenated, dilute blood cardioplegia[83,84] using antegrade induction followed by retrograde perfusion via the coronary sinus. Although a number of myocardial protection strategies are currently available, we[83] and others[46,85,86] continue to use cold oxygenated, dilute blood cardioplegia to protect the heart during surgical correction of a VSD. A total of 1200 to 2000 mL of cardioplegia solution is delivered, depending on the size of the heart and

Table 29–1.

Principles of Repair of Postinfarction Ventricular Septal Defects

1. Expeditious establishment of total cardiopulmonary bypass with moderate hypothermia and meticulous attention to myocardial protection
2. Transinfarct approach to ventricular septal defect with the site of ventriculotomy determined by the location of the transmural infarction
3. Thorough trimming of the left ventricular margins of the infarct back to viable muscle to prevent delayed rupture of the closure
4. Conservative trimming of the right ventricular muscle as required for complete visualization of the margins of the defect
5. Inspection of the left ventricular papillary muscles and concomitant replacement of the mitral valve only if there is frank papillary muscular rupture
6. Closure of the septal defect without tension, which in most instances will require the use of prosthetic material
7. Closure of the infarctectomy without tension with generous use of prosthetic material as indicated, and epicardial placement of the patch to the free wall to avoid strain on the friable endocardial tissue
8. Buttressing of the suture lines with pledgets or strips of Teflon felt or similar material to prevent sutures from cutting through friable muscle

Source: Reproduced with permission from Heitmiller et al.[70]

the degree of hypertrophy.[87] Although we have not employed warm cardioplegic induction,[88] we do administer warm reperfusion cardioplegia just before removing the aortic cross-clamp.[89] Patients with multivessel coronary disease and critical coronary stenoses are revascularized before opening the heart in order to optimize myocardial protection. In most of these patients, the saphenous vein rather than the left internal mammary artery is utilized.

Apical septal rupture

The technique of apical amputation was described by Daggett and colleagues in 1970.[16] An incision is made through the infarcted apex of the left ventricle. Excision of the necrotic myocardium back to healthy muscle results in amputation of the apical portion of the left ventricle, right ventricle, and septum (Fig. 29-1A and B). The remaining apical portions of the left and right ventricle free walls are then approximated to the apical septum. This is accomplished by means of a row of interrupted mattress sutures of 1-0 Tevdek that are passed sequentially through a buttressing strip of Teflon felt, the left ventricular wall, a second strip of felt, the interventricular septum, a third strip of felt, the right ventricular wall, and a fourth strip of felt (Fig. 29-2A and B). After all sutures have been tied, the closure is reinforced with an additional over-and-over suture, as in ventricular aneurysm repair, to ensure hemostasis of the ventriculotomy closure.

Anterior septal rupture

The approach to these defects is by a left ventricular transinfarct incision with infarctectomy (Fig. 29-3). Small defects

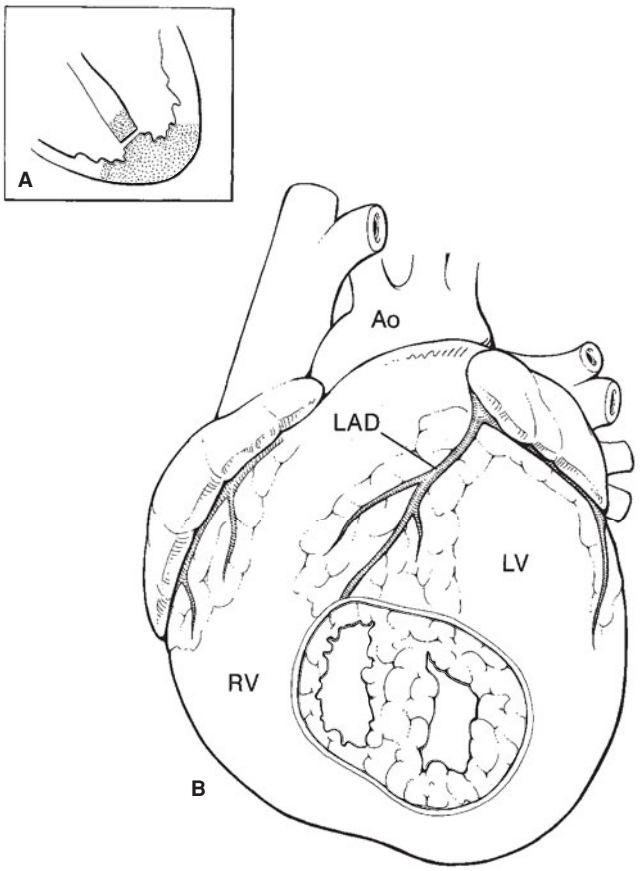

Figure 29-1. (A) Apical postinfarction ventricular septal defect. (B) View of the apical septal rupture, which is exposed by amputating the apex of the left and right ventricles. Ao = aorta; LAD = left anterior descending coronary artery; LV = left ventricle; RV = right ventricle; stippled region = infarcted myocardium.

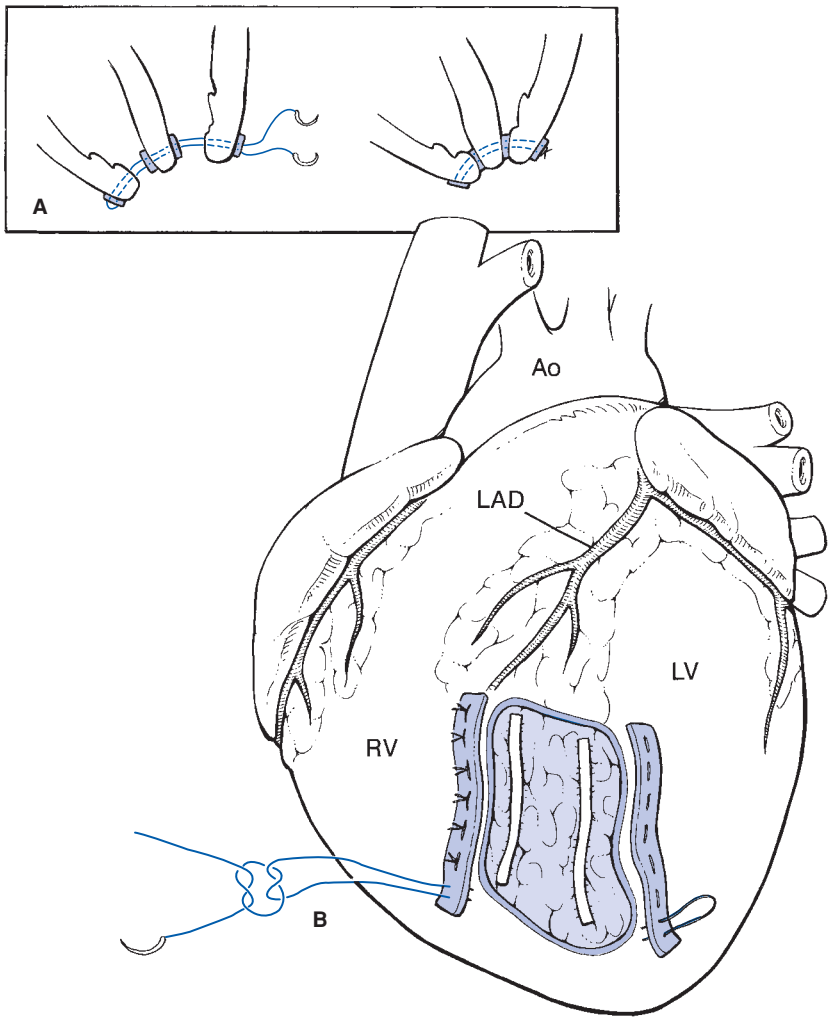

Figure 29-2. (A) The necrotic infarct and the apical septum have been débrided back to healthy muscle. Repair is made by approximating the left ventricle, apical septum, and right ventricle using interrupted mattress sutures of 1-0 Tevdek with buttressing strips of Teflon felt. Felt strips are used within the interior of the left and right ventricles as well as on the epicardial surface of each ventricle. (B) All sutures are placed before any are tied. A second running over-and-over suture (not shown) is used, as in left ventricular aneurysm repair, to ensure a secure hemostatic ventriculotomy closure. Ao = aorta; LAD = left anterior descending coronary artery; LV = left ventricle; RV = right ventricle. (*Adapted with permission from Daggett et al.*[16])

beneath anterior infarcts can be closed by the technique of plication as suggested by Shumacker.[90] This involves approximation of the free anterior edge of the septum to the right ventricular free wall using mattress sutures of 1-0 Tevdek over strips of felt (Fig. 29-4A). The transinfarct incision is then closed with a second row of mattress sutures buttressed with strips of Teflon felt (Fig. 29-4B, C, and D). An over-and-over running suture completes the ventriculotomy closure.

Most anterior defects require closure with a prosthetic patch (DeBakey Elastic Dacron fabric, USCI Division of C.R. Bard, Inc., Billerica, Mass) in order to avoid tension that could lead to disruption of the repair (Fig. 29-5). After débridement of necrotic septum and left ventricular muscle, a series of pledgeted interrupted mattress sutures are placed around the perimeter of the defect (Fig. 29-5A). Along the posterior aspect of the defect, sutures are passed through the septum from right to left. Along the anterior edge of the defect, sutures are passed from the epicardial surface of the right ventricle to the endocardial surface. All sutures are placed before the patch is inserted, and then passed through the edge of a synthetic patch, which is seated on the left side of the septum (Fig. 29-5B). Each suture is then passed through an additional pledget and all are tied. We use additional pledgets on the left ventricular side overlying the patch (Fig. 29-5C) to cushion each suture as it is tied down to prevent cutting through the friable muscle. The edges of the ventriculotomy are then approximated by a two-layer closure consisting of interrupted mattress sutures passed through buttressing strips of Teflon felt (or glutaraldehyde-preserved bovine pericardium) and a final over-and-over running suture.

Posterior/inferior septal rupture

Closure of inferoposterior septal defects, which result from transmural infarction in the distribution of the posterior descending artery, has posed the greatest technical challenge.[20,21] Early attempts at primary closure of these defects by simple plication techniques similar to those used in the repair of anterior defects were frequently unsuccessful because of the sutures tearing out of soft, friable myocardium that had been closed under tension. This resulted in either reopening of the defect or catastrophic disruption of the infarctectomy closure. It was, in large part, the analysis of such early results that led to the evolution of the operative principles enumerated in Table 29-1.

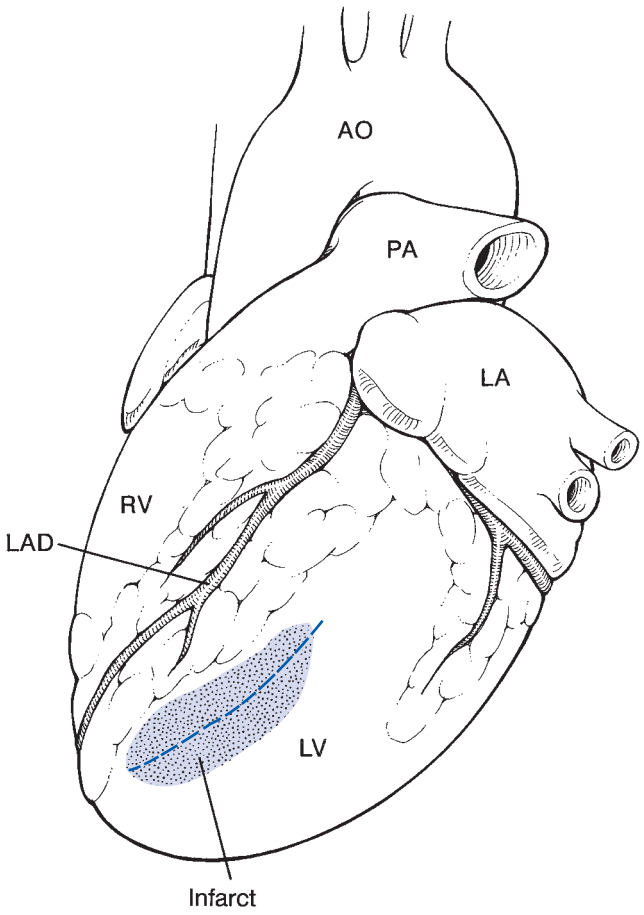

Figure 29-3. Transinfarct left ventricular incision to expose an anterior septal rupture. An incision (dashed line) is made parallel to the anterior descending branch of the left coronary artery (LAD) through the center of the infarct (stippled area) in the anterior left ventricle (LV). Ao = aorta; LA = left atrium; PA = pulmonary artery; RV = right ventricle.

Use of the following techniques has been associated with an improved operative survival. After the establishment of bypass with bicaval cannulation, the left side of the heart is vented via the right superior pulmonary vein. The heart is retracted out of the pericardial well as for bypass to the posterior descending coronary artery. The margins of the defect may involve the inferior aspects of both ventricles, or of the left ventricle only (Fig. 29-6A). A transinfarct incision is made in the left ventricle, and the left ventricular portion of the infarct is excised (Fig. 29-6B), exposing the septal defect. The left ventricular papillary muscles are inspected. Only if there is frank papillary muscle rupture is mitral valve replacement performed. When it is indicated, we prefer to perform mitral valve replacement through a separate conventional left atrial incision, to avoid trauma to the friable ventricular muscle. After all infarcted left ventricular muscle has been excised, a less aggressive débridement of the right ventricle is accomplished, with the goal of resecting only as much muscle as is necessary to afford complete visualization of the defect(s). Using this technique, delayed rupture of the right ventricle has not been a problem. If the posterior septum has cracked or split from the adjacent ventricular free wall without loss of a great deal of septal tissue, then the septal rim of the posterior defect may be approximated to the edge of the diaphragmatic right ventricular free wall using mattress sutures buttressed with strips of Teflon felt or bovine pericardium (Fig. 29-6C and D).

Larger posterior defects require patch closure (Fig. 29-7). Pledgeted mattress sutures are placed from the right side of the septum and from the epicardial side of the right ventricular free wall (Fig. 29-7B). All sutures are passed through the perimeter of the patch and then through additional pledgets, and are then tied (Fig. 29-7C). Thus, as in closure of large anterior defects, the patch is secured on the left ventricular side of the septum. Direct closure of the remaining infarctectomy is rarely possible because of tension required to pull together the edges of the gaping defect. A prosthetic patch is generally required. Originally, we cut an oval patch from a Cooley low-porosity woven Dacron tube graft (Meadox Medicals, Inc., Oakland, NJ). Currently, we cut this patch from a Hemashield woven double velour Dacron collagen-impregnated graft (Meadox Medicals, Inc., Oakland, NJ). Pledgeted mattress sutures are passed out through the margin of the infarctectomy (endocardium to epicardium) and then through the patch (Fig. 29-7D), which is seated on the epicardial surface of the heart. After each suture is passed through an additional pledget, all sutures are tied (Fig. 29-7E). The cross-sectional view of the completed repair (Fig. 29-8) illustrates the restoration of relatively normal ventricular geometry, which is accomplished by the use of appropriately sized prosthetic patches.

Endocardial patch repair with infarct exclusion

The concept that the preservation of left ventricular geometry plays a crucial role in the preservation of left ventricular function[19,91] has laid the groundwork for evolution in the surgical approach to postinfarction VSDs—the technique of endocardial patch repair of postinfarction VSDs described by David,[82,85] Cooley,[92,93] and then by Ross[94] in the early 1990s. This operative technique, which is an application to ventricular septal rupture repair of Dor's technique of ventricular endoaneurysmorrhaphy,[91] involves intracavitary placement of an endocardial patch to exclude infarcted myocardium while maintaining ventricular geometry. Thus, instead of closing the septal defect, it is simply *excluded* from the high-pressure zone of the left ventricle. Institutions have reported impressive results using infarct exclusion,[46] but results in other hands have been mixed. A detailed description of the technique is provided here. The following descriptions are taken from the work of David and associates (with permission).[40,46,85]

In patients with anterior septal rupture, the interventricular septum is exposed via a left ventriculotomy, which is made through the infarcted anterolateral wall starting at the apex and extending proximally parallel to, but 1 to 2 cm away from, the anterior descending artery (Fig. 29-9A). Stay sutures are passed through the margins of the ventriculotomy to aid in the exposure of the infarcted septum.

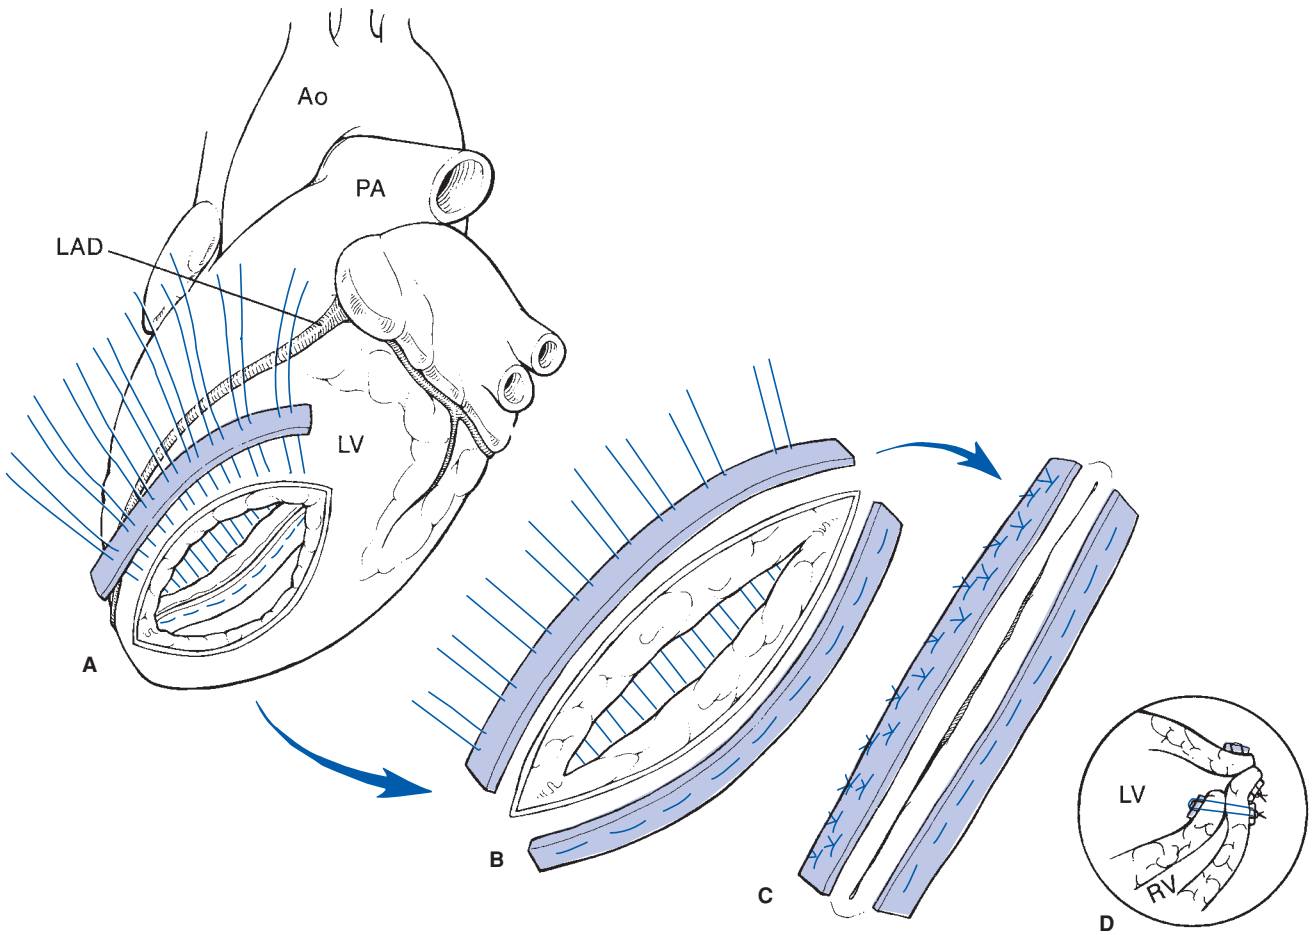

Figure 29-4. (A) Repair of an anterior septal rupture by plicating the free anterior edge of the septum to the right ventricular free wall with interrupted 1-0 Tevdek mattress sutures buttressed with strips of Teflon felt. (B, C, and D) The left ventriculotomy is then closed as a separate suture line, again with interrupted mattress sutures of 1-0 Tevdek buttressed with felt strips. A second running suture (not shown) is used to ensure a secure left ventriculotomy closure. Ao = aorta; LAD = left anterior descending coronary artery; LV = left ventricle; PA = pulmonary artery; RV = right ventricle. (*Adapted with permission from Guyton SW, Daggett WM: Surgical repair of post-infarction ventricular septal rupture, in Cohn LH (ed): Modern Techniques in Surgery: Cardiac/Thoracic Surgery. Mt. Kisco, NY, Futura, 1983; installment 9, p 61-1.*)

The septal defect is located and the margins of the infarcted muscle identified. A glutaraldehyde-fixed bovine pericardial patch is tailored to the shape of the left ventricular infarction as seen from the endocardium but 1 to 2 cm larger. The patch is usually oval and measures approximately 4 × 6 cm in most patients. The pericardial patch is then sutured to healthy endocardium all around the infarct (Fig. 29-9B). Suturing begins in the lowest and most proximal part of the noninfarcted endocardium of the septum with a continuous 3-0 polypropylene suture. Interrupted mattress sutures with felt pledgets may be used to reinforce the repair.[93] The patch is also sutured to the noninfarcted endocardium of the anterolateral ventricular wall. The stitches should be inserted 5 to 7 mm deep in the muscle and 4 to 5 mm apart. The stitches in the patch should be at least 5 to 7 mm from its free margin so as to allow the patch to cover the area between the entrance and exit of the suture in the myocardium.[40] This technique minimizes the risk of tearing muscle as the suture is pulled taut. If the infarct involves the base of the anterior papillary muscle, the suture is brought outside of the heart and buttressed on a strip of bovine pericardium or Teflon felt applied to the epicardial surface of the left ventricle. Once the patch is completely secured to the endocardium of the left ventricle, the left ventricular cavity becomes largely excluded from the infarcted myocardium. The ventriculotomy is closed in two layers over two strips of bovine pericardium or Teflon felt using 2-0 or 3-0 polypropylene sutures as illustrated in Fig. 29-9C. No infarctectomy is performed unless the necrotic muscle along the ventriculotomy is sloughing at the time of its closure, and even then it is minimized, since infarcted muscle will not be exposed to left ventricular pressures when the heart begins to work (Fig. 29-9D). Alternatively, sutures can be passed through the ventricular

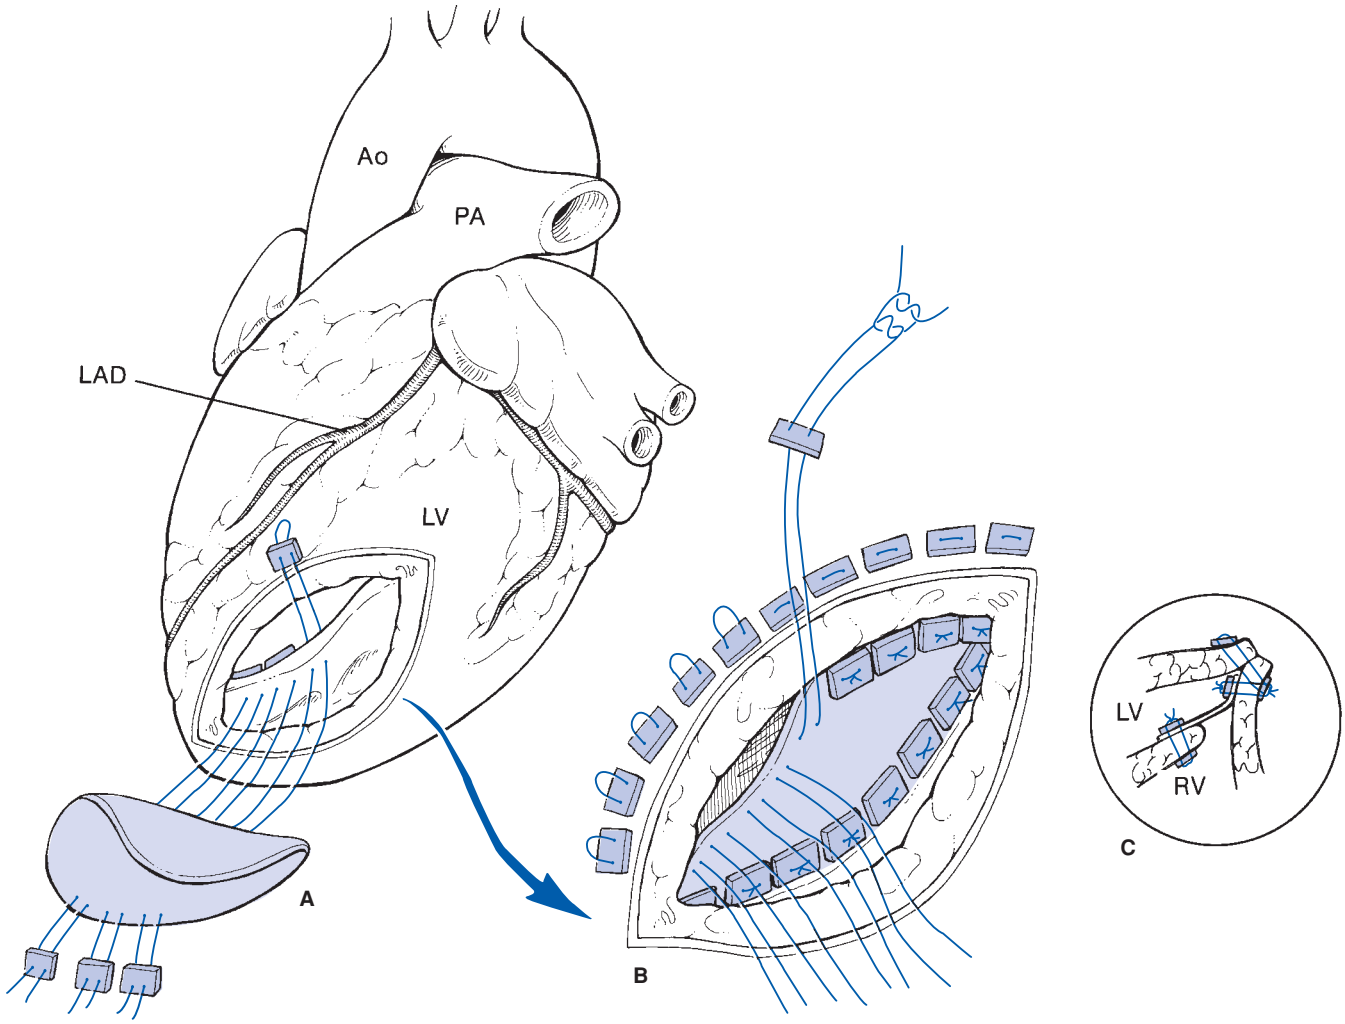

Figure 29-5. (A) Larger anterior septal defects require a patch (DeBakey Dacron fabric, USCI Division of C.R. Bard, Inc., Billerica, Mass), which is sewn to the left side of the ventricular septum with interrupted mattress sutures, each of which is buttressed with a pledget of Teflon felt on the right ventricular side of the septum and anteriorly on the epicardial surface of the right ventricular free wall. All sutures are placed before the patch is inserted. (B and C) We use additional pledgets on the left ventricular side overlying the patch to cushion each suture as it is tied down to prevent cutting through the friable muscle. Ao = aorta; LAD = left anterior descending coronary artery; LV = left ventricle; PA = pulmonary artery; RV = right ventricle. (*Adapted with permission from Guyton SW, Daggett WM: Surgical repair of post-infarction ventricular septal rupture, in Cohn LH (ed): Modern Techniques in Surgery: Cardiac/Thoracic Surgery. Mt. Kisco, NY, Futura, 1983; installment 9, p 61-1.*)

free wall and through a tailored external patch of Teflon or pericardium (Fig. 29-10).[71,89]

In patients with posterior septal defects, an incision is made in the inferior wall of the left ventricle 1 or 2 mm from the posterior descending artery (Fig. 29-11A). This incision is started at the midportion of the inferior wall and extended proximally toward the mitral annulus and distally toward the apex of the ventricle. Care is taken to avoid damage to the posterolateral papillary muscle. Stay sutures are passed through the fat pad of the apex of the ventricle and margins of the ventriculotomy to facilitate exposure of the ventricular cavity. In most cases, the rupture is found in the proximal half of the posterior septum and the posteromedial papillary muscle is involved by the infarction.[46] A bovine pericardial patch is tailored in a triangular shape of approximately 4 × 7 cm in most patients. The base of the triangular-shaped patch is sutured to the fibrous annulus of the mitral valve with a continuous 3-0 polypropylene suture starting at a point corresponding to the level of the posteromedial papillary muscle and moving medially toward the septum until the noninfarcted endocardium is reached (Fig. 29-11B). At that level, the suture is interrupted and any excess patch material trimmed. The medial margin of the triangular-shaped patch is sewn to healthy septal endocardium with a continuous 3-0 or 4-0 polypropylene suture taking bites the same size as those described for anterior defects. In this area of the septum, reinforcing pledgeted sutures may be required.[93] The lateral side of the patch is sutured to the posterior wall of the

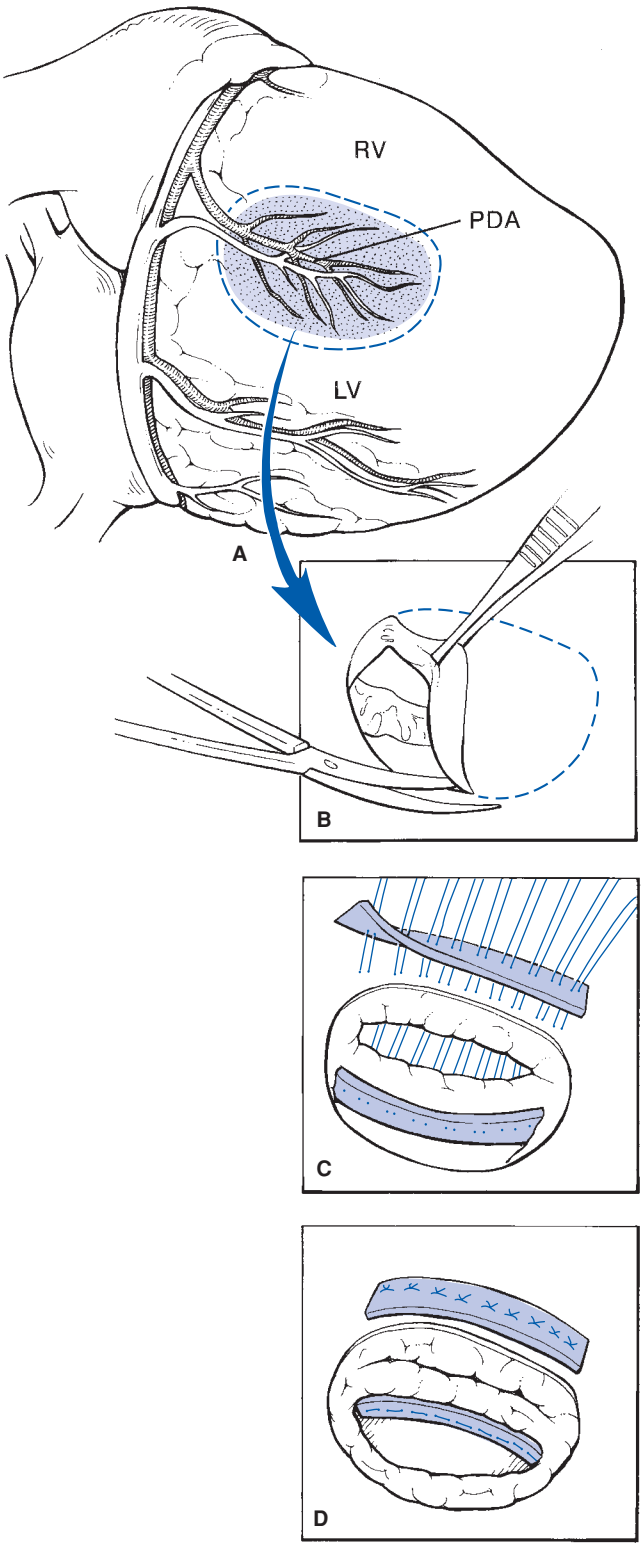

Figure 29-6. (A) View of an inferior infarct (stippled area) associated with posterior septal rupture. The apex of the heart is to the right. Exposure at operation is achieved by dislocating the heart up and out of the pericardial sac, and then retracting it cephalad, as in the performance of distal vein bypass and anastomosis to the posterior descending artery. (B) The inferoposterior infarct is excised to expose the posterior septal defect. Complete excision of the left ventricular portion of the infarct is important to prevent delayed rupture of the ventriculotomy repair. The free edge of the right ventricle is progressively shaved back to expose the margins of the defect clearly. (C and D) Repair of the posterior septal rupture is accomplished by approximating the edge of the posterior septum to the free wall of the diaphragmatic right ventricle with felt-buttressed mattress sutures. The repair is possible when the septum has cracked or split off from the posterior ventricular wall without necrosis of a great deal of septal muscle. The surgeon can perform repair of posterior septal rupture to best advantage by standing at the left side of the supine patient. The left ventriculotomy is then closed as a separate suture line, again with interrupted mattress sutures of 1-0 Tevdek buttressed with felt strips. A second running suture is used to ensure a secure left ventriculotomy closure (not shown). LV, posterior left ventricle; PDA, posterior descending artery; RV, diaphragmatic surface of the right ventricle. (*Adapted with permission from Daggett.*[21])

left ventricle along a line corresponding to the medial margin of the base of the posteromedial papillary muscle. Because the posterior wall of the left ventricle is infarcted, it is usually necessary to use full-thickness bites and anchor the sutures on a strip of pericardium or Teflon felt applied on the epicardial surface of the posterior wall of the left ventricle right at the level of the posteromedial papillary muscle insertion, as shown in Fig. 29-11B. Once the patch is completely sutured to the mitral valve annulus, the endocardium of the interventricular septum, and the full thickness of the posterior wall

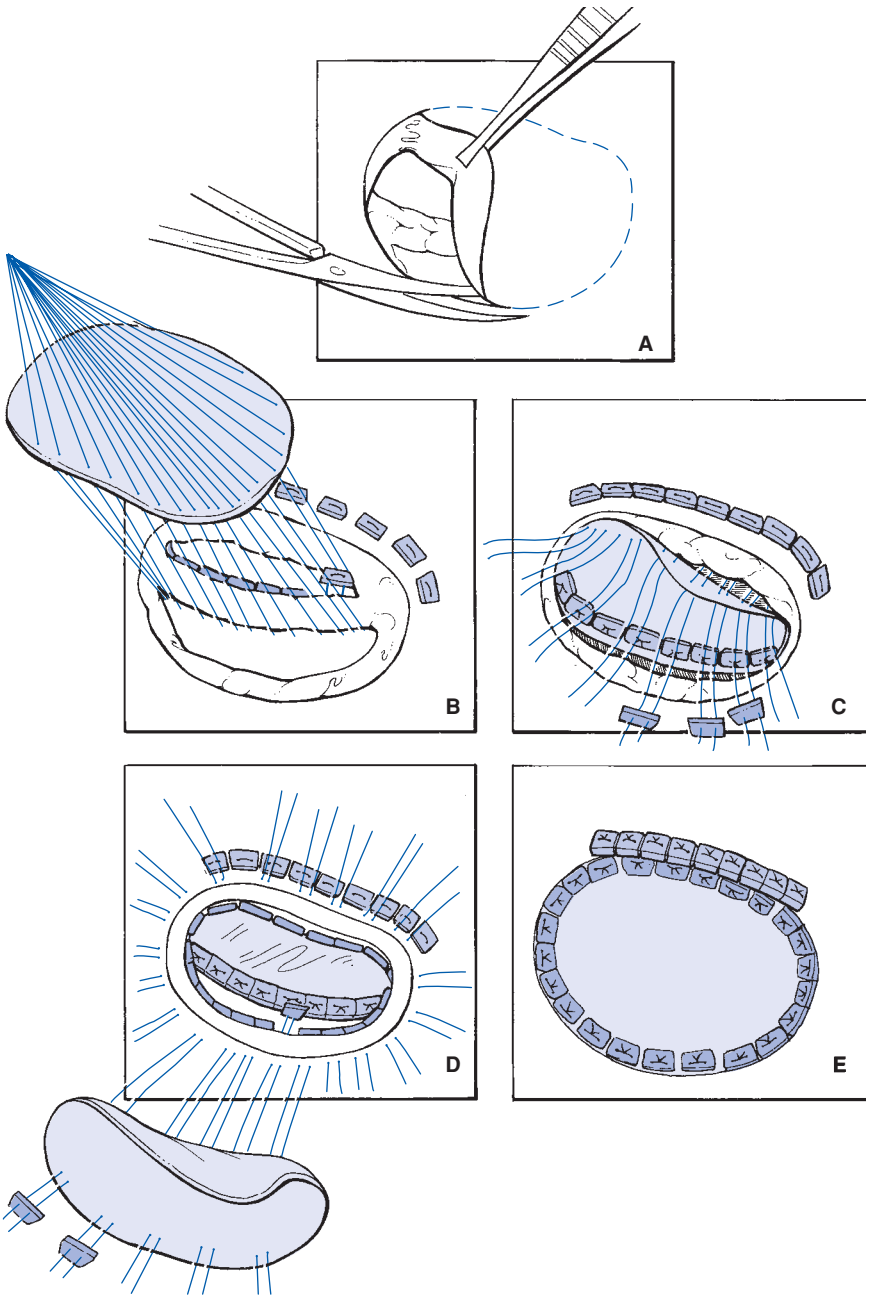

Figure 29-7. (A) Repair of posterior septal rupture when necrosis of a substantial portion of the posterior septum requires the use of patches. (B) Interrupted mattress sutures of 2-0 Tevdek are placed circumferentially around the defect. These sutures are buttressed with felt pledgets on the right ventricular side of the septum and on the epicardial surface of the diaphragmatic right ventricle. (C) All sutures are placed and then the patch (DeBakey elastic Dacron fabric) is slid into place on the left ventricular side of the septum. The patch sutures are tied down with an additional felt pledget placed on top of the patch (left ventricular side) as each suture is tied, to cushion the tie and prevent cutting through the friable muscle. These maneuvers are viewed by the authors as essential to the success of early repair of the posterior septal rupture. (D) Remaining to be repaired is the posterior left ventricular free wall defect created by infarctectomy. Mattress sutures of 2-0 Tevdek are placed circumferentially around the margins of the posterior left ventricular free wall defect. Each suture is buttressed with a Teflon felt pledget on the endocardial side of the left ventricle. With all sutures in place, a circular patch, fashioned from a Hemashield woven double velour Dacron collagen-impregnated graft (Meadox Medicals Inc., Oakland, NJ), is slid down onto the epicardial surface of the left ventricle. An additional pledget of Teflon felt is placed under each suture (on top of the patch) as it is tied to cushion the tie and prevent cutting through the friable underlying muscle. This onlay technique of patch placement prevents the cracking of friable left ventricular muscle that occurred with the eversion technique of patch insertion. (E) Completed repair. (*Adapted with permission from Daggett.*[21])

(Fig. 29-11C), the ventriculotomy is closed in two layers of full-thickness sutures buttressed on strips of pericardium or Teflon felt (Fig. 29-11D). The infarcted right ventricular wall is left undisturbed. If the posteromedial papillary muscle is ruptured, mitral valve replacement is necessary.[85]

There are several theoretical advantages in the technique of infarct exclusion: (1) It does not require resection of myocardium; excessive resection results in depression of ventricular function and insufficient resection predisposes to recurrence of septal rupture; (2) it maintains ventricular geometry, which enhances ventricular function;[43] and (3) it avoids tension on friable muscle, which may diminish postoperative bleeding.[46]

Other techniques

Most other operative techniques that have resulted in successful management of postinfarction of ventricular septal rupture have adhered to the same general principles described above. For example, daSilva and associates[95] report a technique whereby a nontransfixing running suture has been used to secure a large prosthetic patch to the left side of the ventricular septum, with little or no resection of septum muscle. Tashiro and colleagues[96] described an extended endocardial repair in which a *saccular* patch of glutaraldehyde-fixed equine pericardium was used to exclude an anterior septal rupture. Usui and coworkers[97] reported the successful repair of a posterior septal rupture using two sheets of equine pericardium to sand-

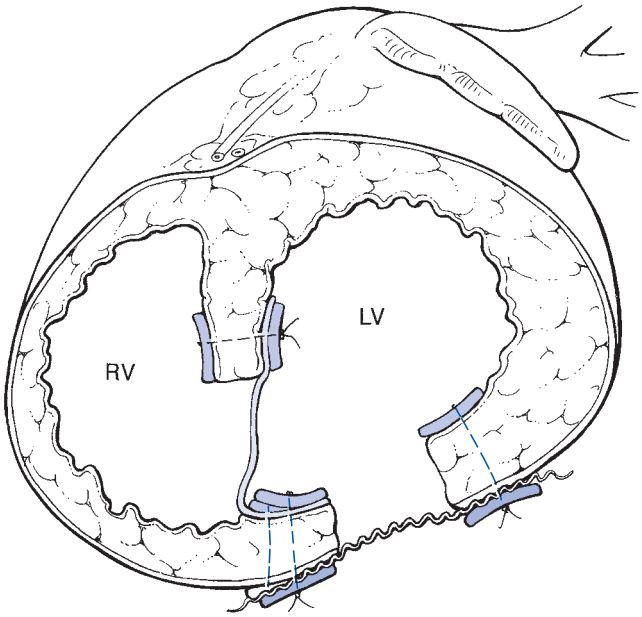

Figure 29-8. Cross-sectional view of the completed repair of posterior septal rupture with prosthetic patch placement of the posterior left ventricular free wall defect created by infarctectomy. LV, left ventricular cavity; RV, right ventricular cavity. (*Adapted with permission from Daggett.*[21])

wich the infarcted myocardium, including the septal defect and ventriculotomy. Others have modified the exclusion technique by use of tissue sealants to aid in the septal closure.[98]

Percutaneous closure

Successful transcatheter closure of postinfarction ventricular septal rupture has been reported using several types of catheter-deployed devices. Early experience was with the CardioSEAL device, a nitinol double-umbrella prosthesis.[99] The device consists of two attached and opposing umbrellas formed by hinged steel arms covered in a Dacron meshwork that theoretically promotes endothelialization. The arms are manually everted to allow the device to be passed through a narrow percutaneous deployment system. When extruded from the guiding catheter, the arms spring backward, resembling a clamshell. The device approaches the septum via the systemic veins and through the atrial septum (or alternatively via the arterial system through the aortic valve). As reported by Landzberg and Lock,[99] the experience at Boston Children's Hospital and Brigham and Women's Hospital indicates that while the device can be routinely deployed in the setting of an acute infarction, the continued necrosis of septal tissue led to decompensation and death in four of seven patients. In contrast, they reported success in six of six patients treated for residual or recurrent septal defects discovered after primary operative repair.

Other catheter devices have also been attempted, including the Amplatzer septal occluder and the Rashkind double umbrella.[100]

The recently developed Amplatzer VSD device allows closure of muscular and membranous VSDs, and it can be used for larger postinfarction defects, with the septal Amplatzer device favored for smaller lesions.[101] In a series of seven patients treated with the Amplatzer, the size of the device ranged from 12 to 24 mm with only one death.[102]

The best use of such devices in an overall treatment strategy is unclear. As a primary treatment, data suggest that the devices have a high early failure rate, but their potential role in improving the risk of an unstable surgical patient is not yet well characterized. Currently, catheter approaches appear to be most effective in treatment of recurrent or residual defects, and we preferentially employ them for these conditions.[103] Device development is an ongoing process, and the future undoubtedly will see use of new devices, especially in the high-risk patient with multisystem failure.

Of interest, two centers have reported using a standard Swan-Ganz balloon catheter from the groin to abolish the shunt in unstable patients with postinfarction septal rupture.[104,105] Hemodynamic improvement was immediate in both patients, who underwent subsequent surgical repair of the defect.

Role of Ventricular Assist Devices

In patients who present for operation with evidence of potentially reversible multiorgan dysfunction, or in patients who have intractable failure following repair, there may be a role for temporary mechanical heart support. There have been anecdotal cases of unstable patients being successfully managed by mechanical support followed by definitive operation.[106]

The theoretical advantages that make mechanical support attractive as an initial therapy in very sick patients with postinfarction VSD include: (1) the potential to reverse end-organ dysfunction; (2) maturation of the infarct leading to firmer tissue, making the closure less prone to technical failure; and (3) recovery of the stunned and energy-depleted myocardium. However, there are potential hazards with mechanical support that are specific to the patient with postinfarction VSD. High right-to-left shunting across the ventricular septum has been reported to cause hypoxic brain injury in a postinfarction VSD patient placed on a HeartMate left ventricular support device.[107] This anecdotal observation suggests that either partial left heart support or preferably biventricular support should be considered when using mechanical assistance in these patients. In a report using the Hemopump axial flow device, two of two patients supported experienced lethal pump failure. Examination of the device at autopsy disclosed necrotic material clogging the catheter system.[108]

Simultaneous Myocardial Revascularization

There has been controversy in the literature concerning the advantages and disadvantages of concurrent coronary artery grafting in patients undergoing emergent repair of postinfarction ventricular septal rupture.[26,31,65,73,109] Some have argued that revascularization provides no survival benefit and subjects patients to preoperative left heart catheterization, a time consuming and potentially dangerous diagnostic

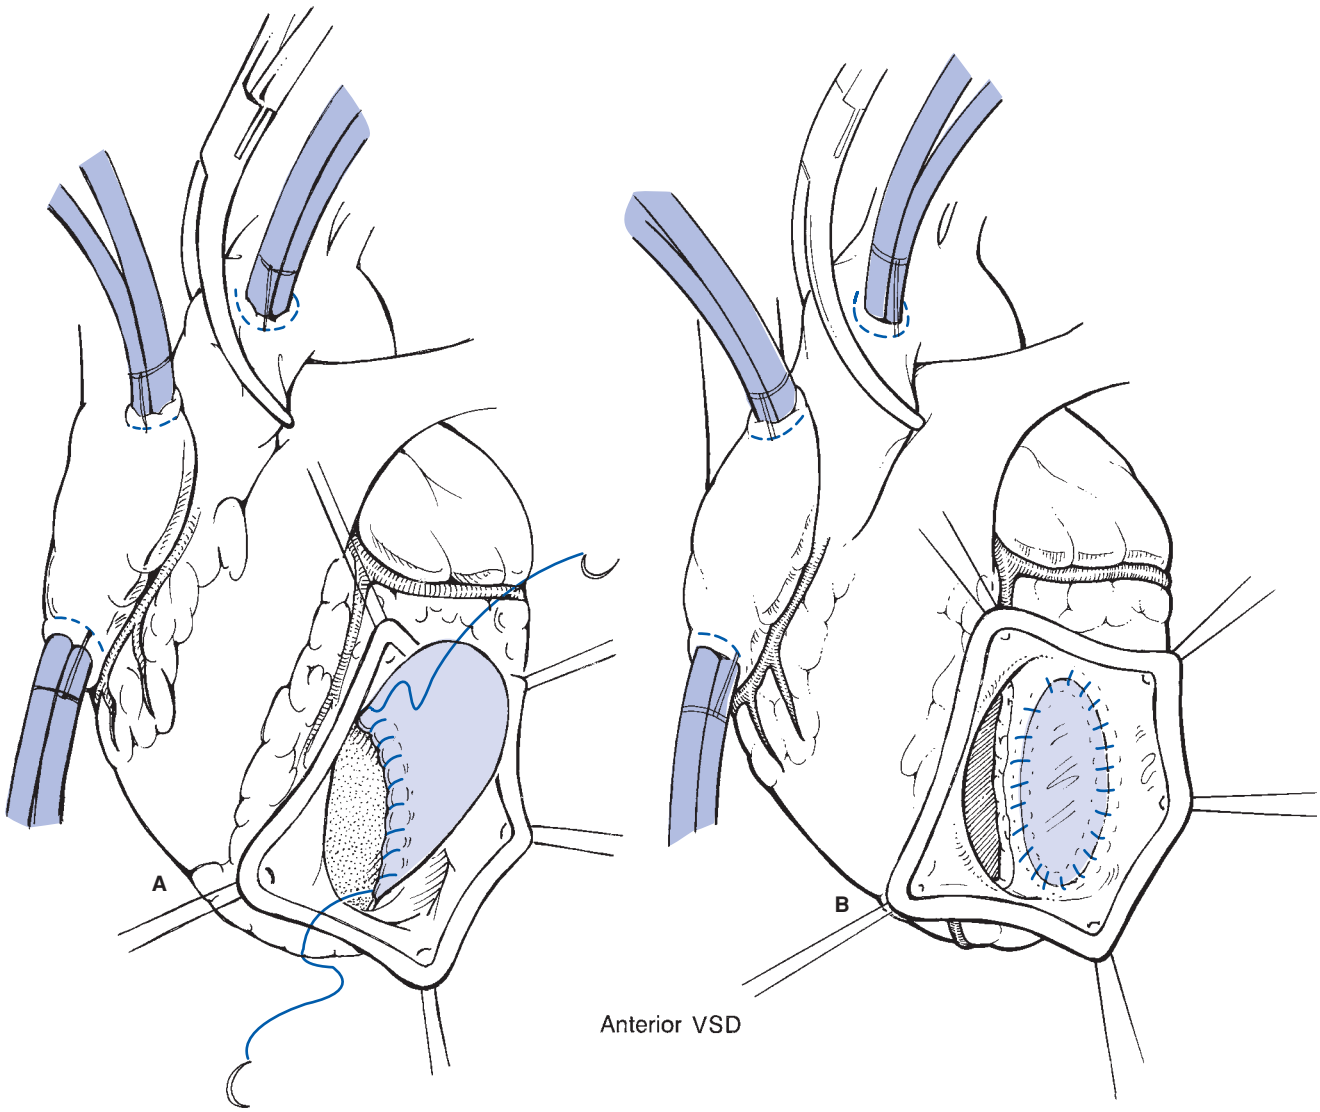

Figure 29-9. Repair of an anterior postinfarction ventricular septal rupture using the technique of infarct exclusion. (A) The standard ventriculotomy is made in the infarcted area of left ventricular free wall. An interior patch of Dacron (Meadox Medicals Inc., Oakland, NJ), polytetrafluoroethylene, or glutaraldehyde-fixed pericardium is fashioned to replace and/or cover the diseased areas (ventricular septal defect [VSD], septal infarction, or free wall infarction). (B) The internal patch is secured to normal endocardium with a continuous monofilament suture, which may be reinforced with pledgeted mattress sutures. There is little, if any, resection of myocardium and no attempt is made to close the septal defect.

procedure.[65] Loisance and associates[109] base their policy of not revascularizing patients with postinfarction septal ruptures on the fact that none of their 20 long-term survivors (five of whom were bypassed) had incapacitating angina or recurrent myocardial infarction.

Some groups use left heart catheterization and coronary bypassing selectively.[25,31] Davies and colleagues[31] found that of 60 long-term survivors (median 70 months; range 1 to 174 months), only five patients developed exertional angina during follow-up and none required revascularization. Their current policy is to avoid left heart catheterization of patients in whom an acquired septal defect is suspected to be a consequence of their first anterior infarction, provided that the patient has no history of angina or electrocardiographic evidence of previous infarction in another territory.[31] This approach is also based on the findings that multivessel disease is much less prevalent in those with an apical septal rupture as a result of anterior infarction.[23]

Weaning from Cardiopulmonary Bypass

The two most common problems encountered in separating from bypass following repair of a postinfarction VSD are low cardiac output and bleeding. Although the treatment of low cardiac output following cardiac surgery is beyond the scope of this chapter, a few agents and principles are worth

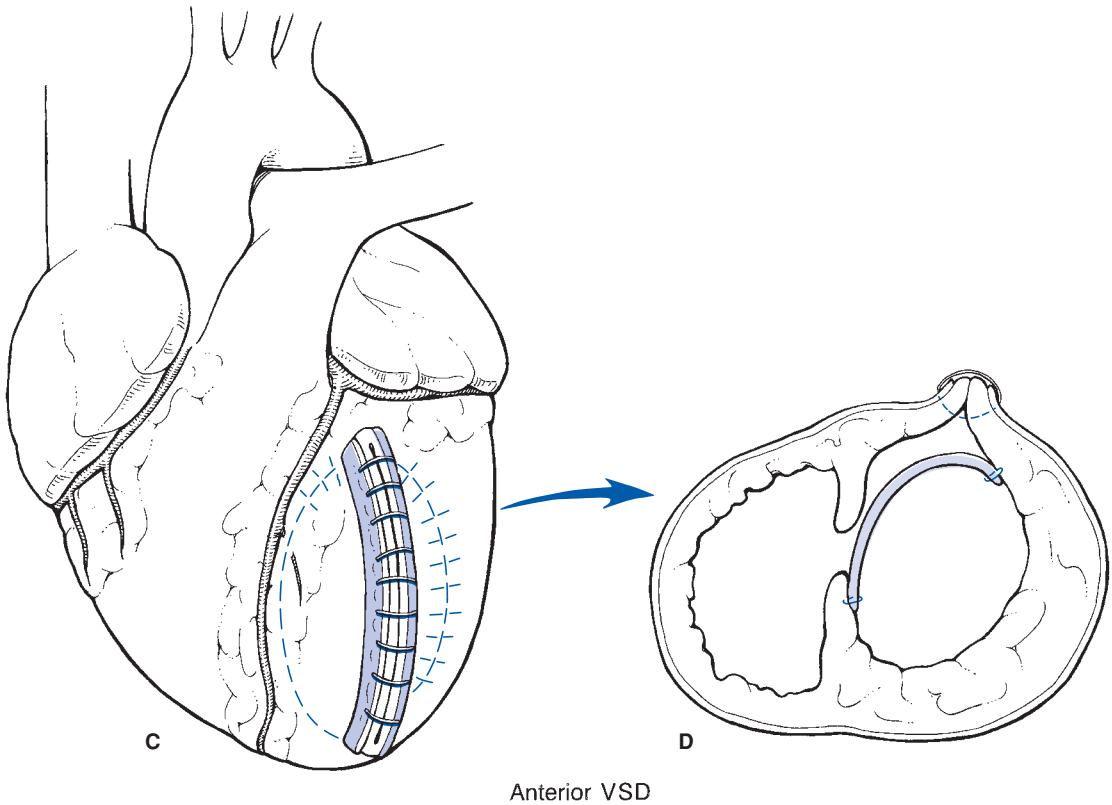

Figure 29-9. (*continued*) Repair of an anterior postinfarction ventricular septal rupture using the technique of infarct exclusion. (C) The ventriculotomy, which is outside the pressure zone of the left ventricle, may be repaired with a continuous suture. (D) On transverse section, one can see that the endocardial patch is secured at three levels: above and below the septal rupture and beyond the ventriculotomy. (*Adapted with permission from David et al.*[46])

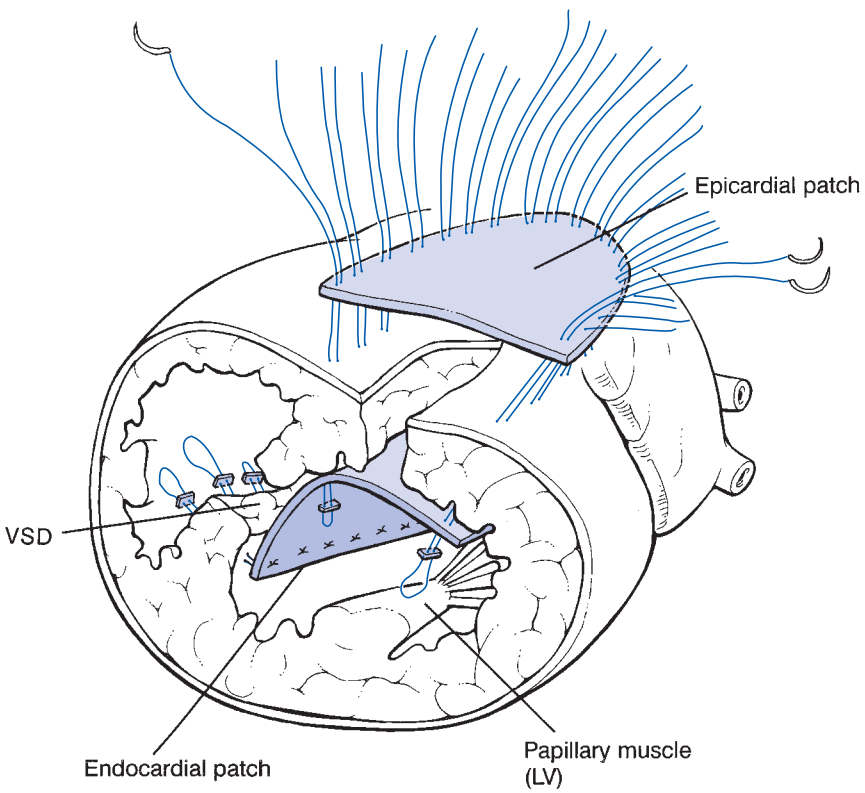

Figure 29-10. Repair of an anterior postinfarction ventricular septal rupture using the technique of infarct exclusion with external patching of the ventricular free wall with tailored Teflon or pericardium. LV = left ventricle; VSD = ventricular septal defect. (*Adapted with permission from Cooley.*[93])

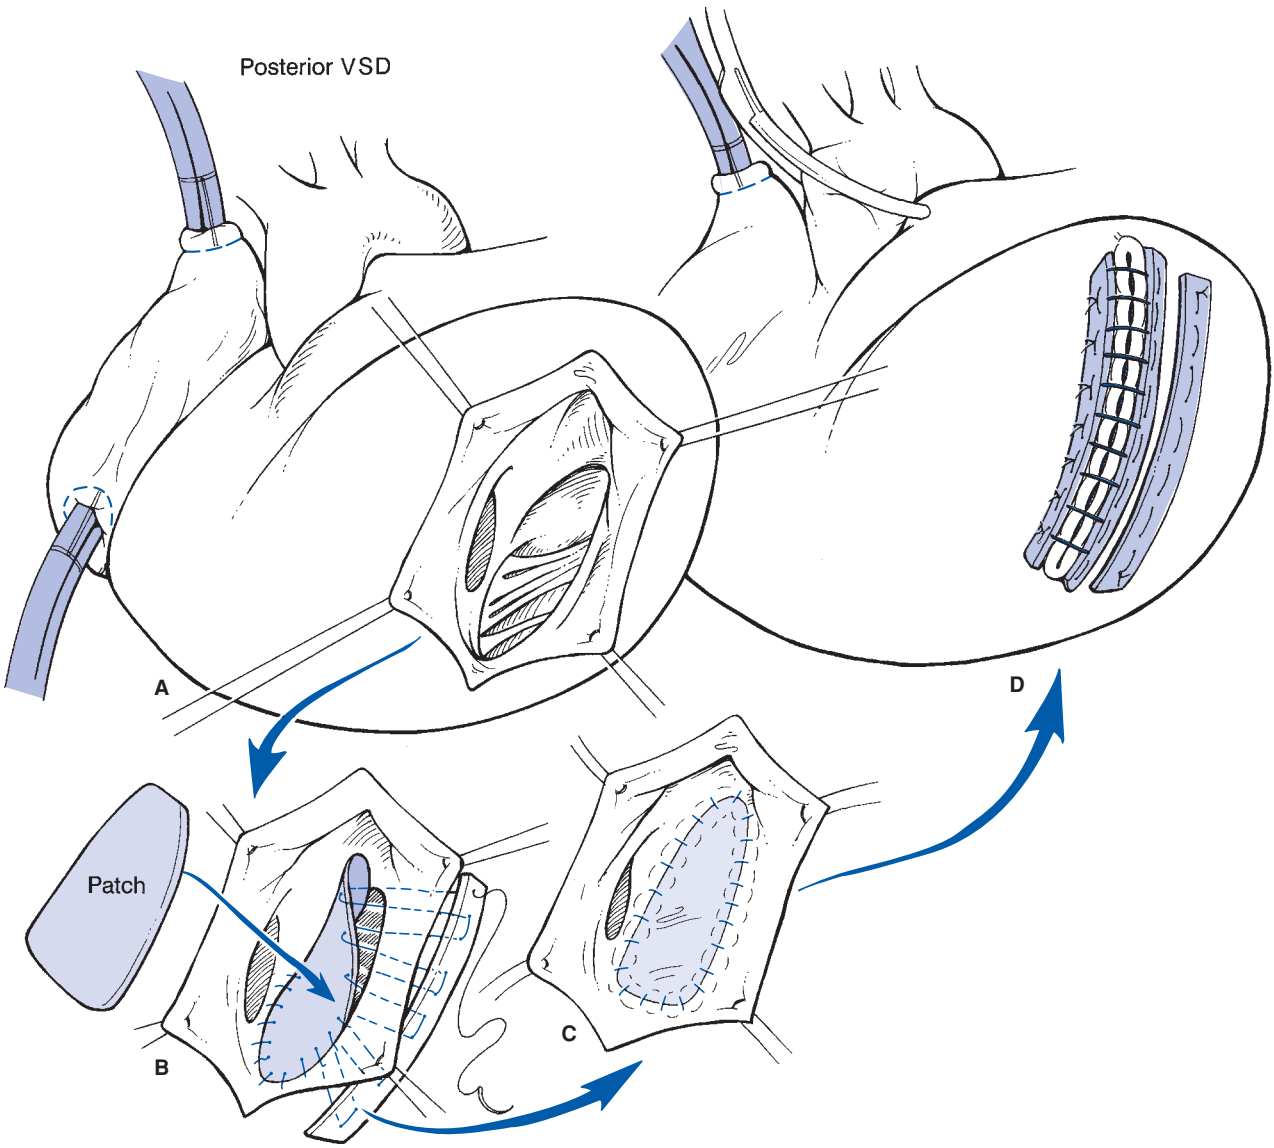

Figure 29-11. Endocardial repair of a posterior postinfarction ventricular septal rupture using the technique of infarct exclusion. (A) An incision is made in the inferior wall of the left ventricle 1 or 2 mm from the posterior descending artery starting at the midportion of the inferior wall and extended proximally toward the mitral annulus and distally toward the apex of the ventricle. Care is taken to avoid damage to the posterolateral papillary muscle. (B) A bovine pericardial patch is tailored in a triangular shape. The base of the triangular-shaped patch is sutured to the fibrous annulus of the mitral valve with a continuous 3-0 polypropylene suture starting at a point corresponding to the level of the posteromedial papillary muscle and moving medially toward the septum until the noninfarcted endocardium is reached. (C) The medial margin of the triangular-shaped patch is sewn to healthy septal endocardium with a continuous 3-0 or 4-0 polypropylene suture. The lateral side of the patch is sutured to the posterior wall of the left ventricle along a line corresponding to the medial margin of the base of the posteromedial papillary muscle. At this point, it is usually necessary to use full-thickness bites and anchor the sutures on a strip of pericardium or Teflon felt applied on the epicardial surface of the posterior wall of the left ventricle. (D) Once the patch is completely sutured to the mitral valve annulus, the endocardium of the interventricular septum, and the full thickness of the posterior wall, the ventriculotomy is closed in two layers of full-thickness sutures buttressed on strips of pericardium or Teflon felt. The infarcted right ventricular wall is left undisturbed. (*Adapted with permission from David et al.*[46])

mentioning. First, most of these patients will have had an IABP inserted before surgery. If not, one should be inserted in the operating room, especially if the low-output state is secondary to LV dysfunction. Also, an IABP may benefit patients with right ventricular failure by improving right coronary artery blood flow due to diastolic augmentation. We have found intravenous milrinone, a phosphodiesterase inhibitor, to be very effective in reversing low-output states secondary to LV dysfunction. Milrinone possesses a balance of inotropic and vasodilatory properties that together produce an increase in cardiac output and reduction in right and left filling pressures and systemic vascular resistance. It is less arrhythmogenic than dobutamine, causes less hypotension than amrinone, and is not associated with thrombocytopenia.[110]

Posterior defects are commonly associated with mitral regurgitation and right heart dysfunction secondary to extensive right ventricular infarction.[38] Management of right heart failure is aimed at reducing right ventricular afterload while maintaining systemic pressure.[104] Initial steps to manage right ventricular dysfunction include volume loading, inotropic support, and correction of acidosis, hypoxemia, and hypercarbia. If patients remain unresponsive to these measures, we have successfully treated right ventricular failure with a prostaglandin E_1 infusion (0.5 to 2.0 μg/min) into the right heart, counterbalanced with a norepinephrine infusion titrated into the left atrium.[111] Inhaled nitric oxide (20 to 80 ppm), which selectively dilates the pulmonary circuit, has also proven efficacious in the treatment of right heart failure.[112]

If a patient cannot be weaned from bypass using conventional therapy, we consider using a ventricular assist device. Indications for a left ventricular assist device are a cardiac index less than 1.8 L/min/m^2, a left atrial pressure above 18 to 25 mm Hg, a right atrial pressure below 15 mm Hg, and an aortic pressure below 90 mm Hg peak systolic. Indications for a right ventricular assist device are a cardiac index less than 1.8 L/min/m^2, an aortic pressure below 90 mm Hg peak systolic, and a left atrial pressure less than 15 mm Hg despite volume loading to a right atrial pressure of 25 mm Hg with a competent tricuspid valve. Important points to remember when instituting ventricular assistance are:

1. Right ventricular failure may not become evident until left ventricular assistance is instituted.
2. Once refractory ventricular failure has been identified, delay in initiating support is associated with increased morbidity and mortality.
3. Closure of a patent foramen ovale is mandatory prior to left ventricular support.
4. Postoperative hemorrhage should be treated aggressively and completely controlled.
5. Residual septal defects may result in right-to-left shunting and severe hypoxia when only left heart support is used.[113]

To prevent postpump coagulopathy, we begin antifibrinolytic therapy with either aprotinin or ε-aminocaproic acid (Amicar) before commencing cardiopulmonary bypass. Since controversy surrounds the issue of increased renal dysfunction and perioperative thrombotic events in patients receiving aprotinin,[114] we prefer to use Amicar in patients who (1) require aortocoronary bypasses, (2) are diabetic, or (3) have known renal dysfunction. Amicar is administered by loading patients with 10 g prior to commencing bypass and then adding another 10 g to the pump prime. During the procedure Amicar is continuously infused at 1 g/h for the duration of surgery. Postpump suture line bleeding may be reduced by application of a fibrin sealant to the ventricular septum around the septal defect *prior* to formal repair.[115] Biological glue may be effective in controlling bleeding suture lines following repair.[116] As a last resort, Baldwin and Cooley[117] have suggested insertion of a left ventricular assist device solely as an adjunct to the repair of friable or damaged myocardium to reduce left ventricular distention and thus control bleeding.

Highlights of Postoperative Care

Early postoperative diuresis and positive end-expiratory pressure ventilation are used to decrease the alveolar-arterial gradient induced by the increased extravascular pulmonary water associated with cardiopulmonary bypass. Once the patient has warmed, we commonly use an intravenous infusion of furosemide combined with mannitol or, if needed, continuous venovenous hemofiltration is employed postoperatively.

Intractable postoperative ventricular arrhythmias secondary to reperfusion injury are sometimes difficult to control using standard therapy. We have been impressed with the efficacy of intravenous amiodarone in these situations (10 to 20 mg/kg over 24 hours).[118]

Operative Mortality and Risk Factors for Death

Table 29-2 summarizes recently reported experience from several centers. Operative mortality, defined as death prior to discharge *or* within 30 days of operation, ranged from 30 to 50%. In the Massachusetts General Hospital experience of 114 patients, operative mortality was 37% (Fig. 29-12A). The risk for death was found to be very high initially, but dropped rapidly (Fig. 29-12B). We identified independent risk factors for early and late death using multivariate methods (Table 29-3). The most important predictor of operative mortality in our study, and in other reports, was preoperative hemodynamic instability. Patients in this group are usually in cardiogenic shock, are emergency cases, are on inotropic support, and usually have intra-aortic balloon pumps. Several variables are highly correlated with hemodynamic instability, and different multivariate models may use one or more of these indicators of severe hemodynamic failure in their final model.

Additional risk factors for early and late death include the presence of left main CAD, previous MI, renal dysfunction, and right heart failure (Fig. 29-13). Other factors have

Table 29–2.

Summary of Recent Clinical Experience with Surgical Repair of Postinfarction Ventricular Septal Defect

Institution	City	Year	No.	Hospital mortality	5-Year survival	Reference

been found to increase the risk of early death. Posterior location of the septal rupture has been associated with an increased operative mortality.[36,38,48,50] This has been attributed to a more technically difficult repair,[19,119] to the increased risk of associated mitral regurgitation, and to associated right ventricular dysfunction that is an independent predictor of early mortality following posterior infarction.[49] A short time interval between infarction and operation selects for sicker patients unable to be managed medically. Older patient age has also been associated with an increased early mortality.[22,78,120,121] In our analysis, we found that the impact of age was more pronounced in the high-risk patient, and should not be used as a reason for denying surgery in an otherwise low-risk elderly candidate (Fig. 29-14).

Our review of the Massachusetts General Hospital experience underscored the large variability of risk to which patients could be segregated using a few clinical variables (Figs. 29-15 and 29-16), most notably indicators of hemodynamic instability (emergency surgery and use of inotropes). The result was that a small group of high-risk patients dramatically affected the overall mortality rate. We believe that this phenomenon makes it very difficult to compare mortality between institutions. A slight difference in practice patterns, such as a tendency of a surgeon or referring cardiologist to deny operation, could substantially affect results. Additionally, any difference in transport dynamics to certain centers could lead to loss of unstable patients, which could create another type of selection bias. In our opinion, these issues are by far the most important source of mortality differences in modern series.

Several centers have reported improved early results with an "exclusion" repair.[46,122,123] Our group has not been able to replicate these results, with a disappointing 60% mortality in 10 patients (higher than the rate achieved historically with traditional techniques).

Regardless of the technique, the most common cause of death following repair of acute postinfarction VSD was low cardiac output syndrome (52%). Technical failures, most commonly recurrent or residual VSD, but including bleeding, were the second most common (23%). Other causes of death include sepsis (17%), recurrent infarction (9%), cerebrovascular complications (4%), and intractable ventricular arrhythmias.

Long-Term Results

Long-term results have been favorable with regard to both mortality risk and functional rehabilitation. Actuarial survival at 5 years for most recent series generally ranges between 40 and 60% (see Table 29-2). Due to the overall high risk of the operation, it is rewarding to note that hospital survivors enjoy excellent longevity, with 1-, 5-, and 10-year survival of 91, 70, and 37%, respectively. They also are quite functional—among 15 of our patients contacted during the most recent follow-up of long-term survivors, 75% were in New York Heart Association functional class I, and 12.5% were class II.[32]

Recurrent Ventricular Septal Defects

Recurrent or residual septal defects have been diagnosed by Doppler color flow mapping early or late postoperatively in 10 to 25% of patients.[23] They may be due to reopening of a closed defect, to the presence of an overlooked defect, or to the development of a new septal rupture during the early postoperative period. These recurrent defects should be closed when they cause symptoms or signs of heart failure or when the calculated shunt fraction (pulmonary-to-systemic flow ratio) is large (Qp:Qs >2.0). When they are small (Qp:Qs <2.0) and either asymptomatic or controlled with minimal diuretic therapy, a conservative approach is reasonable and late spontaneous closure can occur.[23] Intervention in the catheterization laboratory may be useful in closing symptomatic residual or recurrent defects postoperatively.

Chronic Ventricular Septal Defects

In 1987 Rousou and associates reported successful closure of an acquired posterior VSD by means of a right transatrial approach.[124] Filgueira and colleagues have used the transatrial approach for *delayed* repair of chronic acquired posterior septal defects.[125] Approaching a postinfarction

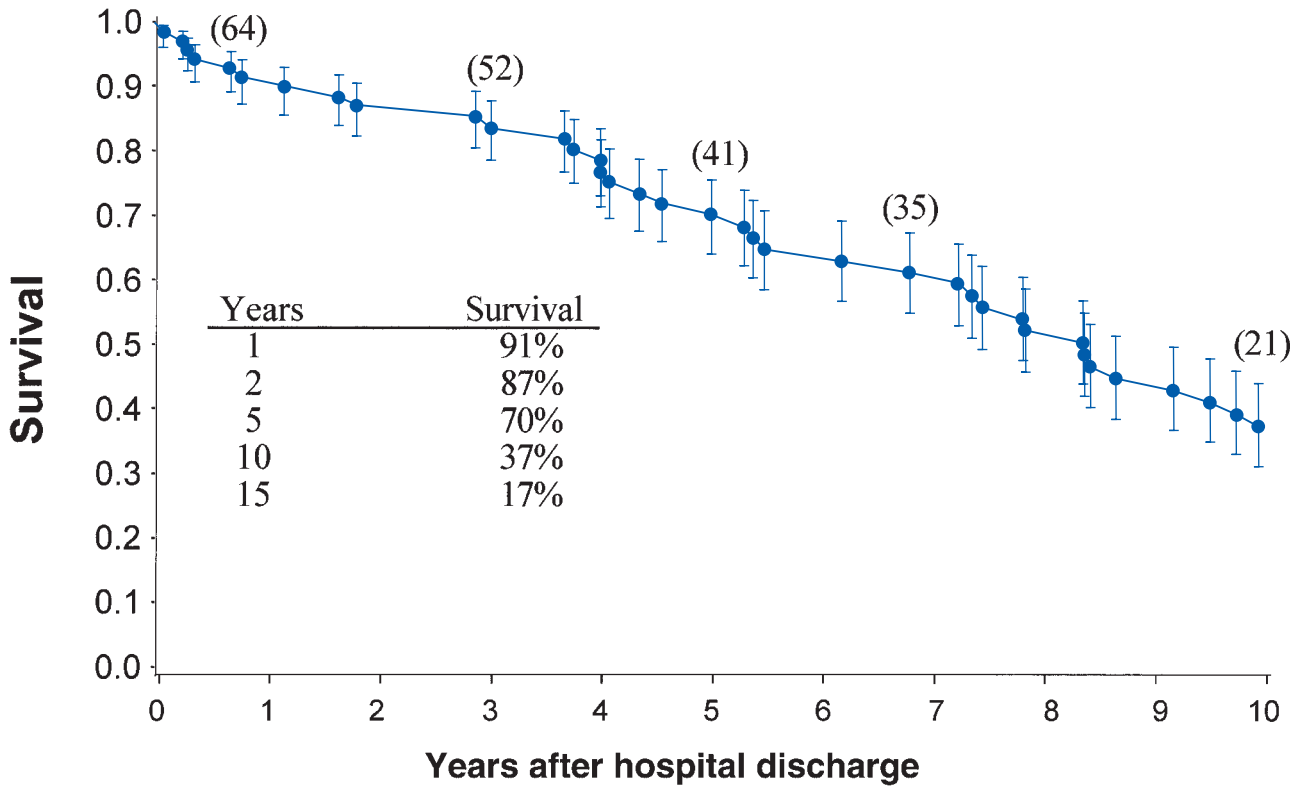

Figure 29-13. Survival in patients who were discharged after repair of postinfarction ventricular septal defect (Massachusetts General Hospital, n = 72). The horizontal axis is expanded and represents the time from hospital discharge to death. The depiction is otherwise similar to that seen in Fig. 29-12A.

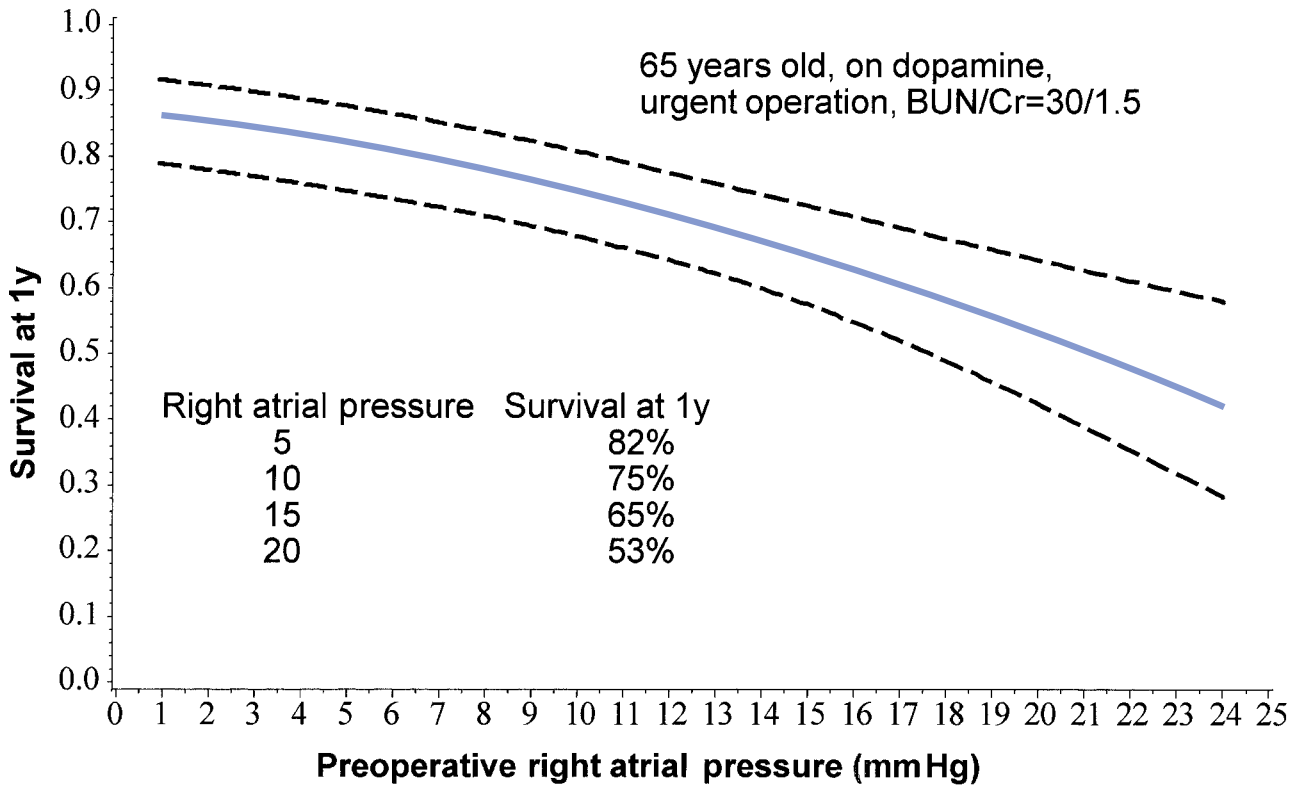

Figure 29-14. Survival at 1 year vs. preoperative right atrial pressure (Massachusetts General Hospital; n = 114). The depiction is a solution of the multivariate equation for a 65-year-old with a blood urea nitrogen of 30 mg/dL, a creatinine of 1.5 mg/dL, not on catecholamines, not an "emergency" case, and without a history of myocardial infarction or left main coronary artery disease.

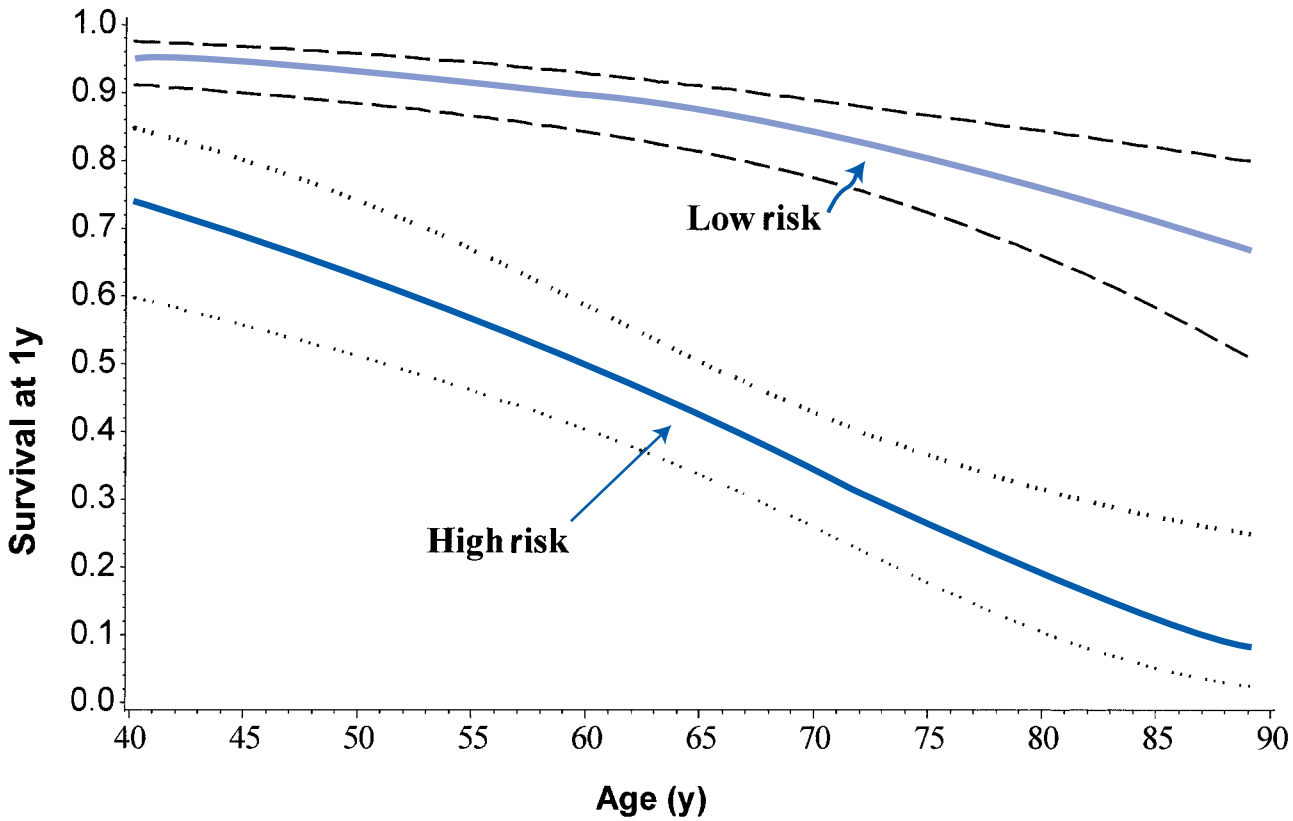

Figure 29-15. Nomograms (specific solutions to the multivariate equation) depicting the effect of age on risk in two different hypothetical patients. In both curves the patient was considered to have no left main disease, a blood urea nitrogen of 30 mg/dL, creatinine of 1.5 mg/dL, and no history of previous myocardial infarction. The curve for "low-risk" was solved for a patient who was not emergent and not on catecholamines. The curve for "high-risk" was for an emergent patient on inotropes. The vertical axis represents the calculated survival at 1 year.

VSD through the tricuspid valve should not be used in acute cases because of the friability of the necrotic septum, poor exposure, and because this technique does not involve infarctectomy, and thus cannot achieve the hemodynamic advantages of elimination of a paradoxically bulging segment of ventricular wall. However, the right heart approach can be used in chronic postinfarction VSD when the septum is well scarred and the patch can be safely sutured to it from the right atrium. We emphasize that while the transatrial approach may be used selectively for the closure of chronic defects, it is unlikely to be an appropriate choice for the closure of acute defects, except perhaps in the rare circumstance when an infarct is localized to the septum with no evidence of necrosis of the free wall of the left ventricle.[40]

POSTINFARCTION VENTRICULAR FREE WALL RUPTURE

History

William Harvey first described rupture of the free wall of the heart after AMI in 1647.[126] In 1765, Morgagni reported 11 cases of myocardial rupture found postmortem.[127] Ironically, Morgagni later died of myocardial rupture.[128] Hatcher and colleagues from Emory University reported the first successful operation for free wall rupture of the right ventricle in 1970.[129] FitzGibbon and associates[130] in 1971 and Montegut[131] in 1972 reported the first successful repairs of left ventricular ruptures associated with ischemic heart disease.

Incidence

Autopsy studies reveal that ventricular free wall rupture occurs about 10 times more frequently than postinfarction ventricular septal rupture, occurring in about 11% of patients following AMI.[24,132] The incidence has been found to be as high as 31% in autopsy studies of anterior MI.[133] Ventricular rupture and cardiogenic shock are now the leading causes of death following AMI, and together account for over two-thirds of early deaths in patients suffering their first acute infarction. Postinfarction ventricular ruptures are more common in elderly women (mean age of 63 years) suffering their first infarction.[134] In the prethrombolytic era, 90% of ruptures occurred within 2 weeks after infarction

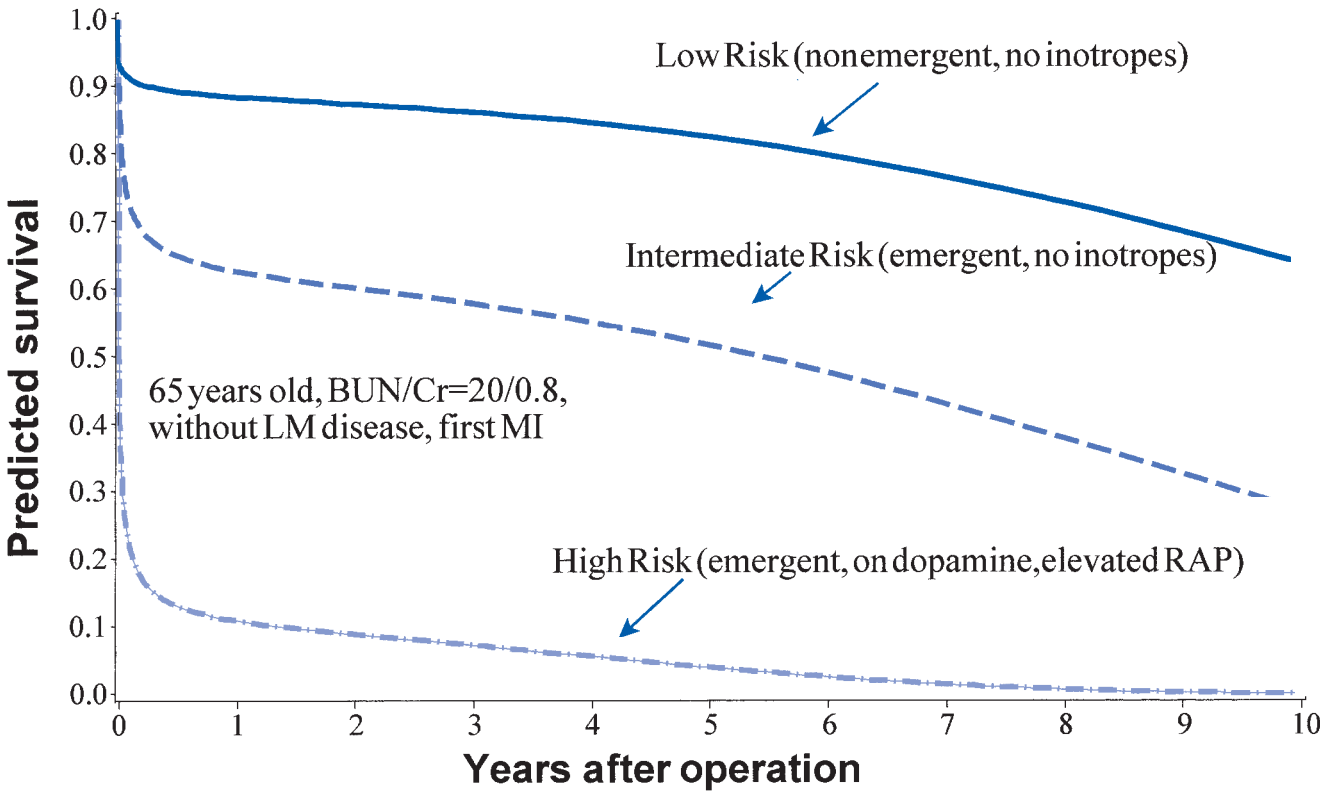

Figure 29-16. Nomograms (specific solutions of the multivariate equation) depicting the predicted survival in three hypothetical 65-year-old patients who present with ventricular septal defect. Each solution is for a patient who has no history of myocardial infarction and without left main coronary artery disease, blood urea nitrogen of 20 mg/dL, and creatinine of 0.8 mg/dL. The "low-risk" patient is nonemergent and not on inotropes with right atrial pressure (RAP) of 8 mm Hg. The "intermediate-risk" patient is emergent and not on inotropes with RAP of 12 mm Hg. The "high-risk" patient is emergent and on inotropes with RAP of 20 mm Hg. Confidence limits have been eliminated to improve clarity.

with the peak incidence at 5 days.[135] In contrast, the time to cardiac rupture (not frequency of rupture) seems to be accelerated by thrombolysis and coronary reperfusion, sometimes occurring within hours from the onset of symptoms.[136] Thus, free ventricular ruptures occur most frequently in hypertensive women over the age of 60 who develop symptoms within 5 days of their first transmural MI.

Opinions differ as to the most common site of left ventricular rupture. The older literature suggests that the anterior wall is the most frequent site.[137] However, more recent series have observed a preponderance of lateral and posterior wall ruptures.[28,132,135] David[138] has suggested that a lateral wall infarction is more likely to rupture than is an anterior or inferior one, but since anterior infarctions are much more frequent than lateral infarctions, overall the most common site of rupture is the anterior wall. Like postinfarction ventricular septal rupture, free wall ruptures may be simple or complex.[42] A simple rupture results from a straight through-and-through tear that is perpendicular to the endothelial and epicardial surfaces, whereas a complex rupture results from a more serpiginous tear, often oblique to the endocardial and epicardial surfaces.[138] Batts and coworkers[135] reported 100 consecutive cases of left ventricular free wall rupture and found that half were simple ruptures and the rest were complex.

Pathogenesis and Pathophysiology

Left ventricular free wall rupture can be divided into three clinicopathologic categories: acute, subacute, and chronic.[139,140] An *acute* or "blow-out" rupture is characterized by sudden recurrent chest pain, electrical mechanical dissociation, profound shock, and death within a few minutes due to massive hemorrhage into the pericardial cavity. This type of rupture is probably not amenable to current management. A *subacute* rupture is characterized by a smaller tear, which may be temporarily sealed by clot or fibrinous pericardial adhesions. These usually present with the signs and symptoms of cardiac tamponade, and eventually cardiogenic shock. Subacute rupture may mimic other complications of AMI such as infarct extension and right ventricular failure, and may be compatible with life for several hours or days or even longer.[138] A *chronic* rupture with

false aneurysm formation occurs when the leakage of blood is slow and when surrounding pressure on the epicardium temporarily controls the hemorrhage. Adhesions form between the epicardium and pericardium, which reinforce and contain the rupture.[30] The most common clinical presentation of patients with false aneurysms of the left ventricle is CHF.[141] A false aneurysm may also be an echocardiographic finding in an otherwise asymptomatic patient recovering from AMI. Angina, syncope, arrhythmias, and thromboembolic complications occur in a small percentage of patients.[141] There are four major differences between a true and false aneurysm of the left ventricle:

1. The wall of a false aneurysm contains no myocardial cells.
2. False aneurysms are more likely to form posteriorly.
3. False aneurysms usually have a narrow neck.
4. False aneurysms have a great propensity for rupture.[142–144]

Rupture of the free wall of the left ventricle may occur in isolation or with rupture of other ventricular structures such as the interventricular septum, papillary muscles, or right ventricle.[141,144]

The pathogenesis of cardiac rupture remains poorly understood. However, cardiac rupture occurs only with transmural MIs and infarction expansion appears to play an important role in its pathogenesis.[39,43,145] Infarct expansion is an acute regional thinning and dilatation of the infarct zone, seen as early as 24 hours following acute transmural MI and not related to additional myocardial necrosis.[146] This regional thinning and dilatation of the infarct zone is a consequence of slippage between muscle bundles, resulting in a reduction in the number of myocytes across the infarcted area.[147] Infarct expansion increases the size of the ventricular cavity, with a consequent increase in wall tension (Laplace effect) that subjects the infarct zone to more tension and predisposes to endocardial tearing.[138] Systemic hypertension aggravates the problem of thinning and dilatation of the infarct wall and increases the probability of rupture.[148] Lack of collateral flow may also promote ventricular rupture.[149]

Since myocardial rupture occurs in regions of complete transmural myocardial necrosis, usually after extensive hemorrhagic transformation of the acute infarct,[145,150,151] and because thrombolytic therapy is associated with the conversion of a bland infarct into a hemorrhagic infarct,[152] there has been an ongoing concern that thrombolysis might increase the likelihood of ventricular rupture.[153] Honan and associates[150] performed a meta-analysis of four large clinical trials (1638 patients) in which streptokinase was used to treat AMIs and concluded that the risk of cardiac rupture was directly related to the timing of thrombolytic therapy. Early treatment (within 7 hours from the onset of symptoms) decreased the risk of cardiac rupture, whereas late treatment (after 17 hours) increased the risk of this complication even though, surprisingly, the overall mortality rate was diminished when streptokinase was given late after acute infarction. In a prospective ancillary study of 5711 patients, Late Assessment of Thrombolytic Efficacy, Becker and colleagues[136] were unable to show an increased risk of cardiac rupture in patients treated with recombinant tissue plasminogen activator 6 to 24 hours after the onset of symptoms. Thus, there is general agreement that early successful thrombolysis decreases the overall risk of cardiac rupture, probably by limiting the extent of necrosis, resulting in a nontransmural instead of transmural infarct, but the impact of late thrombolytic therapy on cardiac rupture remains unclear.

Diagnosis

The clinical picture of a subacute ventricular rupture is primarily that of pericardial tamponade, with pulsus paradoxus, distended neck veins, and cardiogenic shock. Although 5 to 37% of patients with AMI but no rupture may develop a pericardial effusion,[154] echocardiographic signs that increase the sensitivity and specificity for cardiac rupture include effusion thickness greater than 10 mm, echodense masses in the effusion, ventricular wall defects, and signs of tamponade (e.g., right atrial and right ventricular early diastolic collapse and increased respiratory variation in transvalvular blood flow velocities).[155,156] Pericardiocentesis and aspiration of uncoagulated blood has historically been considered the most reliable criterion of subacute ventricular rupture;[157,158] however, false-positive and false-negative diagnoses have been reported.[155] The demonstration of a clear pericardial fluid on pericardiocentesis definitively excludes cardiac rupture.[155] Pericardiocentesis is of therapeutic value in some patients, often providing a short-term circulatory improvement.[159]

In an attempt to define symptomatic, electrocardiographic, and hemodynamic markers that may permit the prospective identification of patients prone to rupture of the heart after AMI, Oliva and colleagues[132] retrospectively studied 70 consecutive patients with rupture and 100 comparison patients with AMI but without rupture. They found a number of markers that were associated with a significant increase in the risk of rupture (Table 29-4). The presence of a lateral infarction, especially with associated inferior or posterior infarction, identified a subset of patients at increased risk for rupture. Persistent, progressive, or recurrent ST-segment elevation, and especially, persistent T-wave changes after 48 to 72 hours, or the gradual reversal of initially inverted T waves, are associated with an increased risk of rupture. Finally, the development of pericarditis, repetitive emesis, or restlessness and agitation, particularly two or three of these symptoms, conveyed predictive value.[133]

Natural History

Acute rupture of the free wall of the left ventricle is invariably fatal, with death usually occurring within minutes of the

Table 29–4.

Sensitivity, Specificity, and Predictive Value of Symptoms and Electrocardiographic Criteria for Cardiac Rupture

	Sensitivity (%)	Specificity (%)	Predictive value (%)
Pericarditis	86	72	68
Repetitive emesis	64	95	90
Restlessness and agitation	55	95	86
Two or more symptoms	84	97	95
ST-segment deviations	61	72	58
T-wave deviations	94	66	66
ST-T–wave deviations	61	68	64

onset of recurrent chest pain.[135,138,149] In most of these cases, the sequence of events leading to death is so rapid that there is not enough time for surgical intervention. In contrast, patients with a subacute rupture usually survive hours or days, rarely weeks, following the myocardial tear.[140] Pollack and colleagues[156] found that in 24 cases of postinfarction subacute rupture, survival time (i.e., time from critical event to death) varied between 45 minutes and 6.5 weeks, with a median survival of 8 hours. Núñez and coworkers[160] found that in 29 cases of subacute rupture, 20 (69%) died within minutes of the onset of symptoms, and 9 (31%) lived several hours, allowing time for treatment. Subacute ventricular ruptures are generally considered to be less common than acute free wall ruptures. In recent studies, with high autopsy rates, 21 to 42% of all postinfarction free wall ruptures followed a subacute course.[156,161,162]

Because of its rarity, the natural history of false aneurysm of the left ventricle has not been established.[138] It is believed to have a poor prognosis because of its high probability of rupture;[142,163,164] however, there are patients in whom the diagnosis was made many years after MI.[141,165,166] The increasingly wide application of echocardiography after AMI gives promise of altering clinical outcome for many patients with the various forms of ventricular wall rupture.

Preoperative Management

Usually, the sequence of events leading to death is so rapid in patients with acute rupture of the free wall of the left ventricle that there is not enough time for surgical intervention.[138] These patients usually die within minutes of the onset of recurrent chest pain.[160] However, a high index of suspicion, combined with a novel technique of percutaneous intrapericardial infusion of fibrin glue immediately following pericardiocentesis,[167,168] may afford at least a chance of survival in this surgically untreatable subgroup of patients.

In contrast, patients with subacute left ventricular rupture can be saved with surgery. Once the diagnosis of rupture of the free wall is established, the patient should be immediately transferred to the operating room. No time should be wasted attempting to perform coronary angiography.[136,141,166,175] Inotropic agents and fluids should be started while preparing for surgery. Pericardiocentesis often improves hemodynamics temporarily,[169] and insertion of an intra-aortic balloon pump may be beneficial, even though the principal problem is cardiac tamponade.[158]

The timing of surgery following the diagnosis of false aneurysm of the left ventricle is dependent upon the age of the MI. When a false aneurysm is discovered within the first 2 to 3 months after coronary infarction, surgery is urgently recommended after coronary angiography and ventriculography because of the unpredictability of rupture.[144,172] However, when the diagnosis is made several months or years after MI, the urgency of the operation is not determined so much by the risk of rupture, but rather by symptoms and the severity of the CAD.[138,165]

Operative Techniques

Subacute rupture of the free wall

As soon as the diagnosis of rupture of the free wall of the left ventricle is confirmed by echocardiography, the patient should be transferred to the operating room. In patients with tamponade, severe hypotension may result during the induction of anesthesia. Therefore, we usually complete the sterile preparation and draping of the patient before inducing anesthesia. Some even advocate femoral artery cannulation before the induction of anesthesia.[170] A median sternotomy is performed and upon decompressing the pericardium, the blood pressure commonly rises quickly. This should be anticipated and controlled because hypertension can cause ventricular bleeding to start again, or may even increase the size of the ventricular rent.[138] In most cases, however, the ventricular tear is sealed off by clot, and there is no active bleeding.

Traditionally, postinfarction rupture of the free wall of the left heart has been repaired on cardiopulmonary bypass;[146,157,158,160,170,171] however, some surgeons have suggested that cardiopulmonary bypass is not necessary except perhaps in patients with posterior wall rupture, severe mitral regurgitation, ventricular septal rupture, or graftable CAD.[138,169] Although the ventricular tear can be repaired without aortic cross-clamping, cardiac standstill and left ventricular decompression make the procedure

easier when the rupture is in the posterior wall of the left ventricle.[138]

The term *ventricular double rupture* has been applied when there is rupture of two of the following three structures: the ventricular septum, the ventricular free wall, and papillary muscle.

Four surgical techniques have been used to control ventricular rupture. The first technique involves closing the rent with large horizontal mattress sutures buttressed with two strips of Teflon felt.[129] This method is not recommended because the sutures are placed into necrotic, friable myocardium that can easily tear. The second method combines infarct excision and closure of the defect with interrupted, pledgeted sutures[130,158,170] or a Dacron patch.[172,173] This method usually requires aortic cross-clamping and is probably best reserved for those patients who have an associated VSD.[160] The third technique, described by Núñez and colleagues,[160] involves closing the defect with horizontal mattress sutures buttressed with two strips of Teflon felt, and then covering the closed ventricular tear and surrounding infarcted myocardium with a Teflon patch sutured to healthy epicardium with a continuous polypropylene suture (Fig. 29-17). Good control of active ventricular hemorrhage has been achieved with this method. The fourth method consists of simply gluing a patch of either Teflon[169] or autologous glutaraldehyde-preserved bovine pericardium to the ventricular tear and infarcted area using a biocompatible glue of either fibrin (Tissucol, Immuno AG, Vienna, Austria), butyl-2-cyanoacrylate monomer (Histoacryl Blue, B. Braun, Melsungen AG, Germany), or gelatin-resorcin-formaldehyde (Pharmacie Centrale, C.H.V. Henry Mondor, Créteil, France). This technique does not necessarily require institution of cardiopulmonary bypass and may be the repair of choice when the ventricle is not actively bleeding.[169]

False aneurysm of the left ventricle

Acute false aneurysms are probably best repaired with an endocardial patch using the same methods as those used in repairing true ventricular aneurysms.[138] Chronic anterior false aneurysms can usually be closed primarily if the neck is fibrotic. However, primary closure of the neck of a posterior false aneurysm may exacerbate mitral regurgitation, and it therefore probably should be reconstructed with a patch of Dacron graft or glutaraldehyde-fixed bovine pericardium.[141,144]

Results

Subacute rupture of the free wall

The surgical experience with this entity is largely anecdotal. The single largest experience with surgical repair of postinfarction left ventricular free wall rupture was reported by Padró and colleagues.[169] They treated 13 patients using a Teflon patch glued onto the ventricular tear and surrounding infarcted muscle, and utilized cardiopulmonary bypass in only 1 patient who presented with a posterior defect. All of their patients survived and were alive after a mean follow-up of 26 months. Eleven of them were asymptomatic and two had exertional angina.[169] Núñez and associates[160] operated on seven patients, four of whom survived. Recently the use of unsupported felt secured with cyanoacrylate glue has been described by several authors with encouraging results.[158,173,174]

In ventricular double rupture involving the free wall and the septum, a recent series achieved an operative survival of 60% in five patients.[175] Four of the patients initially had only septal rupture but progressed to include free wall rupture, making this diagnosis a consideration in acute deterioration of medically managed patients with postinfarct VSD.

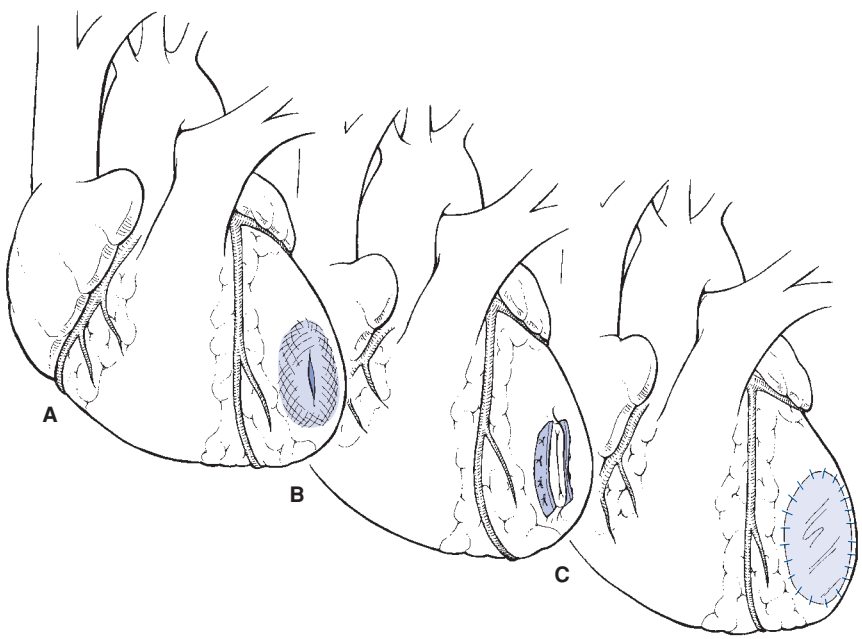

Figure 29-17. Technique to repair rupture of the free wall of the left ventricle. (A) Left ventricular free wall rupture. (B) A limited infarctectomy is closed with horizontal mattress sutures buttressed with two strips of Teflon felt. (C) Then the whole area is covered with a Teflon patch sutured to healthy epicardium with a continuous polypropylene suture. Alternatively, the Teflon patch can be glued to the ventricular tear and the infarcted area using a biocompatible glue. *(Adapted with permission from David.[138])*

Although operative risk cannot be determined from these small numbers, it is likely that without surgery all these patients would have died, and patients who survive surgery tend to do well afterward.[138]

False aneurysm of the left ventricle

Komeda and David[141] treated 12 patients with postinfarction left ventricular false aneurysms; four of them also had mitral valve replacements, one had repair of a fistula between the false aneurysm and the right ventricle, and nine had coronary artery bypass surgery. There were three operative deaths, all in patients who needed mitral valve replacements. Of the eight patients who underwent isolated repair of false aneurysms, all were alive after a mean follow-up of 62 months. Seven patients were asymptomatic and one had angina pectoris.[141] Mackenzie and Lemole[143] reported 14 cases of left ventricular false aneurysm, 12 of which were related to a previous MI. There were three operative deaths. Long-term follow-up was not reported.

Overall, the literature suggests that patients who have isolated repair of false aneurysms of the left ventricle have low operative mortality.[138]

CHAPTER 30

Ischemic Mitral Regurgitation

Wilson Y. Szeto • Robert C. Gorman • Joseph H. Gorman, III • Michael A. Acker

Ischemic mitral regurgitation (IMR) is associated with poor long-term outcome and survival. Although extensive research regarding its mechanism has been conducted, the optimal management of IMR remains elusive. Clinical studies in the past often included mitral regurgitation of nonischemic origin, leading to confusion and incorrect conclusions regarding the true long-term outcome of IMR and its natural history. Recognition of this has improved our understanding of the mechanisms and natural history of IMR.

IMR, often termed *functional mitral regurgitation,* is mitral insufficiency as a result of myocardial infarction or ischemia.[1–6] By definition, the mitral valve leaflets are normal. Whether owing to acute rupture of papillary muscles or chronic changes in left ventricular geometry and remodeling, IMR ultimately is due to ischemic injury to the myocardium. It is important to distinguish IMR from mitral regurgitation resulting from other etiologies. Mitral regurgitation often is associated with coronary artery disease without a direct cause-and-effect relationship. The prevalence of coronary artery disease[7] makes the association of myocardial infarction and nonischemic mitral regurgitation a common clinical entity. IMR also must be distinguished from mitral insufficiency owing to degenerative, rheumatic, congenital, and infectious etiologies. Although likely a related process of left ventricular remodeling, idiopathic dilated cardiomyopathy associated with mitral regurgitation also should be distinguished from IMR.

The wide clinical spectrum of IMR is due to the fact that the disease is a manifestation of postinfarction ventricular remodeling. The size, location, and transmurality of the myocardial infarction (MI) sets in motion left ventricular remodeling that determines the severity, time course, and clinical manifestations of IMR. The presentation may be either acute (with or without papillary muscle rupture and immediately life-threatening) or develop insidiously over time in association with congestive heart failure (CHF).

PREVALENCE

The advancement in catheter-based intervention for coronary artery disease has resulted in improved survival in ischemic heart disease. This improvement in survival most likely will result in an increasing number of patients who subsequently will develop left ventricular dysfunction and IMR. Although many of the previous series[8–13] did not distinguish IMR from other etiologies accurately, the data do give us a reflection of the magnitude of this clinical entity.

Early after an acute myocardial infarction (AMI), between 17% and 55% of patients develop a mitral systolic murmur or echocardiographic evidence of IMR.[2,14–16] Of patients who have cardiac catheterization within 6 hours of the onset of symptoms of AMI, 18% have IMR.[4] In 3.4% of these patients, the degree of mitral insufficiency is severe.[4] Many of the murmurs early after AMI are transient and disappear by the time of discharge.[2,15]

In one study, 19% of 11,748 patients who had elective cardiac catheterization for symptomatic coronary artery disease (CAD) had ventriculographic evidence of mitral regurgitation (MR).[17] In most of these patients, the degree of mitral insufficiency was mild, but in 7.2% of patients the degree of regurgitation was 2+ or greater, and in 3.4% MR was severe with evidence of heart failure.[17] In another study of consecutive cardiac catheterizations, 10.9% of 1739 patients with CAD had MR.[18]

Collectively, these data indicate that IMR is frequent early after AMI but in many patients is mild or disappears completely. The relatively high incidence of IMR (10.9 to 19%) in catheterized patients with symptomatic CAD suggests that chronic IMR persists in many patients after AMI and may develop subsequently in others.[15] Approximately 12.6 million Americans have angina or a history of MI, and untold millions more have asymptomatic coronary atherosclerosis.[7] Using these figures,[7,17,18] the incidence of IMR in

the United States is estimated to be 1.2 to 2.1 million patients, with approximately 425,000 patients having moderate or severe IMR with heart failure.[7,17]

CLASSIFICATION

IMR traditionally has been classified based on the time course of clinical presentation. Acute IMR occurs in the immediate postinfarction period, and patients are often in hemodynamic distress. Fortunately, this population of patients represents a minority of patients with IMR. Chronic IMR represens the clinical presentation for the majority of patients with IMR. The presentation is one of progressive and insidious nature and often is associated with decremental decrease in left ventricular function.

Carpentier's classification for MR provides an insightful way to approach the specific mechanisms of IMR (Fig. 30-1). It is a functional classification and categorizes the improper leaflet coaptation of MR into three types based on leaflet and chordal motion. In type I, the leaflet motion is normal, and MR is a result of mitral annular dilatation. Type II is MR as a result of leaflet prolapse or excessive motion. In type III, there is leaflet restriction, or tethering, and this type is subclassified further into IIIa (i.e., tethering during diastole) and IIIb (i.e., tethering during systole).

IMR can result from type I, type II, or type IIIb dysfunction. Acute postinfarct MR can be a result of type II dysfunction, where there is papillary muscle rupture. However, acute IMR is associated more often with much more subtle changes in the mitral valve apparatus. Chronic IMR can be a result of type I or type IIIb dysfunction. Pure annular dilatation with normal leaflets (type I) results from left ventricular remodeling and its geometric sequelae on the mitral valve apparatus. Type IIIb is the more common dysfunction associated with chronic IMR, and it is the result of papillary muscle displacement and tethering of leaflets. Often, both type I and type IIIb dysfunctions are seen in patients with chronic IMR and cardiomyopathy. The pathophsyiology is a result of left ventricular remodeling as a consequence of ischemia and will be discussed in detail in the next section.

PATHOPHYSIOLOGY

Normal Valve Function

The mitral valve has six anatomic components: leaflets, chordae tendineae, annulus, papillary muscles, left ventricle, and left atrium. The mitral annulus is saddle-shaped (actually a hyperbolic paraboloid with two-directional curvature) with cephalad promontories near the midportions of the anterior and posterior leaflets and caudad depressions at the commissures[19] (Fig. 30-2). This unique shape is present in all mammalian mitral valves and has been shown, using finite-element analysis, to reduce leaflet, annular, and chordal stress.[20] Function of the normal mitral valve is complex and involves precisely timed interactions among the six components. These interactions are described most easily by relating the changes in each of the six components during a cardiac cycle. For this description, the cardiac cycle is divided into four periods: systole, diastole, isovolemic relaxation (IVR), and isovolemic contraction (IVC), as defined below.

End-systole (ES) is defined as the maximum negative left ventricular *dP/dt*,[21] and *end-diastole* (ED) is defined as the peak of the QRS complex. *End isovolemic contraction* (EIVC) is defined as the first time point at which the aortic root *dP/dt* is greater than zero. *End isovolemic relaxation* (EIVR) is defined as the time at which the left ventricular pressure (LVP) is 10% of LVP_{max} and the left ventricular $dP/dt < 0$.[21]

During IVC, *left atrial* filling begins immediately after the mitral valve closes and before the aortic valve opens.[22]

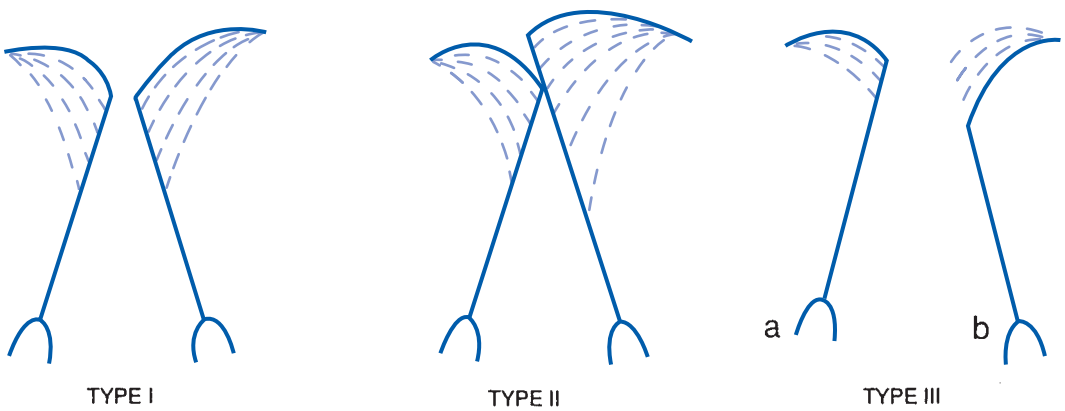

Figure 30-1. Carpentier's functional classification of mitral regurgitation. In type I, the leaflet motion is normal, and mitral regurgitation is a result of mitral annular dilatation. In type II, there is leaflet prolapse or excessive motion. In type III, there is leaflet restriction or tethering, and this type is subclassified further into IIIa (tethering during diastole) and IIIb (tethering during systole). (*Used with permission from Carpentier A: Cardiac valve surgery: The "French correction." J Thorac Cardiovasc Surg 1983; 86:323.*)

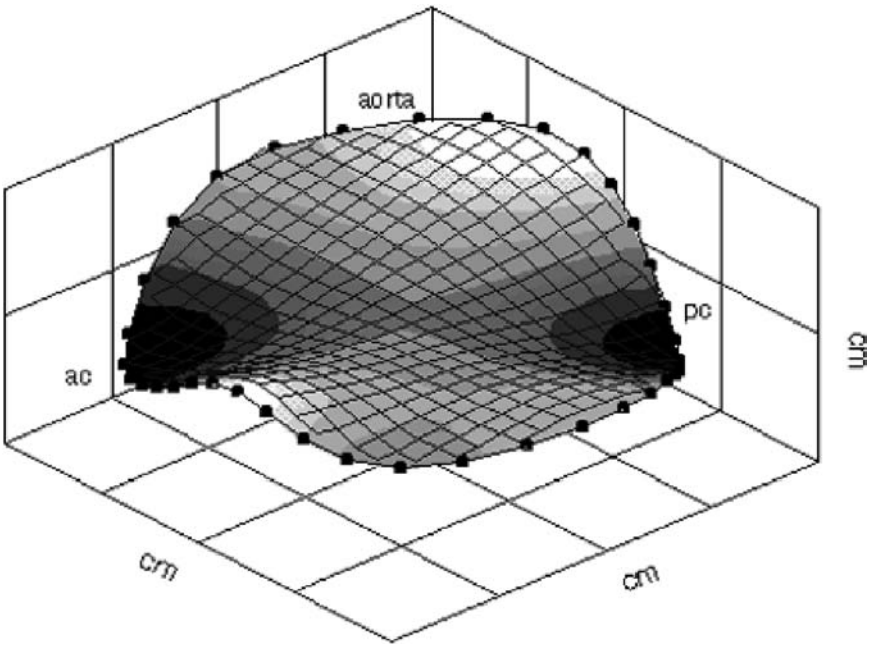

Figure 30-2. Image of a human mitral annulus obtained using three-dimensional transesophageal echocardiography (TEE). The image is reconstructed from two-dimensional images sampled every 10 degrees using a rotational omniprobe gated for heart rate and respiration. The annulus is viewed from posterior annulus (*near*) to aorta (*far*). The pronounced saddle shape of the human mitral annulus is well demonstrated.

Flow through the mitral valve briefly reverses as the leaflets coapt and bulge toward the atrium.[23]

During systole, the left atrium fills rapidly[22] and reaches maximum near ES. The position of the *annulus* ascends (away from the apex) slightly during atrial contraction,[22,24,25] which occurs during late diastole, does not change during IVC, and descends progressively 1 to 1.5 cm toward the apex throughout systole.[22,25,26] The annulus contracts asymmetrically[26,27] during atrial and ventricular systole and in humans reaches a minimal area (mean reduction of 27%) in midsystole.[28] Immediately after atrial contraction, the mitral *leaflets* approach each other and close within 20 to 60 ms after pressure crossover when LVP exceeds left atrial (LA) pressure.[22] Since the total area of leaflet tissue is approximately twice the total area of the annulus,[29,30] the apposition point of the two leaflets at the time of pressure crossover is very near the plane of the annulus.[31,32] At closure, approximately 30% of the anterior cusp and 50% of the longer posterior cusp are in apposition.[31] *Chordae tendineae* attached to the free edges and body of the leaflets[31] restrict the upward movement of the slightly compliant leaflets and produce a tight seal along the line of apposition.[31] Chordal tension peaks in early systole and begins to fall slowly in late systole and rapidly during IVR.[33] *Papillary muscles* begin to shorten during late IVC and throughout systole in synchrony with shortening of the adjacent ventricular wall.[34] The actual distance the papillary muscles shorten is small and ranges between 2 and 4 mm.[35,36] During systole, the directions and timing of *left ventricular* contraction are not necessarily uniform throughout because of the complex anatomic arrangement of muscle bundles[37,38] and the timing produced by the impulse-conduction pattern.[39] Left ventricular shortening is greater in both equatorial axes than in the long axis.[39] Left ventricular wall thickness increases during IVC and decreases rapidly during IVR.[40] Peak wall thickness occurs near ES, but timing of the exact peak varies slightly between ventricular wall segments. During systole, the ventricle twists counterclockwise progressively (as viewed from the apex) along its longitudinal axis to reach a maximum at ES.[41]

During IVR, the *left atrium* begins to empty when LA pressure crosses over and exceeds LVP.[22,23] The atrium empties rapidly in early diastole and diminishes further with atrial contraction in late diastole just before IVC.[42] The left ventricle actually may generate negative pressure in early diastole if LA pressures are low.[43] During IVR, the *mitral annulus* to left ventricular apex distance lengthens as the mitral annulus ascends in early diastole, descends slightly, and ascends again with atrial contraction.[22,27] The area of the mitral orifice increases slightly during IVR and continues to increase during diastole until it reaches a maximum just before the left atrium contracts.[27,28] In humans, the annular area index reaches a maximum of 3.9 ± 0.7 cm^2/m^2.[28] As the annular area increases, its shape changes asymmetrically; most of the area increase is due to lengthening in the posterior and lateral parts of the annulus (away from the fibrous trigone).[27] During IVR, the *mitral leaflets* separate approximately 30 ms before LA pressure exceeds LVP.[22] Peak blood flow through the valve occurs early in diastole, but the mitral leaflets reach their maximal open position *before* peak flow occurs and begin closing while flow is still accelerating.[44]

The *papillary muscles* may shorten very slightly during early IVR[21,34,36,45] but do not begin to lengthen until the beginning of diastole. Papillary muscles reach maximum length shortly after ED during IVC. *Chordal tension* decreases rapidly during IVR and remains near zero until late diastole, when a small increase occurs.[33,44] The *left ventricle* relaxes and dilates after ES and reverses the complex

deformations of left ventricular shape produced by systole. During early diastole and the period of rapid filling, the ventricle dilates primarily along both equatorial axes and much less along the longitudinal base-to-apex axis.[39] Only a little shape change occurs in middiastole and after atrial contraction. Ventricular wall thickness decreases[40] primarily during IVR. Lastly, the ventricle untwists rapidly (rotating clockwise) during early diastole and more gradually during middle and late diastole.[41]

Mechanism of IMR

Acute IMR

Papillary muscle rupture is a rare complication, occurring in 1 to 5% of patients who die after MI.[46] The rupture involves the posteromedial papillary muscle in approximately two-thirds of acute, severe IMR.[15,46–48] This is due to the fact that the vascular supply to the posteromedial papillary muscle depends on one coronary artery (the right coronary artery, or the circumflex artery in a left-dominant system), whereas the anterolateral papillary muscle receives dual supply from the left anterior descending and circumflex arteries.[49] Papillary muscle rupture results in prolapse of the mitral leaflets, often causing severe acute IMR and hemodynamic instability. Acute MR in this setting carries a poor prognosis with high mortality rate.[46,47,50–52]

However, acute IMR often occurs with subtle changes in the mitral valve apparatus in the absence of leaflet prolapse. Annular dilatation traditionally has been regarded as the mechanism of acute IMR. Laboratory work involving an ovine model from the Stanford group has demonstrated the importance of the septolateral (SL) dimension of the mitral annulus in the pathophysiology of IMR.[53–55] The SL dimension, the vertical distance of the mitral annulus from the middle of the anterior annulus to the middle of the posterior annulus, is referred to clinically as the *anteroposterior* (AP) dimension. Timek and colleagues demonstrated that correcting SL distance alone may abolish acute IMR.[54]

However, other experimental studies have demonstrated subvalvular geometric changes as an important contributor to the pathophysiology of acute IMR. With ischemia or infarction, the posterior papillary muscle elongates 2 to 4 mm in the sheep and dog[34,36]; the tip moves 1.5 to 3 mm closer to the annulus.[36,56] In the sheep model of acute IMR, the uninfarcted anterior papillary muscle contracts earlier and more vigorously than before infarction. This moves the tip 4 to 5 mm further away from the annular plane at midsystole than before infarction.[57] The Stanford group has meticulously characterized this discoordination of normal synchronous papillary muscle contraction and its complex effect on leaflet coaptation.[58,59] More recently, Tibayan and colleagues demonstrated that by using mitral suture annuloplasty (Paneth type), altered annular and subvalvular geometry can be corrected, and acute IMR is abolished.[60] Neilsen and colleagues in a pig model of acute IMR demonstrated that imbalanced chordal force distribution is directly related to the development of acute IMR.[61] The authors showed a decrease in tension of the primary chorda from the ischemic posterior left ventricular wall to the anterior leaflet, whereas the tension of the chorda from the nonischemic anterior left ventricular wall to the anterior leaflet increased.

These data suggested that acute IMR is a result of complex interaction of small changes in the mitral valvular complex and not merely simple annular dilatation, as believed previously.[57,62,63] These small changes are difficult to demonstrate by standard imaging technique, making repair challenging in this acute setting. In addition, recent finite-element analysis of the mitral annulus has suggested an association between the normal annular saddle shape of the mitral valve and its competency.[64] Current repair techniques use ring annuloplasty that is essentially flat. Future investigation and more thorough understanding of the mitral apparatus will be needed to improve the results of mitral valve repair.

Chronic IMR

In chronic IMR, mitral valve prolapse has been described[65] in occasional patients, but the vast majority have incomplete mitral valve closure owing to the effect of left ventricular remodeling. Remodeling often manifests as annular dilatation with papillary muscle and chordal restriction of leaflet motion.[65–70,71] Pathologic studies consistently show fibrosis and atrophy of infarcted papillary muscles,[3,15,29,72] and none demonstrate papillary muscle or chordal elongation. Nevertheless, surgeons describe elongated chordae in some patients with MI and MR.[5,73,74] Elongated chordae and mitral valve prolapse without MR probably antedate the infarction in these patients.[75,76] In a patient with pre-existing mitral valve prolapse, ventricular infarction may cause the previously competent valve to leak. This hypothesis explains sporadic observations of mitral valve prolapse in patients with chronic IMR but needs preinfarction echocardiograms for confirmation.

Ovine experiments using sonomicrometry array localization to study postinfarction MR that evolves during the first 8 weeks after MI have added insight relevant to the pathogenesis of chronic IMR. As a result of ischemic left ventricular remodeling, a combination of asymmetric annular dilatation and leaflet tethering by *both* papillary muscles occurs to alter the normal saddle shape of the annulus and produce chronic IMR.[77] Previously thought to be fixed, the anterior portion of the annulus does dilate.[78] The intertrigonal distance has been shown to increase, in addition to the increase in the SL dimension.[79] The annular area dilates by at least 60% at all time points during systolic ejection, but the dilatation involves all the muscular annulus. The posterior or mural portion of the annulus directly adjacent to the infarct moves away from the relatively fixed anterior commissure (at the anterior fibrous trigone) and stretches the anterior portion of the mural annulus and the posterior portion of the aortic-based annulus, which are remote from the infarct. This finding illustrates how a moderately sized (21% of the left ventricular mass) localized infarct remodels and distorts remote, uninfarcted myocardium, including the mitral valve annulus[80] (Fig. 30-3A).

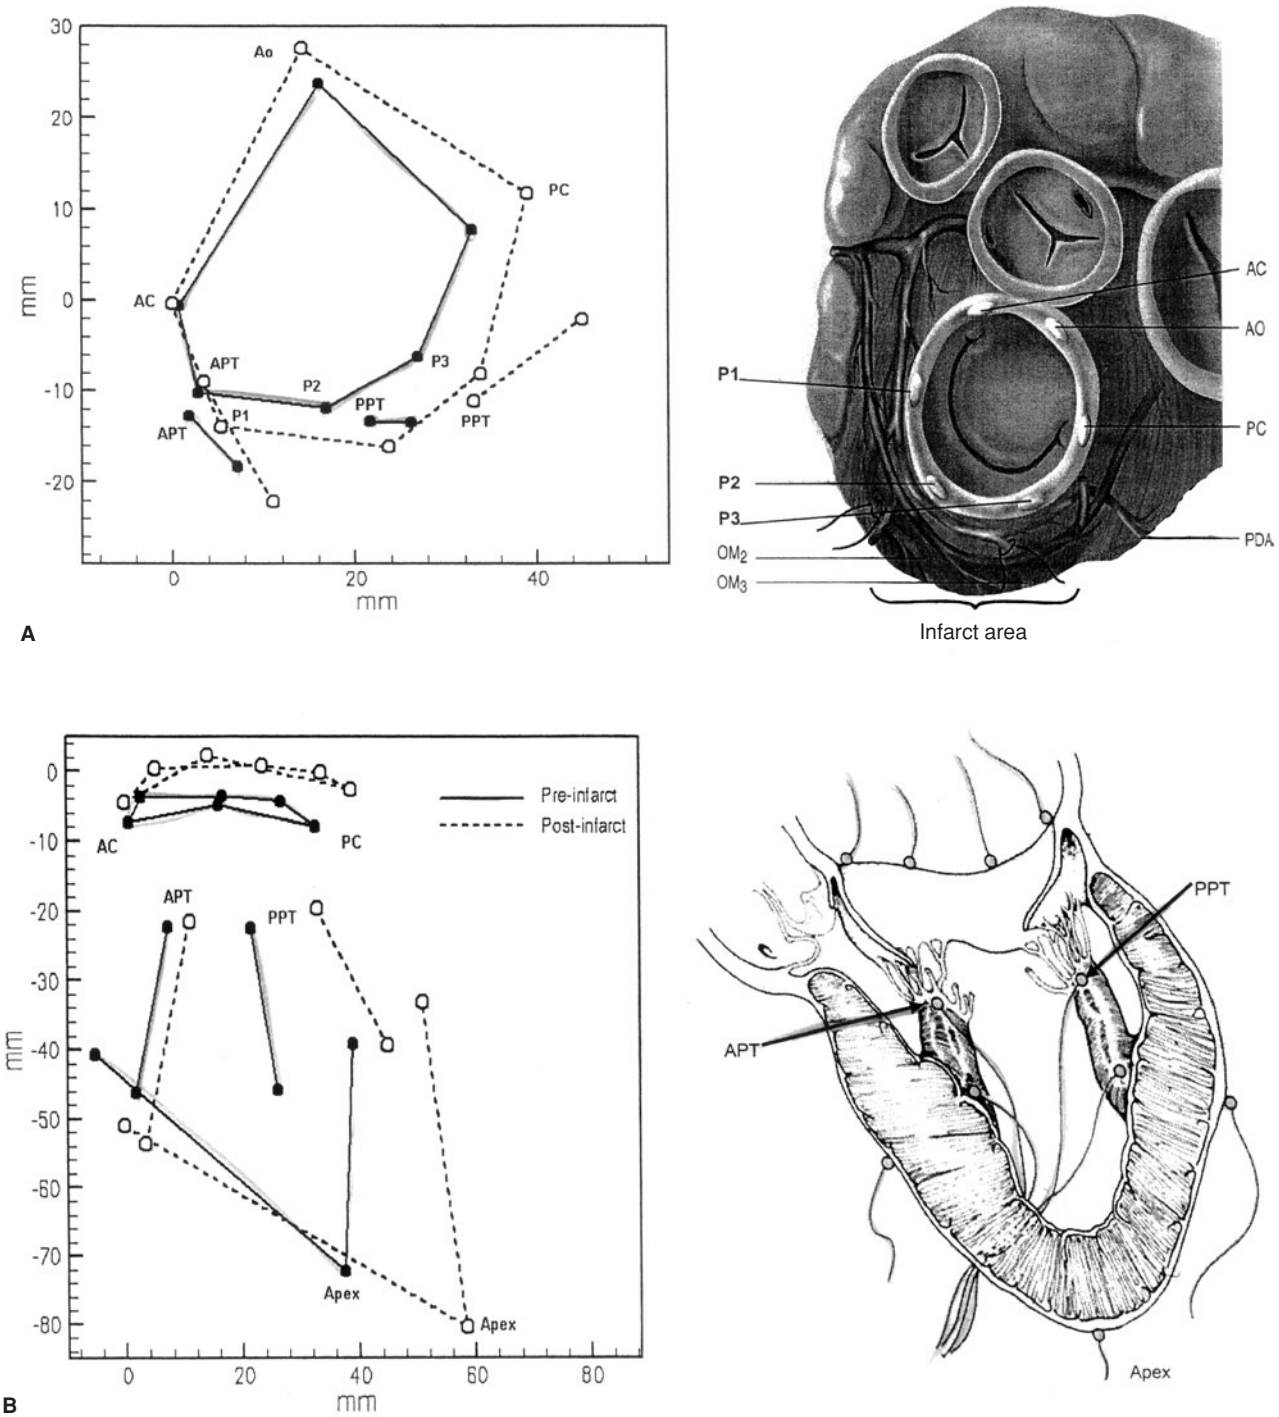

Figure 30-3. (*A*) (*Left*) Two-dimensional axial view of the mitral valve annulus and papillary muscle transducers before (*solid line*) and 8 weeks after (*dashed line*) infarction. (*Right*) An artist's drawing of how the transducers are placed in relation to the mitral annulus and the location of the infarct. Note the stretching of both the posterior part of the aortic portion of the annulus (Ao to PC) and the anterior part of the mural portion of the annulus (Ao to P1 to P2). Also note how the portion of the annulus between P2 and PC along with the posterior papillary muscle tip (PPT) pulls away from the relatively fixed anterior commissure. (*B*) (*Left*) Two-dimensional sagittal view of the sheep mitral annulus and its relationship to the left ventricle and papillary muscles before and 8 weeks after infarction. (*Right*) An artist's drawing is provided for orientation of the sonomicrometry transducers. Note how the PPT and the posterior annulus are retracted away form the anterior commissure. The heart shown in this figure is the same one shown in Fig. 30-2. (*Used with permission from Gorman JH III, Gorman RC, Jackson BM, et al: Annuloplasty ring selection for chronic ischemic mitral regurgitation: Lessons from the ovine model. Ann Thorac Surg 2003; 76:1556.*)

Lateral displacement of the posterior papillary muscle appears to play a major role in the development of chronic IMR.[79] Interestingly, the posterior papillary muscle tip to posterior commissure relationship does not change significantly. Both these points are displaced *together,* away from the relatively fixed anterior commissure as a result of the remodeling process (see Fig. 30-3*B*). This indicates that posterior papillary muscle tethering is more pronounced at its most anterior connection with both leaflets near the center of the coaptation line and not at the commissure. The anterior papillary muscle tip is displaced significantly from both commissures but further from the posterior commissure. This indicates the tethering effect of the anterior papillary muscle is greatest along both leaflets from the anterior commissure to the middle of the coaptation line. Together these findings suggest that in this model the postinfarction ventricular remodeling process tethers the anterior portion of both leaflets.

The concept of leaflet tethering as a contributing factor in the pathogenesis of chronic IMR is not new.[70,81,82] Two recent echocardiographic reports, one studying the same sheep model presented here and one human study, demonstrated findings consistent with the experimental results cited earlier. Otsuji and colleagues applied a very effective three-dimensional echocardiographic technique to quantify leaflet tethering in the same ovine model.[81] These authors also reported midsystolic distortions between both papillary muscle tips and the anterior commissure but did not observe changes between papillary muscle tips and the posterior commissure or annular dilatation. Yiu and colleagues used quantitative two-dimensional echocardiography to corroborate these findings clinically by comparing normal control individuals with a cohort of patients with varying degrees of chronic IMR.[70] They found that ventricular distortions, which most closely correlated with the degree of MR, occurred between the posterior papillary muscle tip and the anterior commissure ($R = 0.55$) and posterior displacement of the anterior papillary muscle tip ($R = 0.65$).

To summarize, the geometric changes that lead to acute IMR are multiple but extremely subtle (<5 mm) and are not reliably imaged by currently available clinical imaging modalities. Chronic IMR involves larger changes (1 to 2 cm) that cause moderate annular dilatation and complex leaflet tethering along the anterior and midleaflet coaptation line. It is a process resulting from complex geometric alteration of the mitral valve apparatus as a result of ischemic left ventricular remodeling.

CLINICAL PRESENTATION AND MANAGEMENT

Acute IMR

Clinical presentation

Clinically, acute IMR usually presents abruptly with chest pain and/or shortness of breath. The presentation is that of an AMI and occasionally may be silent.[46,47,51] These patients often are hemodynamically unstable and in cardiogenic shock. They often are in extremis with symptoms of CHF. These symptoms including pulmonary edema, systemic hypotension, and oliguria, acidosis, and poor periperhal perfusion. On physical examination, most patients will have a loud apical holosystolic murmur that radiates to the left axilla.

Nearly all electrocardiograms (ECGs) are abnormal,[46,47,51] but only slightly more than half are diagnostic of AMI. Some of the nondiagnostic changes include right or left bundle-branch block and nonspecific ST- and T-wave changes in the anteroseptal, lateral, or inferior leads.[46,47,50,51] Most patients are in sinus rhythm.[51,83] In autopsy series, the incidence of subendocardial infarctions is approximately equal to the incidence of transmural infarctions.[46,47] Frequently patients with ruptured papillary muscle have electrocardiographic evidence of an inferior infarction. When the ECG is diagnostic, inferior wall infarctions are much more common than anterior and lateral wall infarctions. Conduction abnormalities are relatively uncommon and are found more often in patients with postinfarction ventricular septal defects.[84]

Chest x-rays nearly always show signs of pulmonary congestion, interstitial pulmonary edema, and pulmonary venous engorgement.[51] Cardiomegaly usually is not present, and there usually are no signs of LA enlargement.[46]

The differential diagnosis includes postinfarction ventricular septal defect, massive AMI without significant MR, and ruptured chordae tendineae without AMI. Right-sided heart catheterization usually shows elevated pulmonary arterial pressures with prominent *v* waves reaching 40 mm Hg or higher.[51,85] Mean pulmonary artery wedge pressures are greater than 20 mm Hg unless cardiac output is very low. Mixed venous oxygen saturations often are well below 50% and reflect low cardiac output, with indices that range from 1.0 to 2.9 L/m^2 per minute.[85] In the presence of a loud systolic murmur, absence of an oxygen stepup in the pulmonary artery is strong evidence against the diagnosis of postinfarction ventricular septal defect. Electrocardiographic evidence of AMI distinguishes acute IMR from acute chordal rupture, but in some instances the two diseases cannot be distinguished until after operation or death.[51]

Transthoracic echocardiography (TTE) assesses the degree of MR, confirms wall motion abnormalities, and may demonstrate flail mitral leaflets. Transesophageal echocardiography (TEE) is the diagnostic imaging tool of choice. This modality definitively documents the degree and characteristics of the MR jet, associated wall motion abnormalities, and the status of the posterior papillary muscle.[86,87] The information provided by TEE is vital in the decision to repair versus replace the mitral valve. Typically, the left atrium is not enlarged, but the left ventricle shows signs of volume overload and segmental wall motion abnormalities. Color-flow Doppler velocity mapping documents the presence of MR after MI[88] and semiquantitates its severity.[89] Ejection fractions vary widely but do not reflect the extent of the left ventricular infarction.

Despite hemodynamic instability, most patients have a diagnostic cardiac catheterization primarily for definition of coronary arterial anatomy; however, the wisdom of prescribing cardiac catheterization for patients in cardiogenic shock is highly questionable in that revascularization of obstructed, remote coronary vessels is not likely to improve a patient's chances for immediate survival.[93] Approximately half of catheterized patients have single-vessel disease, most often of the right coronary artery.[51,85] Most of the remainder have three-vessel disease.[46,47,50,51] Ventriculography shows increased left ventricular volume at both end-diastole and end-systole, severe MR, segmental wall motion abnormalities,[90] and a wide range of ejection fractions, which are generally over 40% and frequently over 60%.[50,85] Left ventricular end-diastolic pressures are elevated with prominent left atrial *v* waves and moderate pulmonary hypertension. Occasional patients have mild or moderate tricuspid regurgitation. Cardiac output usually is low.

Indications for surgery

Prompt surgery is the best chance for survival for most patients with acute, severe postinfarction MR. The goal of medical therapy is to stabilize the patient and to optimize circulatory status in preparation for surgical intervention. A few highly selected patients without papillary muscle rupture early in their presentation have been treated by emergency percutaneous transluminal coronary angioplasty (PTCA) and/or thrombolytic therapy in an attempt to reduce the size of the infarct and thereby reduce MR.[4,65,91,92] PTCA or thrombolysis carried out within 4 hours of the onset of AMI on occasion may produce spectacular reversal of both the infarction and MR.[65,91,92] However, less rapid PTCA may not succeed in pre-empting the infarct and aborting MR.[92] PTCA and thrombolysis in catheterized patients are potentially worth trying if patients reach medical attention soon after the onset of symptoms, are sufficiently stable, and can be followed by echocardiography. However, in many patients, PTCA and thrombolysis do not provide a favorable outcome.[4] In one study, 17% of patients with acute IMR and successful thrombolysis died in the hospital; in those with successful PTCA, 50% died shortly afterward, and 77% were dead in 1 year.[4] Of the survivors, the majority continue to have 3+ or 4+ MR.[4]

For patients who have acute postinfarction angina with 1+ or 2+ MR, urgent myocardial revascularization is indicated to relieve angina and to prevent extension of the infarction. It is important to prevent progression of MR and the development of CHF or cardiogenic shock. This usually is accomplished by thrombolysis, PTCA, or an intracoronary arterial stent. If these measures are unsuccessful, operation is rarely completed in time to reverse the infarction, but early operation may reduce the size of the ultimate infarct.[93–95] The presence of mild to moderate IMR does not increase operative mortality,[96–98] but the presence of CHF is a risk factor.[99] In these patients, the mitral valve generally is not addressed unless intraoperative TEE indicates 3+ or 4+ MR.

Indications for emergency surgery for acute, severe postinfarction MR vary among institutions[4,48,51,52,85,100,101] and probably explain wide discrepancies in reports of hospital mortality.[100,102] In this group of patients, medical therapy does not produce survivors,[50,51] and patients denied operation are not reported.[51] Aged patients are less likely to survive operation,[65,102] and there are only anecdotal reports of successful operation in octogenarians.[103] Other risk factors for hospital death are severe CHF, the number and severity of comorbid diseases such as renal or pulmonary problems, presence of an intra-aortic balloon pump, reduced ejection fraction, and greater number of diseased coronary arteries.[66] Contemporary concerns regarding costs and longevity beyond immediate hospital survival also influence indications for operation and reported mortality.

Operation for acute, severe postinfarction MR consists of mitral valve repair or replacement with or without myocardial revascularization. Nearly all surgeons recommend revascularization of all significantly obstructed coronary vessels away from the site of the infarction.[100] Improved methods of cardioplegia and the open-artery hypothesis support this recommendation even in patients with preoperative cardiogenic shock who have had cardiac catheterization. The wisdom of blind revascularization of remote coronary vessels in patients who have not had preoperative cardiac catheterization and revascularization of the infarct artery more than 4 to 6 hours after onset of pain is less clear.[48] On a statistical basis, only half of patients with acute IMR have multivessel coronary artery disease.[46,51,85] Revascularization of completed infarctions favorably influences subsequent ventricular remodeling.[94–96]

With echocardiographic findings amendable to repair, most surgeons will consider mitral valve repair in the acute setting. Echocardiographic findings favorable to repair include a simple, central regurgitant jet, minimally tethered leaflets, and no papillary muscle pathology such as rupture. However, replacement of the diseased valve should be considered if the effectiveness and durability of the repair are in question. These patients often are critically ill[6] and will not tolerate mitral valve replacement after failed mitral repair. When performing mitral valve replacement, it is important to preserve the chordal attachments to the annulus (Fig. 30-4). The prosthetic valve is sutured to the annulus with running or interrupted sutures. A bioprosthestic valve is a reasonable choice because anticoagulation is not benign and durability is relatively a minor concern in these patients with poor long-term prognosis.[5,6]

Results

Published results of mitral valve replacement for acute IMR are poor.[48,51,52,85,100,102,104] Hospital mortality ranges from 31 to 69% and probably reflects the selection process more than the quality of care. Variables that increase early mortality include patient age, cardiogenic shock, comorbid conditions, the amount of infarcted myocardium, and delay in operation.[50,51,85,102] More recent experience may be better[5,6,105] because of prompt diagnosis, early surgery, complete

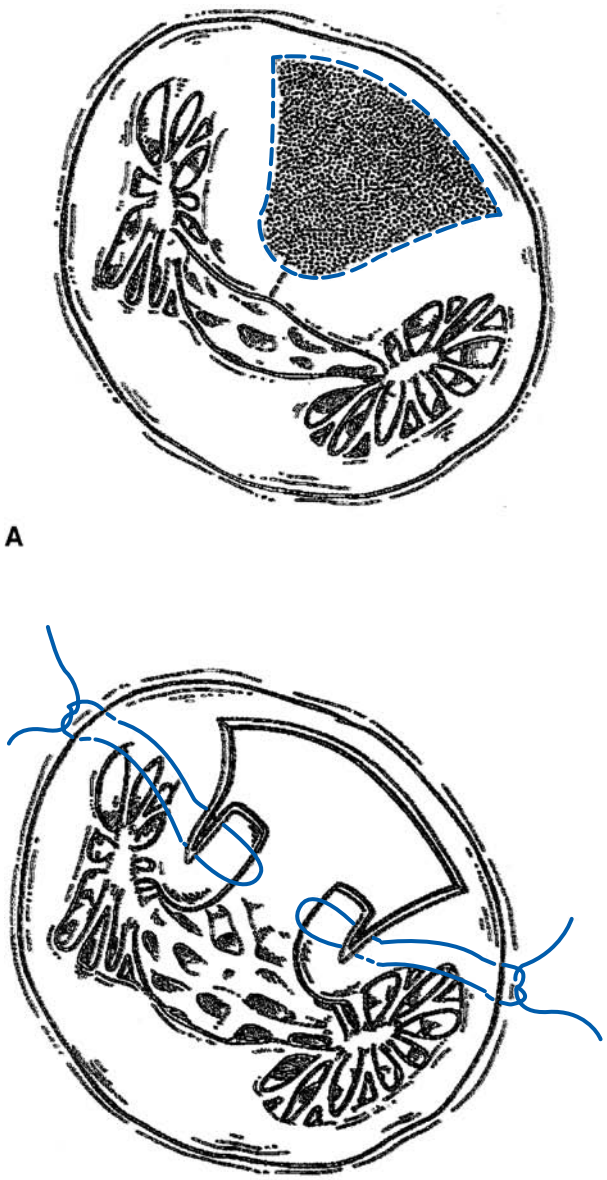

Figure 30-4. Okita's method for retaining chordal attachment to the mitral annulus during replacement of the mitral valve. (A) Diagram showing the mitral valve from the left atrium. The center of the anterior leaflet is excised (*shaded area*), and the leaflet is divided, retaining the chordae from each papillary muscle attached to the residual anterior leaflet tissue. The posterior leaflet may be divided at its midpoint if necessary. (B) Remnants of the anterior leaflets are sutured to the annulus using a single stitch as shown. This tissue is later included in sutures used in sewing the valve to the annulus. (*Modified slightly with permission from Okita Y, Miki S, Kusuhara K, et al: Analysis of left ventricular motion after mitral valve replacement with a technique of preservation of all chordae tendineae. J Thorac Cardiovasc Surg 1992; 104:786.*)

revascularization, and application of chordal preservation techniques that better preserve left ventricular function.[106–110] Several techniques are available for preserving chordae[106,111,112] (see Fig. 30-4). David reported a hospital mortality of 22% in 18 patients using chordal preservation techniques.[105]

Many surgeons do not recommend mitral valve repair for acute IMR,[6,48,51,101,105] but others do.[5,66,111,113] Repair of the valve in acute IMR poses difficult problems. As demonstrated earlier, the anatomic derangements may be very subtle. A reasonable repair option therefore is undersized ring annuloplasty. In cases of papillary muscle rupture, successful reimplantation in conjunction with ring annuloplasty has been reported, but these patients are uncommon and usually much less ill.[5] Intraoperative TEE and color-flow Doppler velocity mapping are essential adjuncts to operation to assess the quality of the repair.[86,87] Long-term (5-year) survival in patients who survive the perioperative period is poor and even in modern reports hovers around 50%.[5,6] Even with the poor prognosis, we believe that mitral valve ring annuloplasty is a reasonable option for pathology amendable to repair.

Chronic IMR

Clinical presentation

Chronic IMR represents the majority of patients with IMR. Between 10.9% and 19.0% of patients with symptomatic CAD who have cardiac catheterization[17,18] and 3.5 to 7.0% of patients who have myocardial revascularization have IMR.[114–117] Most of these patients have 1+ or 2+ MR without heart failure.[17,18,114–116] In patients with chronic IMR, three major variables interrelate to produce the clinical spectrum of patients with varying combinations of symptomatic ischemia and heart failure. As with acute IMR, the three variables are (1) the presence and severity of ischemia, (2) the severity of MR, and (3) the magnitude of left ventricular dysfunction. Patients with obstructive CAD may have no symptoms or have stable, progressive, unstable, or postinfarction angina or its equivalent. Because of disabling symptoms, threat to left ventricular mass, or statistically shortened survival, ischemia is a compelling problem that must be addressed therapeutically. The approach and methods do not differ materially from those for similar patients who do not have IMR. The second variable is the severity of MR. At present, 1+ or 2+ MR in patients without symptoms of heart failure does not compel invasive therapy for MR. More severe MR and/or symptoms of heart failure require evaluation for possible operation irrespective of the therapy needed for ischemia. The third variable is the degree of left ventricular dysfunction, and this is the most difficult to assess in the presence of MR. Symptoms of heart failure may be due to left ventricular dysfunction secondary to ischemia, MR, or both.

The primary purpose of diagnostic studies is to determine the severity of CAD and its anatomy, the severity and mechanism of MR, and the degree of left ventricular dysfunction. In chronic IMR, the ventricular geometry and function reflect remodeling owing to both the MR and the infarction; therefore, these patients may require diagnostic studies and perhaps operative procedures that are different from those for patients with CAD *associated* with MR. It is also important to define comorbidity of other organ

systems by appropriate diagnostic studies dictated by the patient's history, physical examination, and screening laboratory findings.

In patients with IMR, the ECG usually shows evidence of a prior MI.[115,116,118,119] The incidence of arrhythmias varies, but atrial fibrillation, as noted earlier, is quite common. In patients without heart failure and with mild MR, heart size by chest x-ray is normal or slightly enlarged; the left atrium is seldom enlarged. In those with moderate or severe MR and/or severe left ventricular dysfunction, the heart is enlarged, and usually the left atrium is also enlarged.[120]

TTE and TEE are useful in determining the etiology of MR. Two-dimensional echocardiography reliably detects ruptured chordae, annular calcification, and myxomatous degeneration, which are not features of chronic IMR, and differentiates rheumatic valve disease, endocarditis, and congenital deformities. Echocardiography also effectively assesses regional wall motion abnormalities and global left ventricular function. The degree of MR is also well quantified by color-flow Doppler measurements. Characteristics of the MR demonstrated by TEE also will aid in the decision to repair or replacement the mitral valve. An extremely dilated annulus and severe bileaflet tethering and an eccentric or complex regurgitation jet are echocardiographic indications that repair may not be effective or durable.

Cardiac catheterization provides information regarding the coronary arterial anatomy and pathology. Ventriculograms add little to the data provided by TTE or TEE and should be avoided, especially in patients with impaired renal function. Measurements of chamber pressures and estimates of cardiac output contribute to the overall evaluation of left ventricular function. Pulmonary hypertension, when present, typically is moderate and correlates with the degree of left ventricular dysfunction and/or severity of MR.

Indications for surgery

The decision to intervene surgically in IMR can be a challenging process. Chronic IMR represents a set of patients with symptoms of insidious onset and often of chronic duration. Patients may present primarily with symptoms of ischemic CAD and on preoperative workup are found to have significant MR. Although this group of patients may have preserved left ventricular function, compromised ventricular function is not uncommon. The indication to the operating room in this group of patients is CAD not amenable to interventional cardiology. However, intervention on the MR must be considered. Important factors to consider in the decision to intervene on the MR include the following: the impact of coronary artery bypass grafting (CABG) alone on the progression of IMR, the impact of CABG with or without mitral valve repair (MVR) on survival, the additional risk of MVR at the time of CABG, and the choice of valve repair or replacement.

Other patients may present primarily with symptoms of CHF and signs of significant MR. Preoperative catheterization subsequently may reveal significant CAD. These patients tend to have more compromised left ventricular function compared with the first group. The indication for surgery is CHF. In reality, most patients present in a clinical spectrum somewhere along the two clinical scenerios. In this section, however, the indications for surgery of each scenerio will be discussed separately.

IMR AND CAD: In the setting of CABG today, most surgeons agree that concomitant moderate to severe (3 to 4+) MR should be addressed at the time of CABG and that revascularization alone will not ameliorate MR. On the other hand, most surgeons agree that trace to mild (1+) MR should be left alone. The optimal management of mild to moderate (2+) MR remains controversial. Those who advocate the conservative approach of revascularization alone point out that revascularization will improve regional wall motion abnormality and potentially correct IMR.[114,121,122] They also point out that there are data to suggest that survival is not prolonged with MVR[123,124] and thus question subjecting the patient to higher operative risks. Those who advocate an aggressive approach to address the mitral valve point out that studies have suggested that revascularization does not correct IMR[125] and that uncorrected IMR may result in late symptoms and decreased long-term survival.[126] Furthermore, MVR with ring annuloplasty is nearly always technically feasible, obviating the need for replacement. Operative risk with combined CABG/MVR today is much better than the older series previously published, closer to an operative mortality of 3 to 4%.[127–129] Considering the possibility of redo sternotomy with patent grafts for MVR for recurrent IMR, some feel that aggressive management of IMR is justified.

Multiple factors are involved in the decision to address the IMR at the time of CABG. IMR portrays a negative impact on long-term survival. Studies have documented the negative impact of IMR on survival after AMI.[121,130–132] After percutaneous coronary intervention (PCI), IMR was demonstrated to have similar impact on survival. Three-year survival ranged from 46 to 76%, based on the severity of MR, suggesting that the concomitant IMR should be addressed to affect survival.[133] In the setting of CABG, myocardial revascularization alone in patients with chronic IMR has a higher hospital mortality than in patients without IMR.[117] Mild (1+) IMR increases operative mortality to 3.4 to 4.5%,[115–117,134] and moderate (2+) IMR raises operative mortality to 6 to 11%.[115–117,135] Five-year survival is influenced by the severity of left ventricular dysfunction at the time of operation, age, and comorbid disease.[66] Two-year survival for revascularization alone in patients with 1+ and 2+ MR is 88% and 78%, respectively.[126] Five-year survival rates for patients with mild MR range between 70% and 80%.[17,115,118,136] For moderate MR, 5-year survival ranges between 60% and 70%.[137,138]

The impact of CABG alone on the progression of IMR has been examined. Previous data have suggested that CABG alone improves IMR and functional status.[114,121,122] More recent reports have suggested that CABG alone is not the optimal therapy for moderate IMR.[125,139,140] A study published

recently from the Cleveland Clinic Foundation reported that moderate (2+) IMR does not resolve with CABG alone and furthermore is associated with reduced survival.[141] The study suggested that a mitral valve procedure is warranted for such patients presenting for CABG. Between 1980 and 2000, 467 patients with moderate IMR underwent CABG alone. Longitudinal analysis of 267 follow-up echocardiograms from 156 patients demonstrated that early postoperative improvements in IMR did not persist. IMR of moderate or greater severity is present in 60% of patients by postoperative week 6. Interestingly, the risk of postoperative IMR severity was not predicted by cardiac function or extent of CAD. Furthermore, early survival of patients with unrepaired moderate IMR is reduced compared with similar patients without IMR. Campwala and colleagues recently reported their experience with MR progression following isolated CABG surgery.[142] A retrospective review of their registry examined 438 patients with preoperative MR of 2+ or less requiring CABG. New 3 to 4+ MR developed in 10% of patients with no prior MR, 12% with pre-CABG 1+ MR, and 25% with pre-CABG 2+ MR. Preoperative left ventricular dysfunction and large left ventricular size were identified as predictors of MR progression after CABG. Although no correlation was identified between the extent of CAD or the number of grafts performed, incomplete revascularization in the posterior descending artery territory was identified as a significant predictor of MR progression, suggesting a role for incomplete revascularization and left ventricular remodeling in the progression of IMR.

Previous studies have compared the results of CABG alone versus CABG with concomitant MVR in the setting of IMR.[132,143–147] The data suggested that postoperative MR is improved with CABG with concomitant MVR. However, improvement in long-term survival remains controversial. While some studies suggested no improvement in long-term survival with concomitant MVR,[144,146–148] two studies[132,143] comparing CABG versus CABG + MVR in patients with CAD and IMR suggested a significant improvement in survival. Both studies involved patients with 2 to 3+ IMR with depressed left ventricular ejection fraction. A recent study[145] examined 111 patients with moderate to severe IMR and multivessel CAD undergoing either medical therapy, CABG alone, or CABG + MVR. After adjusting for baseline differences, CABG alone and CABG + MVR had a significant risk reduction (>50%) of cardiac death when compared with medical therapy. However, only CABG + MVR independently predicted survival. In addition, history of CHF was an independent predictor of cardiac death. These studies suggested that concomitant MVR with CABG may improve late survival, especially in patients with CHF.

The final factor to consider is the decision to repair or replace the valve. Gillinov's report demonstrated that MVR is effective (at least in the short term) in 97% of patients undergoing elective surgery for 3+ to 4+ chronic IMR.[5] Ring annuloplasty was employed in 98% of these repairs and was the sole surgical maneuver on the valve in over 80%. There was a distinct inclination in this study to undersize the valvuloplasty ring; 79% of the rings were 30 mm or less. Iatrogenic mitral stenosis was not seen even in the patients who received 26-mm annuloplasty devices. However, the benefit of repair versus replacement appears to diminish with high-risk patients. Risk factors included older age, higher New York Heart Association (NYHA) functional class, greater wall motion abnormality, and renal dysfunction.

In summary, patients with CAD and concomitant moderate to severe (3 to 4+) IMR should undergo CABG + MVR. In patients with moderate (2+) IMR, recent studies suggest that an aggressive approach with CABG + MVR is justified, given the lower rate of morbidity and mortality in the current series. Patients with symptoms of CHF appear to benefit most from CABG + MVR. Left ventricular dysfunction and increased left ventricular dimension, along with incomplete revascularization, may predict a higher rate of progression of IMR, suggesting that CABG + MVR should be performed in this particular group of patients. Mild (1+) IMR should be left alone unless (1) preoperative signs and symptoms are suggestive of periods of more severe MR, and (2) intraoperative TEE demonstrates anatomic findings requiring MVR (i.e., significant annular dilatation and leaflet tenting). Most patients with IMR benefit from MVR. In the most complex, high-risk settings, replacement may be preferable, with no demonstrable difference in survival between repair and replacement.

IMR AND CHF: Patients who present primarily with symptoms of CHF and IMR provide surgeons with a fairly straightforward indication for intervention. Preoperative coronary angiogram may demonstrate significant CAD. With the history and/or evidence of prior MI in the presence of left ventricular dysfunction, these patients' clinical scenarios are considered to be consistent with chronic IMR. The indication for the operating room in this group of patients is similar to MR of nonischemic origin. Symptoms of CHF and depressed left ventricular function are indications for surgical repair or replacement, although there are no randomized data to suggest better symptomatic relief and improved survival with surgery. Most surgeons agree that concomitant CABG is indicated in the presence of significant CAD.

In the past, high perioperative morbidity and mortality had made surgeons cautious regarding MVR and MVR + CABG in the setting of left ventricular dysfunction. In the so-called pop-off valve hypothesis, MR associated with left ventricular dysfunction was believed to provide a low-pressure runoff. Surgeons were concerned that correction of the MR might increase ventricular afterload in an already compromised left ventricle. However, this hypothesis has been challenged.[149–152] With so-called reverse remodeling, correction of MR would alleviate excessive ventricular workload and stop the geometric changes of the ventricle associated with heart failure. The Stanford group has reported in an ischemic sheep model of MR that reduction of the annulus by an annuloplasty ring reduces the radius of curvature of the left ventricle at the base, equatorial, and apical levels.[153] This

decrease in the radius of curvature supports the concept that a small ring can restore a more elliptical shape. Reduction of left ventricular dimensions to a more elliptical shape, so-called reverse remodeling, after annuloplasty also has been demonstrated by others in clinical studies.[154–156]

More recent series indeed have demonstrated much lower perioperative morbidity and mortality with mitral valve surgery in the setting of left ventricular dysfunction.[5,6,157,158] Data from most recently published series[124,132,149,150,159–161] demonstrate improvement in left ventricular ejection fraction, MR, and symptoms (NYHA classification) with surgical intervention. However, questions remain regarding improvement in long-term survival and its overall effect on the natural history of IMR. Some have raised questions recently despite previous data about the potential improvement in long-term survival in patients with IMR in the setting of depressed left ventricular ejection fraction.[132,143,145] Two recent studies confirm the dismal prognosis of IMR in end-stage cardiomyopathy.[123,124] In perhaps the largest experience of MVR in patients with severe left ventricular dysfunction, Wu and colleagues[123] examined the impact of mitral valve annuloplasty on mortality risk in patients with MR and left ventricular dysfunction. Reviewing their echocardiographic database ($n = 682$), the authors identified 419 patients who met criteria for surgical intervention: 126 patients underwent MVR, whereas 263 continued conservative medical therapy. The etiology of MR included both ischemic and nonischemic causes. The analysis demonstrated no improvement in long-term survival in the MVR group versus medical therapy. Talkwalkar and colleagues[124] reported a series of 338 patients who underwent MVR. Compared with the control group, depressed left ventricular ejection fraction was more likely to be associated with IMR, concomitant CABG, and NYHA class IV symptoms. Five-year survival was 54%, and when associated with prior CABG, prior MI, or concomitant CABG, it was 0%, 37%, and 63%, respectively.

In agreement with previous reports, these recent studies confirmed the poor prognosis associated with IMR. In Wu's series,[123] 5-year survival in the setting of IMR and left ventricular dysfunction was less than 50%, regardless of surgical versus medical therapy (Fig. 30-5). A randomized study comparing surgical versus medical therapy for IMR is needed to clarify the benefit of mitral valve surgery in this population of patients.

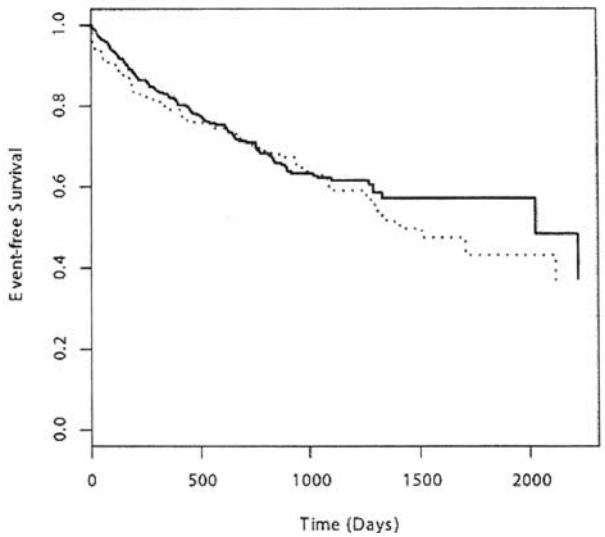

Figure 30-5. Survival in patients with mitral regurgitation and left ventricular dysfunction in the mitral valve annuloplasty group (*dotted line*) and the medical therapy group (*solid line*). (*Used with permission from Wu AH, Aaronson KD, Bolling SF, et al: Impact of mitral valve annuloplasty on mortality risk in patients with mitral regurgitation and left ventricular systolic dysfunction. J Am Coll Cardiol 2005; 45:381.*)

Results

An undersized annuloplasty ring is effective in the acute correction or reduction of IMR in the majority of patients. However, recurrent MR after annuloplasty is seen in 15 to 30% of patients.[162–164] The Cleveland Clinic reported its series of 585 patients who underwent annuloplasty alone for IMR between 1985 and 2002. A total of 678 postoperative echocardiograms were evaluated in 422 patients. The majority of recurrent IMR occurred within the first 6 months. Overall, 28% of patients 6 months after surgery demonstrated 3 to 4+ MR. The risk factors for recurrent IMR were higher grade of preoperative MR, complex regurgitant jet, and preoperative left ventricular dysfunction.[162]

Evidence of left ventricular reverse remodeling after ring annuloplasty has been demonstrated in small clinical studies with excellent results and freedom from recurrent IMR for up to 2 years.[154–156] Braun and colleagues reported a series of 87 patients with IMR and depressed left ventricular function (mean 32%) who underwent undersized mitral ring annuloplasty and coronary revascularization. MR grade decreased significantly from a mean of 3.1 to 0.6 at 18 months. Both left ventricular end-systolic and end-diastolic dimensions decreased significantly when compared with preoperative echocardiograms. Interestingly, left ventricular end-diastolic dimension was found to be the best predictor of reverse remodeling. Left ventricular end-diastolic dimension exceeding 65 mm was associated with a lower probability of reverse remodeling, suggesting a relationship between recurrent IMR and ventricular geometric dimension. Further studies would be useful to identify preoperative echocardiographic parameters predictive of durable MVR.

Operative results for mitral valve surgery with or without concomitant CABG have improved, with recent series reporting operative mortality of 3 to 4%.[5,6,127–129,157,158] However, 5-year survival remains between 30% and 40%.[17,73,115,116,118] More recently, Gillinov and colleagues reported 5-year survival in the propensity-matched best risk group of 58% for valve repair and 36% for replacement. This group had significantly fewer NYHA class IV patients and less severe MR preoperatively. In the propensity-matched poorer-risk groups (i.e., more severe CHF, MR, and emergency surgery), and for the group as a whole, there was no

difference between repair and replacement, and 5-year survival was uniformly less than 50%.[5]

There has been no randomized study demonstrating a survival benefit with mitral valve repair/replacement in IMR. In a retrospective analysis of cardiomyopathy including both ischemic and nonischemic etiology, Wu and colleagues reported 5-year survival of less than 50% regardless of surgical versus medical therapy in patients with MR and left ventricular dysfunction.[123] Other series also have demonstrated no survival benefit with mitral valve surgery in patients with IMR.[146–148] The similarity of results between surgical and medical therapy points out a need for better understanding of the pathophysiology of IMR and left ventricular remodeling. Furthermore, a randomized study examining the clinical outcome and survival benefit of mitral valve surgery for IMR is needed.

OPERATIVE TECHNIQUE

Operation for acute, severe postinfarction MR often is urgent or an emergency; a high percentage of patients have an intra-aortic balloon pump inserted before induction of anesthesia.[48,85] Monitors include the ECG, arterial blood pressure, a Swan-Ganz catheter with mixed venous oxygen electrode, nasopharyngeal and rectal (or bladder) temperatures, and a catheter for urine output.

For chronic IMR, operation usually is elective, except in patients with uncontrolled symptoms of coronary ischemia, who may require emergency or urgent operation to prevent infarction. Preoperative preparation and intraoperative monitors do not differ from those for other cardiac operations, with the exception of TEE and color-flow Doppler velocity mapping. After induction of anesthesia, the degree of MR, anatomy of the valve, and dimensions and segmental wall motion of the left ventricle are assessed carefully to determine whether or not the mitral valve needs to be addressed. Since anesthesia generally reduces systemic vascular resistance and afterload, assessment of the valve after administration of phenylephrine may unmask more severe MR. If the amount of MR is 2+, transfusion after aortic cannulation to increase preload to 1.5 to 2.0 times resting pulmonary capillary wedge pressure may unmask more severe MR and prompt a decision to expose and repair the valve.[165] If there is a significant discrepancy between the intraoperative degree of MR and that diagnosed by preoperative TEE, it is probably best to treat according to the preoperative value because this is likely what the patient experiences under normal loading conditions. In patients with marginal left ventricular function, a Swan-Ganz catheter with an oxygen electrode and a femoral arterial catheter for possible intra-aortic balloon insertion are recommended.

The most common exposure to the mitral is via median sternotomy. If revascularization is required, arterial and venous conduits are harvested prior to cannulation and imitation of cardiopulmonary bypass. Bicaval cannulation is preferred for exposure of the mitral valve. Both antegrade cardioplegia and retrograde cardioplegia are recommended to minimize myocardial stunning and postbypass left ventricular dysfunction. After initiation of cardiopulmonary bypass, the aorta is cross-clamped, and cardioplegia is given. The left atrium is opened to decompress the left ventricle. If revascularization is needed, the distal coronary anastomoses are performed first to reduce manipulation of the heart and prevent atrioventricular disruption after mitral valve repair or replacement.

In patients with a history of CABG, right thoracotomy is an option to avoid injury to previous bypass grafts during a redo sternotomy. Patent grafts, especially the left internal mammary artery (LIMA) graft to the left anterior descending artery, may be immediately under the sternal table from previous surgery. Owing to the inability to isolate and control the LIMA graft from a right thoracotomy, fibrillatory arrest is needed. Significant aortic valve insufficiency cannot be present for this technique.

Once exposed, the left atrium is opened after developing the interatrial groove, extending the incision behind the inferior vena cava. In cases of redo sternotomy or acute IMR (in which case the left atrium may be small), exposure to the mitral valve can be difficult, and a transseptal approach via the right atrium may be required. Improved exposure also may be obtained by extending the atrial incision superiorly behind the superior cava–right atrium junction. Using a specialized retractor, the left atrium is lifted, and the mitral valve should be exposed for inspection.

An initial inspection reveals the amount of annular dilatation and may indicate segments of the mural annulus that appear disproportionately elongated. Traction sutures in the annulus at each commissure elevate the valve and facilitate exposure of the leaflets, chordae, and papillary muscles. Careful inspection searching for ruptured, elongated, or sclerosed chordae; fibrotic, atrophied papillary muscle; and redundant or defective leaflet tissue is made. Most often the entire valve appears normal; sometimes the posterior papillary muscle seems slightly more yellowish brown than the rest of the ventricle, and the posterior part of the mural annulus seems slightly elongated.

Echocardiographic evaluation is important in the decision to repair or replace the valve. A central regurgitant jet with a dilated annulus is suggestive of a successful repair with a ring annuloplasty. In contrast, eccentric, complex regurgitant jets with severe bileaflet tethering and papillary muscle pathology such as elongation or rupture suggest that mitral valve replacement may be the best durable option.

For mitral valves amendable to annuloplasty repair, usually 2-0 braided sutures are used. Often, exposure to posterior and medial portions of the mitral annulus is easier to achieve. These sutures should be placed first and used to place tension of the mitral annulus to facilitate exposure of the lateral and anterior portions of the annulus. It is essential that the full curve of the needle is used to ensure optimal placement of the sutures in the mitral annulus. Significant tension can develop when these dilated annuli are downsized, so sutures should be placed close together, and crossover may be warranted.

Sizing of the annuloplasty ring can be performed before or after placement of the annuloplasty sutures depending on the size of the left atrium and adequate exposure. Introduced by Bolling, the concept of reducing annular dilatation with aggressive annuloplasty downsizing aims to optimize leaflet coaptation. When choosing an annuloplasty ring, the intertrigonal distance and the surface area of the anterior leaflet are measured. Aggressive downsizing of the annulus (one or two sizes smaller than predicted by measuring the fibrous intertrigonal annulus) can be achieved with minimal risk of the development of systolic anterior motion because the posterior leaflet in IMR often is tethered and restricted. After the size of the ring is chosen, the annuloplasty sutures are placed in accordance with the geometry of the mitral annulus. Once all sutures are placed, the annuloplasty ring is slipped down onto the mitral valve annulus, and the sutures are tied to secure the ring. At this point, a saline test usually is employed to interrogate the competency of the mitral valve repair. If the repair is acceptable, the left atrium then is closed.

If on inspection the valve is not amendable to annuloplasty repair, mitral valve replacement should be performed. Chordal sparing techniques[106–108,111,112,166] should be used if the valve is replaced. These methods have significantly reduced postoperative ventricular dysfunction observed after valve excision in the past and produce no more left ventricular dysfunction than reparative operations.[112] Aged patients in sinus rhythm and patients with a life expectancy of fewer than 10 years who otherwise do not need anticoagulation are candidates for bioprosthetic valves; mechanical valves are recommended for others. The valve is inserted after excising portion of anterior leaflet[107,112] and transposing[111] remaining leaflet tissue to the commissures (see Fig. 30-4). Pledgeted everting sutures (atrial to ventricular) are used for intra-annular placement if downsizing and/or a low-profile valve (i.e., mechanical valve) is desired. Noneverting (ventricular to atrial) pledgeted sutures may be used if a high-profile bioprosthetic valve or friable annulus is encountered. The mural leaflet is plicated into the valve insertion suture line, and the struts of the prosthetic valve are placed along the commissural plane to prevent interference with the valve mechanism and left ventricular outflow tract obstruction.

The atriotomy is closed using running sutures, and any proximal coronary anastomoses are completed. Prior to removing the aortic clamp, all air is evacuated from the ventricle, and the mitral valve is kept incompetent using a transvalvular catheter with ventricular and atrial holes. Absence of air is checked and assessment of ventricular wall motion is made by TEE. Anticipated pharmacologic support is started, and satisfactory left ventricular contractility is established before loading the heart. After weaning, cardiopulmonary bypass is restarted if the left ventricle begins to dilate and wall motion deteriorates; every effort is made to prevent any distension of the ventricle that might reduce myocardial contractile force.[166] Decisions for using intra-aortic balloon pumping or even temporary left ventricular assistance are better made early than after multiple attempts to wean from cardiopulmonary bypass have failed.

FUTURE DIRECTION

Despite best efforts, results with standard annuloplasty with regard to mortality and recurrent IMR have been disappointing. The 5-year survival for surgical therapies for infarction-induced heart failure has hovered stubbornly around 50%. Recurrent IMR after MVR has been reported to be as high as 30% of patients.[162–164,167,168] Although the standard repair (annuloplasty reduction) is effective in correcting the annular dilatation associated with IMR, many investigators point out that it does not address the geometric subvalvular changes associated with postinfarction left ventricular remodeling and may explain the current poor long-term prognosis of IMR. As opposed to the planar standard annuloplasty ring, three-dimensional rings designed to address left ventricular remodeling and its effect on the mitral annulus have been introduced recently. These disease-specific annuloplasty rings will need further investigation before definitive conclusions can be made.

Recent evidence argues that the development of IMR is a complex, multifactorial process resulting from left ventricular remodeling involving the entire mitral apparatus. Many investigators postulate that adjunctive surgical therapy directed at the remodeled ventricle may prove to be a potential therapeutic strategy in the treatment of IMR. Many have stated that IMR is not a valvular process but a ventricular disease process. In a sheep model, Moaine and colleagues demonstrated that external restraint of the infarct zone attenuated remodeling and reduced chronic IMR.[169] Guy and colleagues demonstrated that prophylactic ring annuloplasty before infarction prevented the development of IMR but did not alter the outcome of ischemia-related remodeling.[170] Furthermore, external infarct restraint with mesh before infarction prevented left ventricular remodeling compared with the annuloplasty group. The data suggested that left ventricular remodeling associated with infarct expansion may serve as an important therapeutic target. The Acorn cardiac restraint device (CorCap) is a mesh device that is implanted around the heart to reduce wall stress and address left ventricular remodeling. Clinical trials with the Acorn device have shown that it is safe and effective in patients with advanced heart failure and remodeled ventricles.[171–173] Further investigation is needed before definitive conclusions can be drawn.

Leaflet tethering suggests that surgical strategies aimed at leaflet and subvalvular structures may provide therapeutic benefits as an adjunct to standard annuloplasty repair. Multiple ideas and concepts have been described in the literature. Designed to address both the annular dilatation and subvavular changes associated with IMR, the Coaspsys device consists of an annular head that corrects annular dilatation and a papillary head that repositions the laterally displaced papillary muscles. Animal and human studies have shown

promising results, with this device reducing IMR.[174–176] Chordal cutting of two critical basal chordae of the anterior leaflet first described by Messas[177,178] has been shown to be effective in treating IMR. By relieving leaflet restriction and eliminating the angulation of the anterior leaflet, chordal cutting improves leaflet coaptation while the intact marginal chordae continue to prevent prolapse. Conflicting data from the Stanford group[179,180] demonstrated that cutting of second-order chords neither prevented nor decreased the severity of IMR in a sheep. Kron and colleagues recently reported a successful subvalvular repair as an adjunct to standard annuloplasty.[181] Direct reposition of the displaced posterior papillary muscle toward the right fibrous trigone appeared to ameliorate IMR. In a sheep model, Langer and colleagues confirmed Kron's findings.[182] Anchoring a suture at the right fibrous trigone and passing it through the posterior papillary muscle tip and the ventricular wall, the investigators demonstrated reduction of IMR by tightening the suture. Other groups have demonstrated that reapproximation of both papillary muscles may be beneficial in reducing leaflet tethering and hence IMR.[183–185] The long-term results of these adjunctive procedures are not available, and further investigation is needed.

Finally, despite the mechanistic complexity of IMR, annuloplasty alone proves to be effective in ameliorating IMR in up to 80% of patients.[186] This suggested that a less invasive method to address IMR may benefit this growing population of patients. A catheter-based or percutaneous approach to the treatment of IMR has been investigated. Rigid coronary sinus–based mitral annuloplasty devices deployed percutaneously have been demonstrated to reduce IMR in an animal model.[187–189] Much more work is needed to explore the potential effectiveness and clinical applicability of this new technology.

CHAPTER 31

Left Ventricular Aneurysm

Donald D. Glower • James E. Lowe

DEFINITION

Left ventricular aneurysm (LVA) has been strictly defined as a distinct area of abnormal left ventricular diastolic contour with systolic dyskinesia or paradoxical bulging[1] (Fig. 31-1). Yet a growing number of authors favor defining LVA more loosely as any large area of left ventricular akinesia or dyskinesia that reduces left ventricular ejection fraction (LVEF).[2–4] This broader definition has been justified by data suggesting that the pathophysiology and treatment may be the same for both ventricular akinesia and ventricular dyskinesia.[3,5] Intraoperatively, an LVA also may be defined as an area that collapses on left ventricular decompression.[2,5,6] True LVAs involve bulging of the full thickness of the left ventricular wall, whereas a false aneurysm of the left ventricle is, in fact, a rupture of the left ventricular wall contained by surrounding pericardium.

HISTORY

Left ventricular aneurysms have long been described at autopsy, but LVA was not recognized to be a consequence of coronary artery disease (CAD) until 1881.[7] The angiographic diagnosis of LVA was first made in 1951.[7] A congenital LVA was first treated surgically by Weitland in 1912 using aneurysm ligation. In 1944, Beck[8] described fasciae latae plication to treat LVAs. Likoff and Bailey[9] successfully resected an LVA through a thoracotomy in 1955 using a special clamp without cardiopulmonary bypass. The modern treatment era began in 1958 when Cooley and colleagues[10] successfully performed a linear repair of an LVA using cardiopulmonary bypass. More geometric ventricular reconstruction techniques were devised subsequently by Stoney and colleagues,[11] Daggett and colleagues,[12] Dor and colleagues,[13] Jatene,[14] and Cooley and colleagues.[15,16]

INCIDENCE

The incidence of LVA in patients suffering myocardial infarction (MI) has varied between 10 and 35% depending on the definition and the methods used. Of patients undergoing cardiac catheterization in the Coronary Artery Surgery Study (CASS), 7.6% had angiographic evidence of LVAs.[17] The absolute incidence of LVAs may be declining due to the increased use of thrombolytics and revascularization after MI.[18,19]

ETIOLOGY

Over 95% of true LVAs reported in the English literature result from CAD and MI. True LVAs also may result from trauma,[20] Chagas' disease,[21] or sarcoidosis.[22] A very small number of congenital LVA also have been reported and have been termed *diverticula* of the left ventricle.[23]

False aneurysms of the left ventricle result most commonly from contained rupture of the ventricle 5 to 10 days after MI and often occur after circumflex coronary arterial occlusion. False aneurysm of the left ventricle also may result from submitral rupture of the ventricular wall, a dramatic event that generally occurs after mitral valve replacement with resection of the mitral valve apparatus.[24] Left ventricular pseudoaneurysm also may result from septic pericarditis[25] or any prior operation on the left ventricle, aortic annulus, or mitral annulus.

PATHOPHYSIOLOGY

The development of a true LVA involves two principal phases: early expansion and late remodeling.

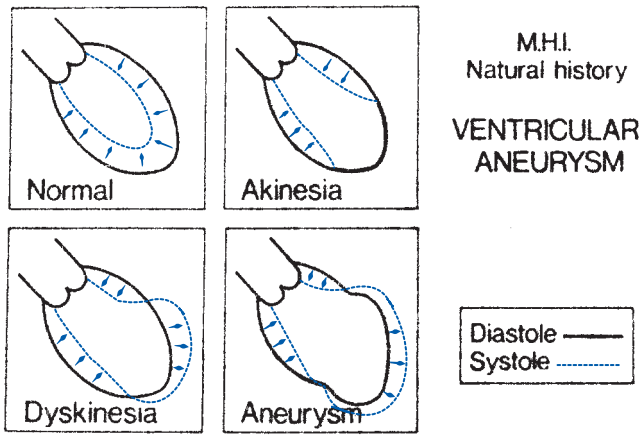

Figure 31-1. Diagrammatic distinction between aneurysm and other states of the left ventricle. (*Reproduced with permission from Grondin et al.*[39])

Early Expansion Phase

The early expansion phase begins with the onset of MI. Ventriculography can demonstrate LVA formation within 48 hours of infarction in 50% of patients who develop ventricular aneurysms. The remaining patients have evidence of aneurysm formation by 2 weeks after infarction.[26]

True aneurysm of the left ventricle generally follows transmural MI owing to acute occlusion of the left anterior descending artery (LAD) or dominant right coronary artery. Lack of angiographic collaterals is strongly associated with aneurysm formation in patients with acute myocardial infarction (AMI) and LAD artery occlusion,[27] and absence of re-formed collateral circulation is probably a prerequisite for the formation of a dyskinetic LVA (Table 31-1). At least 88% of dyskinetic ventricular aneurysms result from anterior infarction, whereas the remainder follow inferior infarction.[7] Posterior infarctions that produce a distinct dyskinetic LVA are relatively unusual.

In experimental transmural infarction without collateral circulation, myocyte death begins 19 minutes after coronary occlusion. Infarctions that result in dyskinetic aneurysm formation are almost always transmural and may show gross thinning of the infarct zone within hours of infarction. Within a few days, the endocardial surface of the developing aneurysm becomes smooth with loss of trabeculae and deposition of fibrin and thrombus on the endocardial surface in at least 50% of patients. While most myocytes within the infarct are necrotic, viable myocytes often remain within the infarct zone. In a minority of patients, extravascular hemorrhage occurs in the infarcted tissue and may further depress systolic and diastolic function of involved myocardium. Inflammatory cells migrate into the infarct zone by 2 to 3 days after infarction and contribute to lysis of necrotic myocytes by 5 to 10 days after infarction. Electron microscopy demonstrates disruption of the native collagen network several days after infarction. Collagen disruption and myocyte necrosis produce a nadir of myocardial tensile strength between 5 and 10 days after infarction, when rupture of the myocardial wall is most common. Left ventricular rupture is relatively rare after the ventricular aneurysmal wall becomes replaced with fibrous tissue.

Table 31–1.

Factors Contributing to Left Ventricular Aneurysm Formation

Preserved contractility of surrounding myocardium
Transmural infarction
Lack of collateral circulation
Lack of reperfusion
Preserved contractility of surrounding myocardium
Elevated wall stress
Hypertension
Ventricular dilatation
Wall thinning

Loss of systolic contraction in the large infarcted zone and preserved contraction of surrounding myocardium cause systolic bulging and thinning of the infarct. By Laplace's law ($T = Pr/2h$), at a constant ventricular pressure P, increased radius of curvature r and decreased wall thickness h in the infarcted zone both contribute to increased muscle fiber tension T and further stretch the infarcted ventricular wall.

Relative to normal myocardium, ischemically injured or infarcted myocardium displays greater *plasticity* or *creep,* defined as deformation or stretch over time under a constant load.[28] Thus, increased systolic and diastolic wall stress in the infarcted zone tends to produce progressive stretch of the infarcted myocardium (termed *infarct expansion*)[29] until healing reduces the plasticity of the infarcted myocardium.

Transmural infarction without significant hibernating myocardium within the infarct region is necessary for subsequent development of a true LVA. Angiographic ventricular aneurysms with evidence of hibernating myocardium (lack of Q waves or presence of uptake on technetium scan) may resolve over several weeks and thus do not represent true LVAs by strict criteria.[30]

Due to increased diastolic stretch or preload and elevated catecholamines, remaining noninfarcted myocardium may demonstrate increased fiber shortening and, ultimately, myocardial hypertrophy in the presence of an LVA.[31] This increased shortening and increased wall stress increase oxy-

gen demand for noninfarcted myocardium and for the left ventricle as a whole.

In addition to increased regional wall stresses, LVA can increase ventricular oxygen demand and decrease net forward cardiac output by producing a ventricular volume load because a portion of the stroke volume goes into the aneurysm instead of out the aortic valve. Net mechanical efficiency of the left ventricle (external stroke work minus myocardial oxygen consumption) is decreased by reducing external stroke work (volume times pressure) and increasing myocardial oxygen consumption.

Left ventricular aneurysms can produce both systolic and diastolic ventricular dysfunction. Diastolic dysfunction results from increased stiffness of the distended and fibrotic aneurysmal wall, which impairs diastolic filling and increases left ventricular end-diastolic (LVED) pressure.

Late Remodeling Phase

The remodeling phase of ventricular aneurysm formation begins 2 to 4 weeks after infarction when highly vascularized granulation tissue appears. This granulation tissue is replaced subsequently by fibrous tissue 6 to 8 weeks after infarction. As myocytes are lost, ventricular wall thickness decreases as the myocardium becomes largely replaced by fibrous tissue. In larger infarcts, the thin scar often is lined with mural thrombus.[32]

After AMI, animal studies show that ventricular load reduction with 8 weeks of nitrate therapy may reduce expected infarct thinning, decrease infarct stretch, and lessen hypertrophy of noninfarcted myocardium.[33] Interestingly, nitrate therapy for only 2 weeks after infarction does not prevent aneurysm formation. This observation emphasizes the importance of late remodeling from 2 to 8 weeks after infarction. Angiotensin-converting enzyme (ACE) inhibitors also reduce infarct expansion and subsequent development of ventricular aneurysm.[34] Because animal studies show that ACE inhibitors nonspecifically suppress ventricular hypertrophy, it is not clear whether suppression of the compensatory hypertrophy of surrounding myocardium ultimately is beneficial or harmful. Intravenous administration of atrial natriuretic factor for 4 weeks has improved ventricular function, dimensions, and fibrosis in rats.[35]

Lack of coronary reperfusion probably is a prerequisite for development of LVA. In humans, reperfusion of the infarct vessel either spontaneously,[30] by thrombolysis,[36] or by angioplasty[37] has been associated with a lower incidence of aneurysm formation. It is speculated that coronary reperfusion as late as 2 weeks after infarction prevents aneurysm formation by improving blood flow and fibroblast migration into the infarcted myocardium. The role of delayed infarct healing in aneurysm development is supported by observations that steroids after MI may increase the likelihood of aneurysm formation.[38]

Arrhythmias such as ventricular tachycardia may occur at any time during the development of ventricular aneurysm, and all these patients have the substrate for reentrant conduction pathways within the heterogeneous ventricular myocardium. These pathways tend to involve border zones surrounding the ventricular aneurysm (see Chap. 54).

NATURAL HISTORY

The excellent prognosis of asymptomatic patients with dyskinetic ventricular aneurysms who were treated medically was demonstrated in a series of 40 patients followed for a mean of 5 years.[39] Of 18 initially asymptomatic patients, 6 developed class II symptoms, whereas 12 remained asymptomatic. Ten-year survival was 90% for these patients but was only 46% at 10 years in patients who presented with symptoms (Fig. 31-2).

Although earlier autopsy series reported relatively poor survival in patients with medically managed left ventricular dyskinetic aneurysms (12% at 5 years), most recent studies report 5-year survivals from 47 to 70%.[17,39–42] Causes of death include arrhythmia in 44%, heart failure in 33%, recurrent MI in 11%, and noncardiac causes in 22%.[39] The natural history of patients with akinetic rather than dyskinetic LVAs is less well documented.

Factors that influence survival with medically managed left ventricular dyskinetic aneurysm include age, heart failure score, extent of CAD, duration of angina, prior infarction, mitral regurgitation, ventricular arrhythmias, aneurysm size, function of residual ventricle, and left ventricular end-diastolic pressure.[39,42] Early development of aneurysm within 48 hours of infarction also diminishes survival.[26]

In general, the risk of thromboembolism is low for patients with aneurysms (0.35% per patient-year),[40] and long-term anticoagulation is not usually recommended.

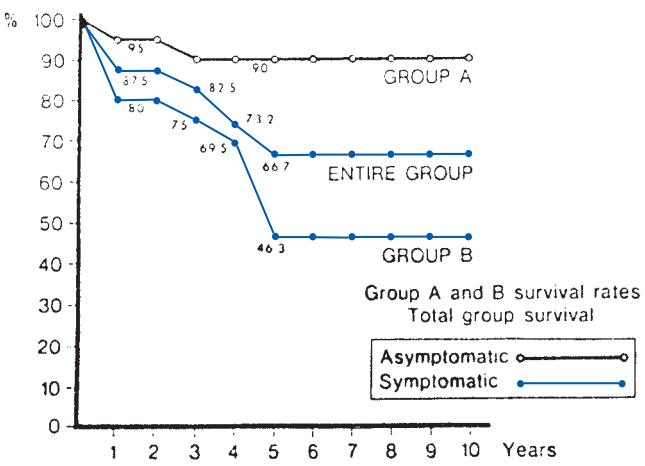

Figure 31-2. Survival in medically treated patients with left ventricular aneurysm based on presence (group B) or absence (group A) of symptoms. (*Reproduced with permission from Grondin et al.*[39])

However, in the 50% of patients with mural thrombus visible by echocardiography after MI, 19% develop thromboembolism over a mean follow-up of 24 months.[43] In these patients, anticoagulation and close echocardiographic follow-up may be indicated. Atrial fibrillation and large aneurysmal size are additional risk factors for thromboembolism.

The natural history of left ventricular pseudoaneurysm is not well documented. Frank rupture of chronic left ventricular pseudoaneurysms is less common than one might expect.[44] Rupture of left ventricular pseudoaneurysms may be most likely in the acute phase or in large-sized pseudoaneurysms.[45] Left ventricular pseudoaneurysms tend to behave similarly to true aneurysms in that they may present a volume load to the left ventricle or may be a source of embolization or endocarditis. Left ventricular pseudoaneurysms after prior cardiac surgery also have been reported to compress adjacent structures such as the pulmonary artery or esophagus.

CLINICAL PRESENTATION

Angina is the most frequent symptom in most series of operated patients with LVA. Given that three-vessel CAD is present in 60% or more of these patients, the frequency of angina is not surprising.[46]

Dyspnea is the second most common symptom of ventricular aneurysm and often develops when 20% or more of the ventricular wall is infarcted. Dyspnea may occur from a combination of decreased systolic function and diastolic dysfunction.

Either atrial or ventricular arrhythmias may produce palpitations, syncope, or sudden death or aggravate angina and dyspnea in up to one-third of patients.[46] Thromboembolism is unusual but may produce symptoms of stroke, MI, or limb or visceral ischemia.

DIAGNOSIS

The electrocardiogram (ECG) frequently demonstrates Q waves in the anterior leads along with persistent anterior ST-segment elevation (Fig. 31-3). The chest radiograph may show left ventricular enlargement and cardiomegaly (Fig. 31-4), but the chest radiograph usually is not specific for LVA.

Left ventriculography is the "gold standard" for diagnosis of LVA. The diagnosis is made by demonstrating a large, discrete area of dyskinesia (or akinesia), generally in the anteroseptal-apical walls. Occasionally, left ventriculography also may demonstrate mural thrombus. Quantitative definition of LVAs has been accomplished using a centerline analysis of left ventricular wall motion on left ventriculography in the 30-degree right anterior oblique view.[4] Hypocontractile segments contracting more than two standard deviations out of normal range are defined as aneurysmal[47] (Fig. 31-5). Outward motion is termed *dyskinetic*, and remaining aneurysmal segments are termed *akinetic*. The fraction of total left ventricular circumference that is aneurysmal thus can be computed as the value %*A*.[4]

Two-dimensional echocardiography is also a sensitive and specific means of diagnosing LVA (Fig. 31-6). Mural

thrombus and mitral valve regurgitation are detected most readily by echocardiography. Echocardiography is also useful for distinguishing false aneurysm from true aneurysm by demonstrating a defect in the true ventricular wall. Tomographic three-dimensional echocardiography and magnetic resonance imaging (MRI) are the most reliable means of assessing left ventricular volume in the presence of LVA.[48] Gated radionuclide angiography reliably detects LVAs, and thallium scanning or positron-emission tomography (PET) can be helpful early after infarction to differentiate true aneurysm from hibernating myocardium with reversible dysfunction. Magnetic resonance imaging (MRI) accurately depicts LVAs and is a reliable means for detecting mural thrombus.[49] Yet, distinguishing true aneurysms from pseudoaneurysms remains difficult, even with MRI.[50]

INDICATIONS FOR OPERATION

Because of the relatively good prognosis for asymptomatic LVA,[39] no indications for repairing chronic, asymptomatic aneurysms are established. Yet, in low-risk patients during operation for associated CAD, investigators report repairing large, minimally symptomatic aneurysms.[7,51]

On the other hand, operation is indicated for symptoms of angina, congestive heart failure (CHF), or selected ventricular arrhythmias (see Chap. 54) (Table 31-2). For these symptomatic patients, operation offers better outcome than medical therapy. To be worthy of operation, a dyskinetic or akinetic LVA should significantly enlarge left ventricular end-systolic volume index (over 80 mL/m^2) and end-diastolic volume (over 120 mL/m^2). These volume criteria, however, are poorly defined and limited by technical difficulty measuring left ventricular volume in aneurysmal left ventricles. Because results are not affected by whether aneurysms are akinetic or dyskinetic, Dor and colleagues feel that dyskinesia is not a prerequisite for aneurysm repair.[3,4]

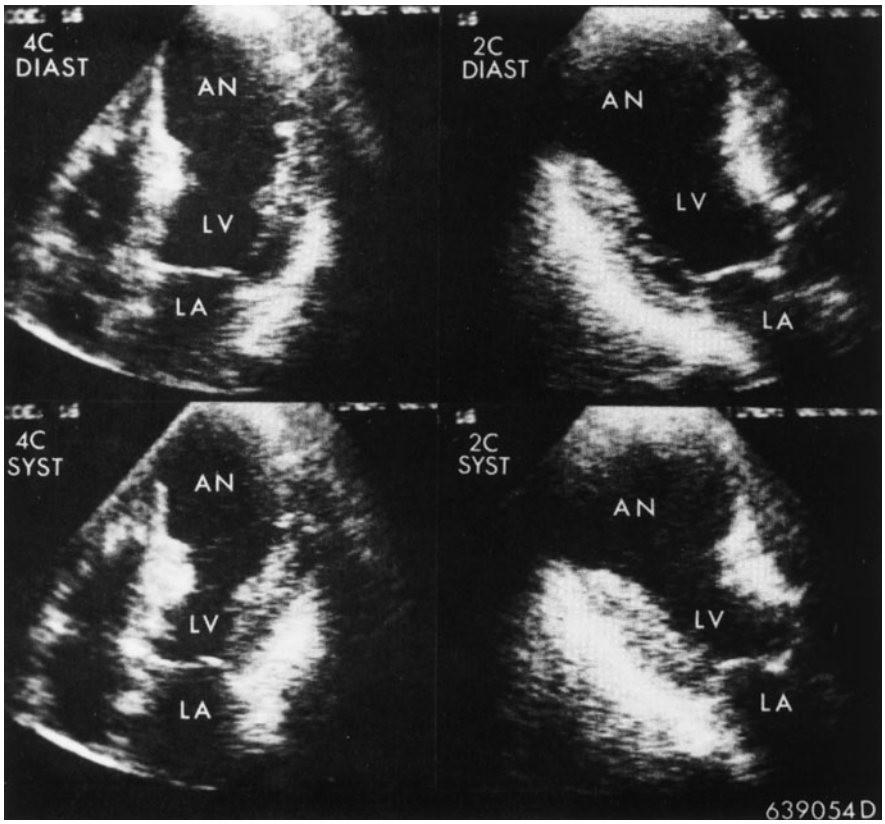

Figure 31-6. Four-chamber (4C) and two-chamber (2C) two-dimensional echocardiograms demonstrating a left ventricular aneurysm (AN) during systole (SYST) and diastole (DIAST). (LV = left ventricle; LA = left atrium.) (*Reproduced with permission from Feigenbaum H: Echocardiography. Philadelphia, Lea & Febiger, 1986; p 484.*)

Operation is also indicated in viable patients with contained cardiac rupture, with or without the development of a false aneurysm. Because left ventricular pseudoaneurysms may have a tendency to rupture when acute or of larger size (either with or without symptoms), operation is indicated.[44,45,52] Similarly, congenital aneurysms have a presumed risk of rupture and should undergo repair independently of symptoms. Rarely, embolism is an indication for operation in medically treated patients at high risk for repeated thromboembolism. The role of operation in asymptomatic patients with very large aneurysms or documented expansion of aneurysms is uncertain.

Table 31–2.

Relative Indications for Ventricular Aneurysm Operation

Documented expansion/large size
Angina
Congestive heart failure
Arrhythmia
Rupture
Pseudoaneurysm
Congenital aneurysm
Embolism
Documented expansion/large size

Relative contraindications to operation for LVA include excessive anesthetic risk, impaired function of residual myocardium outside the aneurysm, resting cardiac index of less than 2.0 liters/m^2 per minute, significant mitral regurgitation, evidence of nontransmural infarction (i.e., hibernating myocardium), and lack of a discrete, thin-walled aneurysm with distinct margins. Global ejection fraction may be less useful than ejection fraction of the basal, contractile portion of the heart in determining operability.[53]

Angioplasty has an uncertain role in the treatment of LVAs but may be indicated in patients with suitable coronary anatomy, one- or two-vessel disease, a contraindication to operation, or asymptomatic status with inducible ischemia.

PREPARATION FOR OPERATION

All patients being considered for operation should undergo right- and left-sided heart catheterization with coronary arteriography and left ventriculography. Patients with at least 2+

mitral regurgitation at cardiac catheterization should have echocardiography to assess the mitral valve and to look for intrinsic mitral valve disease not amenable to annuloplasty.

Preoperative electrophysiologic study is clearly indicated in any patient with preoperative ventricular tachycardia or ventricular fibrillation. The decision to perform an electrophysiologic study in patients without preoperative ventricular arrhythmias is controversial because the incidence of postoperative ventricular arrhythmias is low and not changed by endocardial resection at the time of operation.[7] Electrophysiologic study frequently is not helpful in patients with polymorphic ventricular tachycardia occurring within 6 weeks of MI.[7]

OPERATIVE TECHNIQUES

General Operation

Operation for LVA (i.e., aneurysmectomy, aneurysmorrhaphy, and ventricular restoration) requires cardiopulmonary bypass and a balanced anesthetic technique as generally used for coronary bypass grafting. After induction of anesthesia and endotracheal intubation, an ECG monitor, a Foley catheter, a radial arterial line, and a Swan-Ganz catheter are placed. A median sternotomy is performed, and the patient is given heparin. Saphenous vein or arterial conduits are prepared.

Cardiopulmonary bypass is begun after cannulating the ascending aorta. A single two-stage cannula generally is adequate to cannulate the right atrium, but dual venous cannulation should be considered if the right ventricle is to be opened. Epicardial mapping is performed if necessary. The left ventricle is inspected to identify an appropriate area of thinned ventricular wall. A linear vertical ventriculotomy, generally on the anterior wall 3 to 4 cm from the LAD, is made (Fig. 31-7). The left ventricle is opened (Fig. 31-8), all mural thrombus is removed carefully, and endocardial mapping is performed if necessary. A left ventricular vent now is placed through the right superior pulmonary vein–left atrial junction after mural thrombus is removed. Coronary arteries to be grafted are identified. Endocardial scar, if present, is

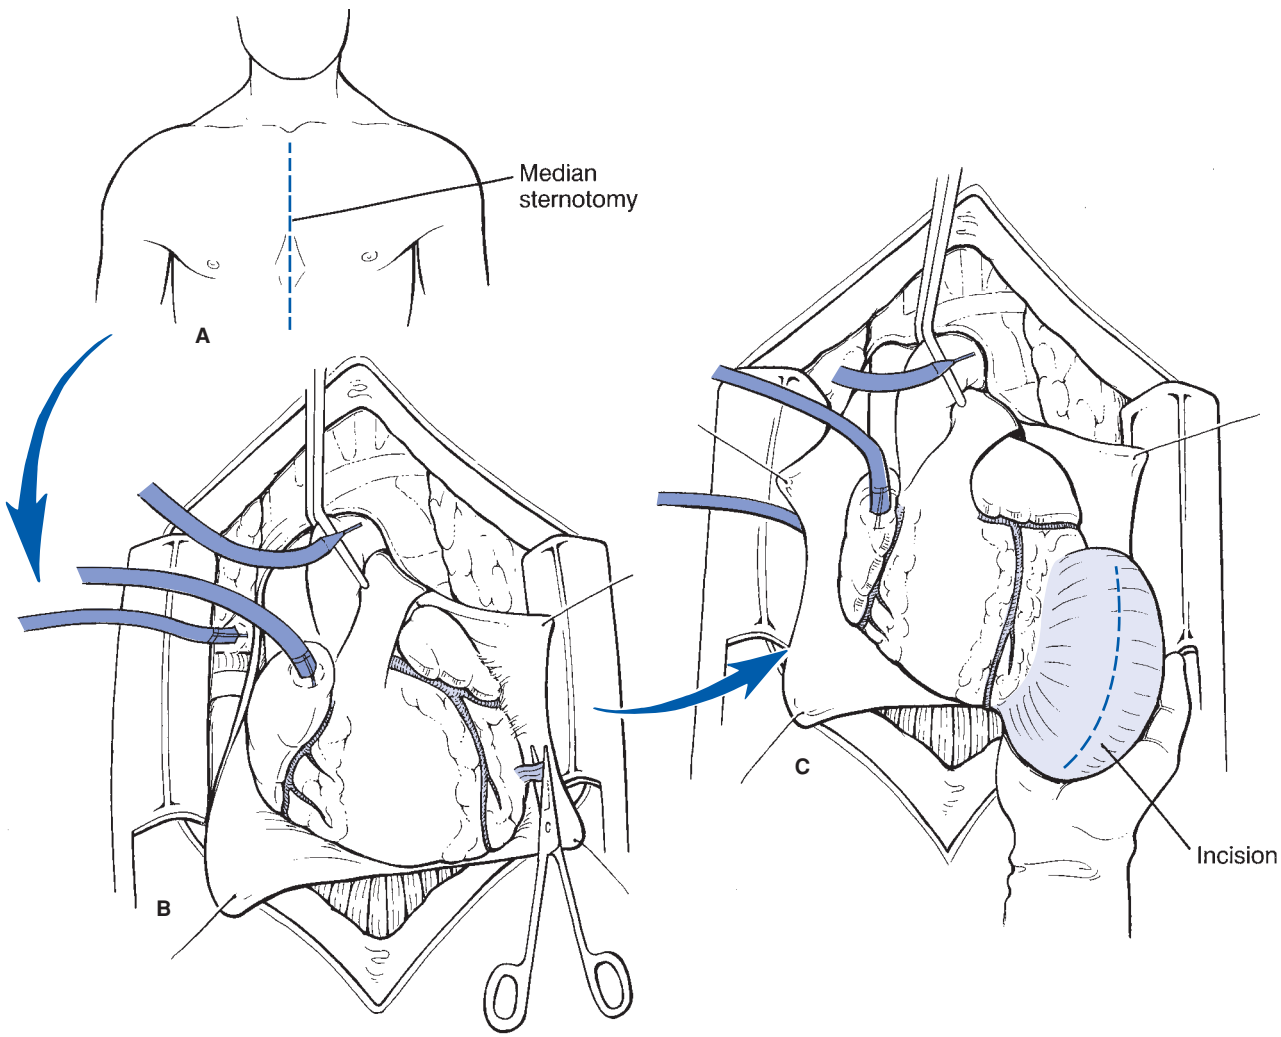

Figure 31-7. Technique of exposure for left ventricular aneurysm repair through a median sternotomy. The ascending aorta and right atrium are cannulated. A left ventricular vent is placed through the right superior pulmonary vein. Pericardial adhesions are divided, and the aneurysm is opened.

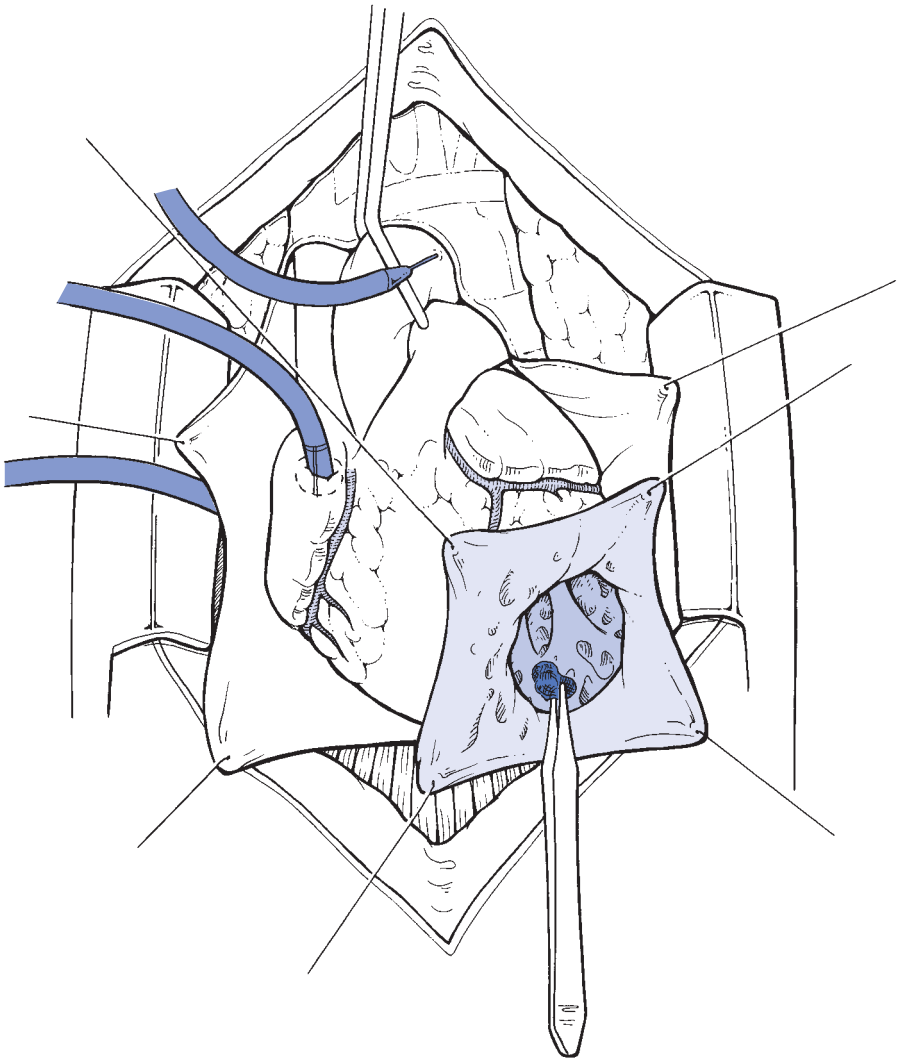

Figure 31-8. With the aneurysm wall opened, thrombus is removed without injury to the papillary muscles.

resected, and afterwards, endocardial mapping is repeated. Body temperature is maintained at 37°C until intraoperative mapping is completed; thereafter, temperature is decreased to 28° to 32°C.

The ascending aorta is clamped, and the heart is arrested with cold anterograde cardioplegia solution. Alternatively, the aorta is not clamped, and the entire procedure is done during hypothermic fibrillation. The LVA is repaired using one of the techniques described below. The distal coronary anastomoses are performed, followed by releasing the aortic clamp.[54] Air is removed by venting the ascending aorta and left ventricle while filling the heart and ventilating the lungs with the patient in the Trendelenburg position. The patient is rewarmed, and proximal coronary anastomoses are performed. Once normothermia is achieved, an electrophysiologic study may be repeated if indicated. Temporary pacing wires are placed on the right atrium and right ventricle, cardiopulmonary bypass is discontinued, and heparin is reversed. The heart is decannulated, and the median sternotomy is closed with mediastinal drains after hemostasis is achieved.

Weaning from cardiopulmonary bypass frequently requires some degree of inotropic support. Typically 5 μg/kg per minute of dopamine, nitroglycerin to prevent coronary spasm, and nitroprusside for afterload reduction are used. An intra-aortic balloon pump (IABP) may be needed in patients with borderline ventricular function. Transesophageal echocardiography is useful for assessing left ventricular function and to detect residual intracardiac air.

Additional inotropic support may not increase cardiac output significantly because of abnormal ventricular compliance and may produce arrhythmias and poorly tolerated tachycardia. Hypokalemia and hypomagnesemia are corrected immediately to minimize arrhythmias. Intraoperative and postoperative ventricular ectopy is treated aggressively with intravenous lidocaine. Intravascular volume shifts are poorly tolerated in these patients because of poor ventricular compliance; therefore, rapid transfusions are avoided by meticulous hemostasis before closing. Because the left ventricle is poorly distensible, stroke volume is relatively fixed, and a resting heart rate of between 90 and 115 beats per

minute is not unusual to maintain a cardiac index of approximately 2.0 L/m^2 per minute.

Growing experience suggests that the ultimate size of the left ventricular cavity at the end of the procedure is critical to patient outcome. Using preoperative and postoperative three-dimensional techniques to image the left ventricle, Cherniavsky and colleagues proposed that the aneurysm resection or patch should produce a postoperative left ventricular end-diastolic volume of about 150 mL.[55]

Plication

Plication without opening the aneurysm is reserved for only the smallest aneurysms that do not contain mural thrombus. A two-layer suture line of 0 monofilament is placed across the aneurysm using a strip of Teflon felt on either side. The suture line is oriented to reconstruct a relatively normal left ventricular contour and does not exclude all aneurysmal tissue.

Linear Closure

After removing all mural thrombus, the aneurysmal wall is trimmed, leaving a 3-cm rim of scar to allow reconstruction of the normal left ventricular contour (Fig. 31-9). Care is taken not to resect too much aneurysmal wall and overly reduce ventricular cavity size. A monofilament 2-0 suture may be used to reduce the neck of the aneurysm to the proper size before closure of the ventricular wall.[14] Anterior aneurysm defects are closed vertically between two external 1.5-cm strips of Teflon felt, two layers of 0 monofilament horizontal mattress sutures, and finally, two layers of running 2-0 monofilament vertical sutures with large-diameter needles (Fig. 31-10).

Circular Patch

Inferior or posterior aneurysms generally require circular patch closure, which also can be applied to anterior aneurysms. After opening the aneurysm (Fig. 31-11) and after débridement of thrombus and aneurysm wall (Fig. 31-12), a Dacron (Hemashield) patch is cut to be 2 cm greater in diameter than the ventricular opening. Interrupted, pledgeted 0 monofilament horizontal mattress sutures are placed through the ventriculotomy rim and then through the patch, leaving the pledgets outside the ventricular cavity (Fig. 31-13). Sutures are tied, and additional interrupted sutures or a second layer of running 2-0 monofilament is placed for hemostasis.

Endoventricular Patch

The endoventricular patch technique is suitable for anterior aneurysms but is less suited for inferior or posterior aneurysms, for which the standard (circular) patch technique is used. After débridement of thrombus, a running 2-0 polypropylene suture may be placed at the aneurysm rim to optimize

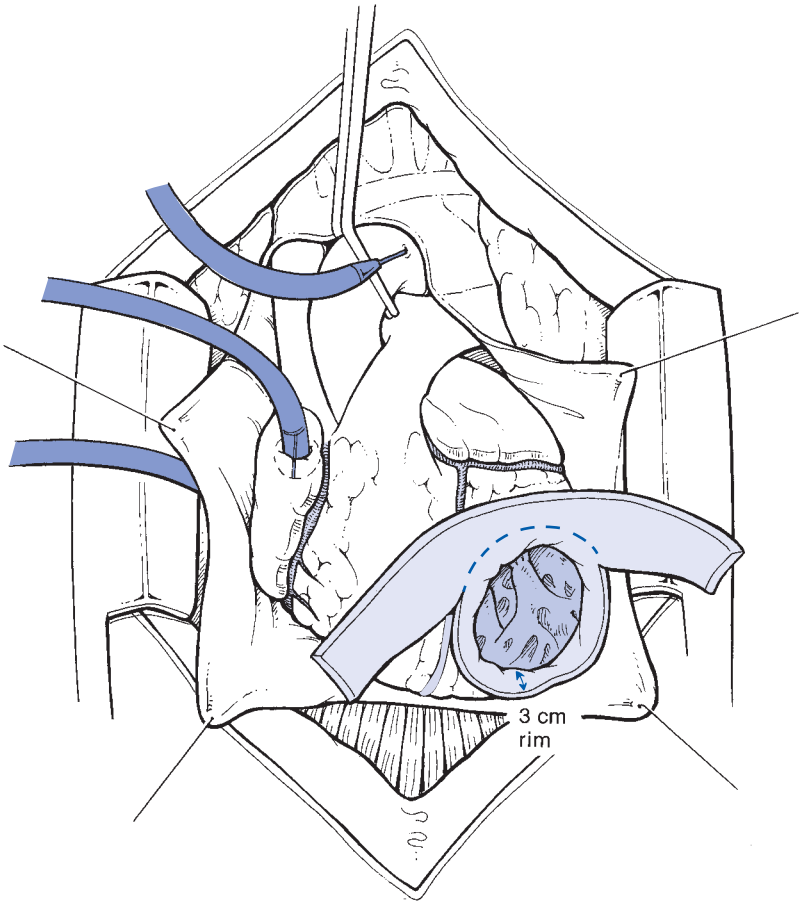

Figure 31-9. Linear repair. The fibrous aneurysm wall is excised, leaving a 3-cm rim of fibrous aneurysm wall attached to healthy muscle.

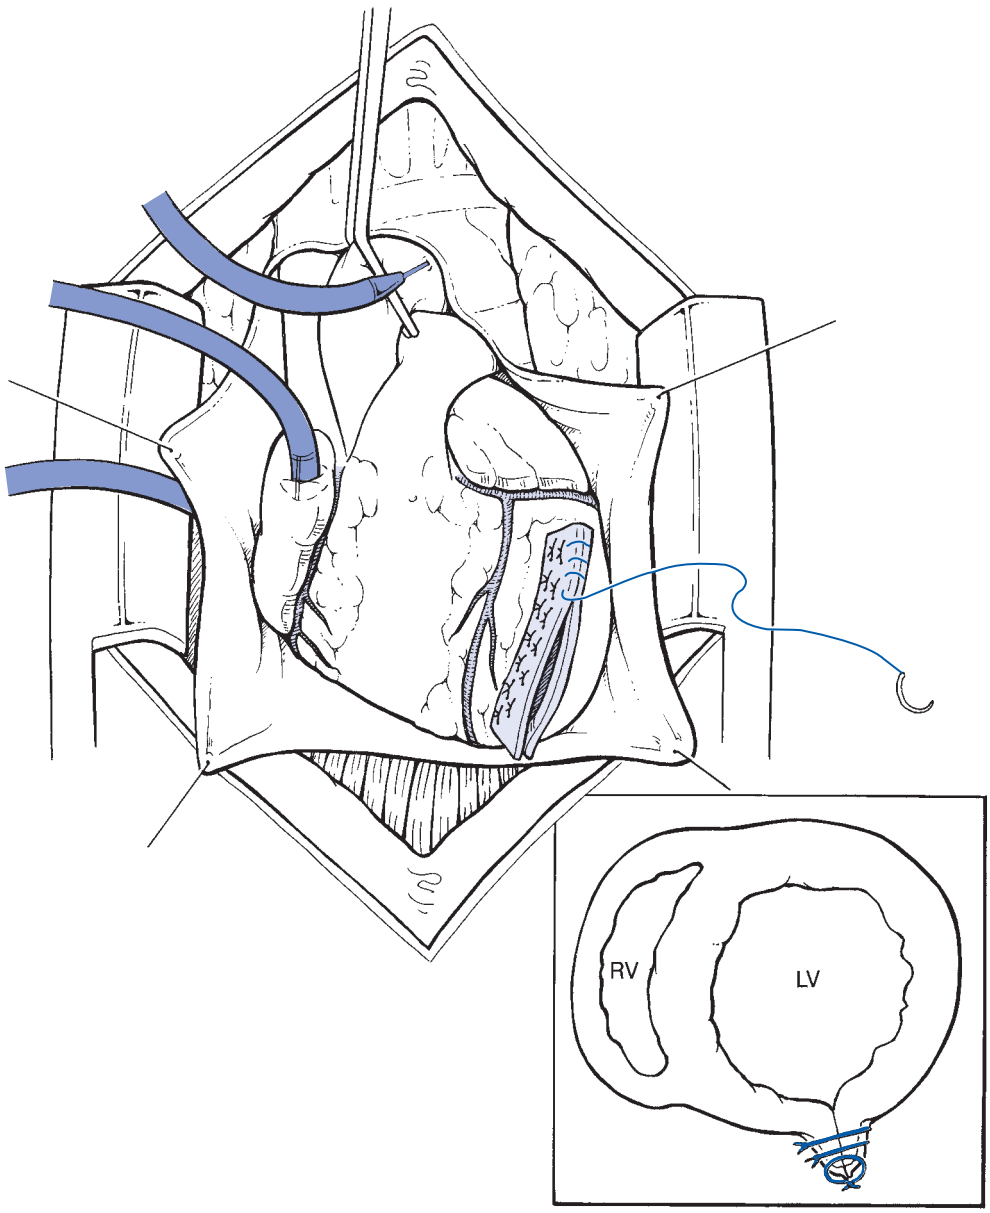

Figure 31-10. Linear repair. The aneurysm walls are closed in a vertical line between two layers of Teflon felt. Two layers of 0 monofilament interrupted horizontal mattress sutures are reinforced with two layers of running 2-0 monofilament sutures.

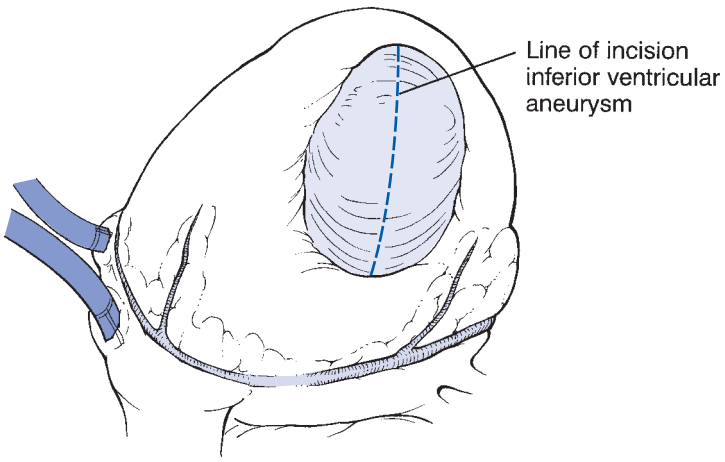

Figure 31-11. Circular patch repair. The aneurysm wall is incised. An inferior aneurysm is shown.

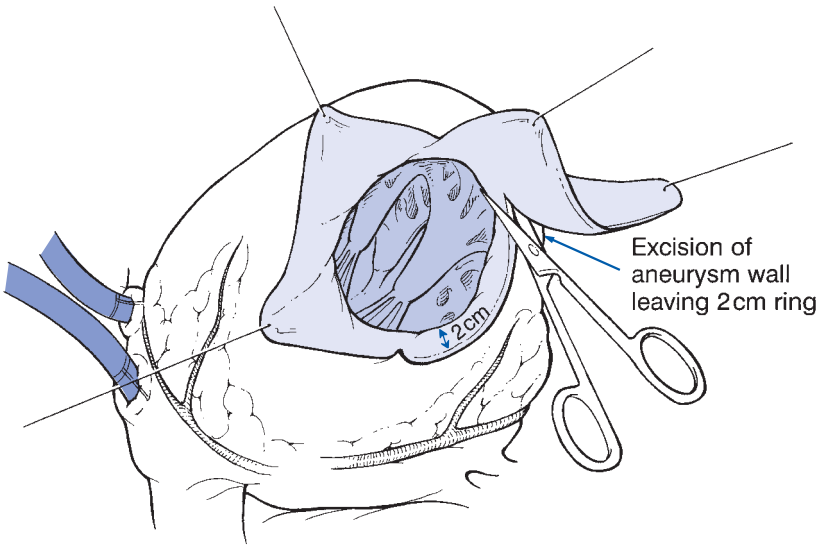

Figure 31-12. Circular patch repair. The aneurysmal wall is excised, leaving a 2-cm rim of fibrous aneurysmal wall attached to healthy muscle.

left ventricular size.[3,14,47,53] If the remaining ventricular defect is small (<3 cm), then the ventricular wall may be closed linearly.[14] More commonly, a patch (e.g., bovine pericardium, Dacron cloth, or polytetrafluoroethylene) is cut to size sufficient to restore normal ventricular size and geometry when secured to the aneurysmal rim (Fig. 31-14). The patch is sutured to normal muscle at the aneurysmal circumference using a running 3-0 polypropylene suture and is secured with single sutures at three or four places around the patch circumference. The patch may extend onto the interventricular septum,[3,47,53] or the aneurysmal septum may be plicated.[14] Interrupted 3-0 sutures are placed as needed to ensure good fit. Care is taken not to distort the papillary muscles. The aneurysmal rim is trimmed to allow primary closure of the native aneurysmal wall over the patch using two layers of running 2-0 monofilament suture without pledgets (Fig. 31-15).

As compared with linear and circular patch techniques, the endoventricular patch technique has technical advantages. An endoventricular patch preserves the LAD for possible grafting and leaves no external prosthetic material to produce heavy pericardial adhesions. The technique facilitates patching the interventricular septum and is suitable for acute infarctions when tissues are friable.[7,16,56]

Other Ventricular Remodeling Techniques

In addition to the techniques just listed, in which left ventricular infarct tissue is excised and/or replaced with patch material, an alternative would be to alter the biologic properties of the infarct scar. Remaining infarct scar (whether aneurysmal or not) then can be seeded with myoblasts or stem cells, which offer the potential to restore cardiac muscle mass and contraction. This technique has been termed *cellular*

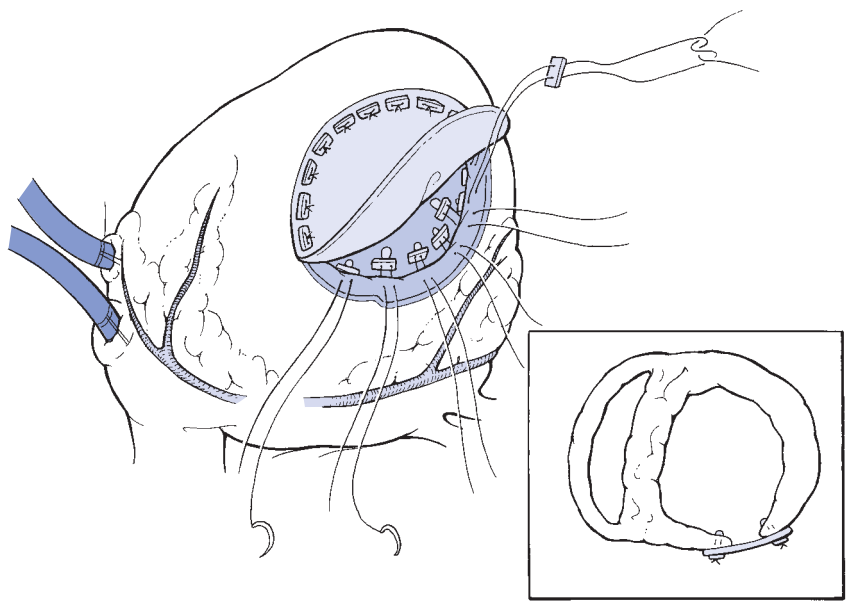

Figure 31-13. Circular patch repair. The aneurysmal defect is closed with a Dacron patch using interrupted 2-0 monofilament horizontal mattress sutures with reinforcing pledgets.

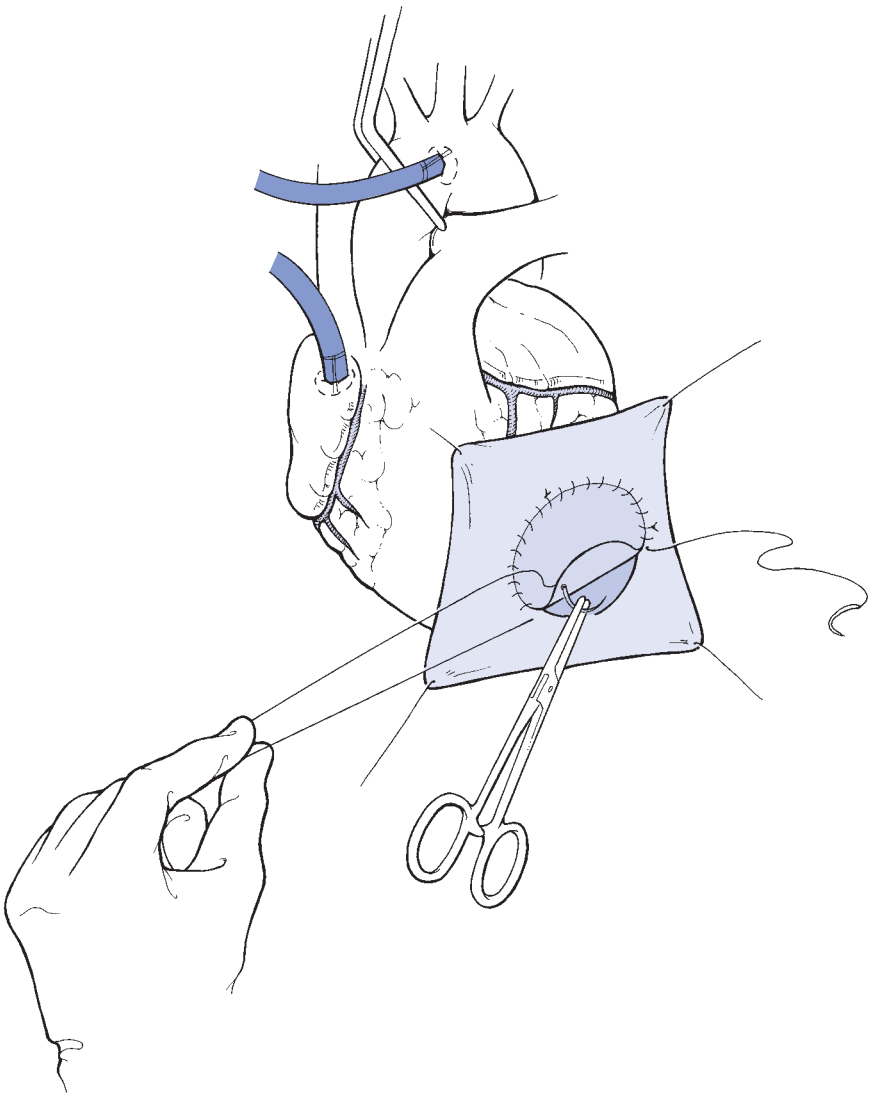

Figure 31-14. Endocardial patch. Without excising the aneurysm wall, the ventricular defect is closed with a Teflon felt patch using 3-0 polypropylene suture secured at three or four points along the suture line. Additional 3-0 pledgeted horizontal mattress sutures may be used to achieve hemostasis.

cardiomyoplasty and has been done only on a limited basis in humans.[57] In animals, cellular cardiomyoplasty has improved global left ventricular performance and geometry using either myoblasts, stem cells that differentiate into myocytes, fibrocytes, or cells seeded onto a graft matrix.[58–62] Only myoblasts or stem cells that differentiate into myocytes have improved regional ventricular contractility. Cellular cardiomyoplasty could be done by direct injection of cells at the time of coronary revascularization or even by transcoronary or intramyocardial injection in the cardiac catheterization laboratory.

Coronary Revascularization

Concurrent coronary revascularization is performed as in standard coronary bypass procedures. Since the endoventricular patch technique does not encroach on the LAD, the left internal mammary artery may be used to graft the LAD coronary artery.

Mitral Regurgitation

The severity of mitral regurgitation should be evaluated before cardiopulmonary bypass by intraoperative transesophageal echocardiography. The need for concurrent mitral valve operation increases as the preoperative ejection fraction decreases[63] (Fig. 31-16). The mitral valve is also inspected from below after opening the aneurysm and beginning repair of the aneurysm. Transventricular mitral valve repair may be done by placing pledgeted polypropylene sutures at both mitral commissures to reduce the circumference of the annulus.[64] This technique produces satisfactory short-term results, but long-term results are not known. Usually the mitral valve is repaired via left atriotomy after completion of the distal coronary artery anastomoses and before releasing the aortic cross-clamp. If mitral regurgitation results from annular dilatation and systolic restriction of leaflet motion (Carpentier type IIIB), Carpentier mitral annuloplasty is done.[65]

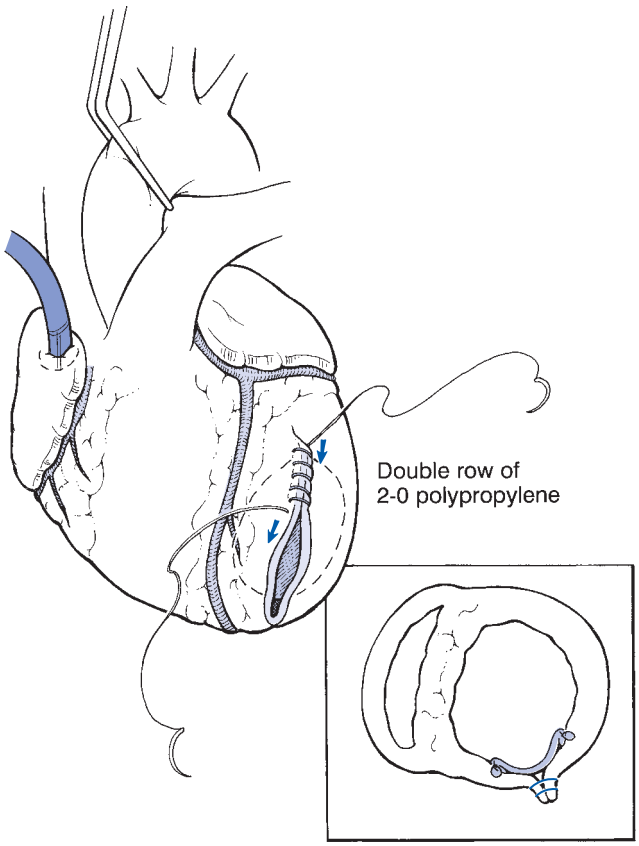

Figure 31-15. Endocardial patch. The aneurysm wall is closed over a Teflon patch after resecting excess aneurysm tissue. A double row of running vertical 2-0 polypropylene sutures is used.

Cardiac Transplantation

In symptomatic patients with sufficient depression of global left ventricular function to preclude aneurysm repair, transplantation is a reasonable alternative. Relative contraindications to cardiac transplantation in patients with LVA include current amiodarone therapy and prior placement of an internal defibrillation device.

Ventricular False Aneurysm

Ventricular false aneurysms are repaired with the same techniques used for true ventricular aneurysms based on the location and size of the aneurysm. The circular patch technique is particularly useful because inferior false aneurysms are common and typically have narrow necks. Usually the wall of the false aneurysm is inadequate to close over the defect.

Ventricular Rupture

Any of the techniques just described may be used to manage a contained ventricular rupture. Because infarcted tissue is particularly friable 5 to 10 days after rupture, closure may be difficult. The endoventricular technique is particularly well suited for this uncommon operation because the patch can be sewn to the margins of healthy endocardium, which may be at some distance from the site of rupture. Patient survival also has been reported by gluing a biologic patch to the ventricular epicardium over the site of the rupture.

EARLY RESULTS

Hospital Mortality

In a compilation of 3439 operations for LVA between 1972 and 1987, hospital mortality was 9.9% and ranged from 2 to 19%.[18] More recent reports indicate that hospital mortality has fallen to 3 to 7% in the last decade using either patch[7,16,63,66,67] or linear closures.[19,51,67] The most common cause of hospital mortality is left ventricular failure, which occurs in 64% of deaths.[51]

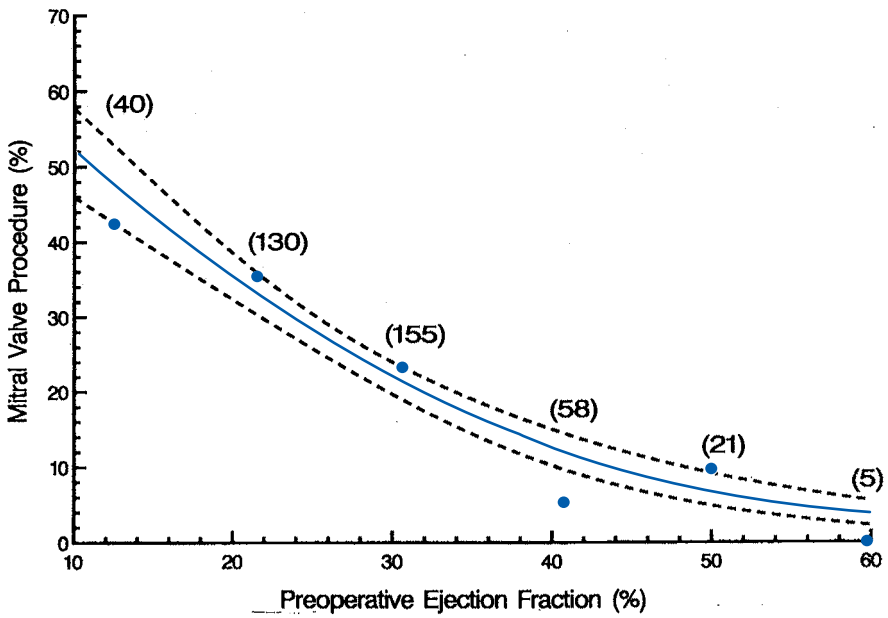

Figure 31-16. Prevalence of performing concomitant mitral valve procedures as a function of preoperative ejection fraction. (*Reproduced with permission from Athanasuleas.*[63])

Table 31–3.

In-Hospital Complications of Ventricular Aneurysm Repair

Low cardiac output 22–39%
Ventricular arrhythmias 9–19%
Respiratory failure 4–11%
Bleeding 4–7%
Dialysis-dependent renal failure 4%
Stroke 3–4%

Risk factors for hospital mortality include increased age,[18,51,63,67] incomplete revascularization,[51] increased heart failure class,[18,67–69] female gender,[18] emergent operation,[18] ejection fraction of less than 20 to 30%,[63,67,68] concurrent mitral valve replacement,[7,18,63] preoperative cardiac index of less than 2.1 L/m^2 per minute,[4] mean pulmonary artery pressure greater than 33 mm Hg,[4] serum creatinine concentration greater than 1.8 mg/dL,[4] and failure to use the internal mammary artery.[69]

In-Hospital Complications

The most common in-hospital complications are shown in Table 31-3 and include low cardiac output, ventricular arrhythmias, and respiratory failure.[18,19,66,67,70] Low cardiac output may be more common in patients undergoing intraoperative mapping due to perioperative cardiac injury.[71]

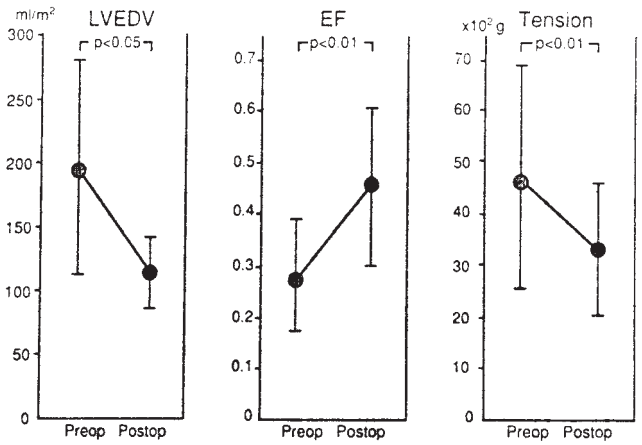

Figure 31-17. Effects of linear aneurysmectomy on left ventricular end-diastolic volume (LVEDV), ejection fraction (EF), and wall tension. (*Reproduced with permission from Kawachi et al.*[74])

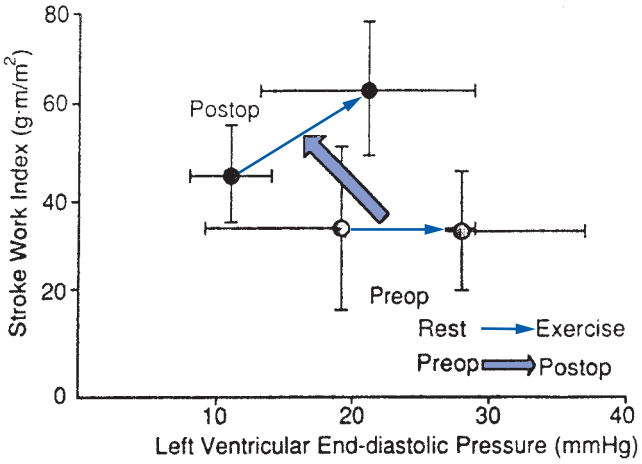

Figure 31-18. Relationship between stroke work index and left ventricular end-diastolic pressure. Data are shown at rest and during exercise before (preop) and after (postop) linear aneurysmectomy. Stroke work index increased only with exercise postoperatively. (*Reproduced with permission from Kawachi et al.*[74])

Left Ventricular Function

The preponderance of data from the last two decades have shown that left ventricular function improves in most patients undergoing operation for LVA. Operation improves

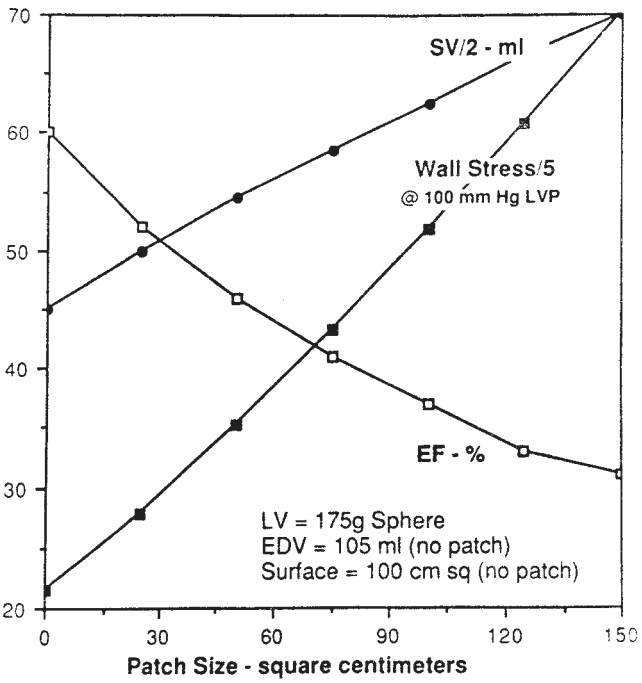

Figure 31-19. Computer prediction of the effects of patch size on stroke volume (SV), ejection fraction (EF), and wall stress (afterload) at a chamber pressure of 100 mm Hg. Predictions are based on data from an animal model of simulated aneurysm repair, neglecting the effects of afterload on stroke volume. Because increasing afterload in reality decreases muscle shortening, patch reconstruction can increase stroke volume only if contractile reserve is sufficient to overcome the afterload from increased ventricular size. (*Reproduced with permission from Nicolosi et al.*[91])

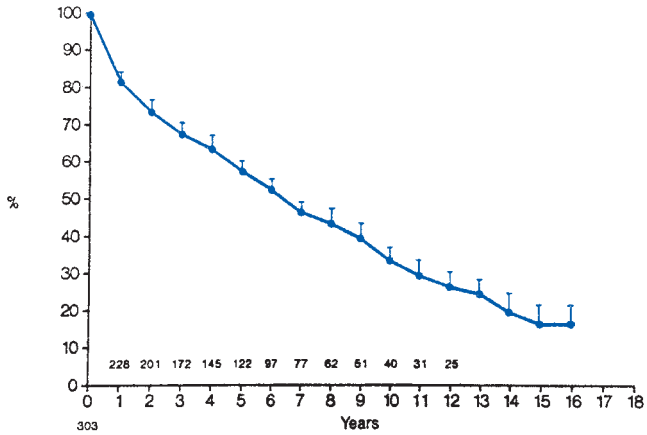

Figure 31-20. Survival in 303 patients undergoing left ventricular aneurysmectomy. (*Reproduced with Modified from Couper et al.*[68])

ejection fraction (EF) whether linear repair[5,8,72–74] or patch repair[13,16,63,75–78] is used (Fig. 31-17). Both techniques decrease end-diastolic and end-systolic volumes[63,73,76,78] and improve exercise response[16,74] (Fig. 31-18). Aneurysmal repair in general also improves diastolic filling, left ventricular diastolic compliance, left ventricular contractility, effective arterial elastance (Ea), and left ventricular efficiency.[31,77–80]

Controversy remains strong regarding whether patch techniques provide results superior to those achieved with linear closures. Stoney and colleagues[11,81] noted lower left ventricular end-diastolic pressure (LVEDP) when more geometric reconstructions were performed. Hutchins and Brawley[82] first noted at autopsy that some patients had severe reduction and distortion of ventricular volume after linear repair. The authors proposed that a more geometric repair might avert these problems. Although no prospective studies compare results from

the two procedures, several very experienced groups attribute improved symptoms, less low cardiac output, and greater improvement in EF to a switch to patch techniques.[7,16,83–86] In other retrospective comparisons, no differences were seen in postoperative symptoms, EF, echocardiographic ventricular dimensions, or late survival between linear and patch repairs.[73,87–90] In an animal model of simulated aneurysm repair, Nicolosi and colleagues[91] found no difference in left ventricular systolic or diastolic function between linear and patch techniques. Two groups reported that switch to patch techniques was associated with increased operative mortality, perhaps owing to excessive volume reduction,[92,93] whereas other groups found improved survival when switching from linear to patch techniques.[94]

The durability of functional benefit from aneurysm repair remains poorly documented. In animals and humans, there is a tendency for the initial improvement in EF, ventricular volume, and filling pressures to diminish over the next 6 weeks to 12 months,[95,96] especially in patients with residual mitral regurgitation.[97]

Although technical differences exist between patch and linear repairs, good functional results are possible with either technique. Suboptimal outcomes result from either technique when left ventricular cavitary volume is overly reduced with resulting decreased stroke volume and impaired diastolic filling.[82,85,96] Excessively small patches reduce stroke volume and impair diastolic filling, but excessively large patches reduce EF and increase wall stress (Fig. 31-19).

LATE RESULTS

Survival

Survival after operation for LVA is variable largely due to differences among patient populations. Five-year survival in recent series varies between 58 and 80%,[5,68] 10-year overall survival is 34%,[68] and 10-year cardiac survival is 57%[51] (Fig. 31-20). Cardiac causes are responsible for 57% of late deaths,[71] and most cardiac deaths result from new MIs. In aneurysm patients randomized to medical or surgical therapy in the CASS (most of the patients had minimal symptoms), survival was not different between medical or surgical therapy, except for patients with three-vessel disease.[42] These patients had better survival with surgery (Fig. 31-21).

Preoperative risk factors for late death include age, heart failure score, EF of less than 35%, cardiomegaly on chest radiograph, LVEDP greater than 20 mm Hg, and mitral regurgitation[42,51,71,87] (Figs. 31-22 and 31-23). The prospective, randomized STICH (Surgical Treaments for Ischemic Heart Failure) trial may provide more definitive data regarding the effect of surgical ventricular restoration on survival, ventricular size and function, quality of life, and exercise capacity.[98]

Symptomatic Improvement

Studies consistently demonstrate improvement in symptoms after operation relative to preoperative symptoms[5,72] (Fig. 31-24). In the study of Elefteriades and colleagues,[72] using a linear repair, mean angina class improved from 3.5 to 1.2 and mean congestive heart failure class improved from 3.0 to 1.7. In the randomized CASS, the subset of patients with LVA achieved a better heart failure class with surgical therapy than with medicine, and rehospitalization for heart failure was less common for the surgical therapy group than for the medicine group.[42] At 18 months, 85% of patients are free of rehospitalization for congestive heart failure, with rehospitalization peaking at 2 to 4 months.[63]

CHAPTER 32

Pathophysiology of Aortic Valve Disease

Tomislav Mihaljevic • Mohammed R. Sayeed • Sotiris C. Stamou • Subroto Paul

The aortic valve is a semilunar valve positioned strategically at the end of the left ventricular outflow tract (LVOT). The normal working of this valve is critical to maintaining efficient cardiac function. This chapter looks to explore the anatomic and physiologic properties of the aortic valve.

EMBRYOLOGIC DEVELOPMENT

Embryologic development of the aortic valve is closely associated with development of the LVOT. During the early stages, the main arterial segment (truncus arteriosus) of the primary heart tube is connected to the primitive right ventricle. With subsequent cardiac loop formation, the truncus arteriosus, together with distal segments of the ventricular outlet component, is divided by endocardiac cushion tissue into subaortic and pulmonary outflow tracts. The truncus arteriosus eventually develops into the pulmonary arteries and aorta. As seen in Fig. 32-1, a septum develops within the truncus arteriosus and subsequently fuses with the underlying ventricular septum. At the point of fusion between these two septal components, separation of the ventricular chamber is accomplished by development of the aortic valve.

The right and left cusps of the aortic valve develop from the aortic side of the truncal septum. Opposing this septum, the embryonic posterior aortic valve develops from the truncoconal lining. As development continues, the aortic valve leaflets grow to become nearly uniform in size.

ANATOMY

The aortic valve separates the terminal portion of the LVOT from the aorta. It is a tricuspid valve consisting of three semilunar cusps (left, right, and noncoronary) and the aortic valve annulus (Fig. 32-2). The cusps themselves are attached within the expanded aortic sinuses. The sinus of Valsalva is defined as the space between the edge of the leaflets and the aorta.

Because two of these sinuses give rise to coronary arteries, conventionally they have been named as the *right coronary, left coronary,* and *noncoronary sinuses.* Because of the oblique position of the aortic root, the sinuses themselves are rarely in strictly right and left position. The ostia of coronary arteries usually open from the upper part of the sinus of origin, the ostium of the left coronary artery often being a little higher than the ostium of the right. Areas where attachments of two adjacent cusps to the aorta meet comprise commissures. The commissure between the noncoronary and left coronary leaflets is positioned along the area of aortic valve–mitral valve continuity. Beneath this commissure is the so-called fibrous aortomitral curtain. This is an important anatomic landmark that guides the surgeon toward root enlargement procedures; also, spread of infection/calcification commonly occurs along this curtain. To the right of this commissure, the noncoronary leaflet is attached to the posterior diverticulum of the LVOT. This is the part where the aortic valve is directly related to the right atrial wall. The commissure between the noncoronary and right coronary cusps is positioned directly above the penetrating atrioventricular bundle and membranous septum. The commissure between the right and left coronary cusps is positioned opposite a facing commissure of the pulmonary valve. The adjacent parts of these two aortic cusps are directly related to the right ventricular infundibulum. The lateral part of the left coronary sinus is the only part of the aortic valve that is not related to another cardiac chamber but is in direct relationship with the free pericardial space.

The aortic valve may be described as having a passive valve mechanism that is quite different from the mitral valve. Because of its passive mechanism, the structure of the aortic valve must open and close with minimal pressure differences between the ventricle and aorta. During closing, this same

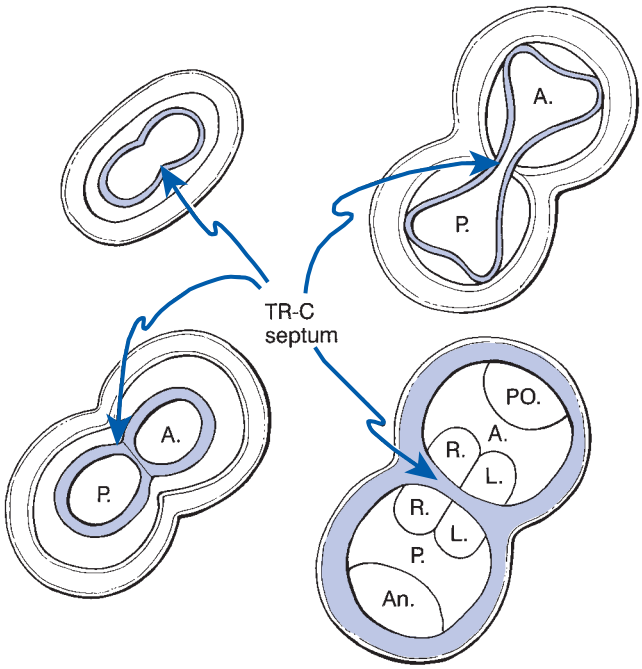

Figure 32-1. Development of the aorta and pulmonary artery is shown, with subsequent development of the aortic valve leaflets. (*Top left*) The truncoconal (TR-C) septum is beginning to divide the truncoconal segment. (*Top right*) This septum continues until division of the aorta and pulmonary artery is completed (*shown at bottom left*). (*Bottom right*) The right and left aortic valve leaflets are derived from the truncoconal septum, whereas the posterior leaflet is derived from the endocardial tissue opposite the truncoconal segment.

mechanism must prevent backflow by perfectly aligning the cusps, which must have enough structural integrity to withstand systemic pressures. The line of closure of the valve is just below the free edge. At the center of the free edge is a nodular thickening called the *nodule of Arantius* from which a thin fibrous projection, Lambl's excrescence, often emanates.

There is no true aortic valve annulus in contrast to the mitral valve. The commonly designated "annulus of the aortic valve" is actually an aortic ring and is the last impediment to flow prior to blood reaching the aorta.

The junction between the ventricular chamber and the aorta is designated as the *ventricular arterial junction.* This must be viewed as either an anatomic or physiologic junction. The physiologic junction is marked by attachments of the semilunar valves that define the separation between the ventricular outflow chamber and proximal aorta. However, there is a discrepancy between this physiologic junction and the anatomic junction owing to, in part, muscular tissue of the ventricle and, in part, fibrous tissue of the septum and mitral valve. As can be seen in Fig. 32-3, the commissures are above the anatomic junction, but the bases of the semilunar attachments of the aortic leaflets are at the true anatomic junction.[1] The fibrous skeleton of the heart forms the posterior wall of the outflow tract, where the leaflets are in fibrous continuity with those of the mitral valve[1] (see Fig. 32-3).

A valve leaflet is composed of collagen, elastin, and glycosaminoglycans. These are the main components for the three principal layers of the leaflet: the fibrosa or arteriosa, the spongiosa, and the ventricularis. As can be seen in Fig. 32-4, the arterial and ventricular sides of the aortic leaflet are associated with the corresponding aortic and ventricular walls. There is no demarcation between the outer layers of the leaflet and the corresponding wall.[2] The outer layers of the leaflet form a continuum with the aortic or ventricular endothelium.

The ventricular side of each aortic valve cusp contains elastin-rich fibers aligned in a radial direction, perpendicular

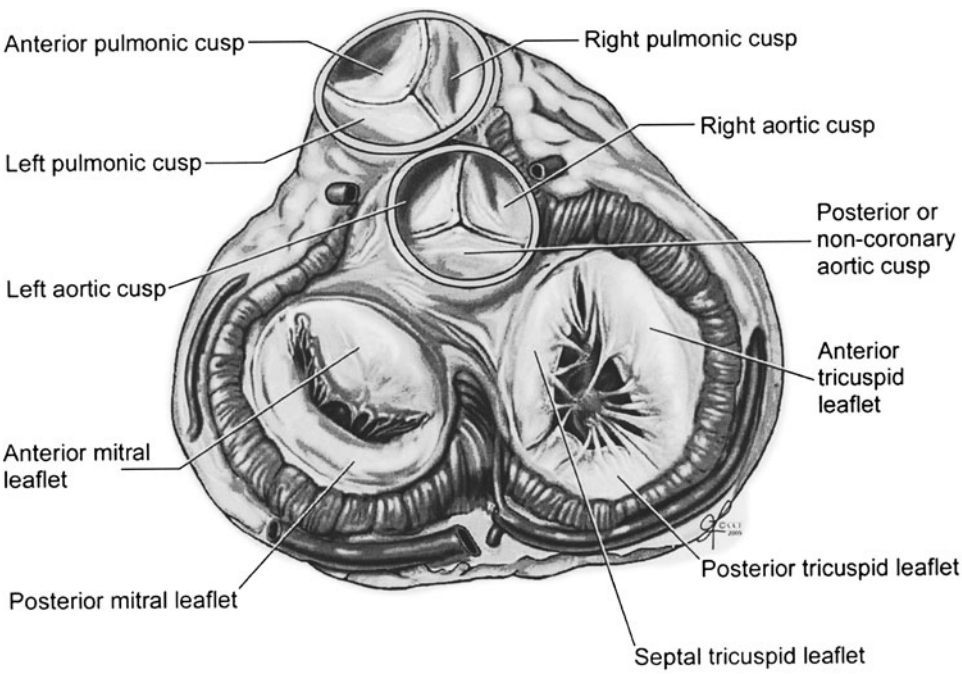

Figure 32-2. Anatomic relationship between the aortic valve and surrounding structures.

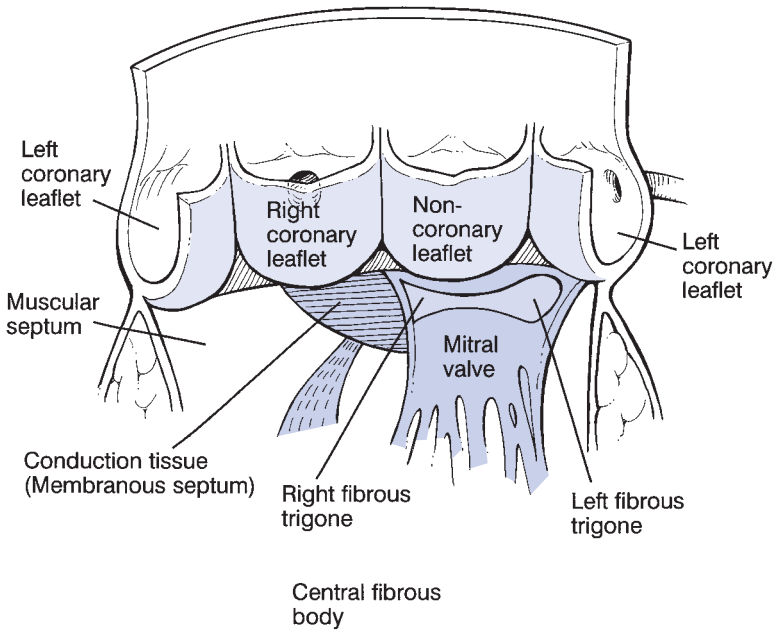

Figure 32-3. A schematic diagram of the relationship of the aortic valve leaflets to the structures underlying the commissures. The noncoronary leaflet straddles the central fibrous body overlying the anterior leaflet of the mitral valve. The conduction tissue traversed the membranous septum between the right coronary and noncoronary leaflets.

to the leaflet free margin. Elastin is mechanically coupled to collagen. The purpose of elastin in the aortic valve leaflet is to maintain a specific collagen fiber configuration and return the fibers to their initial state once the external forces of blood flow subside.[3] In addition, there is a collagen component lying parallel to the free margin in a circumferential direction. The aortic side contains a collagen-rich layer referred to as the *corrugated fibrosa.* These fibers are arranged in a circumferential direction and, in a relaxed state, assume a waveform pattern. The middle layer, referred to as the *spongiosa,* consists mainly of loose connective tissue or mucopolysaccharides. These principal layers of the aortic leaflet provide the necessary biomechanical properties for proper valve function.

On the arteriosa (fibrosa) side of the valve leaflet, endothelial cells are present. Endothelial cells normally align in the direction of stress. In an artery, endothelial cells are aligned in the direction of blood flow because flow stress is the major stress. However, endothelial cells on the aortic valve leaflet are arranged in a circumferential pattern; i.e., they are arranged perpendicular to blood flow. Therefore, shear stress of blood flow across the aortic valve is not the major stress. The major stress across the aortic valve is in the circumferential direction and is perpendicular to blood flow.[4]

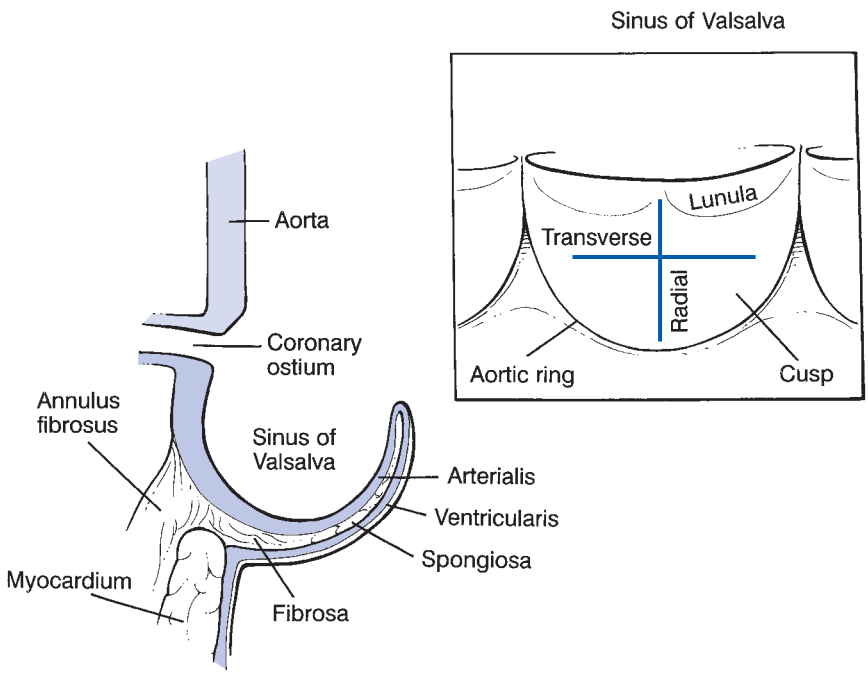

Figure 32-4. Schematic representation of a cross section through the aortic valve leaflet showing the continuity of endocardial and endothelial components with the aortic valve. Inset illustrates the radial and transverse (circumferential) axes of the valve leaflet and the line of attachment to the aortic wall.

MECHANICS OF MOVEMENT

The opening and closing of the aortic valve constitute a passive mechanism responding to the pressure fluctuations of the cardiac cycle and pressure differences between the ventricular chamber and the aorta. Although pressure changes during the cardiac cycle may create some structural changes in the valve mechanism to facilitate opening or closing, the principal component is the pressure difference between the ventricle and the aorta. Under normal circumstances, the valve leaflets offer little impediment to flow because the specific gravity of the leaflets is equal to that of blood.[5] Proper function depends on rapid closure in response to minimal forces moving the valve leaflets.

Opening

During diastole, the pressure difference between the aorta and the ventricle creates stress on the valve leaflets. This stress toward the central portion of the aortic opening constricts the base of the aortic root. In addition, the elastic properties of the aortic root contribute to this decrease in diameter. During late diastole, as blood fills the ventricle, a 12% expansion of the aortic root occurs approximately 20 to 40 ms prior to aortic valve opening.[6,7] Dilatation of the root alone helps in opening the leaflet to about 20%. Actually, the leaflets begin to open even before any positive pressure is applied owing primarily to the effect of aortic root dilatation.[8] As pressure rises in the ventricular outflow tract, tension across the leaflets lessens. As pressure continues to rise, the pressure difference across the valve leaflets is minimal, and no tension is present within the leaflet.[6] At this point, without constriction of the aortic root at the leaflet attachments owing to redistributed stress during diastole, the aortic root expands to allow the valve to open rapidly at the beginning of ejection. Ejection takes place with a brisk upward movement of the straightened leaflets, and the angle at their bases becomes more acute. These mechanisms permit the valve to open quickly and to offer minimal resistance to ejection.[9]

Closure

Closure of the aortic valve is one of the more elegant mechanisms of the valve apparatus.[10] A principal theory involved in closure is the *vortex theory*. The vortex theory recognizes the importance of the sinus of Valsalva in providing a reservoir of blood for small developing vortices. These small vortices allow full expansion of the opened valve leaflets. However, by maintaining the space between the edge of the leaflet and the aortic wall, reversal of flow at the end of systole provides rapid closure. As ejection occurs, deceleration of blood at the stream edge creates small eddy currents of vortices. These small vortices along the aortic wall move gradually toward the base of the ventricular arterial junction at the edge of the leaflet and the top of the sinus of Valsalva. As flow declines at the end systole, the pressure difference across the opened aortic valve leaflets decreases. At the end of ejection and prior to valve closure, the vortices within the sinus of Valsalva balloon the valve leaflets toward the center of the aorta. The angle at the base of each leaflet becomes more obtuse and rounded, in contrast to the sharp angle at maximal valve opening. This point of flexure begins to move up the valve leaflet and eventually terminates at the free margin of the valve cusp.[9] Therefore, the mechanism of valve closure begins during ejection with development of vortices within the sinus of Valsalva priming the leaflets for valve closure. When pressure between the ventricular outflow tract and aorta equalizes, a small reversal of flow occurs owing to the deceleration of ejected blood. This small flow reversal causes the leaflets to close rapidly.

Apposition of the valve leaflets occurs briskly. The second heart sound occurs after complete closure of the aortic valve.[11] The valve leaflets act as an elastic membrane, with stretch and recoil producing the sound; the sound is not produced by physical apposition of the valve leaflets. The second heart sounds depends on the elasticity of the valve leaflets and diastolic blood pressure to cause reverberation of the leaflets.

AORTIC STENOSIS

Prevalence and Etiology

Valvular aortic stenosis (AS) without accompanying mitral valve disease is more common in men than in women and is rarely rheumatic in etiology. Age-related degenerative calcific AS is currently the most common cause of AS in adults and the most frequent reason for aortic valve replacement (AVR) in patients with AS.[12]

The prevalence of aortic valve abnormalities as detected by population-based echocardiographic study increases with age, with 2% of people 65 years of age or older having isolated calcific AS, whereas 29% exhibit age-related aortic valve sclerosis without stenosis.[12]

Acquired aortic stenosis

The most common cause of AS is degenerative calcification of the aortic valve. Although previously considered to be the result of years of mechanical stress on an otherwise normal valve, the evolving concept is that the degenerative process leads to proliferative and inflammatory changes, with lipid accumulation, upregulation of angiotensin-converting enzyme (ACE) activity, and infiltration of macrophages and T lymphocytes ultimately leading to calcification of the aortic valve.[12–17] Progressive calcification, initially along the flexion lines at their bases, leads to immobilization of the cusps. The characteristic pathologic findings are discrete, focal lesions on the aortic side of the leaflets that can extend deep into the aortic annulus. The deposits may involve the sinuses of Valsalva and the ascending aorta. The risk factors for the development of calcific AS are similar to those for atherosclerosis and include elevated serum levels of low-density lipoprotein

(LDL) cholesterol and lipoprotein A [Lp(a)], diabetes, smoking, and hypertension.[18,19] Age-related aortic valve sclerosis is associated with an increased risk of cardiovascular death and myocardial infarction (MI). Beta-HMG CoA reductase inhibitors (statins) have emerged as a potential therapy for treating aortic valve calcification. Experimental animal study has shown that aortic valves from a 2-month experimental hypercholesterolemia study develop atherosclerosis and that treatment with atorvastatin produces improvement in the valve lesion.[20] Growing evidence from retrospective studies demonstrates that therapy with statins is a potential approach to the treatment of aortic valve disease. Up to 50% of annual reduction in measurable disease progression, whether quantified by Doppler echocardiographic jet velocity or valve area or by electron-beam tomographic valve calcium scores, was noticed in patients treated with statins.[21–23] The largest prospective clinical trial (Schottische Aortic Stenosis and Lipid Lowering Trials, SALTIRE), however, failed to demonstrate a slowing of progression of AS in patients treated with high doses of atorvastatin.[24] Furthemore, there is conflicting evidence indicating that statins may stimulate bone cell calcification and ossification of the aortic valve.[25] Currently, there are two ongoing prospective trials in Europe evaluating the cholesterol-lowering medications as a therapeutic strategy to slow the progression of aortic valve stenosis (AVS): Simvastatin and Szetimide in Aortic Stenosis (SEAS)[28] and RAAVE (rosuvastatin).[26] Results of these studies will be helpful in our further understanding of potential therapies for this disease.

Calcific AS is also observed in a number of other conditions, including Paget disease of bone and end-stage renal disease. Ochronosis with alkaptonuria is another rare cause of AS, which also can cause a rare greenish discoloration of the aortic valve.

Bicuspid aortic stenosis

Calcified bicuspid aortic valve represents the most common form of congenital AS. Bicuspid aortic valves are present in approximately 2% of the general population. Gradual calcification of the bicuspid aortic valve results in significant stenosis most often in the fifth and sixth decades of life, earlier in unicommissural than in bicuspid valves and earlier in men than in women.[30] The abnormal architecture of the unicommissural or bicuspid aortic valve induces turbulent flow, which injures the leaflets and leads to fibrosis, increased rigidity, leaflet calcification, and narrowing of the aortic valve orifice.[31] Bicuspid valves often are associated with dilatation of the ascending aorta related to accelerated degeneration of the aortic medium that in some cases may progress to aneurysm formation.[32] Recent work suggests that a DNA transcriptional error, possibly for the gene encoding endothelial nitric oxide synthetase, may be implicated in the genetic abnormality that leads to bicuspid aortic valve.[33] It appears that the microfibrils within the aortic valve and the aortic root are defective in structure in patients with bicuspid aortic valve disease. This leads to a decrease in mechanical support for the valve, thereby contributing to accelerated "wear and tear" and, hence, degenerative changes in the valve matrix.[33]

Rheumatic aortic stenosis

Rheumatic AS represents the least common form of AS in the adult population.[34] Rheumatic AS is rarely an isolated disease and usually occurs in conjunction with mitral valve stenosis.[35] Rheumatic AS is characterized by diffuse fibrous leaflet thickening of the tricuspid valve with fusion to a variable extent of one or two commissures. The early stage of rheumatic AS is characterized by edema, lymphocytic infiltration, and revascularization of the leaflets, whereas the later stages are characterized by thickening, commissural fusion, and scarred leaflet edges.

Overall distribution of causes of AS varies significantly among different age groups. Among patients younger than 70 years of age, congenitally calcified bicuspid valves were responsible for half of surgical cases. In contrast, in patients over 70 years of age, degenerative calcific stenosis is by far the most prevalent cause of stenosis, accounting for 48% of all surgical cases.[36]

Pathophysiology

Myocardial response

AS causes gradual obstruction to left ventricular outflow. Left ventricular output is maintained by the development of left ventricular hypertrophy (LVH), which may result in a large pressure gradient across the stenotic valve for a period of many years without any decrease in cardiac output, dilatation of the left ventricle, or development of symptoms. As the left ventricle becomes less compliant, atrial systole becomes more important for maintaining cardiac output, and onset of atrial fibrillation may result in clinical worsening and ventricular decompensation.

Critical obstruction to the left ventricular outflow is reached with (1) an increase in peak systolic pressure gradient of greater than 50 mm Hg in the presence of normal cardiac output and (2) a decrease in effective aortic orifice area of less than 0.5 cm^2/m^2 of body surface area (usually <0.8 cm^2).

Myocardial hypertrophy in patients with AS is characterized by increased gene expression for collagen I and II and fibronectin that is associated with activation of the renin-angiotensin system.[35] Reduction in renin-angiotensin parallels regression of hypertrophy after AVR.[37] In late stages of severe AS, the left ventricle decompensates with resulting dilated cardiomyopathy (Fig. 32-5). Cardiac output declines, and the pulmonary artery pressure rises, leading to pulmonary hypertension. Experimental studies have indicated a role of apoptotic mechanisms in the progression of LVH to failure in patients with AS.[38] For the 50% of patients who present with symptoms of congestive heart failure (CHF), mean survival is less than 1 year.[39]

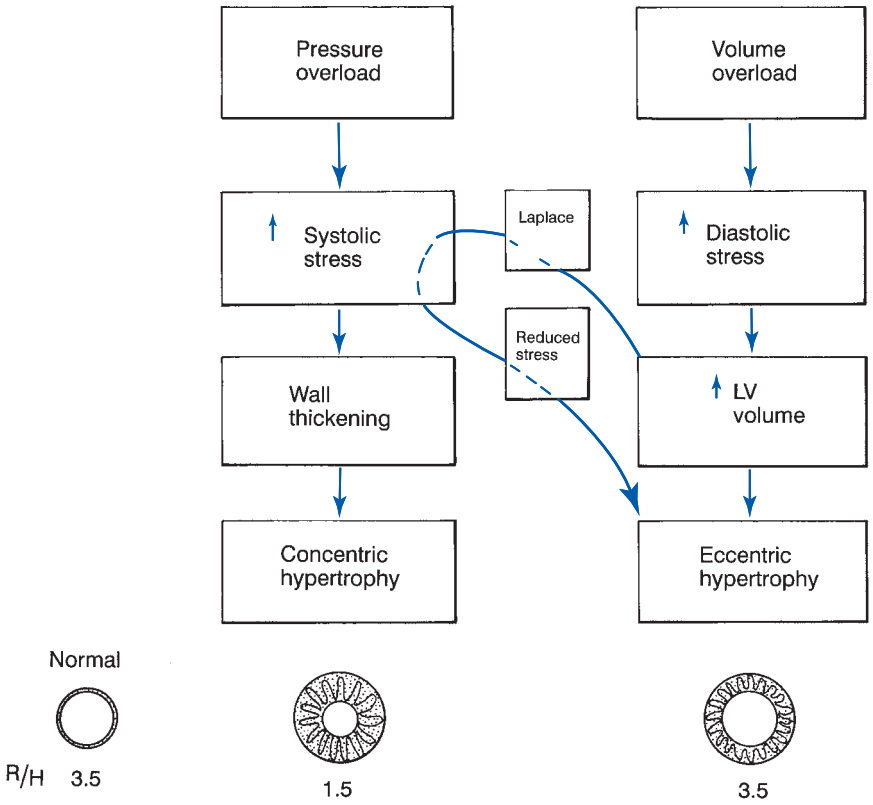

Figure 32-5. Schematic representation of the pathophysiology of pressure and volume overload. With pressure overload, an increase in systolic wall stress provides the stimulus to increase wall thickness and normalizes peak systolic stress. This progresses to concentric hypertrophy, where the ratio of the radius to wall thickness is markedly less than normal. This development is in sharp contrast to volume overload, wherein the increase in diastolic stress provides a stimulus for elongation of myofibrils to increase left ventricular (LV) volume. Because of the increase in LV volume, by Laplace's law, systolic stress increases to induce wall thickening, which reduces stress and produces eccentric hypertrophy. Eccentric hypertrophy increases LV volume and wall thickness; however, the ratio of ventricular radius to wall thickness (R:H) remains normal. (*Modified with permission from Grossman W, McLaurin LP, Stefadouros MA: Left ventricular stiffness associated with chronic pressure and volume overloads in man. Circ Res 1974; 35:793.*)

Coronary circulation

Left ventricular outflow obstruction results in elevation of left ventricular systolic and diastolic pressures, decreased aortic pressure, and increased left ventricular ejection time. Increased left ventricular pressure with left ventricle volume overload results in left ventricular failure. Prolonged left ventricular ejection time (LVET) results in a decrease in diastolic time and thus myocardial perfusion time. Left ventricular hypertrophy, increased systolic pressure, and prolongation of ejection result in increased myocardial oxygen consumption. Reduced coronary artery flow also may lead to inadequate myocardial oxygen supply in patients with AS, even in the absence of coronary artery disease (CAD). Myocardial ischemia in patients with AS can be induced by an increase in myocardial oxygen demand as a result of exercise or isoproterenol administration, as documented by an increase in the lactate levels, even in the absence of CAD. Myocardial oxygen supply-demand disparity is the main mechanism for angina in patients with AS (Fig. 32-6). Rarely, angina results from calcium emboli to the coronary arteries.

Syncope

Syncope most commonly is due to the reduced cerebral perfusion that occurs during exertion secondary to the decrease in arterial pressure consequent to peripheral vasodilation in the presence of a fixed cardiac output. Syncope also may be the result of dysfunction of baroreceptor mechanisms and a vasodepressor response to the increased left ventricular systolic pressure during exercise. Approximately 15% of patients present with syncope; only 50% survive 3 years.

Hemodynamics

The severity of AS is assessed by estimating the mean systolic gradient and aortic valve area (AVA). The Gorlin formula is used to determine the stenotic orifice area derived from the pressure gradient and cardiac output from the fundamental relationships linking the area of an orifice to the flow and pressure drop across the orifice. The AVA is calculated from the Gorlin formula using the following equation:

$$\text{Aortic valve area} = \frac{\text{cardiac output}}{44.3(\text{SEP})(\text{HR})\sqrt{\text{mean gradient}}}$$

The systolic ejection period (SEP) is a time period (in seconds) defined from aortic valve opening to closure. The cardiac output can be measured using the Fick or thermodilution technique. The normal AVA is 2.6 to 3.5 cm^2 in adults. Valve areas of 0.8 cm^2 or less represent severe AS. In low-output states, the Gorlin formula systematically may predict smaller valve areas than are actually present. Several reports also indicate that the AVA area from the Gorlin formula increases with increases in cardiac output.[40]

In patients with AS, the transvalvular pressure gradient is best measured with a catheter in the left ventricle and another in the proximal aorta. Pressure gradients can be estimated by obtaining catheter-derived pressures on both sides

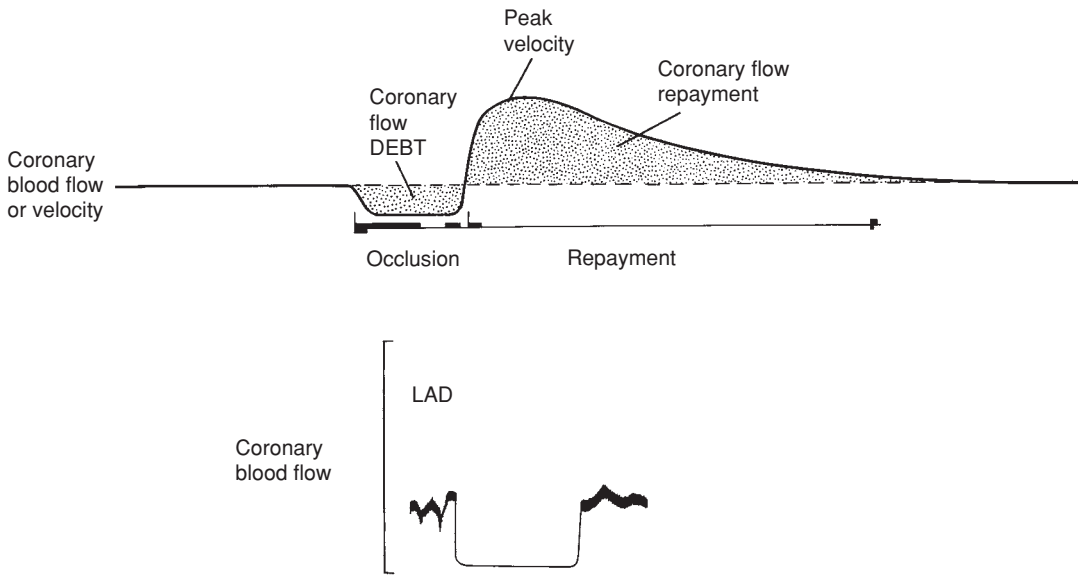

Figure 32-6. (*Top*) Coronary flow dynamics during temporary occlusion in a normal heart. (*Bottom*) Coronary blood flow is interrupted in the left anterior descending coronary artery (LAD) in a patient with aortic stenosis. In the normal heart, during 10 seconds of occlusion, the myocardium incurs a coronary flow deficit that is more than repaid during a hyperemic response after flow resumes. In a patient with aortic stenosis, either an attenuated or no hyperemic response occurs after 10 seconds of occlusion, indicating little or no coronary flow reserve.

of the valve. The mean pressure gradient across the aortic valve is determined by planimetry of the area, and it is this gradient that is applied to calculation of the valve orifice area. The peak-to-peak gradient, measured as the difference between peak left ventricular pressure and peak aortic pressure, is used commonly to quantify the valve gradient.

Using Doppler methods, velocity is converted to gradient using the Bernoullli equation: Gradient $= 4 \times V^2$.

Echocardiographic measurements of AVA represent the current clinical standard for assessment of the severity of AS. Transesophageal echocardiography (TEE) offers an alternative method for assessment of AVA using planimetry of the multiplane systolic TEE short-axis views of the aortic valve.[41]

Decrease of AVA by about 50% to 1.5 cm^2 results in only a small gradient. However, further progression of AS results in a more significant increase in gradient. The average increase in gradient is 7 to 10 mm Hg per year; however, there is large individual variation.[42] The unpredictable rate of progression of AS mandates careful follow-up. Although most patients with AS have surgery when the AVA is less than 0.7 cm^2 or there is a mean systolic gradient of more than 50 mm Hg, patients may become symptomatic sooner and require AVR before these thresholds are reached.

Clinical Presentation

Symptoms

The cardinal manifestations of acquired AS are *angina pectoris, syncope,* and ultimately, *heart failure.* Patients with congenital or rheumatic AS present with symptoms most commonly in the fifth or sixth decade of life, whereas patients with degenerative calcific AS symptoms commence in the seventh through ninth decades. Angina usually occurs in two-thirds of the patients with critical AS and is precipitated by exertion and relieved by rest. Syncope is due to decreased cerebral perfusion during exertion. Syncope at rest may be due to transient arrhythmias, i.e., atrial fibrillation with loss of the atrial "kick" contribution to left ventricular filling with a resulting decrease in cardiac output or to transient atrioventricular block owing to extension of the calcification into the conduction system. Some patients may have severe or even massive gastrointestinal bleeding secondary to angiodysplasia, occurring predominantly in the right colon as well as in the small bowel or stomach. This complication arises from shear-stress-induced platelet aggregation with reduction in high-molecular-weight multimers of von Willebrand factor and increases in proteolytic subunit fragments. These abnormalities correlate with the severity of AS and are correctable by aortic valve repair.[43] Exertional dyspnea and orthopnea usually are late symptoms. Other late manifestations of severe AS include atrial fibrillation and pulmonary hypertension. Infective endocarditis can occur in younger patients with AS; it is less common in elderly patients with a severely calcified valve.

The interval from the onset of symptoms to the time of death is approximately 2 years in patients with heart failure, 3 years in those with syncope, and 5 years in those with angina.[44]

Signs

Signs of AS include systolic ejection crescendo-decrescendo murmur that radiates to the neck and is often accompanied

by a thrill. In some patients, a regurgitant systolic murmur may be present, representing rupture of mitral chordae tendineae. A previous report has indicated that patients with ruptured chordae tendineae have extensive calcification of the mitral annulus and no evidence of rheumatic or myxomatous mitral pathology.[45] These data suggest that mitral annular calcification in conjuction with elevated left ventricular pressures predisposes the patient with AS to rupture of the mitral chordae tendineae.[45] Other signs of AS include delayed second heart sound (S_2) because of prolongation of the systolic ejection time. The S_2 also may be single when the aortic component is absent, and if the aortic component is audible, this may give rise to a paradoxical splitting of S_2.

The classic *pulsus parvus,* or small pulse, is a sign of severe AS or decompensated AS and occurs when stroke volume and systolic and pulse pressures fall. A wide pulse pressure is also characteristic of AS. Prolongation of the ejection phase with slow rise in the arterial pressure also gives rise to the *pulsus tardus. Pulsus parvus et tardus* is diagnosed by palpation. As ejection begins, work is lost at the stenotic valve with a resulting decrease in amplitude and delayed timing of carotid upstroke.

Left ventricular hypertrophy is evident as a sustained apical thrust or heave. This sign is present only when failure occurs because until failure occurs, the hypertrophy is not accompanied by dilatation, and the apical impulse is not displaced. Conversely, absence of an apical thrust (except in muscular patients, those with emphysema, and those with adiposity) suggests a mild or moderate AS. Other physical findings of significant AS include prominence of a jugular venous *a* wave secondary to a decreased right ventricular compliance because of right ventricular hypertrophy, as well as evidence of the prominent left atrial kick.[45]

Electrocardiogram

Most patients with severe AS present with QRS complex or ST-T interval abnormalities reflecting LVH. Patients with a higher gradient are more likely to show a "strain" or "systolic overload" pattern. The conduction abnormalities may result from septal trauma secondary to high intramyocardial tension from hypoxic damage to the conducting fibers or from extension of valvular calcifications into the fibrous septum.

Roentgenogram

The roentgenographic characteristics of compensated AS include concentric hypertrophy of the left ventricle without cardiomegaly, poststenotic dilatation of the aorta, and calcification of the valve cusps. With decompensation, there is cardiomegaly in the posteroanterior projection and pulmonary venous congestion. It is important to recognize that a routine chest x-ray (CXR) may be within normal limits in patients with hemodynamically compensated AS. The rounding of the lower-left heart border may be subtle, the poststenotic aortic dilatation may be equivocal, and the valvular calcification may be invisible on posteroanterior view. Of equal importance, the presence of cardiomegaly in a normotensive patient with isolated AS indicates a decompensated AS.

Echocardiography

Ultrasonic examination of the heart is an invaluable diagnostic tool in confirming the diagnosis of AS and in quantifying disease severity. The recommendations for the diagnostic use of echocardiography were established by an American College of Cardiology/American Heart Association (ACC/AHA) task force in 1998.[46] In echocardiographic evaluation of AS, the purpose of echocardiography is to (1) define the severity and etiology of the primary valvular lesion, (2) define the hemodynamics, (3) define coexisting abnormalities, (4) detect secondary lesions, (5) evaluate cardiac chamber size and function, and (6) re-evaluate the patient after intervention. There are several typical and important echocardiographic findings in patients with AS: The aortic leaflets are thickened and calcified with reduced movement; the reduced valve orifice often can be visualized; in the case of bicuspid aortic valve, the cusps are asymmetric; and the left ventricle shows significant myocardial hypertrophy with usually preserved systolic function. Doppler echocardiography may be used to estimate the degree of stenosis using the planimetry technique (Fig. 32-7). It also can be used to assess valve thickening and calcification, as well as reduced leaflet motion. Distinction between bicuspid and tricuspid valve is often possible, particularly when the amount of calcification is small. Left ventricular hypertrophy can be estimated by calculating left ventricular mass. Transvalvular pressure gradient and valve area can be calculated with Doppler studies.

The normal area of the adult aortic valve measures, on average, 3.0 to 4.0 cm^2; this reduction of the normal area usually does not produce symptoms until the valve reaches one-fourth of its normal dimension. Currently accepted criteria for the gradation of AS define:

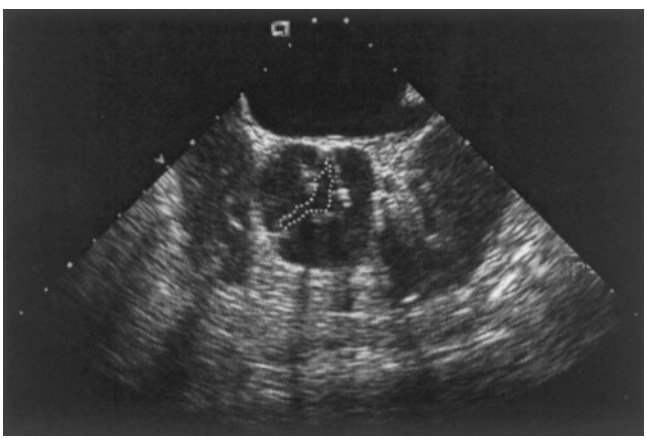

Figure 32-7. Transesophageal echocardiographic image of severely calcified aortic stenosis. Dotted lines highlight the significantly reduced aortic valve orifice.

1. Mild AS as area >1.5 cm^2
2. Moderate AS as area of 1 to 1.5 cm^2
3. Severe AS as area <1.0 cm^2

Doppler echocardiography is also used to determine diastolic dysfunction by the presence of abnormal left ventricular relaxation. Patients with AS are known to have diastolic dysfunction. Moderate to severe diastolic dysfunction does not increase early mortality but may increase late mortality after AVR.[46] *Asymptomatic diastolic dysfunction* is used to refer to asymptomatic patients with normal ejection fraction and an abnormal echo-Doppler pattern of left ventricular filling. Stress echocardiography is used in patients with normal left ventricular function (LVF) to demonstrate the presence of diastolic dysfunction (i.e., signs of elevated left ventricular filling pressure) as the cause of symptom development during exercise. Diastolic dysfunction in patients with normal LVF may cause exercise intolerance for several reasons: First, elevated left ventricular diastolic and pulmonary venous pressures increase the work of breathing and cause dyspnea; second, patients with LVH exhibit a limited ability to use the Frank-Starling mechanism during exercise, resulting in a decrease in cardiac output during exercise; third, elevated left ventricular diastolic and pulmonary venous pressures result in abnormalities in the diastolic properties of the ventricle. Combining transmitral flow velocity with annular velocity obtained at the level of the mitral annulus with tissue Doppler (E/E') has been used to assess left ventricular filling pressures that combine the influence of transmitral driving pressure and myocardial relaxation.[47] Patients with rest E/E' can be classified as having elevated filling pressure, whereas E/E' of less than 8 represents normal filling pressure. Filling pressures between 8 and 15 represent a gray zone.

Echocardiographic follow-up studies should be frequent to identify left ventricular dysfunction, LVH, and mitral regurgitation. Studies should be performed yearly in patients with severe AS, every 2 years in patients with moderate AS, and every 5 years in patients with mild AS.[48]

Exercise testing

Traditionally, severe AS has been regarded as a relative contraindication to exercise testing.[49] Indeed, it should be avoided in symptomatic patients with AS. More recent reports, however, have indicated that quantitative exercise Doppler echocardiography can be performed safely in asymptomatic patients with AVAs of less than 1 cm^2.[50] An increase in mean transaortic pressure gradient by 18 mm Hg or more during exercise, an abnormal exercise test, and an AVA of <0.75 cm^2 predict higher risk for cardiac events (i.e., death or heart failure) by multivariate analysis in a subset of asymptomatic patients with AS. Dobutamine stress echocardiography is often a useful modality to estimate valve area and gradient at a higher cardiac output. It is particularly useful in patients with moderate to severe AS with a low gradient and depressed LVF.[51,52]

Cardiac catheterization

Cardiac catheterization is useful to determine the transvalvular gradient and to evaluate LVF from the left ventriculogram. Coronary artery disease may be present in up to 25% of patients with AS who do not have angina. Thus, coronary angiography is performed in most patients to assess coronary anatomy and evaluate the need for combined AVR and myocardial revascularization. Right-sided heart catheterization is also used to calculate the AVA based on the Gorlin equation, as described earlier. Cardiac catheterization also may provide information about the presence or absence of other valve lesions.

Cardiac computed tomography

The ability of computed tomography (CT) to detect and quantify calcification has been applied recently to aortic valve stenosis. Electrocardiographically gated multidetector row CT has shown high accuracy and reproducibility in quantifying aortic valve calcification and its progression.[53] This may develop into clinical applications with respect to the prognostic relevance of aortic valve sclerosis, as well as the problem of calcification of the bioprosthesis.

Magnetic resonance imaging

Cardiac magnetic resonance imaging (MRI) may be used in assessing left ventricular volume, function, and mass. MRI also may be useful in quantifying the severity of AS. Valve area can be assessed by direct planimetry using a cross-sectional plane immediately downstream from the valve. Cardiac MRI is useful when acoustic windows in the echocardiogram are poor or when there is discordant imaging and catheterization results. Bicuspid aortic valves or fused valve leaflets can be identified readily. Moreover, after AVR for stenosis, cardiac MRI is used to demonstrate improvement in LVF, myocardial metabolism, and diastolic function, as well as reduced hypertrophy.[54]
